E.s.r. spectra were recorded on a Nihon Denshi JES-3BSX e.s.r. spectrometer using X-band and 100 kHz field modulation. Temperature was varied from -160° to 100°C using the JES-VT-3A temperature controller and the JES-UCT-2A gas flow cryostat. The sample temperature was measured by a thermocouple inserted into a sample tube during the e.s.r. measurements. For exact estimation of theoretical correlation frequency of the probe from the linewidth of e.s.r. spectra, the modulation width and the microwave power level were carefully controlled to decrease the line broadening and the power saturation, respectively, while maintaining necessary sensitivity of the spectrometer.

The glass transition temperature of the samples was measured by the dilatometry at the rate of temperature elevation, $0.5^\circ\text{C}/\text{min}$.

RESULTS AND DISCUSSION

Line shape of e.s.r. spectra

Figure 1 shows the e.s.r. spectra of NBR at various temperatures. At liquid nitrogen temperature, both NR and NBR show similar broad asymmetric triplet spectra caused by the interaction of an unpaired electron with a nitrogen atom, the broad line shape indicating that the probe is in a rigid matrix. These broad spectra change into sharp ones with narrower line separation with increasing temperature, indicating that the probes begin to move at higher temperatures. A small subsplitting appears at around -90°C , increasing in intensity as temperature is increased for both NR and NBR. This aspect seems to be superposition of two kinds of spectra with broad and narrow line separation. The broad spectral component narrows almost simultaneously with increase in intensity of the narrow component, and the spectral shape finally changes into a sharp triplet.

This multiplicity of spectra has already been interpreted in two ways as described before¹⁴. One of them is the superposition of a broad and a narrow spectra caused by the inhomogeneity of fine structure of a matrix. Another may intrinsically occur by the partial averaging of anisotropic hyperfine interaction and g -value in an intermediate frequency range¹⁶. As far as the present data are concerned at least the former case may be conceivable since the effect of fine structure of the polymer on the spectra is observed; namely the higher the content of combined sulphur of the samples the clearer the separation of two peaks in the intermediate temperature becomes, as shown for NR in Figure 2.

Figure 1 E.s.r. spectra of NBR at various temperatures: A, 75°C ; B, 25°C ; C, -20°C ; D, -90°C ; E, -180°C

Figure 2 E.s.r. spectra of NR at around T_g . A, $S_c = 1.1\%$ at 16°C ; B, $S_c = 7.5\%$ at 25°C ; C, $S_c = 15.1\%$ at 33°C

Figure 4 Relations between T_n and T_g , \circ , NR; \bullet , NBR

Moreover, it has been reported¹⁷ that vulcanized *cis*-1,4-polybutadiene rubber showed the increase of microstructural inhomogeneity with increasing sulphur content. The increase in the peak separation with increasing combined sulphur content may be similarly related.

Variation of extreme line separation with temperature

It has been proposed as mentioned before, that extreme line separation of a triplet pattern, W , can be used as a measure of the motion of the probe. Figure 3 shows the variation of W with temperature for NBR samples. The line separation is about 69 gauss at liquid nitrogen temperature and shows rapid narrowing above the glass transition. Since the spectra show a complex pattern, the Figure shows the line separation of two components. The temperature difference of the two narrowing temperatures is found to increase with increase in the content of combined sulphur in accordance with the increasing double peak separation (Figure 2).

For convenience, the average temperature narrowing at which the intensity of the two peaks becomes equal as shown in Figure 2 is taken as the temperature narrowing, T_n . The relation between T_n and T_g is shown in Figure 4, indicating a correlation between T_n and T_g . T_n is found to increase with increasing T_g . From these curves it can be deduced that T_n will coincide with T_g at 34°C for NR and 28°C for NBR, respectively, and T_n exceeds T_g above 23°C for NBR. These relations between T_n and T_g will be discussed later.

Correlation frequency of tumbling motion of probes

When temperature is increased to cause enough sharpening of the line width, the correlation time of isotropic tumbling motion of the probe can be calculated using the Kivelson theory¹⁵ viz.:

$$\tau_c = W_0[(h_0/h_1)^{1/2} - (h_0/h_{-1})^{1/2}]C \quad (1)$$

$$\tau_c = W_0[(h_0/h_1)^{1/2} + (h_0/h_{-1})^{1/2} - 2]C' \quad (2)$$

where W_0 is the maximum slope line width of central peak of the three line spectrum, h is the peak height, whose subscript represents the nuclear quantum number of nitrogen atom, C and C' are constants determined by experimental conditions such as the hyperfine interaction characteristic of the probe and the magnitude of a static magnetic field. These equations are mathematically equal, but accuracy in employment has been discussed by Strukov¹. In this theory the rate conditions mentioned in a previous paper¹⁴ must be fulfilled.

Figure 5 shows the plots of the logarithmic correlation frequency ($1/\tau_c$) versus the reciprocal of observation temperature. The correlation frequency increases with increasing combined sulphur content over the whole temperature range indicating that the polymer matrix is immobilized by the increase of combined sulphur. Slight upward departure in the frequency from the linear plot at low temperatures is found for NR samples with low sulphur content (No. 1-3), and progressive decrease in the frequency at higher temperatures is seen also for NR samples with high sulphur content (No. 5-7).

On the other hand, for NBR the upward departure can be found and, in turn, a progressive decrease at higher temperatures is seen for all samples. The decrease becomes larger with increasing sulphur content.

The activation energy of the motion of the probe is calculated by the equation:

$$E = R \ln(1/\tau_c) / d(1/T) \quad (3)$$

The linear parts of the curves of Figure 5 are shown in Table 2.

For NR samples which show two linear relations, the activation energy at higher, E_1 , and lower temperatures, E_2 were estimated. The values of E_1 and E_2 are comparable to those of bulk polyethylene¹³, although much higher than those estimated from the Arrhenius plots of the lower temperature region of polyethylene single crystals¹⁴.

As has been suggested in a previous paper¹⁴, this relatively large activation energy E_2 may possibly be associated with the jumping mode of the probe into adjacent holes. Andrew¹⁵ has shown by the measurements of second moment of wideline n.m.r. that cyclohexane molecules begin to diffuse through the crystal lattice between -53° and -33°C. In this case, the activation energy of molecular motion was estimated as 8 kcal/mol, which is supposed to be two-thirds of the lattice energy, suggesting the occurrence of the self-diffusion of cyclohexane molecules. This explanation provides a valuable indication of the existence of the self-diffusion of the probe in the rubbers. The value of 9-11 kcal/mol in the present study and the fact that the activation energy is almost independent of the sulphur content, implies that the probe is not restricted in a local potential barrier in a polymer matrix so-called cavity model but diffuses through polymer matrix.

At low temperatures the probe is in a rigid state and begins restricted rotational oscillation, and then free rotation as the temperature increases. The rotational oscillation and the free rotation may possibly average out the anisotropic hyperfine interaction and g -value, causing the narrowing of the line separation until the self-diffusion takes place. However, appearance of the narrowing depends on the rotational frequency of the probe, the narrowing being recognized only when the frequency exceeds the e.s.r. frequency of 10^{7-8} cycles/sec. Since the motional mode of the probe and its frequency depends on the nature of the probe such as size, shape and the aspect of

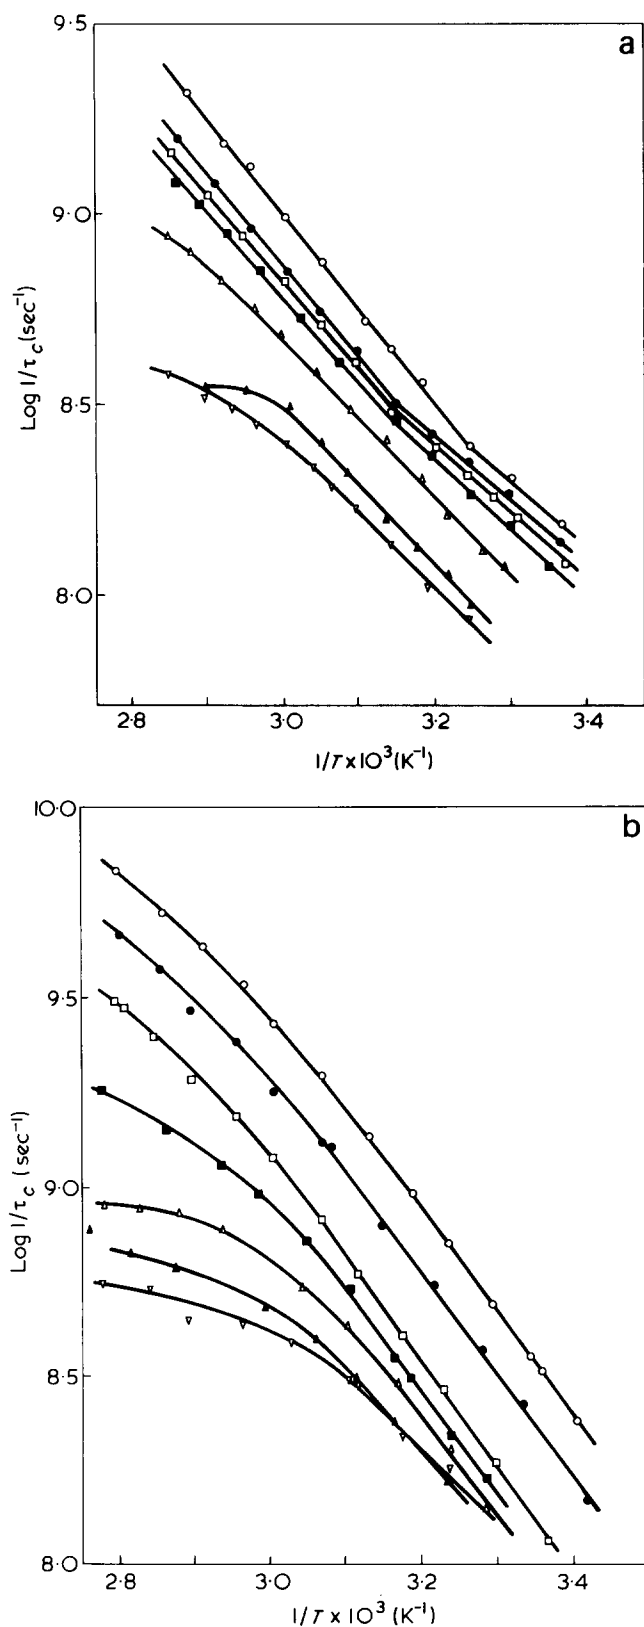

Figure 5 Arrhenius plots of correlation frequency. interaction with the polymer, the cause of the narrowing is not always the same.

However, when the narrowing occurs by the rotational mode, the activation energy will be ~ 10 kcal/mol. The

energies below 6 kcal/mol obtained for the low temperature region in polyethylene^{13,14} may be associated with this mode.

In the present study, the appearance of the break point around 50°C in the Arrhenius relations in Figure 5a suggests that the rotational mode of the probe is mixed and leads to a change in the slope of the curves in the low temperature region.

Theoretical treatment of the relation among T_n , T_g and the molar volume ratio of the segment to the probe

As has been discussed in the previous section the motional mode of the probe in NR in the highest temperature range can be the self diffusion of the probe in the polymer matrix. Further, the correlation between T_n and T_g implies that this self-diffusion takes place in a similar manner to the segmental diffusion of the polymer above glass transition.

In terms of the hole theory, the segments of polymer molecules begin to jump into adjacent holes formed by displacement of the segment and the thermal expansion of polymer matrix around T_g . At the same time, if the probe has a comparable size to a segment it will jump into an adjacent hole as well as the polymer segment. According to the theory by Bueche¹⁹ let us consider a polymeric system which consists of polymer molecules with n segments, probes and the free volume, V_f as shown in Figure 6. V_f is supposed to be the summation of packets with the volume of v_f :

$$V_f = n \times v_f \quad (4)$$

Table 2 Activation energy of the tumbling motion of the probe

No	NR

1	7.8	11	12
2	7.4	11	12
3	7.2	10	12
4	7.6	10	12
5	—	10	12
6	—	10	10
7	—	9	10

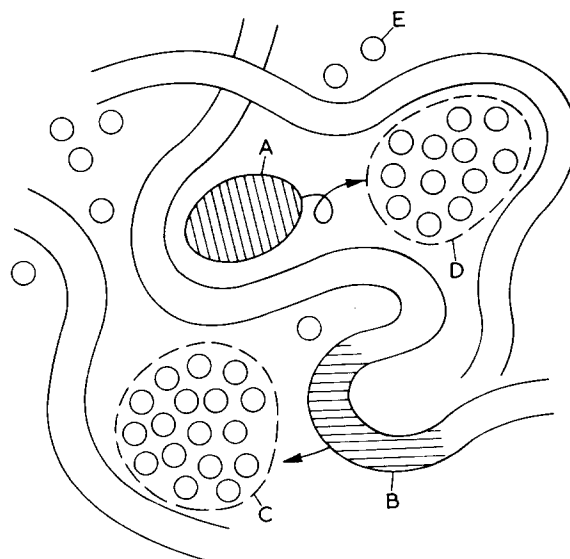

Figure 6 Schematic model of jumping of probe and segment: A, probe (volume v_p); B, segment (volume v_f); C, hole (volume $v_f > v_m^*$); D, hole (volume $v_f > v_p^*$); E, packet (volume v_f)

Provided that q packets are gathered to form a hole with the volume of v_f' in the vicinity of a segment or probe, the segment or the probe will jump into this hole when v_f' exceeds the activation volume for jumping, v_m^* and v_p^* , which are for the segment and the probe, respectively. In this system, the probability that q packets are gathered around a certain segment is given by:

$$p(q) = (1 - 1/n)^{n-q} (1/n)^q [n!/q!(n-q)!] \quad (5)$$

This calculation is comparable to the case where a person throws n balls towards n boxes and has the possibility of getting q balls in a certain box. The ball corresponds to the hole and the box to the segment. Let us consider the case where a few of the boxes are replaced by ones differing in size and having q balls in one of them. This corresponds to the case where q balls are gathered around the probe in a polymer matrix. In this case, the difference in interaction between the probe and the segment and inter-segments is ignored. When the number of the probe is negligibly small compared with that of segments, the probability of q holes around the probe may approximately be given rewriting equation (5) as:

$$p(q) = (1 - v_p/nv_m)^{n-q} (v_p/nv_m)^q [n!/q!(n-q)!] \quad (6)$$

where v_p and v_m denote the molar volume of the probe and the segment, respectively. In equation (5) the possibility of a hole around a segment is $1/n$, therefore, this possibility is modified in equation (6) as being proportional to the volume ratio of the segment to the probe.

Assuming $n \gg q$ and using:

$$\lim_{n \rightarrow \infty} (1 - v_p/nv_m)^n = \exp[-v_p/nv_m]$$

and

$$n!/q!(n-q)! = n(n-1) \cdots (n-q+1)/q! \approx nq/q!$$

equation (6) is rewritten as:

$$p(q) = \exp[-v_p/v_m] \times (v_p/v_m)^q (1/q!) \quad (7)$$

While the gamma function $\Gamma(2)$ is: $\Gamma(n+1) = n!$ and from the Stirling formula: $\lim_{n \rightarrow \infty} (n+1)/(2n\pi)^{1/2} (n/e)^n = 1$.

Therefore, when q is not so small:

$$1/q! = (2\pi q)^{-1/2} \times (q/e)^{-q} \quad (8)$$

Substituting equation (7) into equation (8):

$$p(q) = (2\pi q)^{-1/2} (v_m q/v_p)^{-q} \times \exp(q - v_p/v_m) \quad (9)$$

$q = v_f'/v_f$, therefore the probability that the probe encompasses the free volume of v_f' :

$$p(v_f') = (2\pi v_f'/v_f)^{-1/2} \exp[-(\beta + \ln v_m/v_p) v_f'/v_f - v_p/v_m] \quad (10)$$

where $\beta = \ln(v_f'/v_f) - 1$.

The probe jumps into the hole when $v_f' \geq v_f^*$, therefore the probability is:

$$\int_{v_p^*}^{\infty} p(v_f') dv_f' \approx (\text{const.}) \exp[-(\beta^* + \ln v_m/v_p) v_p^*/v_f - v_p/v_m] \quad (11)$$

The jumping frequency is:

$$\Phi = \Phi_0 \exp[-(\beta^* + \ln v_m/v_p) v_p^*/v_f - v_p/v_m] \quad (12)$$

The microscopic free volume v_f changes with temperature above T_g :

$$v_f = v_{fg} + v_{mg} \Delta\alpha (T - T_g) \quad (13)$$

where, v_{fg} and v_{mg} are the free volume and the occupied volume of a segment at T_g , respectively. $\Delta\alpha$ is the difference between thermal volume expansion coefficients above and below T_g . This relation is valid in a temperature range $T_g \leq T \leq T_g + 120^\circ\text{C}$.

Substituting equation (13) into equation (12) and rearranging the formula we obtain:

$$T - T_g = \left\{ \frac{[\ln(v_m/v_p) + \beta^*] v_p^* v_{fg} v_m^*}{\ln(\Phi_0/\Phi) \times v_{fg} \times v_m^* - v_p v_m^* v_{fg}/v_m} \right\} v_{mg} \Delta\alpha \quad (14)$$

The Doolittle relations: $v_{fg}/v_{mg} \Delta\alpha = 52$ and $v_m^*/v_{fg} = 40$ and $\beta^* \approx 1$ are substituted into equation (14) and assuming $\ln\Phi/\Phi_0 \gg f$, we obtain:

$$T - T_g = 52 [40f(\ln 1/f + 1)/\ln\Phi_0/\Phi - 1] \quad (15)$$

where $f = v_p^*/v_m^* = v_p/v_m$.

$\Phi_0 = 10^{14}$ is assumed according to Bueche¹⁹. The narrowing of line separation may occur at $\Phi = 10^8$. This supposition is satisfactory since the extrapolation of almost all curves in Figure 4 to the narrowing temperatures is of the order of 10^8 . Thus, we obtain the simple formula:

$$T_n - T_g = 52 [2.9(\ln 1/f + 1) - 1] \quad (16)$$

When T_n and T_g are determined experimentally and the molar size of the probe is known the segmental size of polymer can be estimated using equation (16).

Figure 7 shows the value of $T_n - T_g$ as a function of f , calculated from equation (16). $T_n - T_g$ has a maximum at $f = 1$. This may mean physically that the probe is not able to jump at T_g , when the size of the probe exceeds that of the segment. The maximum value of $T_n - T_g$ is 98.8°C , indicating that this equation is valid on the supposition $0 \leq T_n - T_g \leq 120^\circ\text{C}$. On the other hand, $T_n - T_g$ becomes negative as mentioned in the previous section. This may occur when the probe is considerably smaller than the segment and the jumping mode occurs by the local motion of the segment. For instance, this will occur in the system which has a wide distribution of segmental size because of the inhomogeneity of a matrix. The deduction that the inhomogeneity of the matrix becomes larger with increasing content of combined sulphur may explain this phenomenon. This may also occur by the local relaxation mode. In such a case, macroscopic volume expansion and total increase in free volume, is not necessary for the displacement of the probe. The diffusion of the probe due to the displacement of the local free volume may afford the narrowing of e.s.r. pattern. The case where $T_n - T_g < 0$ is also seen in a polymeric system which has large side groups such as polystyrene. For this polymer it was found²⁰ that $T_n - T_g$ is -15°C when di-*t*-butylnitroxide $(\text{CH}_3)_3\text{C}(\text{NO})\cdot$ $\text{C}(\text{CH}_3)_3$ is used as a probe, while it is 35°C for the probe used in this study. The molar volume of di-*t*-butylnitroxide

$\Delta T = T_n - T_g$, v_m and d_m are from atomic volume at boiling point²¹, v'_m and d'_m are calculated by the Slonimskii's method²², N is the number of backbone atoms of the segment

is 88% of the latter, accordingly the narrowing can occur at lower temperatures. The effect of the probe size is well interpreted by equation (16). The details of the data will be reported elsewhere.

From Figure 7 we can estimate the segmental size of polymers above glass transition measuring T_n and T_g since the molar volume of the probe is known. Table 3 lists the estimated values of f , the molar volume of the segment, the number of backbone atoms of the segment and the diameter of the segment, calculated assuming the spherical shape of the segment.

For calculation of v_m and v'_m the atomic volume at boiling point²¹ and the Slonimskii's method²² were employed.

 Figure 8 Relation between the number of backbone atoms of the segment and T_g . ○, NR; ●, NBR

The latter case includes only the excluded volume of the segment, therefore this may be the smallest value estimated. The number of backbone atoms of the segment was estimated by multiplying the number of backbone atoms of the repeating unit of the polymers to the excluded volume ratio of the repeating unit to the segment. Thus, 45–98 and 65–215 backbone atoms are included in the segment of NR and NBR, respectively depending upon the content of combined sulphur. For this calculation, sulphur is not taken into consideration. However, the values are almost coincident with those estimated by dividing the number of backbone atoms of the probe (12) by f within $\pm 2\%$, therefore the number estimated may be valuable as a first approximation. These values may be comparable to the case of polypropylene ($T_g = -10^\circ\text{C}$), where the size of the segment has been estimated as 30 monomeric units corresponding to 90 backbone atoms, estimated from viscoelastic data²³.

Figure 8 shows the number of backbone atoms as a function of T_g . The values of NBR are found to be located above the T_g of NR. When the segmental size of NBR is the same as that of NR T_g is about 5–15°C higher than that of NR. This fact may be due to the cohesive energy of NBR molecule being larger than that of NR.

Letter

Determination of concentration dependence of the hydrodynamic dimensions by differential g.p.c.

The decrease in hydrodynamic dimensions of macromolecules with increasing concentration is a well established phenomena¹⁻³. The elution volume of macromolecules in gel permeation chromatography is a measure of the hydrodynamic radius of such molecules⁴⁻⁶. Measurement of hydrodynamic volumes as a function of concentration has been done only in a limited number of cases^{7,8}. Rudin⁹ determined molecular dimensions at finite concentrations using gel permeation chromatography to confirm calculations based on dilute solution viscosity measurements. In this case the calculated values were compared against those determined experimentally by varying the concentration of the polymer injected into the gel permeation chromatograph. This requires the assumptions that the sample is injected instantaneously onto the column so that the initial concentration is applicable to the hydrodynamic volume of the solute in the column and that the samples are monodisperse in terms of molecular weight. These assumptions probably do not affect the results. A further assumption that the longitudinal diffusion is negligible may be an over simplification and cause appreciable uncertainty in the results, as suggested by Rudin.

The method of differential gel permeation chromatography (g.p.c.) involves dissolving a polymer in the solvent so that solvent contains a known concentration of polymer. The g.p.c. measurements are then made in the usual way. This method was introduced by Chuang and Johnson¹⁰ who used it to determine small differences in molecular weight distributions. The method appears to overcome the assumptions made by Rudin and to be able to directly determine molecular dimensions as a function of concentration.

Results and Discussion

The data used in this report were taken from Chuang and Johnson¹⁰. Calculations of the hydrodynamic volume from viscosity parameters, densities and molecular weight were carried out in the same manner using the same constants as Rudin. The hydrodynamic dimensions were calculated based on zero concentration or infinite dilution for samples containing no polymer in the solvent, although the concentrations were in actuality 0.016 mg/ml with an injection

volume of 0.318 ml. Calibration curves were then determined by plotting the log of the hydrodynamic radii vs. the elution volume. Elution volumes determined at finite concentrations of polymer using the differential method were then used with the equation resulting from the previously described plots to calculate hydrodynamic radii. The results are shown in *Table 1*. The values at concentrations of 0.667 mg/ml are in reasonable agreement with those calculated by the method of Rudin. At the higher concentration of 4.10 mg/ml, the values are appreciably lower. It should be emphasized that the polymer used to establish the known concentration was that of a moderately broad distribution polystyrene having a \bar{M}_w of 424 000 and a \bar{M}_w/\bar{M}_n of 1.8.

From this we conclude that the values are reasonable and that this appears to be a convenient, reasonably precise way of determining the change of the hydrodynamic dimensions as a function of concentration. Further measurements are in progress and will be reported in the near future.

Book Reviews

Natural & Synthetic Polymers An Introduction

Henry I. Bolker

Marcel Dekker, New York, 1974, \$29.75

This is a book written for students of polymer chemistry wherein the author makes the novel approach of treating knowledge of natural and synthetic polymers in a unified manner. To achieve his objective he has of necessity had to restrict his coverage to organic and biological material and to exclude any physical concepts.

Following a short introductory chapter in which polymers and macromolecules are defined, polymers of life and commerce are introduced, some basic definitions given and sufficient history of a range of big molecules presented to whet the appetite.

The author divides his book into 3 Parts subdivided into 12 chapters and an Appendix. Part I is concerned with linear homopolymers and its first chapter is an essay on linear polysaccharides, 60% of which is devoted to cellulose. From the wide literature on this remarkable molecule, the author condenses a truly vast amount of information into an essay which makes really exciting reading for the students. The account of the uses of cellulose is particularly timely. A very brief introduction is given to the molecules of amylose, amylopectin, chitin etc. and to the nucleosides involved in the synthesis of polysaccharides.

Chapter 3 gives an account of synthetic condensation polymers and covers polyesters, polyamides, polysiloxanes, polycarbonates and a great deal of information all clearly crowded into a small compass. Interfacial polycondensation and the theoretical aspects of condensation polymerization are well done.

Addition or chain-growth polymers are next considered beginning with an account of the methods of polymerization, plastication and stabilization. All the well known polymers such as poly(vinyl chloride), polystyrene, polyethylene, the acrylics, fluoro polymers, etc. receive attention with important aspects such as initiation, propagation and termination being adequately described.

The two succeeding chapters, (nearly one quarter of the book), we are given full accounts of the stereo regularity in addition polymers, the story of branched homopolymers both natural and synthetic, and of natural hetero polymers – mainly polysaccharides and nucleic acids. Then there is a sharp jump to the consideration of copolymers and copolymerization, to cross linking mainly in synthetic polymers and back again we come to learn about polypeptide and proteins with a courageous summary of the Genetics code and the chemical and biosynthesis of peptides, and thence to a study of lignins. Finally, we are given an important if brief introduction to the methods used for measuring the molecular weight of polymers.

Conference Announcement

Theoretical Methods in Polymer Physics

Leeds, 5–7 July 1976

The Institute of Physics Polymer Physics Group is organizing a conference on Theoretical methods in polymer physics at the University of Leeds from 5 to 7 July 1976. The programme will consist of invited lectures given by: Professor Sir Samuel Edwards; Professor C. Domb; Dr M. A. Moore; Professor P. G. de Gennes; Professor M. Gordon; Professor W. H. Stockmayer; Dr M. G. Brereton; and Professor G. J. Morgan, together with a number of contributed papers. Further information and registration forms may be obtained from the Meetings Officer, Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK.

When the late Sir Norman Haworth (whose contribution to polysaccharides are rather neglected in the book) favourably reviewed a book he would write, 'I have had this book at my elbow for 6 weeks', and one can follow him by saying that graduate students of polymer chemistry will greatly benefit by having this book at hand throughout their courses and afterwards. It contains a wealth of well sifted information and achieves the author's objective of presenting a new comprehensive approach to the study of macromolecules.

The book is in typescript reproduced by a photolithographic process – quite adequate for a student text.

Characterization of Materials in Research: Ceramics and Polymers

Edited by John J. Burke and Volker Weiss

Syracuse University Press, Syracuse, New York, 1975, 566 pp. \$32.00

This volume contains the proceedings of the 20th Sagamore Army Materials Research Conference, held during September 1973. It comprises eighteen review Chapters dealing with methods for characterizing the structure of ceramic or polymeric materials in relation to their behaviour and applications.

There can be little doubt about the importance of adequately characterizing materials. This is frequently essential for obtaining conclusive research data, for the preparation of standards and specifications, and for more efficient design with existing materials. A discussion of these points, together with comments on the waste of effort resulting from negligence in characterization, is included in an Introductory Chapter by N. E. Promise on the Concept of Characterization. In the case of polymers, F. W. Billmeyer later emphasizes the difficulties associated with specifying all aspects of structure, and the probable need for compromise. In view of the expanding efforts in materials research and development, the theme of the proceedings is timely and important.

The proceedings are arranged into five sections dealing, respectively, with the Physics of Nonmetallic Solids, Ceramic Characterization, Molecular Characterization of Polymers, Characterization of Polymers in Bulk and Case Histories. The polymer sections contain reviews on molecular weight measurements (J. B. Kinsinger), sequence distribution and tacticity (H. J. Harwood), statistical properties (J. E. Mark), morphology of semicrystalline polymers (L. Mandelkern), characterization of bulk polymer morphology by optical methods (S. B. Clough), rheological characterization (W. W. Graessley) and characterization of molecular and crystalline orientation (C. R. Desper). A chapter by H. K. Herglotz on the characterization of polymers by unconventional X-ray techniques is included in the section of nonmetallic solids, as is a review of amorphous solids by D. R. Uhlmann which includes some reference to polymeric glasses. A discussion by F. R. Barnet and M. K. Norr on the structure of etched carbon fibres, as revealed by the scanning electron microscope, should be of interest to workers in the field of polymer composites. The Chapters relating to ceramics include several informative descriptions of experimental techniques which should interest those concerned with various aspects of polymer structure.

In general, the aims and principles of the different methods of characterization are clearly presented, the methods are well-illustrated with critical discussions of selected data, and comments on recent developments are frequently included. Each Chapter contains a comprehensive list of up-to-date references. The book is carefully and attractively produced with few apparent errors. It should be a useful reference for practical research workers, lecturers and advanced students of polymer or materials science, and for organizations concerned with the development of materials standards and specifications.

Chain-extended polyethylene in context: a review*

D. C. Bassett

*J. J. Thomson Physical Laboratory, University of Reading, Whiteknights, Reading RG6 2AF, UK
(Received 19 December 1975)*

The subject of crystallization of polyethylene at high pressures, commonly known as chain-extended crystallization, is reviewed. An historical approach is taken for the topics of molecular conformation, the relationship to chain-folded growth and the responsibility of the hexagonal phase. With the identification of this new phase and the demonstration that chain-extended growth is crystallization of hexagonal polyethylene, the basis of understanding is established. The field is then surveyed in this new context with discussion of high pressure annealing and molecular mechanisms involved, implications for the understanding of kinetically controlled growth in general and the use of chain-extended polyethylene as a model for crystal growth and mechanical behaviour.

INTRODUCTION

Recent work has brought the understanding of high-pressure crystallization of polyethylene, widely known as chain-extended crystallization, into the context of chain-folded polymers and suggests that this apparently esoteric subject may have important implications for polymeric crystallization in general.

THE PROBLEM

1964 saw the publication of two papers on the interior morphology of bulk polyethylene (PE) as revealed on fracture surfaces. Both showed lamellae fractured in planes containing the *c* axes, a consequence in linear polyethylene of having little or no molecular folding. In one¹, fractions of up to 12 000 molecular weight had been crystallized for up to ten days at 128°C *in vacuo* and formed lamellae approximately equal in thickness to their molecular lengths. The other² showed a similar appearance but of lamellae increased dramatically in thickness (the maximum observed being ~3 μm) to dimensions commensurate with typical molecular lengths. This sample had been crystallized from the melt around 5 kbar. The molecular conformation in the first case was seemingly one of full extension in what were thus denoted as 'extended-chain' lamellae in contrast to the thinner folded-chain crystals produced in similar circumstances with higher molecular weight polymer. This nomenclature seemed appropriate also to the high pressure case and it has become common usage to identify the product of high pressure crystallization as 'extended-chain polyethylene' although this now needs qualification and the alternative 'chain-extended' has been adopted in recent work. The problem presented by chain-extended polyethylene (CEPE) falls into three parts: to understand why the use of high pressures should so alter the morphology of PE crystallized from the melt, but not from solution nor for polymers in general, to describe what that morphology actually is and to explain how it comes about.

With a topic requiring specialized apparatus and, therefore, still limited to only a few laboratories, it was inevitable that the experimental background should be slow to

be established. Nevertheless possible explanations of the effect were soon forthcoming based on the facts as they then appeared to be. In the early papers^{3,4} it was assumed that PE had either crystallized as chain-folded or as 'extended-chain' lamellae i.e. that there were two alternative crystallization processes. Kawai⁵ suggested specifically that these involved folded and bundle-like nucleation respectively and went on to propose detailed explanations^{6,7} generalizing, as we now know incorrectly, from Anderson's atmospheric data¹ that shorter molecules more readily formed chain-extended lamellae at a given pressure. An alternative hypothesis advanced by Peterlin⁸ sought to explain the situation in terms of enhanced lamellar thickening whereby folded-chain crystals formed initially would, under appropriate conditions, undergo an 'avalanche-like long period growth' and transform into extended-chain crystals. The experimental evidence, which merely suggested that one morphological form was appearing at the expense of the other³, could not then decide between these two proposals. Indeed the basic issue of whether there were two independent processes operating at low and high pressures respectively or merely one, suitably modified, remained unresolved for ten years and a major difficulty in clarifying the situation.

Molecular Conformation

The evidence of the very first papers suggested that PE molecules could have become fully extended after high pressure crystallization. Samples crystallized at 5 kbar³ had densities up to 0.994 Mg/m³, maximum melting points of 140°C and were full of lamellae much thicker than any encountered previously, the spectrum of thicknesses extending to 3 μm, with an average value of 2500 Å². The *c* axis direction, identified by electron diffraction and optical birefringence, is parallel to a characteristic striation on fracture surfaces² and is sometimes along but more often moderately inclined to the lamellar normal in similar ways to the oblique structures encountered in chain-folded PE. For full extension, the lamellar thicknesses along *c* must agree with values expected from the molecular weight of the sample; in the case cited² this was $\bar{M}_n = 1.1 \times 10^4$ and $\bar{M}_w = 1.25 \times 10^5$ so that at least the lamellar dimensions were of the right order. However, doubt was expressed⁴ as

* Presented at the Polymer Physics Group (Institute of Physics) Biennial Conference, Shrivenham, September 1975.

to whether extension could be complete after crystallization at 5 kbar because a substantial increase in molecular weight (by comparing polymethylene with Marlex 6050) produced only a marginal increase in crystal thickness. A proper test of this point required a detailed comparison of the distribution of crystal thickness and molecular weight. The first of such was published by Wunderlich and Melillo⁹ followed by similar ones from Prime and Wunderlich¹⁰. From the statistics of fracture surfaces computed for a variety of chain-extended polyethylenes ranging from whole Marlex 50 through fractions of polydispersities from 3.5 to 5.3 to polymethylene it was inferred that the shortest molecules ($\leq 10^4$ in weight) did attain full extension in a separated population of crystals. The remaining molecules crystallized together producing lamellae which were thicker for longer crystallization times¹¹ and for increasing molecular weight, although a rise of 1000 in molecular length only produced a tenfold increase of crystal thickness. In this, the great majority of the material, at least the longest molecules had to be folded to some extent⁹⁻¹².

All the above samples had, however, been treated so as to try and maximize their molecular extension. When the effect of changing crystallization conditions was examined by Rees and Bassett¹³, using fractions of polydispersity 1.14 it was discovered that the lamellar thickness of CEPE increased not only with the molecular length and crystallization time but also, and most markedly, with crystallization temperature. For example, for a 5×10^4 MW fraction crystallized at 4.9 kbar for 30 min, average thicknesses over the attainable range of temperatures increased from 2000 to 3300 Å, whereas the average molecular length was close to 5000 Å. It followed that full molecular extension was the exception rather than the rule and that the conformations of all molecules in CEPE, not just the longest, were generally folded¹³.

All measurements on lamellar thickness at this time came from fracture surfaces, a method which is always under suspicion of bias. However, the data produced can now be seen to have been much more reliable than might have been feared. In fact the most evident bias actually improves the measurement because low-melting (chain-folded) lamellae are much under-recorded¹³ so that fracture surfaces tend to select the chain-extended component from the mixture of chain-folded and chain-extended crystals typically produced by crystallizing whole polymer at 5 kbar. Particular care was taken to establish the reliability of fracture surface measurements by guarding against errors due to chain axes being inclined to the fracture surfaces and by testing for statistical significance. It was found that the fracture surface method gave repeatable values for the same sample and that for example the increases found between samples crystallized at progressively higher temperatures were real¹³. Further confidence in the method came with excellent correlations found between fracture surface measurements and density, melting point and low-angle X-ray data measured on PE annealed at high pressure¹⁴. Most recently the introduction of the entirely different method of nitration followed by g.p.c. analysis which correlates well with fracture surface data over the entire range of molecular weights and pressure treatments¹⁵ shows clearly that statistics derived from fracture surfaces are a reliable means of measuring molecular extension in chain-extended crystals of linear PE. The fracture surface method is not available for chain-extended branched polyethylenes, however, as these generally fracture between lamellae and do not expose the relevant surfaces. For these, the nitration/g.p.c. method

is the only one so far available.

Qualitatively, the change in layer thicknesses of CEPE resembles those found for chain-folded crystallization *in vacuo*. Further examination showed that both conformed to the temperature dependence of kinetic theory formalism connecting lamellar thickness l to supercooling ΔT by the equation:

$$l = \frac{2\sigma_e}{\Delta s_f} \times \frac{1}{\Delta T} + \delta l$$

where σ_e is the fold surface free energy, Δs_f the entropy of fusion and δl is a small length. Indeed, data for CEPE and for chain-folded crystals of low molecular weight material (chosen to have a similar number of folds per molecule) have a common reduced plot of fractional change in crystal thickness against supercooling¹⁶. The implication is that lamellae in CEPE are essentially large-scale copies of chain-folded layers, a conclusion which is reinforced by the similar logarithmic time dependence of long period during annealing at both high and low pressures¹⁷. In view of the most recent developments, this conclusion seems a natural one, but at the same time it carries with it implications concerning the nature of melt growth in general.

Another recent finding is that full chain-extension does not seem to be the upper limit of layer thickness. Two pieces of evidence indicate that, given the right conditions, molecules will fit end-to-end inside one crystal in fully extended conformation. Hatakeyama, Kanetsuna and Hashimoto¹⁸ found that prolonged crystallization of 50 000 MW PE at 237°C and 4.8 kbar for 200 h gave lamellae up to 40 μm thick, with over 20% thicker than 10 μm , whereas only 1.2% of molecules were longer than 10 μm . In a similar way, detailed comparison of fracture surface data, molecular weight measurements and g.p.c. analysis after nitration¹⁵ indicates that the proportion of long molecules in ordinary CEPE samples is often quite insufficient to account for the comparatively large number of thick lamellae present. Having lamellae more than one molecule thick might be anticipated by current thinking on chain-extended growth, and could be expected to occur for prolonged crystallization at low supercoolings. It does, however, raise interesting questions as to how the observed wide variation of crystal thickness with molecular weight under given crystallization conditions comes about if lamellar thickness is not limited by molecular length.

Morphological investigations

From the outset, the morphology of CEPE has been carefully scanned looking for clues to its formation. Almost all studies have been confined to fracture surface replication, a technique which is particularly suited to these often brittle materials. In linear PE fracture is predominantly along prism faces but occasionally basal surfaces are also exposed; both are present in *Figure 1*. The prism faces possess a characteristic striation parallel to c ; this is confined to fracture surfaces and whereas there had been early speculation² that it represented a structural feature, detailed investigation concluded that it did not, but was created at the moment of fracture¹⁹.

Because of exposed side surfaces^{19,20} such striations begin to melt as low as 100°C at 1 bar. By 120°C, a pronounced 'ripple' develops very rapidly (<10 sec), as chain-folded lamellae form as oriented overgrowths on the underlying chain-extended polymer^{9,19}. The importance of this is that

Figure 1 Thick lamellae characteristic of CEPE (D. C. Bassett and B. A. Khalifa, unpublished)

it shows that notwithstanding primary nucleation with highly-extended conformation, lamellar thickness is determined by secondary nucleation at the growing surface^{9,19,21,22}. This is in agreement with observations on solution growth²³ and of the foundations of kinetic theory. Moreover, even with careful annealing at 1 bar such lamellae cannot be thickened to the dimensions of the underlying substrate⁹. This fact, too, is readily understood in terms of recent work.

Replicas of CEPE and the morphologically similar PTFE^{24,25} often reveal a number of threads pulled from the surface. These appear to be produced when specimens are stripped from the backing film during two-stage replication; stripping at a suitably low temperature where the polymer is entirely brittle avoids the phenomenon. The extent of the drawing is intimately related to the degree of folding in a sample, thus in whole polymer threads are pulled preferentially from the thinnest lamellae¹¹; using sharp fractions their number increases for lower crystallization temperatures¹³ (which give thinner lamellae) and the effect can be so pronounced for high molecular weight that it can obscure practically all surface detail.

The most interesting result of morphological studies is, however, that they clearly show lamellae increasing their thicknesses with time. The same lamella is found to become thicker in positions further away from its primary nucleus or branch point⁹. Above all, where they impinge, one on another, the thickest lamellae always show a tapered profile, within which lamellar thickness decreases from perhaps 1 μm or even less^{9,13}. From this and other evidence, Wunderlich^{9,26} concluded that lamellae in CEPE grow by adding molecules to their edges at dimensions of ~1000 Å, i.e. in folded conformation after which there is thickening towards the thermodynamically most stable extended-chain

conformation. Wunderlich and coworkers saw no principle difference between atmospheric and high pressure crystallization but considered that whereas chain-extension is kinetically hindered at 1 bar it is very much enhanced at high pressures. This was thought to be partly due to the pressure but even more to the high temperatures involved. In both cases the driving force for extension was the reduction, as chain-extension increased, of the number of folds introduced by secondary nucleation at the growth face. Wunderlich has also proposed that such a mechanism is responsible for the formation of a class of extended-chain crystals within which he includes PTFE, PCTFE and selenium²⁷. The existence of such a class grown by a distinct mechanism has, however, been disputed²⁵ and does not seem required by recent work.

Faced with rather similar evidence, Rees and Bassett¹³ deduced that the tapered profiles of thick chain-extended lamellae were not due to special circumstances but indicated that in general molecular extension and lamellar thickness increased rapidly behind the growth front. They also had direct evidence from fracture surface statistics of increasing average lamellar thicknesses with time over the longer term and the very marked effect of crystallization temperature. They, therefore, stressed the analogy with chain-folded crystallization at 1 bar, left open the implications of growth proceeding behind a narrowed edge and concluded by remarking that the relationship of lamellar thickening to crystallization and the attainment of high chain extension under pressure are probably different aspects of the same problem. This still appears to be true, the relevant problem being kinetically controlled (i.e. chain-folded) growth from the melt.

The evidence of tapered tips was discounted by Calvert and Uhlmann²⁸, who pointed out correctly that crystals of many kinds grow in this fashion. There are, however, additional implications from molecular connectedness if this shape resembles the profile of a growing edge. In the event, direct observation of the growth of thick chain-extended lamellae has confirmed that they do indeed grow behind a narrowed edge²⁹. These authors also proposed an alternative theory of chain-extended growth²⁸ whereby growth at 5 kbar was similar to that at 1 bar but gives thicker crystals because of a large fold surface free energy, the value of this parameter increasing considerably with pressure. Unfortunately a central part of their argument involved combining two sets of data from the literature which have not been reproduced in subsequent work. Moreover, their basic premise of a continuous change of behaviour from 1 bar to 5 kbar turned out to be incorrect.

The sum of all the work so far described and carried out on CEPE after return to atmospheric pressure was to leave the situation still confused and with no consensus as to what essentially was going on. Although it had been shown that full chain-extension was not the general rule, the question of whether chain-extended growth was independent of or an extrapolation of chain-folded growth was not answered; one did not then know why solution growth did not reproduce the high thicknesses found in the melt³⁰, and explanations of the large increase in thickness of CEPE were still rather speculative. Furthermore, high pressure annealing experiments carried out contemporarily³¹⁻³³ had added to the problems by showing that this was also a means of producing CEPE. In these circumstances increased attention began to be paid to the monitoring of high pressure crystallization of PE *in situ*; it was from these experiments that the essential new information came.

HIGH PRESSURE MEASUREMENTS

Early measurements in which the melting and recrystallization of PE under high pressure were monitored by dilatometric or d.t.a. means were those of Matsuoka³⁴ (to 4 kbar), Osugi³⁵ (to 30 kbar), Baltenas and Igonin³⁶ (to 3 kbar) and Baer and Kardos³⁷ (to 3 kbar). Though not entirely consistent one with another, all the papers showed an apparently unchanging pattern of behaviour from atmospheric conditions into the pressure region where CEPE formed. Above all, Davidson and Wunderlich³⁸ had made high pressure d.t.a. observations to 4.2 kbar, (compared to 2.8 kbar for the first formation of CEPE) without finding any new feature to associate with chain-extended growth.

CEPE had even been watched growing directly in a high-pressure diamond-anvil optical cell by Jackson, Hsu and Brasch³⁹. They observed the formation of what is a characteristic appearance of CEPE by the growth of what they interpreted as rod-like crystals but which are really oriented lamellae viewed edge-on of the same dimensions as lamellae measured in CEPE by Rees and Bassett¹³. Although the pattern of growth was quite different from normal spherulitic growth, no specific indication of its cause or difference from atmospheric behaviour was noted.

The prospects of *in situ* high pressure measurements revealing anything very new about chain-extended growth thus seemed remote but the continuing need to clarify the relationship between chain-folded and chain-extended growth prompted a second look at what Wunderlich and Arakawa³ called the intermediate pressure region, where the high melting points and thick lamellae had begun to appear.

Once it was appreciated that full molecular extension was not a characteristic of CEPE, the meaning of the term had to be redefined. Wunderlich had done this empirically by choosing 2000 Å as the minimum thickness of a chain-extended layer⁴⁰. This is a conformational definition such that basic properties approach sufficiently closely to their ultimate values, e.g. the melting point depression is $< \sim 1\text{K}$. Though this might correspond to a suitable minimum level of thickening in a monotonic approach to infinity, in practice there is a natural pattern of behaviour for which this description is quite unsuitable.

It was shown by Wunderlich and Arakawa³ that PE crystallized between 2.8 and 3.8 kbar at a supercooling of 10K showed two atmospheric melting peaks, the lower apparently continuous with the single peak observed at lower pressures and the higher with the main peak at higher pressures, although the maximum melting points are almost continuous through the pressure range. This behaviour is, *prima facie*, compatible with either a change-over to a different crystallization mechanism or with an 'avalanche-like long period growth'⁸ as is familiar from annealing studies on solution-grown lamellae at 1 bar⁴¹. It is, however, natural to associate the higher melting peak with chain-extended layers and the lower one with chain-folded as was done in early papers⁴. The distinction was carried further when it was noted that for each PE studied there were two non-overlapping ranges of melting point for crystals grown at moderate supercoolings, though these varied with molecular weight so much that there was no one melting point, nor, correspondingly, one crystal thickness, which could always be said to divide off chain-folded from CEPE. Nevertheless, Bassett, Khalifa and Turner⁴² showed that material in the two melting peaks could always be distinguished by their characteristic textures as seen in the polarizing microscope. The lower peak or chain-folded material,

was clearly spherulitic, with rounded or polygonal outlines and sometimes banding, whereas chain-extended material of the higher melting peak had a coarse spikey sheaf-like appearance previously noted at 5 kbar⁹ which while possibly due to embryonic spherulites would nowadays be regarded as similar to the morphology produced by regime 1 crystallization at low supercoolings⁴³. This gave a working distinction between chain-folded and chain-extended material produced by recrystallization at high pressures. It played a significant role in the subsequent advance in the subject but has now been superseded by a fundamental definition following recent work. One of the consequences of using it, however, was a realization that the language chain-extended/chain-folded is not well suited to the description of what actually occurs with high pressure crystallization. For example, with decreasing molecular weight, lamellar thicknesses associated with the chain-extended melting peak drop, and average values as low as 800 Å have been recorded for a 20 000 MW fraction⁴⁴, considerably less than values recorded for chain-folded lamellae of similar molecular weight polymer in other circumstances¹. The absurdity of the terminology has increased following studies of crystallization in thin films showing that lamellae as thin as 100–200 Å should also be regarded as chain-extended^{45,46}. The underlying reason for this is now clear, but the scientific case for a change in nomenclature is extremely strong notwithstanding the current widespread usage.

The first consequence of using this new definition was the demonstration that it is easier for longer molecules to become chain-extended than for shorter ones⁴⁴. This somewhat paradoxical conclusion shows that it is not possible to generalize Anderson's observations at ambient pressure¹ to high pressure behaviour, thus negating theories proposed by Kawai^{6,7}. The relevant observations were that the change-over from chain-folded to chain-extended behaviour for sharp fractions occurs over a narrow temperature range (5K) at a suitable constant pressure and at lower pressures for longer molecules.

The second conclusion was that chain-folded and chain-extended growth are independent processes. The different textures of chain-folded and CEPE had already cast doubts on a thickening hypothesis because it had also been shown that thickening lamellae ten-fold to over 2000 Å on average by high pressure annealing left the gross physical texture unaltered³¹. The conclusion was established, however, following high pressure d.t.a. observations. These showed that at a cooling rate of $\sim 1\text{K}/\text{min}$, crystallization of a 50 000 MW fraction occurred at characteristic supercoolings of $\sim 16\text{K}$ for chain-folded crystallization and $\sim 12\text{K}$ for chain-extended⁴⁷. In the region where both morphologies resulted, two d.t.a. peaks were detected having the characteristic super-coolings and widths measured on either side of this region⁴⁴. There was thus no evidence for a modification of either process when they overlapped, but an indication that both were occurring independently. Finally it was shown that under particular isothermal, isobaric conditions chain-extended polymer formed before chain-folded material⁴⁴. The conclusion is, therefore, that chain-extended material could not in this case have formed by a reorganization of chain-folded material but must have formed independently. This has since been verified by direct optical observation of high pressure crystallization²⁹.

Support for the independence of chain-folded and chain-extended growth also came from the studies of Kanetsuna and coworkers⁴⁸. They, too, observed the sharp change from a chain-folded to a chain-extended product with a

change of a few degrees in the temperature of isothermal crystallization at a fixed pressure of 3 kbar and decided that this was most likely to be a consequence of a different growth mechanism, possibly involving a bundle-like nucleus. Subsequently Maeda and Kanetsuna⁴⁹ reported volumetric data showing the same phenomenon observed with high pressure d.t.a., namely that when crystallization during cooling gave a mixed product, the chain-extended component formed first, at a higher temperature, before the onset of chain-folded growth. Accordingly they supported the conclusion of the Reading group that there were two growth processes involved.

At this stage the subject was in a curious state. The discontinuity in behaviour ruled out the hypotheses of Peterlin⁸, of Calvert and Uhlmann²⁸ and of Wunderlich²⁶ (at least in the form in which it has so far been expressed). The facts showed that there were two independent crystallization processes each producing lamellae containing folded molecules with only a difference of scale between them. The nature of these two processes was, for a while, still obscure but was soon suggested following further *in situ* high pressure measurements.

New phenomena at high pressures

The first reports of a change in the customary pattern of crystallization behaviour came in 1972. Bassett and Turner⁵⁰ reported that at 4.10 kbar and higher pressures an additional high temperature endothermic d.t.a. peak appeared during melting of PE. The change was reversible and a corresponding exothermic peak was detected at 4.3 kbar and higher pressures. The same high pressure d.t.a. phenomena were also reported by Yasuniwa, Nakafuku and Takemura⁵¹ during melting at 4.0 kbar and above and during crystallization at 6.0 kbar. These authors simply referred to the peaks as due to the melting and crystallization of an unknown structure. Bassett and Turner⁵⁰, however, also reported corresponding dilatometric changes and concluded from criteria of reversibility, stability and accord with the Clausius–Clapeyron equation that the changes were first-order transitions into and out of a new high pressure phase intermediate in properties between orthorhombic solid and melt. A phase diagram was published based on melting data for thick crystals and an ‘excellent correlation’ claimed between the formation of chain-extended polymer and the occurrence of the new exotherm during crystallization. It was proposed, in consequence, that crystallization of orthorhombic PE from the melt gave the customary chain-folded polymer while chain-extended polymer resulted, strictly when the sequence melt → intermediate phase → orthorhombic occurred, but was likely simply to be crystallization of the new phase, inferred to be either liquid crystalline or solid, from the melt. This hypothesis explained the main features of chain-extended growth in a straightforward manner, notably the specificity of the phenomenon to melt crystallization of PE, and its absence in dilute solution or for polymers in general and the relationship with chain-folded growth. In particular a substantial increase of thickness would be expected for the chain-extended polymer according to kinetic theories of crystallization because the entropy of fusion of the intermediate phase is reduced below that of the orthorhombic phase by a factor of approximately four.

These two sets of authors were then joined by Maeda and Kanetsuna who reported extensive dilatometric data^{49,52}. While the actual results of the three groups are in good

agreement, the respective interpretations were quite different.

Maeda and Kanetsuna at first doubted⁴⁹, then rejected⁵², the interpretation in terms of a new phase. Partly this was because of their experience of the effect of thermal history of a sample in the moderate pressure region where chain-folded growth gives way to chain-extended and where widespread and delicate fractionation causes great complication. Most of all, though, these authors considered that the additional d.t.a. peak and related volume change concerned not the whole sample as Bassett and Turner believed, but only a part. This part they termed highly-extended-chain crystals in contrast to ordinary extended-chain crystals. These were thought to be present above 4.7 kbar when the additional peaks were well-resolved and were taken to be composed of the crystals ~2 μm thick which are the dominant cause of the characteristic texture of chain-extended polyethylene in the polarizing microscope. They believed that such crystals resulted from reorganization of ordinary extended-chain crystals in a similar way to the reorganization of folded-chain into extended-chain polymer known to occur under high pressure annealing³¹ and confirmed by their own data. This reorganization would not necessarily be detected as a peak in either d.t.a. or volumetric measurements in the same way that a secondary d.s.c. peak is often not recorded during melting of polymer crystals at 1 bar even though reorganization and crystal thickening undoubtedly occur⁴¹. Finally in support of their arguments, Maeda and Kanetsuna reported a distinct population of crystal lengths of order 2 μm, representing about 10% of a sample, when crystal thicknesses are measured by the nitric acid/g.p.c. method. It should be noted, however, that the corresponding peak is not present in the raw g.p.c. data, but only appears after correction to allow for instrumental broadening⁵³.

The interpretation of Yasuniwa, Nakafuku and Takemura⁵¹ is in many ways similar to that of Maeda and Kanetsuna. They also found that on slow cooling at ~3 kbar chain-extended crystals formed before chain-folded and were able to identify the two processes by direct observation with the diamond-anvil optical cell. Moreover, they too, showed that folded-chain crystals can reorganize into extended-chain crystals during the melting of initially chain-folded PE and a continuation of this process is apparently the model for formation of their unknown structure which is said to form later in the sequence by recrystallization after melting of extended-chain crystals. Conversely, during slow cooling at 6 kbar, the two high pressure d.t.a. peaks are said to be of ‘an unknown structure and an extended-chain crystal’. This interpretation also considers the additional d.t.a. peak as relating to only part of a sample as is confirmed firstly, by the listing of separate melting (and crystallization) temperatures for both extended-chain crystals and the unknown structure, secondly, by the (unsuccessful) attempt to isolate the appropriate morphology by pressure quenching a sample from the crystallization temperature of the unknown structure and, thirdly, by the (allegedly successful) demonstration of extended-chain crystals growing directly at their ‘crystallization temperature’. Evidently the unknown structure is taken to be additional to the extended-chain crystals and is only considered to occur above 4 kbar where the additional d.t.a. peaks are observed. The nature of the unknown structure was left open with the statement that ‘it may be a nematic liquid crystal phase — but we have no proof’.

Both the Japanese interpretations are inconsistent with the previously published proposals of Bassett and Turner

Figure 2 X-ray patterns of PE recorded at high pressure and temperature²⁹ showing, on the left, the 110 and 200 orthorhombic rings, and on the right, the single 100 hexagonal ring to which they give way before the polymer melts

based on experiments reported in detail in a full paper⁴⁷. The two major differences are that these authors considered the additional d.t.a. peaks as due to the whole and not merely a part of a sample (neglecting the segregation of the lowest molecular weights) and claimed that even though the extra peak on crystallization could not be resolved below 4 kbar it was still present and necessarily involved in the formation of chain-extended polymer to below 3 kbar where crystallization switched to the chain-folded mode. Regarding the first point, Bassett and Turner had the advantage of working with fractionated polymer (polydispersity 1.14) but despite thorough searching could find no inhomogeneity at atmospheric pressure to correspond to the extra d.t.a. peak at 5 kbar. They thus were forced to conclude that the two high pressure peaks were sequential processes involving the entire sample and did not involve different components within it. Fundamental to their case, also, was the correlation between the formation of CEPE (defined by optical texture and d.s.c. melting point)^{42,44} with the two d.t.a. peaks on cooling. This came from a study of the supercoolings of the beginnings and the maxima of all d.t.a. crystallization peaks as a function of pressure. It was shown that the two separate peaks observed at 5 kbar draw closer together before merging at about 4 kbar into a single peak (assumed to be the unresolved sum of the previous two) which at first was suitably wider, then extrapolated smoothly back to the onset of chain-extended growth when a discontinuous change to the conditions for chain-folded growth occurred⁴⁷.

The situation in which three groups of authors interpreted essentially the same facts in three different ways was resolved by the discovery of the high pressure intermediate phase postulated by Bassett and Turner⁵⁰. This was achieved by Bassett, Block and Piermarini²⁹ using the gasketed

diamond-anvil cell, a device similar to that used in previous optical studies of high pressure crystallization³⁹. The 110 and 200 lines of orthorhombic polyethylene were observed to give way to a single spacing of 4.23 Å before melting at ~6 kbar (Figure 2). Although only one line was recorded this, nevertheless, compares favourably with an earlier view that it is 'not possible to observe the X-ray pattern of a polymer sample with this system'⁵⁴. The new phase was identified as hexagonal and having the prescribed properties i.e. that there was a discontinuous change from orthorhombic to hexagonal then from hexagonal to melt, and that the average chain axis direction c was preserved in the orthorhombic to hexagonal transition. Moreover, a direct correlation was established of the hexagonal X-ray pattern with the optical appearance of chain-extended polymer under the same conditions. The formation of chain-folded polymer correlated similarly with the orthorhombic X-ray pattern. The proposals of Bassett and Turner^{47,50}, were thus confirmed in their essentials. It is the hexagonal phase which causes the changed pattern of behaviour when PE crystallizes from the melt at high pressures. Crystallization of orthorhombic PE from the melt is what has been termed chain-folded growth whereas crystallization of hexagonal PE (followed by a transition to the orthorhombic structure during reduction of pressure and/or temperature) is chain-extended growth.

Hexagonal polyethylene

Although only one X-ray reflection of the new phase was detected²⁹, this was shown to be of $hk0$ type in a uniaxial structure. Knowledge of the volume change during the transition⁴⁷ then eliminated the possibility of a tetragonal structure with a hexagonal/trigonal structure as the only alternative. Since then further confirmation has come from finding the anticipated threefold twinning resulting after an orthorhombic \rightarrow hexagonal \rightarrow orthorhombic sequence of transitions⁵⁵.

There is the well-known precedent of the n -paraffins in which a hexagonal structure also intervenes between the orthorhombic form and the melt. However, whereas the hexagonal form of the paraffins is a well-ordered solid, closer in properties to the orthorhombic phase than to the melt⁵⁶, this does not seem to be the case for PE. The single sharp X-ray line, while incompatible with a nematic liquid crystalline structure merely defines a close-packing of rods. The spacing of these rods is significantly wider for PE (the relevant X-ray spacing is 4.23 Å compared to 4.11 Å for n -C₂₄H₅₀) yet the respective increases in specific volume over the orthorhombic phase are not so different. The value for PE according to Bassett and Turner⁴⁷ is 0.085 cm³/g (more recent values of Maeda and Kanetsuna⁵² suggest a slightly lower figure which, however, probably needs revising upwards because of the presence of a chain-folded component in the samples). This is an increase of only 8.5%, whereas the increase in cross-sectional area per chain is from 18.2 to 20.6 Å², i.e. 13%. It was suggested, therefore, that the average c axis spacing per ethylene unit had to decrease from the presumed 2.53 of an all *trans* configuration to 2.45 Å and shown that this was most unlikely to occur by the adoption of a uniform helix. Hexagonal PE thus seems to have lost the all *trans* configuration and to include a proportion of *gauche* bonds along the chain, so that it is probably not a fully-ordered solid. It is certainly much closer to the melt in its specific volume and enthalpy than to the orthorhombic form as is commonly found in

liquid crystals but is not the case for the hexagonal form of the n-paraffins. This is intuitively reasonable because its formation is favoured by increasing pressure⁵⁰ whereas the hexagonal forms of paraffins are not stable above a few kbar⁵⁶.

High pressure annealing

The effects produced by annealing PE at high pressures are intimately related to the crystallization phenomena, although their role in the development of the subject has been mostly to raise questions rather than to provide many of the answers. Thus the discovery by Rees and Bassett^{31,32} that chain-folded PE in various forms: single crystal mats, drawn fibres, spherulitic films, could be converted into chain-extended, with maintained molecular orientation and gross texture but gradually increasing lamellar thicknesses, by high pressure annealing appeared, at the time, to support the proposal that enhanced lamellar thickening was responsible for the formation of CEPE. It certainly showed that a range of conformations could be produced and not merely that of full molecular extension. These results have now been confirmed by many groups^{14,49,51,58,59} but further work showed that although there is some increase in thickening rate (i.e. the gradient of a plot of crystal thickness against log time) at 5 kbar compared to 1 bar, this was insufficient to account for the large thicknesses of CEPE which were already established at short times¹⁷. They did, however, prompt work looking for the time (and temperature) dependence of lamellar thickness during high pressure crystallization which brought out the similarity in pattern with chain-folded crystallization¹³.

Early criticism of this work was misguided, as is now quite evident. Fischer and Puderbach⁶⁰ were unable to reproduce the high extensions reported by Rees and Bassett, but this was simply because they had not annealed to sufficiently high temperatures and the polymer had not entered the hexagonal phase. Gruner, Wunderlich and Bopp³³, on the other hand, did find the high extensions, but mistook the orthorhombic-hexagonal transition for a change in molecular mechanism from solid-state thickening to 'partial melting' and recrystallization. They also considered, wrongly and without testing the point, that molecular orientation would not be maintained beyond this transition. The first discussion of high pressure annealing in terms of the hexagonal phase was that of Bassett and Carder¹⁴ on drawn sheets, but the behaviour of other samples is essentially the same and the case of spherulitic PE has also recently been placed in this context⁵⁹.

Annealing in the hexagonal phase produces high thicknesses in bulk polymer; these then increase gradually with temperature and time until the final melting of the hexagonal phase which results in a substantial further increase typically from ~2000 Å average to ~4000 Å, achieved mainly by the appearance of very thick lamellae^{14,59}. Annealing which is confined to the orthorhombic phase tends to reproduce phenomena found at 1 bar. Thus X-ray long period gives approximately a common reduction in terms of supercooling for 5 kbar and 1 bar⁶⁰⁻⁶², while the morphology of solution-grown lamellae annealed at high pressures^{61,63} shows features already familiar from atmospheric experiments²³.

It is a strong argument in favour of regarding the effects of annealing as due to a sequence of melting then recrystallizing (at a higher and more stable thickness) part of a sample, perhaps only a few fold stems in the early stages, that

annealing in the hexagonal phase should also give layer thicknesses approaching but lower than those produced by crystallization into this phase, thereby reproducing a pattern familiar in many polymers⁶⁴. Even though the more open structure of the hexagonal phase will tend to assist postulated molecular mechanisms such as solid-state thickening, the rate of thickening actually measured is not large enough to account for the high thicknesses produced¹⁷. The interpretation in terms of local melting followed by recrystallization has been strongly canvassed in several recent papers from Reading^{14,45,55,59}, although in earlier research Rees and Bassett¹³ were not then able to support this point of view because of the known effect of sample prehistory on annealed specimens^{13,65}, a factor which should not have influenced melting/recrystallization according to facts then known. Soon afterwards, however, it was reported that the thicknesses produced in chain-extended samples decreased with sample size. Recent papers show that crystallization of hexagonal PE from the melt and annealing of hexagonal PE can both give lamellae only 100 Å or so thick in the thinnest films whereas bulk specimens treated alongside acquire lamellar thicknesses one to two orders greater^{46,55}.

This phenomenon removes, in principle, the objection based on sample prehistory by allowing local melting of a smaller part of a sample to produce a lower lamellar thickness on recrystallization⁴⁵. A side-effect of work on CEPE has thus been to provide what appears to be a consistent explanation of this second long standing problem in polymer crystallization.

CURRENT STATUS

Pattern of crystallization

The current status of research on CEPE is that the hypothesis of Bassett and Turner^{50,47} allows a simple understanding of the main features within the framework of ideas developed for chain-folding, but that many of the detailed points need thorough testing. At the same time the generalization of behaviour found in CEPE to chain-folded growth as a whole sheds interesting light on some old problems.

Because the hexagonal phase is specific to molten polyethylene, one has a simple answer to the mystery of why crystallization under pressure does not greatly affect the behaviour of other polymers nor indeed the growth of polyethylene from solution^{30,61,66}. Even when new phases do appear with pressure as e.g. in *cis*-polyisoprene⁶⁷ one would not expect these to produce pronounced increases in lamellar thickness unless, as for hexagonal PE, the new phase has a correspondingly reduced entropy of fusion, i.e. it is closer to the melt in properties than to the normal solid.

The independence of chain-folded and chain-extended growth is inherent in this scheme, but the manner in which one gives way to the other is of particular interest. At 5 kbar the expected behaviour is for CEPE to form at low supercoolings and for chain-folded growth to set in at higher supercoolings corresponding to the pattern of the phase diagram. This is observed in practice^{13,48,68}, although crystallization of the hexagonal phase frequently occurs at sufficiently high supercoolings to make it metastable⁴⁷. In a similar way, CEPE is still formed isothermally at temperatures and pressures a little below the estimated orthorhombic/hexagonal/melt triple point^{44,47}. It can also be formed by rapid application of pressure beginning at temperatures

Figure 3 (a) High pressure d.t.a. traces of PE fractions having the molecular weight distributions shown in (b). All samples had previously been crystallized into the hexagonal phase at 4.9 kbar. (R. B. Morris and D. C. Bassett, unpublished)

as low as 170°C for high molecular weight polymer³, but this is merely a consequence of temperature rising during the pressure quenching to conditions close to those where isothermal crystallization occurs⁶⁹. Such temperature rises can be substantial (8K/kbar has been estimated for molten PE in the range 1–4 kbar⁶⁹) and as pressure crystallization has mostly been carried out by the rapid imposition of pressure at a given temperature it is probable that in at least some of the experiments in the literature, crystallization actually occurred at higher temperatures than those reported.

The change from chain-folded to chain-extended growth is very dependent on molecular weight^{42,44,48}. In part this is a consequence of kinetics, but it also reflects the sensitivity of the triple point, the orthorhombic–hexagonal transition and the melting point to this parameter⁴⁷. Unpublished estimates from this laboratory place the extrapolated triple point as low as 2.7 kbar for very high molecular weight linear polyethylene whereas it is above 5 kbar for molecular weights of a few thousand. Figure 3a taken from unpublished work by Morris and Bassett shows that the orthorhombic to hexagonal transition temperature increases at 5.35 kbar from 237° to 245°C and the hexagonal melting point from 245° to 258°C, all samples having previously been crystallized by slow cooling at 4.9 kbar, with average molecular weight rising from 10⁴ to 10⁵. (The effect of increasing the branch content is qualitatively the same as lowering the molecular weight of linear polymer). Inevitably, therefore, fractionation is widespread during high pressure crystallization^{2,4,13}. At 5 kbar, obvious fractionation can be avoided by removing molecules below 10⁴ molecular weight^{70,71,14}, although the impression gained by direct observation of crystallization is that fractionation on a fine-scale still persists with a change in habit and branching frequency with molecular weight; this is in accord with the facts cited above and observations on the

progress of melting through a sample⁷¹. Near the triple point, however, even tolerably good fractions (polydispersity 1.14) undergo internal fractionation⁴⁷ and mixed samples of disparate molecular lengths separate out⁷² because the higher crystallizes into the hexagonal phase and the lower into the orthorhombic. In addition there are time effects, altogether making for a complicated situation whose details remain to be elucidated.

Segregation of lower molecular weight material is responsible for separate low melting peaks of thinner crystals which appear not only in recrystallized PE but also in specimens annealed at high pressures^{14,33,70,71}. The number of such peaks and their explanation vary. There is always at least one clearly attributable to direct crystallization into the orthorhombic phase i.e. chain-folded polymer. The triclinic structure has also been detected⁷³. In addition there is often a peak of intermediate melting point, rising in certain circumstances to ~140°C at 1 bar^{14,33,71}, whose origin was once claimed to be the onset of molecular motion at 1 bar⁴ similar to that of the orthorhombic–hexagonal transition in n-paraffins. Alternatively it was suggested that it referred to PE of intermediate molecular weight in either folded-chain or fully-extended conformation^{33,71}. Most recently it has been proposed⁵⁹ that this is material which is unable to crystallize into the hexagonal phase at the treatment temperature but does so on cooling, thereby being differentiated from the shortest molecules which are incapable of forming the hexagonal phase at the pressure used. Here, too, the details need clarification although they are not likely to affect the broad understanding of chain-extended growth.

Lamellar thickness

Knowing of the existence of the hexagonal phase, it is a natural assumption that the differences between chain-extended and chain-folded growth reflect the properties of the two phases rather than a change in the crystallization process itself, i.e. that chain-extended growth is just kinetically controlled ('chain-folded') growth of the hexagonal phase. There is support for this view in the dependence of lamellar thickness on supercooling¹⁶ and the entropy of fusion^{50,47}, in the similar ratio of σ_{eff} needed to fit the kinetic theory formalism to σ_e , the surface free energy derived from melting points²⁵ and in the similarity to PTFE²⁵. On this basis the lamellar thicknesses produced by chain-extended growth should be higher than those of chain-folded polymer because of the lower entropy of fusion. At pressures ~3 kbar where both forms of PE can be produced at the same temperature, the ratio of lamellar thicknesses of chain-folded and CEPE is about 4⁴⁴, a value consistent with the relative entropies of fusion estimated when they can be resolved i.e. at 5 kbar⁴⁷. This behaviour is that expected from kinetic theory, but for CEPE crystallized at higher pressures (at constant supercooling) there is a large increase of crystal thickness with pressure of ~750 Å/kbar for 50 000 molecular weight polymer⁴⁴. The variation of thickness of chain-folded crystals with pressure has hardly been studied either experimentally or theoretically. A modest increase has been found⁷⁴ for chain-folded PE (~50 Å/kbar) of a magnitude anticipated from the increase with pressure associated with the density deficit of chain-folds in the surface free energy¹³ and little change observed for *cis*-polyisoprene⁷⁵. It is possible, however, that a substantial increase of lamellar thickness might be anticipated on existing theories of chain-folding from the melt.

In his early formulation, Hoffman⁷⁶ found the observed thickness of a melt-grown lamella to be:

$$l = \gamma \left[\frac{2\sigma_e}{\Delta h_f} \times \frac{T_m^0}{\Delta T} + \delta l \right]$$

where $\delta l = kT/b\sigma$, γ expresses the effect of isothermal thickening, b is the lattice translation and the remaining symbols have their previous meaning. Later, Lauritzen and Passaglia⁷⁷ obtained a similar expression:

$$l = \frac{2\sigma_{\text{eff}}}{\Delta h_f} \times \frac{T_m^0}{\Delta T} + \delta l(T)$$

which removes γ , replaces σ_e by σ_{eff} which is a function of temperature and δl by $\delta l(T)$. The latter expression was used by Bassett and Davitt²⁵, with the assumption that $\delta l(T)$ was small, to show that the ratio $\sigma_{\text{eff}}/\sigma_e \approx \gamma$ was approximately the same (~ 2.5) for PTFE, for chain-folded PE and for CEPE in making a case for a common crystallization process. Concerning the increase of lamellar thickness with pressure, Hoffman (personal communication) has pointed out that, in addition to the large increase in l due to the small enthalpy of fusion of the hexagonal phase, δl in the first expression should also increase for CEPE firstly because σ , the lateral surface free energy, is expected to be proportional to Δh_f , the enthalpy of fusion, and so will be proportionately lowered for the hexagonal phase. There should, moreover, be a second and even greater effect because σ is liable to decrease with pressure, in a parallel way to its decrease with falling temperature, as the hexagonal phase and melt become closer in properties. In addition, the theory of lamellar thickening relating to the factor γ predicts⁷⁶ a logarithmic increase with time of a magnitude inversely proportional to σ^2 , so that the initial rate of thickening might become quite large, conceivably accounting for a projectile shaped profile for the growth front as has been observed.

Experimental facts against which to judge any such proposals are still meagre but it has been shown that lamellar thickness increases approximately with inverse supercooling at a given pressure¹⁶, with pressure at a fixed supercooling⁴⁴, with molecular weight (between 2×10^4 and 5×10^4) at a fixed temperature^{4,10,13,44} and pressure and, most markedly of all, with specimen size below $\sim 100 \mu\text{m}$ ^{45,46}. This last parameter can depress lamellar thicknesses by more than an order of magnitude and yet, for lamellae away from a free surface, would not be expected to have much influence in the thickness of a simple molecular strip adding to a crystal in the model envisaged by kinetic theories, but would have a significant role in any subsequent lamellar thickening⁴⁵. It is noteworthy that, in comparison, the factor γ is only ~ 2.5 ²⁵. Secondly, in terms of the rationalization of γ in terms of lamellar thickening, all data have been measured away from the growing edge of lamellae and may well, therefore, not be related to the tapered profiles now observed. It should also be pointed out that these profiles and the effect of specimen size have led to questioning of the basis of kinetic theories^{25,46}. To clarify all these points there is an urgent need for further data which hopefully may be forthcoming from direct observation of chain-extended crystallization in the diamond-anvil cell.

Kinetics

The kinetics of chain-extended growth have been little studied until recently and should be capable of adding sig-

nificantly to our understanding of its nature. Although Davidson and Wunderlich³⁸ reported that both crystallization and melting rates are retarded under elevated pressure, other workers have found the opposite. Thus Kyotani and Kanetsuna⁷⁹ found an increase of crystallization rate with pressure throughout the range from 0 to 5 kbar. In this and other work from this group⁸⁰, dilatometric data obtained for varying molecular weights, pressures and temperatures were analysed in terms of the Avrami equation. Whereas at lower pressures the Avrami exponent was ~ 2 , there was an abrupt change at pressures where CEPE occurred. Data at these higher pressures were interpreted in terms of a single process, whereas we now know that two are involved.

The high pressure d.t.a. data of Bassett and Turner⁴⁷ also show an increasing rate of crystallization with pressure from 1 to 5 kbar. They show, in addition, that this is true of the crystallization of the hexagonal phase just as for the orthorhombic, but that the rate of the hexagonal to orthorhombic transition is more or less constant with pressure. The effect of increasing molecular weight from 5×10^4 to 2×10^6 was to increase the rates of hexagonal crystallization and hexagonal to orthorhombic transition but to decrease the rate of chain-folded (i.e. orthorhombic) crystallization at 2 kbar and below. These authors also presumed that in a given set of crystallization conditions the actual product was the result of kinetic competition between crystallization into orthorhombic and hexagonal phases. In this connection, they pointed out that the observed changeover between chain-folded and CEPE occurred below the triple point by a pressure approximately that needed to alter the melting points sufficiently to offset the difference in rates measured by the relative supercoolings at the triple point. The whole question of kinetic competition is an interesting one which remains to be investigated.

Chain-extended polyethylene as a model system

CEPE is an interesting material in its own right because of its large lamellar thicknesses and the consequent approach to fully crystalline properties. This large lamellar thickness also makes it of particular value as a model system because at least the thickest lamellae can be individually resolved in the optical microscope. So far advantage has been taken of this in two ways, the direct observation of lamellae growing from the melt and the study of mechanical properties in relation to physical texture⁸¹.

The first observations of CEPE forming under pressure by Jackson, Hsu and Brasch³⁹ have been referred to briefly. Further studies of a similar kind have now been reported by Bassett, Block and Piermarini²⁹ and, most fully, by Yasuniwa and Takemura⁷⁸. These have shown the hexagonal-orthorhombic transition and, most significantly, confirmed directly that at least the thickest lamellae of CEPE do grow outwards behind a narrowed edge as had been inferred from observations of fracture-surfaces^{13,21,26} and thin films (e.g. *Figure 4*). This establishes that the final lamellar thickness only appears after very substantial lamellar thickening. The suppression of lamellar thicknesses with decreasing specimen size has also been claimed as evidence of a cooperative process, involving a number of molecules, being involved in the attainment of the familiar large thicknesses⁴⁶. Furthermore, arguments have been brought to bear suggesting that this is likely to be true also of thin-

Figure 4 Thick lamellae with highly-tapered edges viewed edge-on, produced by crystallization of a thin film of a PE fraction ($M_w = 5 \times 10^5$) at 5 kbar. (D. C. Bassett and J. M. Phillips, unpublished)

ner lamellae in CEPE^{13,21} and of lamellae produced by kinetically controlled growth in general²⁵.

Such a process appears to be at variance with the concepts of the LP kinetic theory⁷⁷, which envisages a single strip laid on a substrate as establishing layer thickness with, presumably, only σ_{eff} to look to to account for systematic variations in thickness. In terms of the earlier Hoffman theory⁷⁶, if it can be shown that the thickness at the tip is nucleation controlled, then the observations concern the theory of the factor γ . To date the theory of γ has generalized the logarithmic time dependence observed for thicknesses away from lamellar edges; whether this is relevant to the profile of the edge is not known. As has also been pointed out previously, however, the value of γ for PE is estimated at ~ 2 ⁷⁶ or ~ 2.5 ²⁵, whereas the suppression of thickness by specimen size is at least an order of magnitude.

Mechanical properties

As first prepared, CEPE was notorious for its brittleness² so that its mechanical properties did not seem especially interesting. Even the brittleness, however, is revealing because whereas for the linear polymer CEPE characteristically fractures in $\{hk0\}$ planes, only a small proportion of short-chain branching effects a striking change to fracture between the basal lamellar surfaces. It was subsequently shown by Bassett and Carder⁸¹ that, in an oriented sample, brittleness in tension along the chain axis disappeared if short chains (less than a few thousand Å long) were removed, otherwise they segregate between the large lamellar surfaces. Subsequent investigation has shown that the polymer remains brittle for other directions of stress. This, however, is a matter of molecular weight and in recent work Attenburrow and Bassett⁸² report that Hifax polyethylene (molecular weight in excess of 2×10^6) can be drawn about 5 times at 80°C; at room temperature the material shows ductile fracture.

The first paper on mechanical properties of CEPE was that of Bassett and Carder⁸¹ who investigated the change in chain-axis modulus as a function of annealing temperature at 5.35 kbar. They showed that towards the end of the chain-folded region, the polymer behaved, according to its morphology, melting point, density and stiffness, as a series composite of crystal and intercrystalline regions while average lamellar thickness increased from 500 to 1000 Å. Once in the chain-extended region this simple model broke down, as is not unexpected, in view of the sensitive fractionation indicated by Figure 3.

The modulus parallel to c of CEPE is of particular interest in the quest for attainment of the theoretical stiffness of polymers; for PE this is ~ 300 GN/m², rather more than that for steel⁸³. It is now widely appreciated that it is the interruption by fold surfaces of the sequence of covalent carbon-carbon bonds which leads to the observed chain-axis modulus of PE being often at least 100 times lower than the maximum. To increase the modulus one must, therefore, ensure good orientation, stiffen interlamellar connections and reduce the number of interfaces by increasing chain-extension^{83,84}. Bassett and Carder⁸¹ studied the compromise between the last two factors resulting when drawn fibres, with stiff interfaces but low chain-extension, gradually had their chain-extension increased but simultaneously, their interfaces softened. It was shown that interface stiffening is much more important to modulus than is chain-extension. This is the factor which has now been exploited in the attainment of moduli of order 100 GN/m², through the use of very high draw ratios⁸⁵.

The mechanism of drawing has itself been the subject of much study but its understanding is severely handicapped by the difficulties of establishing the facts in chain-folded systems, especially those concerning the fate of lamellae which cannot, in general, be examined directly. This is no longer the case for CEPE where at least the larger lamellae can be directly observed in bulk specimens in the optical microscope. A second advantage is that whether melting (or quasi-melting) occurs during drawing, a hypothesis which continues to receive support, can be checked very simply. If this were to happen at atmospheric pressure, it could not reproduce the large crystal thicknesses (and high melting point) because these are a legacy of crystallization into (or annealing in) the hexagonal phase and so crystal thicknesses would drop to a few hundred Å and melting points fall to $\sim 130^\circ\text{C}$. In fact Attenburrow and Bassett⁸² have shown that melting does not occur in five-fold drawing and that lamellae survive this process at essentially constant thickness but become highly sheared along c . CEPE is thus proving valuable in yet another context to illuminate major problems in polymer physics.

CONCLUSIONS

The study of CEPE can be summarized as having led to four main conclusions:

(1) In the case of PE, chain-extended growth is crystallization of the hexagonal phase. The chain-folded/chain-extended terminology is confusing; it is probably best avoided and replaced by reference to the orthorhombic and hexagonal phases respectively.

(2) The mechanism of lamellar thickening during annealing of polyethylene can be regarded as due to (it is certainly very little different from) local melting, initially perhaps of only a few fold stems, followed by recrystallization.

(3) There is probably one mechanism of polymeric crystallization with molecular folding common to chain-folded and chain-extended polyethylene as well as to PTFE and other polymers. This process is cooperative, being more than the deposition of a single molecule on a substrate and leads to observed lamellar thicknesses being approximately inversely proportional to the entropy of fusion and to supercooling.

(4) CEPE is a valuable model system particularly in so far as it allows observation of individual lamellae being formed during crystallization and being deformed mechanically.

and P. L. Goggin

Department of Chemistry, University of Bristol, Bristol, BS8 1TL, UK
(Received 16 February 1976)

This study contains a combined application of three different techniques for the study of polyethylenes crystallized from the melt under different circumstances, small-angle X-ray diffraction (SAXD), low frequency Raman spectroscopy to examine the longitudinal acoustic (*LA*) mode, and electron microscopy. In particular, the combination of SAXD and Raman methods enables the separation of the situation where there is only one lamellar structure which displays several orders in the SAXD pattern, from that where there is more than one type of lamellar thickness present. The superior power of the Raman method, which does not depend on the regularity in the lamellar stacking, becomes apparent. The multiplicity of the lamellar population could be associated with lamellae formed isothermally at the preselected crystallization temperature and with lamellae which originated from material which has remained uncrystallized at this temperature and formed subsequently with smaller lamellar thickness during cooling of the sample. The existence of the corresponding double lamellar population could be made directly visible using electron microscopy on freeze-cut and stained sections. The thinner lamellae in the double population could be extracted by solvents, removing the corresponding SAXD and Raman peaks, and leaving blank image areas in place of the thin lamellae in the electron-micrographs. These extracted thinner lamellae correspond to lower molecular weights as assessed by g.p.c. Thus molecular segregation during crystallization is involved. Furthermore the segregated texture units and their arrangement within the full morphology could now be identified. Pronounced changes in lamellar thickness with crystallization time were observed throughout and were associated in the early stages of crystallization with molecular fractionation and in the later stages with thickening of lamellae already present. An unexpected interrelation between nucleation density and the final lamellar thickness through the agency of isothermal lamellar thickening has been established. Examples are quoted which are contrary to the expected trend of lamellar thickness with crystallization temperature, but which are interpretable nevertheless in the light of the effect of isothermal lamellar thickening. The potential significance of all these findings and of this kind of approach for the characterization of crystalline bulk polymers is made throughout.

INTRODUCTION

It has been established that the Raman active longitudinal acoustic mode of vibration (*LA* mode) can be used as a measure of the straight chain length in lamellar crystals of polyethylene¹⁻³. A greater part of the recent discussion involving the Raman method has centred around correlations of the Raman derived chain length with the lamellar spacing determined from small-angle X-ray diffraction. The motivation for this has been to obtain a better description of the lamellar morphology in terms of the crystalline core and an amorphous fold surface. At a quantitative level there are several problems to this approach. In the Raman spectrum a vibrational frequency is observed and the problem becomes one of interpreting this frequency in terms of a chain length. This is usually carried out by using the following relationship developed for the *n*-paraffins⁴: $\nu = (m/2L)E/\rho^{1/2}$ where ν is the vibrational frequency of the

LA mode, *m*, the order of the vibration, *L* the length of the vibrating chain, *E* the Young's modulus and ρ the density. A rigorous treatment however, would require the special features associated with polyethylene for example chain branches and fold surfaces to be taken into account⁵. These effects are known to be small but their precise values on which clearly a meaningful comparison with other techniques depends is as yet unknown. By contrast both SAXD and electron microscopy are established techniques in this field. However, there are still uncertainties surrounding the values of lamellar thickness for melt crystallized polyethylene. Authors differ in their treatment of the SAXD data which in turn affects the long spacings determined. Furthermore in cases where more than one SAXD maximum is observed there is disagreement about which one represents the lamellar spacing^{6,7}. Generally observations by electron microscopy have not shown good agreement with the expectations of lamella thickness given by SAXD⁸.

While pursuing these problems, in particular the relationship of SAXD to Raman data, new information has

* Presented at the Polymer Physics Group (Institute of Physics) Biennial Conference, Shrivenham, September 1975.

Figure 1 Typical (a) SAXD pattern and (b) Raman spectrum of PE single crystals (Marlex 6002, T_c 85°C)

become available on the dependence of the lamellar thickness on the time of crystallization and on the effect of nucleation density when crystallization is carried out from the melt including a tie-up with the wider field of molecular weight segregation during crystallization. These results are presented in this paper and the interrelation of crystallization time, temperature and nucleation density is discussed. In an attempt to confirm deductions made from the Raman spectra about the crystallization process the electron microscope has been used. Here it is possible to show that information obtained from the Raman spectrum on the distribution of lamellar thicknesses is directly related to the fine structure observable using the electron microscope, hence showing the complementary nature of these techniques.

The wider implications of this work are in the control of the structure and properties of polyethylene formed by the process of crystallization from the melt.

EXPERIMENTAL

Raman spectroscopy

Raman spectra were obtained at room temperature using a triple monochromator spectrometer, a Coderg model T800. Laser excitation was provided by a CRL model 52 argon ion laser which was set to give a power of 100 mW at the sample.

In all spectra the *LA* modes appear against a sloping background which tends to distort the band-heads to lower frequencies. In order to minimize this error it is desirable to obtain well resolved peaks when subtraction of a background has only a small effect on the peak frequencies. This was attempted using small slit widths typically 1 cm^{-1} and occasionally 0.5 cm^{-1} for recording spectra below $\Delta\nu = 5 \text{ cm}^{-1}$. Noise on the trace also creates an uncertainty in peak position, although nowadays this is generally not a problem since signal to noise ratios better than 20:1 can be achieved. On this basis we were able to locate strong *LA* mode peaks to better than $\pm 0.5 \text{ cm}^{-1}$ depending upon the individual conditions. The error bars for Raman chain length quoted in this paper correspond to the uncertainty in the frequencies of the *LA* modes.

The frequency shift of a peak with respect to the exciting radiation is denoted by $\Delta\nu$ and expressed in cm^{-1} throughout the text. Values of $\Delta\nu$ were converted into values of chain length using the relationship derived by Schaufele and Shimanouchi⁴. In certain spectra there are two low frequency peaks. In these cases the peak with the lower value of ν is referred to as peak 1 and that with the higher value as peak 2.

Small-angle X-ray diffraction (SAXD)

SAXD photographs were taken at room temperature using a Frank's point focusing X-ray camera. An exposure time of 17 h was used for all samples with a specimen to film distance of 9 cm. On a number of occasions a point collimating Rigaku-Denki camera and rotating anode X-ray generator were used whereby the exposure time could be reduced to 4 h using a specimen to film distance of 30 cm. Experience with the results obtained showed that these cameras were very similar in terms of resolving power and background scatter.

Densitometer traces of the X-ray plates were recorded using a Joyce and Loebel two beam microdensitometer. Bragg's law was applied to the maxima to determine the lamellar long spacings. When two distinct maxima are observed in the SAXD pattern, the one at the smaller angle is referred to as θ_1 and that at the larger angle as θ_2 in accordance with the usual convention.

Recently some discussion has centred around the need to apply a Lorentz-geometric correction to SAXD intensity curves^{7,8}. The Lorentz correction was originally introduced as an intensity correction for wide angle X-ray rotation photographs and allows for the different times for which crystallographic planes are in the reflecting condition. In a randomly oriented sample it should be applied to correct for the different probability of planes being in the reflecting condition. At low angles the combined Lorentz-geometric correction takes the form of a θ^2 multiplication factor.

The application of this correction to SAXD curves from single crystal material (Figure 1), or from bulk material with well defined peaks (Figure 2) creates no problems, and the effect is to shift the peaks only slightly towards a lower spacing. In Figure 1, for example, the peak is moved from 124 to 114 Å, by the application of this correction.

The situation has been found to be rather more complicated in the case of some isothermally crystallized bulk materials. In addition to any background scatter from the instrument or from the air, which can be subtracted from the intensity curve, such materials produce a strong intrinsic background scatter at very small angles. Since we believe that this scatter does not originate from the basic lamellar periodicity, it must be subtracted before the Lorentz correction can properly be applied.

The exact form of the background scatter is unknown, but subtracting various trial backgrounds and then applying the Lorentz correction has the effect of reducing the

Figure 2 (a) SAXD pattern and (b) Raman spectrum of quenched PE (Rigidex 50 as supplied) with two maxima in the SAXD pattern and with one first order *LA* mode in the Raman spectrum

Table 1 SAXD and Raman parameters for polyethylene samples

Figure number	Sample description	SAXD layer thickness*, L_x (Å)		Raman chain† length, L_R (Å)	
		θ_1	θ_2	peak 1	peak 2
1	Single crystals of Marlex 6002, T_c 85°C	124(114)	—	135	—

3	Bulk Marlex 50, T_c 122.9°C	320(260)	170(140)	397 ± 17	—
4	Bulk Carlona 65045, T_c 128.4°C	—	—	601 ± 50	—
5	Bulk Unifes 7006, T_c 126.0°C	231(205)	—	370 ± 17	204 ± 5
6	Bulk Unifes 7006, T_c 127.9°C	220(185)	—	531 ± 35	253 ± 8

* Values in parentheses are those for Lorentz-geometric corrected long spacings

† The error bar arises from the uncertainty in the peak position, for a discussion of the errors in the SAXD long spacings, see text.

measured lamellar periodicity of curves 3 to 6 by ~20%. Whilst the effect is not strongly dependent on the particular background which is subtracted, this introduces an uncertainty in the values of long period estimated by SAXD of about 10%. Because of the uncertainties involved, the SAXD spacings shown in Table 1 are uncorrected, with corrected values shown in parentheses.

Electron microscopy

Some of the specimens were treated so as to make the lamellar structure visible in the electron microscope. The technique used was recently discovered by Kanig^{9,10}, independently of previous similar work by Körösy and Zeiger-son¹¹. Small pieces of the polyethylene were put into chlorosulphonic acid and left at 60°C for 9 h. After washing in concentrated sulphuric acid and then distilled water the samples were left for 3 h in a 0.7% aqueous solution of uranyl acetate. Thin sections were then cut from these stained blocks at temperatures below 150K, using an ultramicrotome with a diamond knife and liquid nitrogen cooling system. The chlorosulphonic acid attacks polyethylene, and it diffuses preferentially into the disordered interlamellar material, and not into the crystalline lamellae. In the reaction with polyethylene, polar groups are substituted for hydrogens, and these polar groups attract the heavy metal ions from the staining solutions. Thus the amorphous or disordered regions are made very electron dense. In the electron microscope at focus, the image seen is the projected electron density distribution in the section, so that when a crystalline lamella extends through the section, it appears as a light, electron transparent region.

Another important effect of the acid treatment on polyethylene is to introduce crosslinks between chains, making the sample rigid. It is then very much less susceptible to the large distortions which are otherwise produced by mechanical damage during cutting and radiation damage during observation in the electron microscope. Because of this stability, no special techniques are required in the actual microscopy, and it is possible to assert confidently that the structures observed are representative of those existing in the bulk material.

Samples

Samples were taken from a range of high density polyethylenes of Marlex, Rigidex, Unifes and Carlona types. Specimens were prepared by pressing pellets between thin microscope coverslips on a hot bench at 180°C and held at this temperature for several minutes to allow any orientation in the material to disappear. The thin discs so formed (~0.1 mm thick × 0.5 cm in diameter) were then cooled to about 150°C on the hot bench and then quickly transferred to a thermostat containing silicone oil at the crystallization temperature. The temperature of the oil bath was constant to within ±0.1°C.

For samples of special interest solvent extractions were carried out in *p*-xylene, the details of which are described later. The results of the extraction were analysed in terms of the molecular weight distribution using a Waters analytical g.p.c. apparatus.

RESULTS AND DISCUSSION

Scope and limitations of the techniques available

Since the techniques of SAXD, low frequency Raman spectroscopy and electron microscopy examine different properties of the material, meaningful comparisons of the results can only be made by bearing in mind how the information is obtained. The difference in density between crystalline lamellae and the disordered interlamellar material is detected directly by X-rays, but a prerequisite for the appearance of a discrete maximum in the small angle region is the regular stacking one upon another of lamellae of reasonably uniform size. The position of the peak then indicates the average repeat distance in the stacks of lamellae.

The Raman active *LA* mode depends upon the average length of the extended chains within the lamellae. This will not necessarily be the same as the thickness of the lamellae because the chains may not be perpendicular to the lamellar surface as earlier work has shown¹². Furthermore the *LA* mode will clearly not depend on how the lamellae are arranged in stacks.

The electron microscope looks at density variations but these are not the density variations that originally existed within the material. They have been artificially induced by staining and so reflect the permeability variations within the material. Low permeability is associated with crystalline order and thus high original density. Again, observation of a lamellar thickness does not depend on regular stacking, indeed the arrangement of lamellae may be observed directly.

In Figures 1–6 we give illustrative examples of typical SAXD patterns and Raman spectra of polyethylene. The values of X-ray long spacings and Raman chain lengths are given in Table 1.

For mats of polyethylene single crystals which are well ordered and consist of fairly small crystals the SAXD pattern gives well resolved peaks and several orders of diffraction as shown in Figure 1. For melt crystallized polyethylene in general the position is not so good. The SAXD maxima in Figures 2–4 tend to be obscured by the intense background scatter. Consequently it is difficult or in some cases impossible to measure or even resolve them. In the Raman spectra the *LA* mode peaks also get nearer to the main beam (in this case the intense laser line) as the lamellar thickness increases. However, the recent introduction of triple monochromators has made it generally possible to

Figure 3 (a) SAXD pattern and (b) Raman spectrum of isothermally crystallized bulk PE (Marlex 50, T_c 122.9°C) with two maxima in the SAXD pattern and with one first order LA mode and a weak corresponding third order in the Raman spectrum

Figure 4 (a) SAXD pattern and (b) Raman spectrum of isothermally crystallized bulk PE (Shell Carlon 65045, T_c 128.4°C) without a maximum in the SAXD pattern but with a well defined LA mode in the Raman spectrum

obtain well defined peaks for melt crystallized material, and peaks can be detected even when the corresponding chain lengths are over 500 Å as illustrated in Figure 4. SAXD patterns from material containing such large lamellae give little or no indication of a maximum. Greater intensity and thus finer collimation may be obtained using slit collimated cameras, but to avoid slit height corrections we have concentrated our efforts on point collimation.

Since the electron microscope looks at lamellae in real space the accuracy is not limited by the lamellar size. However, the accuracy is never high for the following reasons: the possibility of distortion of the specimen during preparation; the very small volume of the sample which is observed; and the difficulty of calibrating the microscope accurately.

To summarize, therefore, the Raman technique can give information on a routine basis in circumstances when the SAXD method cannot, at least not without time consuming procedures. To compare these two techniques quantitatively requires knowledge of the chain obliquity which can be obtained independently using wide angle X-ray diffraction for oriented samples only. By using the two methods together there exists the possibility of distinguishing effects due to individual lamellae and those due to the stacking of lamellae. Electron microscopy gives direct visual information about the stacking and arrangement of lamellae as well as about lamellar size but the procedure is

time consuming and the accuracy for the latter purpose is more limited.

Values for lamellar thicknesses

Since L_R is a measure of the straight chain portion, then it might be expected to be smaller than the total lamellar thickness which is considered to be sub-divided into a crystalline and a more or less disordered (amorphous) surface layer. In previous works³, nevertheless, L_R was found to be larger than L_X . This could be accounted for by the fact that the chains are inclined with respect to the layer surface. In cases where the chain inclination could be assessed L_R was found to be close to $L_X/\cos\phi$ (ϕ = angle between straight chain direction and lamellar normal). This implies that L_R is a measure of the appropriately inclined straight chain traverse across the full layer. As laid out previously³ this leaves little room for amorphous material such as does not partake in the vibration contributing to the Raman peak, a point of potential consequence for the visualization of a polymer crystal. It means that, contrary to much other experimental evidence, there is either

Figure 5 (a) SAXD pattern and (b) Raman spectrum of isothermally crystallized bulk PE (Unifex 7006, T_c 126°C) with one maximum in the SAXD pattern and with two first order LA modes in the Raman spectrum

Figure 6 (a) SAXD pattern and (b) Raman spectrum of isothermally crystallized bulk PE (Unifex 7006, T_c 127.9°C) with one maximum in the SAXD pattern and with two first order LA modes and a weak third order in the Raman spectrum

no appreciable amount of amorphous material at the crystal surface or the amorphous material has some special structure and orientation. While we shall not take this issue further in the present paper we must state that the results to be described will further emphasize this point.

Single crystal mats. Single crystal mats give clear results which are comparatively easy to interpret. They are being used here as control specimens. Three orders are visible in the SAXD pattern and a clear primary *LA* mode in the Raman spectrum as shown by *Figure 1*. As seen from the corresponding entry in *Table 1*, the Raman chain length L_R is larger than the X-ray long period L_X . With reference to the preceding paragraph we may invoke chain inclination as an explanation and test for the relation $(L_X/L_R) = \cos\phi$ which as stated above implies that the entire oblique traverse length partakes in the vibration. We find that $\phi = 25^\circ$ or 32° for the uncorrected and corrected values of L_X respectively. These are within the range for crystals grown at 85°C^{13} .

Melt-crystallized polyethylene. *Figures 2–6* show examples of SAXD patterns and Raman spectra from various melt-crystallized samples. They show that two X-ray peaks may appear when only one Raman peak appears as in *Figures 2* and *3* and that two or more Raman peaks may appear when only one X-ray peak is present as in *Figures 5* and *6*. The new observation of multiple Raman peaks is discussed fully later. Here we will confine the discussion to cases where one Raman peak and two X-ray peaks are observed. We find this behaviour for samples which have essentially fully crystallized at one temperature.

When there is only one Raman peak the chain length is closest to the larger of the two X-ray spacings as shown by *Table 1*. This agrees with the results of Koenig and Tabb². For a rapidly quenched sample, as in *Figure 2*, L_R is closely equal to the uncorrected value of L_X while it is slightly larger than the corrected L_X value. In the latter case the chain inclination, considering again the oblique traverse across the full layer, would be 24° . As the precise temperature at which this sample was crystallized is not known such a tilt could be reasonable; for a quenched sample it is unlikely to be larger¹⁴.

For an isothermally crystallized sample, as in *Figure 3*, $L_R > L_X$, both for the corrected and uncorrected L_X values. This is consistent with the expectation of increasing chain tilt with crystallization temperature as documented in earlier electron diffraction work. For the bulk sample in *Figure 3* this yields tilts of 36° and 49° for uncorrected and corrected L_X values respectively, again taking the oblique traverse as running across the full layer. While the latter may appear on the high side it is still within the range of practical experience in cases where the tilt angle could be directly assessed³. It is to be noted that a traverse length shorter than that across the full layer would require still higher tilt angles.

The observation of two low angle maxima has been reported many times previously. Since in many cases the ratio of the spacings has not been 2:1 they have been interpreted as two independent first orders of diffraction arising from two different lamellar periodicities^{6,7}. Support for this has been found using the electron microscope where different types of lamellae have been observed¹⁵. However, recently it has been shown that if the X-ray data obtained using slit collimated cameras are rigorously corrected then the ratio of spacings becomes closer to 2:1 thus favouring an interpretation based on two orders of diffraction from the same lamellar periodicity.

Multiple SAXD spacings may be due either to higher orders of diffraction from a single lamellar periodicity or the two distinct sets of lamellae. Clearly the observation of a single, primary *LA* mode together with two SAXD maxima in *Figures 2–4* indicate that at least in these cases only one lamellar periodicity is present, consequently the SAXD maxima are 1st and 2nd orders of the same spacing. Even if we did not go to such lengths on the effect of the exact corrections to the L_X values as some other authors⁸ the entries in *Table 1* are certainly in support of this plausible assignment.

This is in contrast to *Figures 5* and *6* where two *LA* modes but only one broad SAXD maximum are observed. As will be apparent below the two *LA* modes correspond to two types of lamellae. Accordingly, the single SAXD maximum may arise either from one set of lamellae only, that due to the second not being resolved, or may result from the superposition of the maxima arising from two sets of lamellae. In any event in this case we find that the Raman effect is the more informative and shall proceed to follow its behaviour more closely.

Observation and interpretation of the multiple Raman peaks in melt crystallized polyethylene

First we have to examine the possibility that a Raman peak appearing at a higher wavenumber than peak 1 corresponds to a higher order vibration of the first Raman peak. The second order *LA* mode is not Raman active but an active third order *LA* mode is predicted in the Raman spectrum and this has been observed previously for melt crystallized polyethylene¹². Occasionally we have observed such a peak at approximately three times the wavenumber shift of the first peak as shown in *Figures 3* and *6*. However, in most cases the higher order is readily distinguishable from peak 2 as shown in *Figure 6*. Furthermore, the wavenumber shifts of peaks 1 and 2 bear no simple numerical relationship to one another. Thus one can say that peaks 1 and 2 are of different origin.

The frequencies of peaks 1 and 2 have been measured for a variety of crystallization temperatures. *Figure 7* shows the data obtained for Rigidex 50. In this and later figures it is assumed in the first instance that both peaks are primary *LA* modes and their frequencies have been converted into Raman chain lengths. Here the data strongly suggest a dependence of the frequency of peak 1 upon the time of crystallization. Hence Raman spectra were measured as a function of time at a constant crystallization temperature of 126°C . This information is given in *Figures 8* and *9* which show the Raman chain lengths and relative intensities of peaks 1 and 2 as a function of crystallization time. The major observations concerning the assignment of these peaks are:

(a) The length corresponding to peak 1 (the longer chain length) increases as a function of crystallization temperature as shown by the upper curve in *Figure 7*.

(b) The length corresponding to peak 2 is largely independent of crystallization temperature as shown by the lower points of *Figure 7*. The length is generally in the range 200–250 Å although we have found that it can be lower for samples which have been cooled rapidly from the isothermal crystallization temperature by quenching into an ice/water mixture.

(c) For a given crystallization temperature peak 2 decreases in intensity relative to peak 1 as the time allowed for crystallisation increases. At long times peak 2, although very weak, is still detectable as shown in *Figure 9*.

Figure 7 Raman chain length as a function of crystallization temperature for Rigidex 50. \circ , data for a crystallization time of 1 h; \bullet , data obtained for more complete crystallization. The times used for the latter were at 123.6°C, 20 h; 125.0°C, 53 h; 126.0°C, 1 day; and 128.6°C, 2½ days

From this we conclude that peak 1 corresponds to an LA vibration in material which crystallized isothermally at the temperature of the oil bath and that peak 2 is an LA vibration in material which remained uncrystallized at the end of the 'crystallization time' and crystallized subsequently while the sample was cooled to room temperature. At longer isothermal crystallization times more material has crystallized and so peak 2 weakens. Eventually after several days all the material crystallizable at the particular bath temperature has crystallized isothermally and consequently peak 1 predominates.

The persistence of peak 2 at long crystallization times suggests that there remains a portion of the material which is able to crystallize only on cooling. During the course of this work our attention was drawn to a recent paper by Mehta and Wunderlich¹⁷ in which a study of molecular segregation during crystallization from the melt was made. Here it was shown that for a given crystallization temperature material below a critical molecular weight does not crystallize. On this basis it is anticipated that a small portion of uncrystallized material will remain when isothermal crystallization is complete. This would crystallize on cooling and would give rise to an additional LA mode such as peak 2. The possibility of making a connection between the structure of the resulting crystals and the process of molecular segregation is explored later.

The immediate implication from the Raman results in Figures 8 and 9 is that polyethylene can be crystallized

from the melt containing two different sets of lamellae. The SAXD patterns of this type of sample commonly contain one maximum only. This can be explained by referring back to the need for regular stacking of lamellae to give a distinct SAXD maximum. Clearly if lamellae of two different sizes are mixed, SAXD will not be able to distinguish them. Decisive further evidence for the existence of two kinds of lamellae and their relative arrangement was sought at this stage using electron microscopy.

Samples were chosen from the series prepared for the Raman study of chain length as a function of crystallization time so that a direct comparison of the results obtained from these different techniques could be made.

A micrograph of material which gives two Raman peaks is shown in Figure 10b. This is a stained section of Rigidex 50 crystallized at 126°C for 78 min. For comparison in Figure 10a a micrograph is shown of the same material crystallized for a longer time of 24 h so that the Raman

Figure 8 Raman chain length as a function of crystallization time for Rigidex 50 crystallized at 126°C. The data were obtained from spectra of the type shown in Figures 5 and 6 and recorded at room temperature. \bullet , peak 1, refers to the LA mode observed at the lower wavenumber shift (larger L_R); \circ , peak 2, refers to the LA mode observed at the higher wavenumber shift (smaller L_R)

Figure 9 Relative intensities of Raman peaks 1 and 2 as a function of crystallization time for Rigidex 50 crystallized at 126°C

Figure 10 Electron micrographs of stained sections of Rigidex 50 crystallized at 126°C all the same magnification. (a) Sample crystallized for 24 h showing predominantly one layer thickness; (b) sample crystallized for 78 min showing a bimodal distribution of lamellar thicknesses. The thinner (light) central area is assumed to contain lamellae whose normals are oblique to the plane of the section; (c) solid residue from the sample in (b) after solvent extraction, showing removal of the thinner lamellae

peak 2 is very weak. In *Figure 10b* two types of lamellae are clearly distinguishable. Some lamellae are thick, long and quite straight while others are much thinner and occur in groups surrounded by the thicker lamellae. Faint tracks or confused areas occur where the lamellar normals do not lie in the plane of the section. By comparison for a longer crystallization time of 24 h the lamellae are all very thick,

long and straight and occur in large parallel bundles as shown in *Figure 10a*. The order in these is sufficiently good for one to be able to distinguish edge and screw dislocations in the lamellar arrangement.

These visual impressions are borne out by measurements of the distributions of lamellar thicknesses which for *Figure 10b* give two peaks at 316 ± 35 and 190 ± 20 Å. Similar measurements for material in *Figure 10a* give a single peak at 437 ± 70 Å. The errors given indicate the sharpness of the peaks, but there is an additional error of 10% due to the magnification calibration of the electron microscope. The corresponding Raman measurements are 425 and 259 Å for the sample giving two peaks and 489 Å for the sample giving one predominant peak. If the difference between these results is to be explained by chain tilt, the angle must be $40 \pm 14^\circ$, $41 \pm 13^\circ$, $25 \pm 25^\circ$ in the three cases. These are very inaccurate results for ϕ , but they are consistent with previous measurements giving $\phi = 35^\circ$ for bulk polyethylene¹⁴. In any case the quantitative aspects of electron microscopy are not so important. What is important is that the presence of two kinds of lamellae are clearly indicated, supporting the original assumption that both peaks in the Raman spectra are due to LAM vibrations. Further, the arrangement of the lamellae strongly supports the hypothesis that the larger grew first, unimpeded, at the higher isothermal crystallization temperature and the smaller lamellae filled in the gaps between the larger on cooling. An area as at the centre right of *Figure 10b* where the large lamellae are further apart contains between them piles of lamellae of a smaller more uniform size, which will have formed later in the cooling process.

Molecular weight and lamellar morphology

As shown in *Figure 7* the relative intensities of the two Raman peaks on storing at the temperature of the oil bath suggest that some form of fractionation occurs during crystallization from the melt. In the past there have been several reports of molecular fractionation especially during crystallization from solution^{18–20} and indications that a similar process may occur during crystallization from the melt^{14,21,22}. It has been suggested that this leads to rejection of the lower molecular weight molecules which may or may not crystallize subsequently.

Mehta and Wunderlich¹⁷ used solvent extraction to remove material which had crystallized on cooling from the isothermal crystallization temperature¹⁷. In order to examine the material constituting the different sets of lamellae observed in our experiments, we carried out similar extractions on samples selected from the series crystallized at 126°C. Samples which had been crystallized for times of 78 and 108 min were chosen since both showed two Raman peaks and for the time of 78 min the lamellar structure had also been observed using the electron microscope as in *Figure 10b*. Specimens of these were placed in *p*-xylene at 102.5°C and held for 50 h. The solid residues left behind and the polymer extracted in solution were then separated by filtration.

The Raman spectra of the solid residues of the 78 min sample and the 108 min sample showed peak 1 only. These appeared at the same frequencies as in the starting materials. This suggested that the thinner lamellae had been dissolved during the extraction. Supporting evidence was found by examining the solid residues of the 78 min sample left behind using the electron microscope. The result is shown in *Figure 10c*. Here it is seen that only the thicker

Figure 11 G.p.c. traces of Rigidex 50 crystallized at 126°C for 108 min before and after solvent extraction in *p*-xylene at 102.5°C for 50 h. A, starting material before extraction; B, solid residue left behind after extraction; C, material dissolved and removed by extraction

lamellae remain and that there is a large number of void spaces which by comparison with *Figure 10b* are likely to have been occupied by the thinner lamellae.

Because the supply of sample crystallized for 78 min had been exhausted by the preparations for the microscopy, g.p.c. analysis was carried out on the 108 min sample. It will be remembered that this sample also showed the removal of peak 2 by the solvent extraction. The results are given in *Figure 11* which, even by inspection, show that, by comparison with the starting material (curve A), the solid residue (curve B) consists of the high molecular weights and that the lower molecular weights have been extracted (curve C). The values of the weight- and number-average molecular weights have been calculated from these curves and are given in *Table 2*. Values of dispersivity so given indicate that the extraction has produced two narrower fractions than the starting material; one of high and one of lower molecular weight corresponding respectively to the solid residues and the extracted material. No attempt was made to optimize the extraction procedure and it appears that the extraction conditions were more rigorous than strictly necessary since curve C also contains some high molecular weights.

We are now in a position to correlate the results of the g.p.c. analysis with the previous electron microscopy and Raman results. The removal of the thinner lamellae in conjunction with the loss of the lower molecular weights both caused by the solvent extraction strongly supports the idea that the thinner lamellae are composed mainly of lower molecular weight material. Since all the evidence indicates that the thinner lamellae crystallized on cooling rather than isothermally this in turn favours the operation of a fractionation process during crystallization from the melt. In addition to showing this we have identified the lamellar thicknesses associated with the segregated material and illustrated their arrangement and location within the overall texture.

Time dependence of lamellar thickness

The upper curve in *Figure 8* gives a direct indication that isothermal thickening occurs upon storage at the crystallization temperature. There are two regions in this plot where thickening occurs. Initially there is rapid thickening at times up to 100 min followed by a slower rate of thicken-

ing which appears to operate even at times greater than ten days. Observations of the thickening of lamellae at the crystallization temperature have been made previously by Kawai²², by Hoffman and Weeks²³ and by Kawai and Keller²⁴. We will now examine our Raman data in the light of the theories of thickening put forward by these authors and also discuss the varying magnitudes of thickening which have been reported.

Hoffman and Weeks explain the increase in X-ray long spacing by the annealing of lamellae after they have crystallized whereas Kawai²² suggests a mechanism involving molecular fractionation during crystallization.

According to Kawai²² the higher molecular weight species crystallize first giving rise to thinner lamellae and with time the lower molecular weight species crystallize with a lower degree of supercooling giving rise to thicker lamellae. Assuming that molecular fractionation operates in this way it should be a simple matter to determine its influence on the lamellar thickness by examination of the Raman data. If, as proposed by Kawai²², molecular fractionation controls lamellar thickness then it is expected that the number of lamellae of a given thickness never decreases. Consequently the distribution of thicknesses should broaden continually in the direction of thicker lamellae. As far as it is possible to determine from the spectra obtained this expectation is not fulfilled, since, when peak 1 shifts to lower frequencies (longer chain lengths), it does so without retention of its previous intensity on the higher side of the peak (shorter chain lengths). This suggests that molecular fractionation may not be totally responsible for the observed thickening.

Further evidence of the complex nature of isothermal thickening is given in *Figure 8*. The form of the curve of lamellar thickness as a function of time suggests a discontinuity at around 150 min. This occurs at about the same time as peak 2 decreases in intensity to a small constant value, as shown in *Figure 9*. Thus when crystallization is essentially complete the lamellae continue to thicken on storing at the crystallization temperature. In this region therefore the evidence favours strongly a thickening mechanism based on annealing as proposed by Hoffman and Weeks²³.

The implications are, therefore, that molecular segregation, coupled with isothermal thickening of the lamellae once they have formed, are responsible for the period of initial rapid thickening, while the continued thickening after crystallization is complete is caused by chain refolding alone.

In so far as it is possible to compare the results of different authors using different experimental procedures a number of comments on the scale of thickening can be made. The results of Kawai and those presented in this work were both obtained on samples examined at room temperature. The scale of thickening indicated by the Raman results is, however, much greater than that in the SAXD study of Kawai. It is notable, however, that in our studies of samples giving two Raman peaks one SAXD maximum only is observed.

Table 2 Molecular weight determinations on Rigidex 50 crystallized at 126°C for 108 min before and after solvent extraction

Sample	\bar{M}_w	\bar{M}_n	Dispersivity \bar{M}_w/\bar{M}_n
Starting material	62 000	10 000	6.2
Solid residue	59 000	18 000	3.3
Material extracted	18 000	5 000	3.6

Figure 12 Raman chain length as a function of crystallization temperature for samples of bulk PE with different nucleation densities. A crystallization time of 1 h was used for all samples. Out of the samples chosen Shell Carlona 65045 (Δ) had the highest nucleation density, and Unifex 7006 (\square) had the lowest nucleation density while that of Rigidex 50 (\circ) was intermediate

Thus the presence of two sets of lamellae and hence the nature of the thickening mechanism remained undetected to us using the SAXD technique. Hoffman and Weeks, however, obtained their SAXD data at the temperature of crystallization and so should have detected only lamellae growing at the crystallization temperature. They observed two maxima but chose the smaller spacing as the lamellar periodicity. This may explain why they obtained much smaller values of lamellar thicknesses than in the experiments reported in this paper.

For a direct comparison with Hoffman and Weeks we have attempted to follow this effect by observing the behaviour of the *LA* mode at the crystallization temperature. This has not been entirely successful due to the smeared-out appearance of the *LA* mode peak at elevated temperatures. We have some indication that thickening occurs in these experiments but precise location of the peaks is not possible. An examination of the behaviour of *LA* mode peaks at high temperatures is to be reported elsewhere²⁵.

Nucleation density

When crystallization takes place isothermally the nucleation density has a dramatic effect on the time required for the completion of crystallization. For example at $T_c = 122^\circ\text{C}$ different samples require between 20 min and several hours before crystallization is complete²⁶. Thus for a range of materials with different nucleation densities crystallized at the same temperature for the same time the average age of lamellae can vary significantly. Consequently the degree of thickening is expected to vary accordingly, and it is anticipated that older lamellae will have thickened more. This effect has indeed been observed as shown by the spread of results for peak 1 in Figure 12. The relative

nucleation densities of these polymers were determined from observations of spherulitic structures in the optical microscope²⁶. The samples with the higher nucleation densities consistently produce thicker lamellae for the same crystallization conditions. Typically the range of variation of spacings is in the region 50–100 Å. Although the effect is usually small it has been observed consistently. Initially we propose that lamellae in all samples are of the same thickness. Subsequently the sample with the larger number of growth centres contains more crystalline material and has on average thickened more than the sample with the smaller number of growth centres.

The greatest effect we have observed is for the sample with the lowest nucleation density (see Figure 12) where peak 1 is not detectable after crystallization for 1 h at 127.4°C . Peak 2, however, is of large intensity which indicates that this sample crystallized mainly on cooling. The value of chain length obtained from peak 2 is ~ 230 Å. This behaviour contrasts with that for samples having higher nucleation densities (Figure 12) where peak 1 is the most intense peak. It appears therefore that for higher nucleation densities under these crystallization conditions the greater proportion of the material crystallized isothermally. Accordingly a higher value of chain length of ~ 420 Å is given.

It will be seen in Figure 7 that using the same crystallization time of 1 h the chain length for a sample crystallized at 127.4°C is almost identical to that for a sample of the same nucleation density crystallized at the lower temperature of 126.5°C . This trend is also shown for other samples with different nucleation densities in Figure 12. This is contrary to expectations based on the usually observed dependence of the lamellar thickness upon the supercooling whereby crystallization at the higher temperature produces the larger lamellar thickness, hence longer chain traverse lengths.

The following explanation for this anomaly is proposed. The larger thickness observed is that arising during primary crystallization followed by subsequent thickening. As the latter is a function of time, its magnitude at a given temperature will depend on the age of the lamellae. At any given instant during crystallization we have a spectrum of ages. At a comparatively short time of crystallization, say at time t_x in Figure 13, the majority of the lamellae present will have formed towards the end of the time interval $t_x - t_0$ in the case of the crystallization conducted at high temperatures (curve 1). Thus the corresponding lamellae will be young in comparison to the average of those formed by further crystallization at a lower temperature (curve 2) by the same time t_x . This means that they have had less time to thicken and although formed with an initially larger chain length the actual value of this length as measured at time t_x can be equal or even lower. We see that we can envisage a situation where thickening can compensate for, or even reverse, the differences in lamellar thicknesses arising due to different crystallization temperatures, particularly at the early stages of crystallization. This particular influence of lamellar thickening to counteract the established trend due to the crystallization temperature itself should diminish with increasing crystallization time. This in fact is observed as shown in Figure 7. For crystallization times of 1 h the data in the lower curve were obtained. For crystallization times much larger than 1 h under the present conditions the data shown in the upper curve followed the commonly observed rapid upsweep of chain length with increasing crystallization temperature.

Figure 13 Schematic diagram of percentage of polymer crystallized as a function of crystallization time. Curve 1 represents crystallization at a higher temperature than curve 2. Curves 1 and 2 illustrate the situation where at a relatively short time of crystallization, t_x , more material has crystallized in case 2 than in case 1

We conclude therefore that nucleation density, through the agency of isothermal thickening, affects the lamellar thickness. This relationship is rarely noted and may go some way towards explaining the comparatively large variations in the values of lamellar thickness reported by various authors using polyethylene from different sources.

CONCLUSION

The power of the combined application of the different structure methods has been demonstrated. The Raman method has proved superior in registering lamellae and identifying their true origin while the more conventional low-angle X-ray scattering method is capable of giving information on their mode of stacking. Electron microscopy, involving novel sample preparation methods, can then provide the visual image corresponding to these diffraction and spectroscopic effects thus providing direct confirmation of the structural units involved and of their arrangements in the overall texture.

The important part played by isothermal thickening has been highlighted. This, together with other factors including nucleation density, determines the measured lamellar thickness and is thus pertinent to the problem of interpreting lamellar thicknesses in terms of the crystallization temperature.

The effect of molecular segregation on crystallization is forcefully brought out by these studies whereby the structural entities comprising the segregated materials have been identified and their lamellar thicknesses measured.

ACKNOWLEDGEMENTS

During the course of this work G.V.F. and D.G. have been supported by the Science Research Council and J.A.O. by the Ministry of Defence. We also wish to acknowledge the assistance of the Science Research Council for the partial provision of the Raman spectrometer. We are indebted to P. Volans for the supply of samples and to Dr J. Stejny, who with the assistance of Mrs A. Halter carried out the g.p.c. analysis.

Diffusion of large molecules in polymers: a measuring technique based on microdensitometry in the infra-red*

J. Klein and B. J. Briscoe

Physics and Chemistry of Solids, Cavendish Laboratory, University of Cambridge, Cambridge CB3 0HE, UK

(Received 18 December 1975)

A technique based on infra-red microdensitometry has been developed for studying the centre-of-mass translational diffusion of large additive molecules in polymeric matrices. In this technique the diffusion broadening with time of a known initial concentration profile of the additive within the bulk polymer is monitored. The shape of the concentration profile after diffusion broadening readily yields D , the diffusion constant; it may also yield the concentration dependence of D where this is significant. The technique is found to be reasonably flexible, and applicable to a number of polymer-additive combinations. Values of D in the range 10^{-5} to 10^{-10} cm²/sec and initial additive concentrations of down to 0.3% may be studied. The technique is viable over a wide range of temperatures and pressures. Some results obtained by this technique are presented, for the case of various linear long-chain amides diffusing in low density polyethylene.

INTRODUCTION

The diffusion of small molecules through polymers has been extensively studied in the past. Several well established techniques for such studies exist and are described in detail elsewhere¹. Studies of the diffusion of large molecules, including polymeric self-diffusion, have been far less common. In this context 'small' molecules refer to those in the gaseous, vapour or liquid phase at room temperature and pressure and 'large' molecules are those forming solids under these conditions. Bueche *et al.*² first described the use of radioactively labelled polymers in the determination of self-diffusion coefficients in polymers. Their technique, with slight variations, has since been used with some success in studying the diffusion of smaller (though still 'large' in this context) additive molecules through various polymeric matrices³⁻⁵. These techniques involving radioactive labelling of the diffusant are, generally speaking, faced with two major shortcomings in addition to the necessity of having to obtain the required labelled material: they fail for the case of diffusants which are surface active with respect to the polymer matrix, and they may also involve significant interfacial resistance which the method does not readily reveal. Nuclear magnetic resonance (n.m.r.) has also been used to determine diffusion coefficients in polymers, as for example by McCall *et al.*⁶. These measurements are limited to the melt or liquid phases of the polymer. Furthermore the n.m.r. technique is limited¹ to measuring values of D , the diffusion coefficient, greater than about 3×10^{-7} cm²/sec. Autoradiographical determination of D for large molecules is at present not a viable technique¹.

We have developed a simple technique for the measurement of the translational diffusion of large molecules in polymeric matrices, based on microdensitometry in the infra-red (i.r.). A preliminary outline of this technique has already appeared⁷. The purpose of the present paper is to describe the procedure and underlying principles in more detail.

THEORY

The principles underlying the technique are simple. When a step function in the concentration of a diffusant is set up within a host matrix it will broaden with time under diffusion, the driving force being the concentration gradient. The shape of the resulting concentration profile is established, as a solution of Fick's equations⁸ with the appropriate boundary conditions, and is expressed in terms of x (the distance along the diffusion direction), D and t , the time over which diffusion broadening has taken place. D may itself depend significantly on the diffusant concentration, C .

Figure 1 shows the diffusion broadening where D is independent of C .

In essence the technique involves setting up a step function in additive concentration within the bulk polymer, allowing this to broaden under diffusion at the required temperature and pressure, terminating the process at a known time t , and comparing the resulting broadening concentration profile with the theoretical case. D is thus readily evaluated.

EXPERIMENTAL

The procedure for setting up a step function in additive concentration within the bulk polymer is illustrated in Figure 2. The concentration C_0 of additive in specimen I is typically 0.5% w/w but values as low as 0.3% w/w of additive have been used. Actual joining (Figure 2b) is effected by local melting of the adjacent surfaces in vacuum for a very short duration and pressing them together. We find this to result in an interface which generally presents little or no resistance to diffusion, and at the same time only negligibly distorts the initial step function (see later, also Figure 5). Dimensions of the specimens are such that the final broadening of the initial distribution is small in comparison, to minimize end effects in the case of surface active additives. After joining, diffusion broadening of the initial step function is allowed to occur at the desired temperature and pressure for a time t , when it is effectively terminated by

Figure 2 Setting up a step-function. (a) Specimen I: polymer containing a concentration C_0 ($\sim 0.5\%$) of additive uniformly dispersed; specimen II: additive-free polymer. Adjacent surfaces melted in vacuum and pressed together; (b) composite immediately after join has been made; (c) slice removed from centre of composite, after diffusion has occurred, and monitored in the microdensitometer. The concentration profiles corresponding to the different stages are also shown

quenching. A thin (typically $150\ \mu\text{m}$) slice is representative of the centre of the specimen removed by microtoming as shown in Figure 2c, and the concentration of additive $C(x)$, along its length x , is monitored.

In order to obtain a measure of the diffusant concentration it is necessary that it absorb at some i.r. frequency unaffected by the bulk polymer. When scanning through the frequency spectrum a sharp absorption peak is observed at this 'labelling' frequency of the additive, and this is shown in Figure 3.

The lateral scanning of the thin slice is then carried out at this 'labelling' frequency. A commercial double beam i.r. spectrometer (Perkin-Elmer 157) has been adapted for this

purpose, and a slit of width $90 \pm 10\ \mu\text{m}$ mounted at the focus of the sample beam. This represents the limiting value of the spatial resolution of the 'microdensitometer'. The spectrometer is then fixed at the labelling frequency, and the slice slowly traversed across the slit on a motorized translation stage.

If I_0 is the incident intensity of the sample beam reaching the slice, then the intensity I passing through the slice at a point x may be written (neglecting the small diffraction effect):

$$I/I_0 \propto \exp \{-\epsilon_0 d(x)C(x)\} \quad (1)$$

if the Beer's relation applies. ϵ_0 is the absorptivity of the additive at the scan frequency ν_0 , d is the slice thickness at x and $C(x)$ is the additive concentration at x . The proportionality factor represents such effects as the polymer matrix absorption at the scan frequency, the reflectivity of the slice and also some instrument effects. If d is constant and $C \ll 1$, however, the proportionality factor in equation (1) may be taken as constant for a given run. We have found d to be constant within 1–2% typically, by micro-meter measurements along the slice.

Taking logarithms, we have:

$$-\log \left\{ \frac{I}{I_0} \right\} \equiv -\log T(x) = \text{constant} + A\epsilon_0 C(x) \quad (2)$$

for constant d , where A is constant. By making up a composite (as in Figure 2) consisting of five layers of known different concentrations and scanning a slice through this composite, we have shown that, within error, (Figure 4):

$$-\log(T(x)) = \text{constant} + A'C(x) \quad (3)$$

thus ϵ_0 , for the additives and concentrations we have used, is independent of concentration.

Figure 3 Spectrogram of a polymer-additive sample in the region of the labelling absorption frequency, ν_0 . T is the percentage transmission through the microdensitometer slit. The sample is a slice $\sim 160\ \mu\text{m}$ thick of low density polyethylene containing 0.5% w/w stearamide. ν_0 corresponds to a wavenumber of $1660\ \text{cm}^{-1}$, an amide absorption peak. (A similar but additive free slice of polyethylene is in the reference beam for compensation, and the inverse-absorption peaks near $1500\ \text{cm}^{-1}$ are due to overcompensation.)

Figure 4 Variation of $\log T$ vs. concentration of stearamide in low density polyethylene. Scan frequency corresponds to 1660 cm^{-1} (see Figure 3)

Figure 5 Observed concentration profiles. (a) $t \approx 0$ (initial step function; $t = 54 \text{ sec}$, $C_0 = 0.5\% \text{ w/w}$ stearamide in low density polyethylene; (b) after time t ($t = 5.22 \times 10^4 \text{ sec}$, $T = 130^\circ \text{C}$, C_0 as in (a)). Both profiles scanned at 1660 cm^{-1} , an amide absorption frequency

The output of the i.r. spectrometer as the slice is traversed along the slit is fed via a linear-to-log converter to the y-axis of an X-Y recorder, the X axis of which is coupled to the lateral traverse of the slice, i.e. x in our notation. This yields concentration profiles directly. Figure 5 shows (on the same scale) both the initial step function and the diffusion-broadened profile for a typical run. Comparison with Figure 1 shows the agreement between Fickian predictions and experiment to be good, and compatible with a D independent of C . The actual value of D is readily evaluated by comparison of observed and calculated curves.

It is possible to calculate the concentration dependence of D , where this is significant, by the Matano-Boltzmann⁸ procedure. If any resistance to diffusional flow across the interface between the two halves exists, it can be detected by predictable⁸ discontinuities in the broadened concentration profile, as in Figure 6.

With the present resolution of the technique we can measure values at D in the range of 10^{-5} to $10^{-10} \text{ cm}^2/\text{sec}$ in times of the order of 1–30 days. Estimated errors are of order 15%.

DISCUSSION AND SOME RESULTS

It is possible to anneal the composite sample after joining its two halves, but prior to measuring the diffusion – this would involve a slightly different procedure for evaluating D .

Preliminary experiments with a number of additives and different polymers indicate that the technique is quite flexible. For example, by suitably labelling molecules of the polymer itself, say by deuteration, self-diffusion constants may be obtained. The labelling frequency here would be that of the C–D bond as against the C–H background.

Figure 6 Concentration profile showing a discontinuity (at A) indicating resistance to diffusional flow at the interface. $C_0 = 0.5\%$ in low density polyethylene

Figure 7 Variation of the diffusion constant D of stearamide in low density polyethylene as a function of temperature T , about the melting point of the polymer. Inset: diffusion constants D of $\text{CH}_3(\text{CH}_2)_n\text{CONH}_2$ in LDPE as a function of n , at 118°C . D decreases as diffusant length increases

We have studied the diffusion of various long chain n-alkyl amides in low density polyethylene (LDPE) about the melting point of the polymer at atmospheric pressure. The additives were incorporated into the bulk polymer by mixing the powders in the required proportions, then milling at 125°C for 20 min. The cylindrical specimens (Figure 2) were prepared by hot pressing in a die *in vacuo*. Their diameter was 30 mm and each half was 30 mm in length. Some results for temperature and chain length dependence are presented in Figure 7. The variation in slope of the Arrhenius plot is probably due in part to the breakdown of crystalline lamellae in the polythene, which at temperatures below about 80°C comprise some 60% of the polymer⁹; this leads to a decrease in the tortuosity of the path taken by the chains in the amorphous polymer regions, over and above the usual temperature dependence. (However, it appears that this variation in slope is not solely due to lamellar breakdown — effects due to annealing of the bulk polymer¹⁰ and to association of the stearamide probably also play a part.) D.s.c. studies show that the discontinuity in the slope of the Arrhenius plot at $T \approx 107^\circ\text{C}$ corresponds, within experimental error, to the melting point of the polythene.

The activation energy in the melt region is 6.2 ± 0.2 kcal/mol. This compares with the activation energies for self-diffusion of 5.3 ± 0.8 and 5.6 ± 0.3 kcal/mol for a low MW (4100) polyethylene fraction and n-C₃₂H₆₆ respectively, as obtained from n.m.r. studies⁶.

The diffusional behaviour of longer molecules, including polymeric self-diffusion, is being explored.

ACKNOWLEDGEMENTS

We thank ICI Plastics Division (Welwyn) for preparing the materials, and one of us (J. K.) thanks Dow Corning Chemicals for a maintenance grant. We are also very grateful to Professor D. Tabor for encouragement.

Radial distribution functions from molten polyethylene by X-ray diffraction*

G. W. Longman†, G. D. Wignall‡ and R. P. Sheldon§

(Received 22 January 1976)

The short range ordering in molten polyethylene has been investigated by radial distribution function (*RDF*) methods. The intramolecular distances resolved are consistent with the presence of *gauche* conformations, whilst no long *trans* sequences are resolved. Broad peaks at ~5, 10 and 15 Å are attributed to intermolecular ordering, which is greater than that observed in glassy amorphous polymers. The results are not inconsistent with the polymer chains adopting a random coil configuration over distances greater than ~20 Å.

INTRODUCTION

Few radial distribution function studies have been made concerning ordering in molten polymers, and almost none have been by X-ray methods. Ovchinnikov and Markova¹ and Ovchinnikov, Markova and Kargin² made extensive studies of molten polyethylene between 136° and 211°C by means of radial distribution functions (*RDF*) derived from electron diffraction. Some of the peaks in the *RDF* curves (i.e. 1.3, 2.3 and 3.7 Å) were attributed to intramolecular distances. Other distinct peaks were observed at 4.8 and 5.8 Å, especially at temperatures near the melting point. These distinct peaks were attributed to intermolecular distances and became more diffuse with increasing temperature. The observed peaks were compared with those occurring in crystalline polyethylene and in an array of hexagonally packed parallel chain segments. On the basis of this comparison the authors proposed that molten polyethylene consisted of ordered regions ~50 Å in diameter, within which the chains were essentially parallel.

Subsequently these experimental findings were challenged by Fischer *et al.*³ and Voigt-Martin and Mijlhoff⁴ who also measured *RDF* curves from molten linear polyethylene at 140° and 200°C. They observed a broad intermolecular peak in the region 4–6 Å with intramolecular peaks at 1.16, 1.53, 2.18, 2.56, 2.99, 3.57, 3.95, 4.51 and 5.08 Å. They criticized the previous work on the grounds that: 'not only is the CH distance missing and the C–C and C–C–C distance in the wrong place and incorrectly weighted, but there are considerable termination and background ripples on the *RDF* curve'³. They concluded 'that there is a distribution of atomic distances between 4–6 Å, rather than tightly packed bundles with a well defined intermolecular distance' as postulated by the Russian workers. The discrepancies between the different data sets derived from electron diffraction, and the conclusions which have been built on the disputed features, point to the need for very careful data correction procedures. These procedures are discussed in detail by Voigt-Martin and Mijlhoff⁴ for the case of electron diffraction. In principle the same *RDF* functions can be obtained from X-ray dif-

fraction measurements though the experimental details naturally differ between the two techniques.

The main experimental problems and procedures necessary to remove artefacts in the X-ray technique have been discussed by Wignall⁵. In an effort to resolve the above discrepancies in the measured *RDF* curves from electron diffraction, we have performed complementary *RDF* measurements on polyethylene by X-ray techniques.

EXPERIMENTAL

The experimental methods employed have already been described in detail⁶. Measurements were performed on a Picker Automatic 4 Circle Diffractometer within the range $0.11 < s < 16.1 \text{ \AA}^{-1}$ where $s = (4\pi/\lambda)\sin\theta$; 2θ is the scatter angle and $\lambda = 0.7107 \text{ \AA}$ is the wavelength of the incident molybdenum K_α radiation. The sample was ~0.125 cm thick and was held in a heated cell and constrained by thin Melinex film (~18 μm thick). The sample was maintained at $160^\circ\text{C} \pm 2^\circ\text{C}$ by tungsten heaters embedded in mica plates and placed each side of the sample. Windows ~1 cm² allowed the passage of the incident and diffracted beams, the irradiated sample volume being ~1 mm³.

The scattered data were corrected for incoherent scattering, absorption in the sample and Melinex cell walls, double scattering and polarization of the scattered beam. The methods for performing these corrections, and for choosing the collimation limits, monochromatizing the incident beam etc. are described in ref 6. The data were normalized using the dispersion corrected form factors of Berghius⁷ and Stewart⁸, and incoherent scattering factors of Keating and Vineyard⁹. The resulting *RDF*, $H(r)$, was calculated from

$$H(r) = \frac{1}{2\pi^2\bar{\rho}r} \int_{s_{\min}}^{s_{\max}} si(s) \sin sr ds \quad (1)$$

where $\bar{\rho}$ is the atomic density (atoms/unit volume) of the sample, and $s_{\min} = 0.11 \text{ \AA}^{-1}$ and $s_{\max} = 16.1 \text{ \AA}^{-1}$. $H(r)$ for molten high density polyethylene is shown in Figure 1, whilst the second moment of the *RDF*, $4\pi\bar{\rho}r^2H(r)$ is shown in Figure 2.

DISCUSSION

The main peaks in the *RDF* of Figure 1 are listed in Table 1 together with those observed previously^{1,4}. The peak posi-

 Figure 2 The second moment of the RDF, $4\pi\bar{\rho}r^2H(r)$ vs. r for molten high density polyethylene

tions are very similar to those observed by Voigt-Martin and Mijlhoff (VMM). In particular we observe a peak at ~ 3.0 Å, which was attributed by VMM to a high concentration of *gauche* bonds, but was absent from the previous work of Ovchinnikov and Markova (OM). There are no resolvable peaks in the RDF consistent with the presence of extended sequences in the *trans* configuration, neither do we see the strong features at 4.8 Å and 5.8 Å reported by OM.

No correction has been made to the data of Figure 1 for truncation errors, but the close agreement obtained with the work of VMM suggests that truncation errors are not a serious problem in the region $1 < r < 6$ Å. This is particularly so in view of the wide differences in truncation limits used in the present work and those used by VMM ($s_{\min} = 1 \text{ \AA}^{-1}$, $s_{\max} = 25 \text{ \AA}^{-1}$) as truncation features generally have a frequency inversely proportional to the truncation limits. The positions of the main RDF peaks of VMM are within a few percent of those resolved in this work, which suggests strongly that the observed peaks are real and not truncation features.

At higher values of r one would not expect to resolve sharp peaks in the RDF, due to the increasing number of overlapping interatomic distances. The small oscillations in the RDF of Figure 1 above ~ 7 Å probably represent residual truncation features, as they have a frequency given approximately by $2\pi/s_{\max} \approx 0.4$ Å. These are small in $H(r)$, but when plotting $4\pi\bar{\rho}r^2H(r)$ (Figure 2) the r^2 weight-

ing factor considerably magnifies these features, and hence the data of Figure 2 have been 'damped' by inclusion of a damping factor $\exp(-\alpha^2s^2)$ in equation (1) before transformation. The value of $\alpha = 0.112$ was chosen to eliminate most of the high frequency oscillations (~ 0.4 Å), whilst leaving the lower frequency structural features unchanged. The high frequency oscillations at ~ 24 Å are probably the residue of these truncation features, and should not be taken as evidence of long range ordering.

The second moment of the RDF (Figure 2) exhibits broad maxima with a period ~ 5 Å. The first broad maximum between 4–7 Å is very similar to that reported by VMM, and supports their conclusion that 'there is a distribution of atomic distances between 4–6 Å', rather than the sharp distinct peaks at 4.8 and 5.8 Å observed by OM. This broad peak is similar to peaks observed for amorphous polycarbonate⁶, and amorphous polystyrenes¹⁰, and has been attributed to interchain packing.

Further broad peaks at 10 and 15 Å (and possibly 20 Å) suggest that there is considerable liquid like order caused by the packing of polymer chains with an effective diameter of ~ 5 Å. Odajima *et al.*¹¹ have derived an RDF for the amorphous regions of solid polyethylene from X-ray diffraction data, and have observed similar broad oscillations with maxima at 5, 10 and 15 Å. These broad oscillations have been compared with a paracrystalline model based on the methods of Hosemann and Bagchi¹². Starting with a pseudo-hexagonal lattice as an initial structure, the positions of atoms were disordered to create a paracrystalline arrangement of atoms. To obtain the RDF, $D(r) = 4\pi r^2 \bar{\rho} H(r)$, a summation was taken over all atoms in a spherical shell about each atom. Odajima *et al.* chose a disorder parameter which gave the best fit to the observed oscillations in solid polyethylene. The amplitude of the oscillation at ~ 5 Å in Figure 2 is ~ 5 compared to a value of ~ 3 observed in amorphous polyethylene and a value of ~ 4 predicted from the model. Thus the amplitude and area of the first peak are consistent with the polymer molecules being arranged in a pseudo-crystalline lattice with parallel packing of chains¹³ and as suggested by OM. A similar conclusion concerning polystyrene was reached by Wecker, Davidson and Cohen¹⁰, from an analysis of RDF plots derived from X-ray diffraction studies of amorphous polystyrenes.

The broad oscillations seen in Figure 2 are fairly rapidly damped and cannot be resolved clearly beyond ~ 15 Å. It therefore appears that any pseudo-crystalline parallel ordering of polymer chains does not persist over large distances.

Table 1 Positions of the main peaks in the RDF plots from molten polyethylene

Ovchinnikov and Markova ¹ ($T = 136^\circ\text{C}$)	Voigt-Martin and Mijlhoff ⁴ ($T = 140^\circ\text{C}$)	This work ($T = 160^\circ\text{C}$)	Predicted from short range intramolecular order ⁴

Complementary neutron scattering measurements have been performed on molten polyethylene^{14,15}. The polymer molecule adopts an overall conformation such that the radius of gyration of the molecule is very close to that measured in θ solvents, and is that predicted by the random coil model¹⁶. Furthermore, analysis of the full neutron scattering curve¹⁵ indicates that the polymer molecule obeys random statistics above 20 Å. These findings are consistent with the *RDF* measurements, which do not resolve interatomic distances associated with extended sequences in the *trans* configuration. The existence of some nearest neighbour intermolecular peaks over short ranges would be expected simply in terms of the geometrical packing of polymer chains with a diameter ~ 5 Å. This packing mechanism is the basis of much of the short range order in liquids, and the existence of this kind of short range liquid like order is not inconsistent with the random coil concept. This may be regarded as being particularly so in the case of polyethylene where the cross-sectional dimensions of the polymer chain are approximately the same in different directions, irrespective of whether the carbon backbone is in the *trans* or *gauche* configuration. It is probable that the chain packing is enhanced by this uniformity of the chain dimensions. Certainly the level of intermolecular ordering observed in molten polyethylene is greater than that observed in glassy amorphous polycarbonate⁶ and poly(ethylene terephthalate)¹⁷. The molecular chains in these latter polymers are both stiffer than polyethylene and the cross-sectional dimensions are different along each of the axes perpendicular to the chain backbone. Apparently, even for molten polyethylene the ordering does not persist beyond ~ 30 Å perpendicular to the polymer molecules, and for distances less than ~ 20 Å along the chains. This level of short range ordering does not conflict with results that show that over larger distances the molecule adopts a random configuration.

Analysis of wide-angle X-ray diffraction patterns of aligned glassy polymers with particular references to polystyrene*

Richard Lovell and Alan H. Windle

Department of Metallurgy and Materials Science, University of Cambridge, Cambridge CB2 3QZ, UK
(Received 19 December 1975)

Improvement of WAXD patterns from aligned glassy polymers by a numerical desmearing technique is reported. This gives a fibre type diffraction pattern that can be more easily interpreted than radial or cylindrical distribution functions. Application to atactic and quenched isotactic polystyrene shows that the molecular conformations that are found are in agreement with those deduced from i.r. and n.m.r. spectroscopy. For isotactic polystyrene there is significant agreement between the fibre pattern of the aligned glassy polymer and that of the drawn crystalline polymer.

INTRODUCTION

The conformation and packing of molecules in solid glassy polymers is not fully understood. Much of the conformational data on these materials has been derived from infrared (i.r.) spectroscopy, the powerful methods of high resolution nuclear magnetic resonance (n.m.r.) analysis being readily applicable only to polymer solutions.

Careful small-angle X-ray and neutron scattering experiments^{1,2} have failed to reveal any density fluctuations on a scale greater than 50 Å which can be attributed to specific microstructural features. Wide-angle X-ray diffraction (WAXD) produces the familiar diffuse peaks. The traditional approach to their analysis is to prepare radial distribution functions (*RDF*) which essentially plot the distribution of the interatomic vector lengths. However, in the case of fairly complicated materials such as most polymers where it is the actual structure which is in doubt, it appears that *RDF* are of limited value only and do not always enable interchain and intrachain distances to be separately identified.

A slightly different approach to the problem of structure determinations is to align the glassy polymer by extension at a temperature a few degrees below its glass transition. This alignment is reflected in the concentration of some of the WAXD halos at particular azimuthal angles which can reveal whether they are of inter- or intra-molecular origin. Ohlberg *et al.*³ have attempted to derive a measure of the molecular orientation from the azimuthal profile of a halo that intensified on the equator although their conclusions have since been queried^{4,5}, and Brady and Yeh⁶ have used measurements of the loss of alignment in WAXD patterns as an indication of the structural reorganization which occurs on annealing glassy polymers. It must be emphasized though, that the observation of optical phenomena⁷ such as birefringence and i.r. dichroism as well as n.m.r. effects⁸ are also established techniques for the measurement of molecular orientation in glassy polymers. However WAXD alignment, where it can be observed, has the possible advantage that it is not controlled by the polarizability or absorption of specific parts of the molecule.

It also gives information as to the distances between adjacent molecular chains.

Cylindrical distribution functions (*CDF*) can be prepared from the WAXD patterns of aligned specimens with fibre symmetry⁹. They are, however, difficult to calculate and interpret. Milberg and Daly¹⁰ have used a difference-*CDF* which shows only the contributions due to orientation. Since it needs few corrections to the measured intensities, it is easier to calculate but the problems of interpretation remains.

In the work reported here we have concentrated on improving the apparent alignment in the diffraction pattern and then approaching its analysis in much the same way as one would a crystalline fibre diagram. In this way we have extracted additional information about the polymer structure from the positions of and intensity distributions along the layer lines.

In this paper we describe in some detail the analytical technique of desmearing developed to improve the azimuthal resolution of the diffraction patterns as well as its application to atactic polystyrene (a-PS) and quenched isotactic polystyrene (i-PS). Polystyrene is a particularly suitable candidate for this technique as its first diffraction halo concentrates only on the equator and hence provides a quantitative measure of the orientation distribution in the aligned specimens.

EXPERIMENTAL

The two polymers investigated were atactic polystyrene (BP Rigidex KLP 35) and quenched isotactic polystyrene (prepared by Dr N. Overbergh at the H. H. Wills Physics Laboratory, Bristol, and kindly loaned to us for these initial experiments. It is the same material as that used by the Bristol group for their gelation-crystallization studies¹¹). For each polymer a degree of chain alignment was obtained by multiple extrusion in a channel die at 85°C. The technique was to extrude to two or three times the original length, then to cut in half and repeat with one half on top of the other. Any one specimen was extruded up to four times in this way, although the improvement in alignment for the stages subsequent to the first was comparatively small.

Figure 1 Relationship between diffractometer coordinate axes (xyz) and specimen coordinate axes ($x'y'z'$). y and y' axes are always coincident i.e. specimen is rotated with the orientation axis (z') in the $x-z$ plane

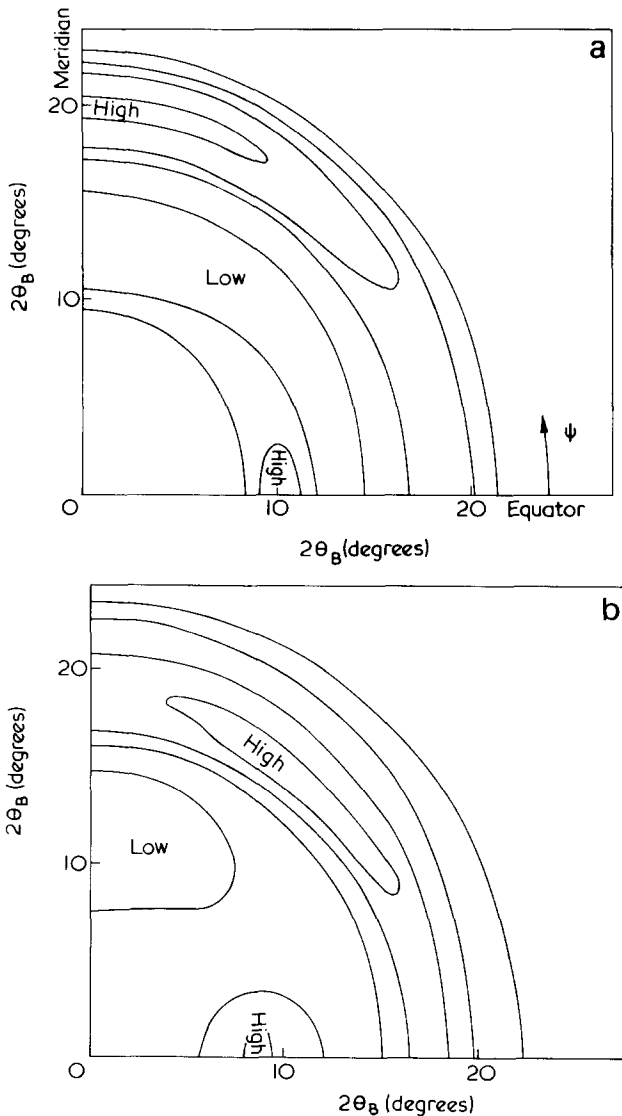

Figure 2 Experimental intensity patterns for (a) aligned atactic polystyrene, a-PS and (b) aligned, quenched isotactic polystyrene, i-PS. The intensity is in arbitrary units and the contours are at equal intervals

X-ray diffraction measurements were made using a texture goniometer set up with the symmetrical transmission geometry as sketched in Figure 1. At each particular $2\theta_B$ setting, the specimen was rotated about the y axis and the azimuthal distribution of scattered intensity plotted on a chart recorder. Figures 2a and 2b show the intensity patterns built up for a-PS and i-PS respectively. No corrections have been made for absorption, polarization, double diffraction or incoherent scattering. The radiation was $\text{CuK}\alpha$.

In view of the fact that n.m.r. has shown a-PS to be predominantly syndiotactic¹² it is perhaps surprising that the WAXD patterns of unaligned a-PS and i-PS are very similar¹³. However, a significant difference is apparent between the aligned diagrams (Figure 2) in that the second halo of a-PS is at maximum intensity on the meridian while that of i-PS shows maxima in the region of $\psi = \pm 45^\circ$.

With fibre patterns from crystalline polymers it is normal to view equatorial and meridional peaks as corresponding to inter- and intra-chain correlations respectively. In order to check that this assumption was valid in the case of glassy a-PS, the positions of the diffuse halos were measured as a function of temperature. The results are plotted in Figure 3. For the first (equatorial) halo at $2\theta_B = 10^\circ$, there was a marked shift towards lower angles (longer spacings) as the temperature was increased, especially above T_g , which appears to confirm that the halo is attributable to interchain spacings. (These results are in agreement with those of Kilian and Boueke¹⁴.) The shift of the second halo as a function of temperature is not nearly as distinctive as in the case of the first. This reflects the appearance of the second halo on alignment where it shows no clear predisposition to concentrate exclusively on either the equator or meridian.

AZIMUTHAL SHARPENING OF ALIGNED WAXD PATTERNS

Aims and assumptions

In this work the interpretation of WAXD patterns from aligned glassy polymers is approached in the same way as for the familiar fibre diagrams of a drawn crystalline polymer. However, in the case of an aligned glassy polymer one has to contend with not only a lack of long range order and

Figure 3 Change in chain spacing as a function of temperature determined from the positions of the first (+) and second (o) halos of unaligned atactic polystyrene

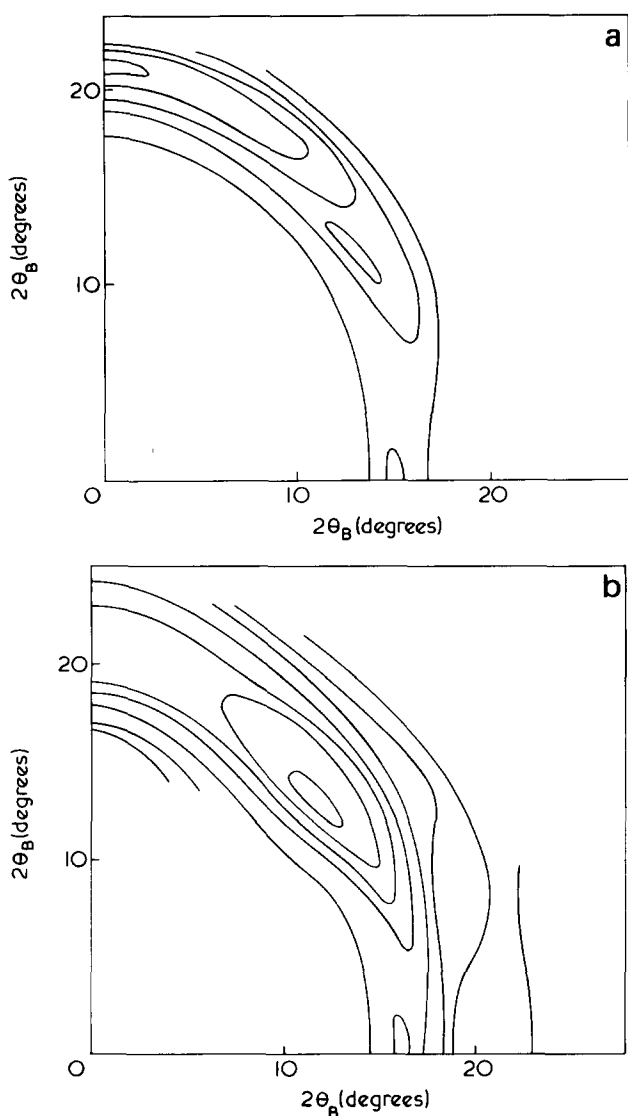

Figure 4 Experimental intensities as in Figure 2, azimuthally deconvolved with the profile of the first halo. (a), a-PS; (b), i-PS

hence diffraction maxima with a half width of several degrees or more, but also with the relatively poor degree of fibre orientation which is the best so far achieved. The analytical method outlined here has been developed to improve the apparent fibre orientation by azimuthally sharpening the X-ray diffraction pattern.

The aligned glassy polymer is treated as containing many entities each with its own fibre symmetry. The axes of the fibre entities are distributed in angle about the macroscopic fibre axis of the sample which we call the orientation axis; (z' axis lying in $z-x$ plane of Figure 1). The individual diffracting domains may not have fibre symmetry, however we are viewing a fibre entity as a collection of all domains which share a common molecular orientation. Thus each fibre entity will contribute to the diffraction pattern according to its angular position in relation to the orientation axis (z'). For the purposes of this analysis it is best to consider the fibre axis of an entity as having two components of 'misorientation' with respect to the orientation axis: one about y' ($\equiv y$) in the $x'-z'$ plane and another about x' in the $y'-z'$ plane. We can assume that the projections of the overall distribution of fibre entities about the orientation axis onto the $x'-z'$ and $y'-z'$ planes are identical. We style the projected distribution $D(\alpha)$ where α is measured from the orientation axis.

First stage desmearing

The projected distribution $D(\alpha)$ on the $x'-z'$ plane can be thought of as azimuthally smearing that diffraction pattern which would be recorded if all the fibre entities were aligned into the $y'-z'$ plane. For a particular $2\theta_B$ we will refer to this pattern as $I_2(\psi)$. Hence we can write that the experimental intensity $I_1(\psi)$ is the convolution of $I_2(\psi)$ and $D(\alpha)$ expressed as $D(\psi')$, i.e.

$$I_1(\psi) = \int_0^{\pi/2} I_2(\psi - \psi') D(\psi') d\psi' \quad (1)$$

For equatorially centred reflections from the fibre entities the distribution $D(\alpha)$ in the $x'-z'$ plane is the only contribution to the smearing which is therefore fully described by the above relation, and $I_2(\psi)$ is the true intensity distribution $I(\psi)$. Hence in the case of PS and other polymers which possess a halo which alignment concentrates onto the equator alone, $D(\alpha)$ can be obtained directly from the halo's azimuthal profile. It must of course be kept in mind that any significant extension of the equatorial maxima in the meridional direction, resulting perhaps from the small size of diffracting domains in this direction or from significantly curved molecules, will complicate the determination of the true $D(\alpha)$. However, in the case of PS, azimuthal smearing is so obviously the dominant factor, that the working approximation has been made that the azimuthal profile of the equatorial peak is equivalent to $D(\alpha)$. For PS therefore, the first stage of azimuthal sharpening is to remove the effect of the $x'-z'$ distribution function by deconvolution with the profile of the inner halo. (With some other glassy polymers such as poly(methyl methacrylate) and polycarbonate where no halo is uniquely equatorial the determination of $D(\alpha)$ will present additional problems.)

Several methods of deconvolution are applicable¹⁵, and one based on iterative procedures has been selected for this work. The convolution of two functions is written:

$$f(x) = g(x) * h(x) \quad (2)$$

Deconvolution is the solution of this equation for $g(x)$ where $h(x)$, the smearing function, is known. The iterative method used is based on a scheme to improve an approximation to $g(x)$.

This is:

$$g_{n+1}(x) = g_n(x) + [f(x) - g_n(x) * h(x)] \quad (3)$$

The first approximation to $g(x)$, $g_1(x)$, is taken as equal to $f(x)$.

The results of azimuthally deconvolving the profile of the equatorial peaks from the experimental intensities, at values of $2\theta_B$ which include the 2nd halo, for a-PS and i-PS are shown in Figures 4a and 4b. This procedure of course totally eliminates azimuthal spread from the first halo which is not represented in the Figures.

Second stage desmearing

For all but equatorial reflections, the distribution in the $y'-z'$ plane smears the diffracted information towards the meridian. Figure 5 shows the construction for calculating the nature of the smearing by considering a 'reflection' at

Figure 5 Construction in reciprocal space for calculating the position and intensity of a reflection from a fibre entity lying in the $y'-z'$ plane. The axis of the entity makes an angle α with the orientation axis (z') and the reflection makes an angle ψ' with the equator of the entity

the angle ψ' to the equator of a fibre entity. In reciprocal space this reflection is derived from the intersection of the small circle (CDE) and the 'reflection' plane, $x'-z'$ at C. If the axis of the entity is tilted away from the orientation axis by an angle α , in the $y'-z'$ plane, then the reflection will appear at an azimuthal angle ψ with its integrated intensity increased according to $\text{cosec } \gamma$. We now have to relate γ to ψ and ψ' , and obtain an expression which relates an increment of α , $\Delta\alpha$, in the $y'-z'$ plane, to an increment of ψ , $\Delta\psi$; in fact the value of $d\alpha/d\psi$. These relations can be obtained with reference to the spherical triangle ABC on Figure 5.

From ABC:

$$\cos\left(\frac{\pi}{2} - \psi'\right) = \cos\left(\frac{\pi}{2} - \psi\right) \cos\alpha + \sin\left(\frac{\pi}{2} - \psi\right) \times \sin\alpha \cos\frac{\pi}{2}$$

$$\text{Therefore: } \cos\alpha = \frac{\sin\psi'}{\sin\psi} \quad (4)$$

$$\text{and } \frac{d\alpha}{d\psi} = \frac{\cos\psi \sin\psi'}{\sin\psi(\sin^2\psi - \sin^2\psi')^{1/2}} \quad (5)$$

And also,

$$\cos\alpha = \cos\left(\frac{\pi}{2} - \psi\right) \cos\left(\frac{\pi}{2} - \psi'\right) + \sin\left(\frac{\pi}{2} - \psi\right) \times \sin\left(\frac{\pi}{2} - \psi'\right) \cos\left(\frac{\pi}{2} - \gamma\right)$$

Therefore:

$$\cos\alpha = \sin\psi \sin\psi' + \cos\psi \cos\psi' \sin\gamma \quad (6)$$

and using equation (4):

$$\text{cosec}\gamma = \frac{\tan\psi}{\tan\psi'} \quad (7)$$

Hence the distribution $D(\alpha)$ in the $y'-z'$ plane will smear intensity around the azimuthal circle according to the function:

$$D\left[\alpha = \cos^{-1}\left(\frac{\sin\psi'}{\sin\psi}\right)\right] \times \frac{\tan\psi}{\tan\psi'} \times \frac{\cos\psi \sin\psi'}{\sin\psi(\sin^2\psi - \sin^2\psi')^{1/2}} \quad (8)$$

The second two terms of this function simplify to:

$$\frac{\cos\psi'}{(\sin^2\psi - \sin^2\psi')^{1/2}}$$

which is plotted for $\psi' = 30^\circ$ in Figure 6.

The function $I_2(\psi)$ (equation 1) obtained after the first deconvolution is therefore the true azimuthal distribution $I(\psi)$ smeared by the function (8). It can be represented by a transform integral of the type:

$$I_2(\psi) = \int_0^{\pi/2} I(\psi - \psi') \times D\left[\cos^{-1}\left(\frac{\sin\psi'}{\sin\psi}\right)\right] \times \frac{\cos\psi' \cdot d\psi'}{(\sin^2\psi - \sin^2\psi')^{1/2}} \quad (9)$$

This is not strictly a convolution because the smearing function changes shape with ψ ; however, it can still be solved for the true distribution $I(\psi)$ using the iterative method. The convolution operation in the final term of equation (3) becomes now strictly one of smearing which nevertheless can still be performed numerically.

The results of this second stage desmearing are shown in the contour plots of Figure 7 (for a-PS and Figure 8 (for i-PS). Comparison with Figures 2 and 4 indicate that the second stage process leads to a smaller improvement in azimuthal sharpness than the first, although its application does emphasize the presence of a discrete meridional maximum at $2\theta_B = 21^\circ$ in the i-PS pattern.

DISCUSSION

In simple terms, a fibre diffraction pattern can provide information as to the structural and residue repeat distances along the chain, the mode of packing of the molecules and

the incidence of longitudinal register between adjacent molecules (as indicated by sampling of the layer lines other than the equator).

If the intensity distributions of Figures 7 and 8 are viewed as fibre patterns then it should be possible to ex-

Figure 6 Plot of $\cos \psi' / (\sin^2 \psi - \sin^2 \psi')^{1/2}$ for $\psi' = 30^\circ$

tract some at least of this structural information. However, compared with diffraction from a crystalline fibre, the patterns from the glassy polystyrenes present additional problems. There is of course considerable disorder along the molecular chains as well as in their packing which is responsible for the general lack of definition in the pattern. In addition it is very probable that there is no unique chain conformation, so that the pattern may have to be treated as the superposition of two or more separate patterns.

In attempting to analyse the diffraction from a-PS and i-PS, we have started by narrowing down the number of possible conformations for isotactic and syndiotactic configurations. We have considered mainly those based on staggered bonds, although one particular possibility involving eclipsed bonds is also included. The relevant bond rotation angles for the carbon backbone are defined in Table 1. In Table 2 the possible conformations with repeats less than 8 Å based on combinations of rotation angles are listed. Conformations which we have successfully constructed from CPK models without undue intrachain steric hindrance are indicated with a + and those which satisfy Natta and Corradini's equivalence principle¹⁶ are marked in addition with an ε. The chain repeat distances for the various conformations are essentially those of Bunn¹⁷ for an unencumbered carbon backbone but modified slightly on the basis of observations of the CPK molecular models to take account of some measure of steric hindrance. In addition the distances only refer to the structures which can be readily built (i.e. those marked with +). The figure of 6.65 Å for $(tg)_3$ is simply the repeat shown by crystalline i-PS (The corresponding Bunn figure is 6.20 Å).

Atactic polystyrene

There is strong evidence that a-PS is predominantly syndiotactic¹². For this reason the analysis of the sharpened diffraction pattern of a-PS (Figure 7) is viewed initially in terms of the possible syndiotactic conformations listed in

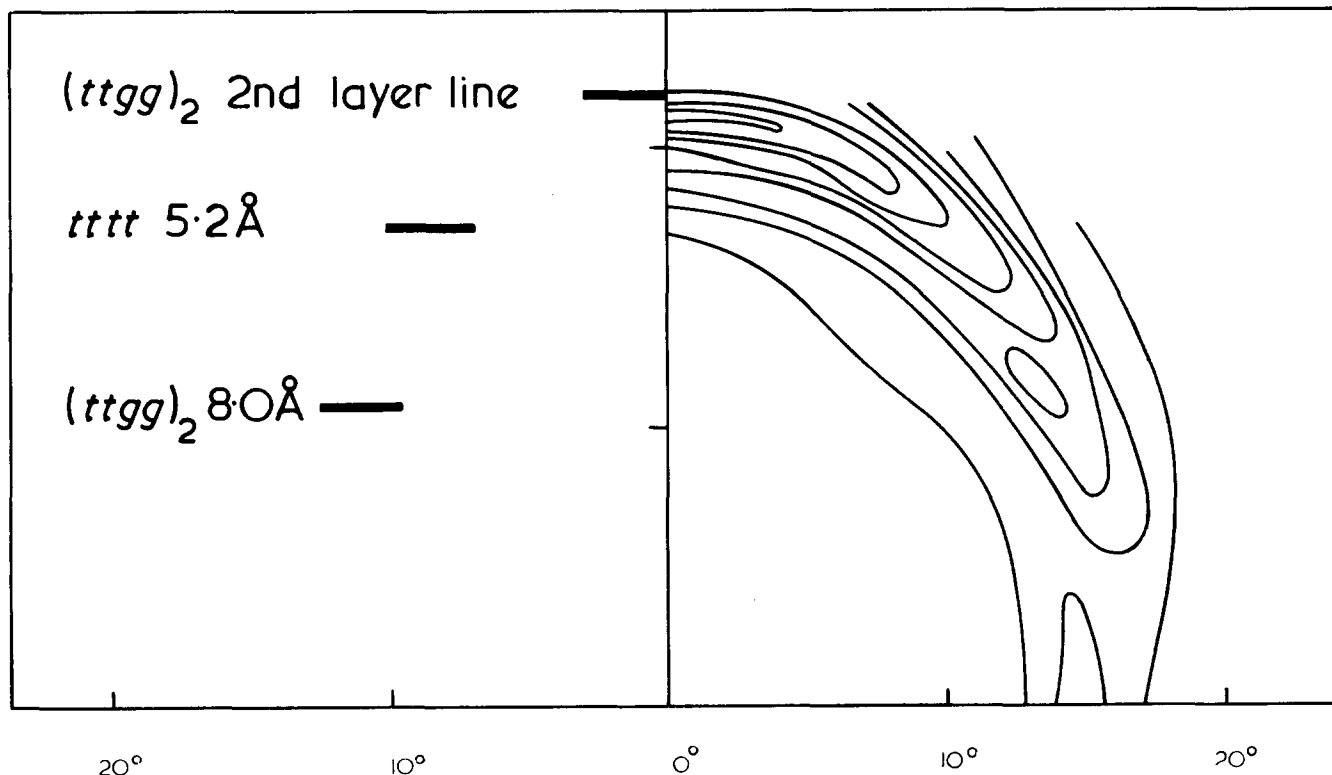

Figure 7 Result of second stage desmearing for aligned atactic polystyrene. The calculated positions of the regions of high intensity on the 1st layer line of $(tttt)$ and on the 1st and 2nd layer lines of $(ttgg)_2$ are shown on the left

Figure 8 Result of second stage desmearing for aligned, quenched isotactic polystyrene. The calculated positions of maximum intensity for the 1st and 2nd layer lines of $(tg)_3$ and $(ttgg)_2$ are shown on the left. The crosses mark the positions of the most intense reflections for aligned crystalline isotactic polystyrene

Table 1 Internal rotation angles

	ϕ (degrees)	
Trans, <i>t</i>	0	} Staggered

Table 2 Possible conformations for polystyrene

Conformation	Chain repeat (Å)	i-PS	s-PS
$g\bar{4}$	4.0	ϵ	ϵ
$tg\bar{t}g$	4.4	—	+ ϵ
$tst\bar{s}$	4.8	+	+ ϵ
$tttt$	5.2	ϵ	+ ϵ
$(tg)_3$	6.65	+ ϵ	—
$(ttgg)_2$	7.8	+	+ ϵ

+, indicates a conformation which does not lead to undue steric hindrance

ϵ , indicates a conformation which satisfies equivalence i.e. each monomer unit has a similar environment

Table 2. The pattern shows equatorial maxima at ($2\theta_B = 10^\circ, \psi = 0^\circ$) and ($15^\circ, 0^\circ$), a small peak at ($17.5^\circ, 40^\circ$) and a broad arc centred on the meridian at ($21^\circ, 90^\circ$).

The peak at ($17.5^\circ, 40^\circ$) corresponds to a chain repeat distance of 7.5–8.0 Å. If we are to interpret this in terms of $(ttgg)_2$ which has a repeat of 7.8 Å, then there should be a second layer line intersecting the meridian at $2\theta_B = 22$ – 23° with its maximum intensity on the meridian. This appears to correspond to the central region of the broad arc.

The calculated positions of the intensity maxima on the first two layer lines of the transform of a s-PS chain in $(ttgg)_2$ conformation (i.e. a 2/1 helix) are represented on the left side of Figure 7. The large azimuthal spread of the ($21^\circ, 90^\circ$) arc appears to deny the effectiveness of the desmearing procedures already applied. An alternative approach however is to consider the 'wings' of the arc as representing off meridional intensity maxima on a layer line intersecting the meridian at $2\theta \approx 18^\circ$, i.e. about 5 Å. Such an intensity disposition would correspond fairly well to the $(tttt)$ planar zig-zag conformation as indicated on the left of Figure 7. The data therefore suggest that atactic polystyrene contains substantial syndiotactic sequences in both $(tttt)$ and $(ttgg)$ conformations, both conformations being present in roughly equal proportions. However, we cannot exclude the possibility of $(tg\bar{t}g)$ which would also lead to an intensity maximum close to the meridional peak at ($21^\circ, 90^\circ$). No other experimental technique has provided direct evidence for the chain conformation in bulk a-PS (or for that matter in s-PS which has not apparently been synthesized) so it is not possible to confirm our predictions. However, it is most encouraging to note that n.m.r. measurements on syndiotactic triphenylheptane (a model for s-PS) in solution have shown that it has equal preference for the conformations $(tttt)$ and $(ttgg)$ ¹⁸. Moreover calculations¹⁹ have shown that for s-PS the two conformations are energetically equivalent. Further support is given to the reasonableness of the prediction of $(tttt)$ and $(ttgg)_2$ by observations of the crystal structure of syndiotactic polypropylene. Two structures are reported, one²⁰ based on $(tttt)$ with a chain repeat of 5.05 Å and the other²¹

based on $(ttgg)_2$ with a chain repeat of 7.4 Å. Since the repeat distance of the 3/1 helix of i-PS is ~3% greater than that of i-PP, we can perhaps expect distances of 5.2 Å for $(tttt)$ s-PS and 7.6 Å for $(ttgg)_2$ s-PS.

It should also be possible, on the basis of the equatorial X-ray data, to make proposals as to the chain packing, which of course should be in line with the predicted conformations. Such studies are in progress but not reported here.

Isotactic polystyrene

Perhaps the most striking feature of the sharpened diffraction pattern from glassy i-PS (*Figure 8*) is the correspondence between some of the maxima and the 'reflection' positions in a corresponding fibre diagram from crystallized and aligned material. That glassy i-PS contains chains in the $(tg)_3$ conformation (3/1 helices) is not particularly surprising as evidence for this conformation in solutions of the polymer has been obtained from infra-red^{22,23} and ultra-violet²⁴ spectroscopy and it is of course present in the crystal²⁵. What is intriguing however is that the correspondence of the patterns implies longitudinal register between adjacent molecules in the glassy phase; that is, some measure of three-dimensional order. Further confirmation of longitudinal register can be obtained by comparing the position of the first maxima on the 6.65 Å layer line of the sharpened pattern, with the calculated position for the maximum on this layer line corresponding to an isolated 3/1 helix. (*Figure 8*) (Its position is not significantly changed if an enantiomeric pair of helices is considered). The two maxima are at different distances from the meridian. This indicates that the first layer line of the glassy polymer is sampled by a reciprocal lattice with the implication of three-dimensional order. It is not clear at this stage whether the glassy structure should be viewed as crystals with a high degree of paracrystalline disorder, as exceptionally small crystallites or as some combination of both.

There is, however, a maximum at $(21^\circ, 90^\circ)$ which, lying between the first and second layer lines of the crystal pattern, implies that a conformation other than $(tg)_3$ is also present. It is difficult to interpret this maximum. Perhaps the best explanation is that it is the second layer line of the isotactic equivalent of $(ttgg)_2$, already proposed for the syndiotactic material, but which does not satisfy the equivalence principle. If this is the case there should also be maximum on a first layer line corresponding to a repeat of about 8 Å. It is just possible that the 'lobes' extending downwards from the prominent peaks on the 6.65 Å layer lines (3/1 helix) represent these maxima.

CONCLUSIONS

Wide-angle X-ray diffraction is a promising technique for the investigation of the structure of oriented glassy polymers.

The fact that it is not possible to obtain a very high level of fibre orientation by mechanical extension has led to the development of a numerical technique to enhance the azimuthal resolution of the aligned diffraction patterns.

The polystyrene results presented are from our first series of experiments only. They do however permit several conclusions to be drawn as to the structure of a-PS and i-PS in the aligned glassy state. For the atactic material there is evidence that the conformations $(tttt)$ and $(ttgg)_2$ are present in roughly equal proportions, whereas the iso-

tactic samples contain some three-dimensional order based on the 3/1 helices, although the diffraction halos still remain broad.

In the light of these results it appears that a useful approach to the problem of the microstructure of glassy polymers may well be through X-ray structural studies of aligned samples.

The structural information derived by these methods is of course only directly applicable to polymers in the aligned state. However, experiments of Colebrooke and Windle²⁶ suggest that as far as chain conformation and packing are concerned, the extra information which can be extracted from the diffraction patterns of the aligned material is also relevant to the normal unaligned material.

ACKNOWLEDGEMENTS

The authors would like to thank Professor R. W. K. Honeycombe for the encouragement given to this work in the Department of Metallurgy and Materials Science at Cambridge. Thanks are also due to Professor J. G. Ball and Mr F. Huggins for the provision and maintenance of facilities at Imperial College where much of the experimental work was carried out. As mentioned in the text, the isotactic polystyrene was prepared by Dr N. Overbergh in Professor Keller's group at Bristol. We acknowledge with many thanks the loan of a sample of this material. We thank the Science Research Council for a grant which enabled this work to be carried out.

Effect of sample geometry on the measurement of mechanical properties of anisotropic materials*

R. G. C. Arridge and M. J. Folkest

*H. H. Wills Physics Laboratory, University of Bristol, Bristol BS8 1TL, UK
(Received 15 December 1975; revised 2 February 1976)*

Experimental observations have been made of the effect of sample geometry on the mechanical properties of anisotropic polymer systems. The non-uniform stresses at the sample ends, arising from the method of clamping are found to persist over much greater distances than in isotropic materials, as judged by their effect on the tensile and torsional modulus. The Principle of St. Venant does not appear to be applicable to anisotropic materials. This is further supported by results obtained using finite element methods. The results raise serious doubts concerning current practice in determining the mechanical properties of anisotropic materials.

INTRODUCTION

In the practical determination of the elastic constants of solids, the most commonly used test methods involve tension, bending or torsion either under dead loading or dynamic conditions. In all of these methods, it is usually assumed that stress concentrations imposed at the ends of the sample as a result of the particular clamping arrangement can be neglected in the calculation of the elastic constants. In practice, the approach has been either to choose appropriate sample dimensions or to measure deformations of the sample by means of strain gauges attached to the surface. There are other limitations to be considered in the experiment namely time effects if the material is viscoelastic and non-linear effects such as are found in many polymers. These problems are not, however, our concern here although they may well interact with the effects of sample end constraint, which is the main subject of this present paper.

The ability to neglect sample end effects in suitably shaped samples rests upon the validity of the so-called Principle of St. Venant proposed by the French elastician in 1855. This states (we quote Love¹) 'the strains that are produced in a body by the application to a small part of its surface of a system of forces statically equivalent to zero force and zero couple, are of negligible magnitude at distances which are large compared with the linear dimensions of the part'. In practice this means that the irregular stress distribution arising from the particular method employed to transfer an external force to the sample, becomes uniform at a distance away from the points of application equal to about one lateral dimension of the sample, and that from this distance further only the *resultant* forces and couples need to be considered.

The irregularity of the stress distribution can be shown to decay away exponentially with distance from the sample ends so that, strictly, end effects are always present. However in the case of isotropic materials, they are usually found to be negligible about one specimen width away from

the sample ends compared to the other errors incurred in the measurement of any mechanical property. This means that in practice, depending on how far one is prepared to go in order to eliminate end effects, a specimen length/width ratio of 10 is sufficient.

Recently, Folkes and Arridge² reported observations made on highly anisotropic material in the form of a polymeric microcomposite, which showed end effects in torsion persisting over very much greater sample lengths compared to those for isotropic materials. Subsequent studies in this laboratory have shown that similar effects exist in other polymeric materials, namely high density polyethylene which has been either extruded in the solid state or drawn to a high draw ratio. All of these observations cast serious doubt on the validity of St. Venant's Principle when applied to anisotropic materials.

It is the purpose of this paper first to summarize the findings of Folkes and Arridge² and then to describe preliminary results on ultra-high modulus polyethylene together with theoretical studies using the finite element method for a two dimensional model of anisotropic material in tension.

The authors feel that the results to be reported have important implications in the accurate measurement of the mechanical properties of anisotropic materials in general and may require current testing standards to be modified.

THEORETICAL DEVELOPMENTS OF ST. VENANT'S PRINCIPLE

The Principle of St. Venant in the form stated in the introduction is not universally true for, as Toupin³ shows, the stresses in a beam of dumbbell cross-section loaded at one end by couples whose resultant is zero will persist far along the beam. St. Venant in fact, stated the principle as being valid for perfect cylinders only, not necessarily for those of arbitrary cross-section. For this reason, mathematicians have recently sought a more general principle and in addition, have examined the case of anisotropic materials.

A criterion based upon elastic stored energy has been proposed by Toupin³ and when applied to anisotropic materials by Horgan⁴ led to the concept of a characteristic decay length for the stored elastic energy. This in turn led

* Presented at the Polymer Physics Group (Institute of Physics) Biennial Conference, Shrivenham, September 1975.

† Present address: Department of Materials, Cranfield Institute of Technology, Cranfield, Bedford MK43 0AL, UK.

Figure 1 Dependence of shear modulus in torsion of S-B-S 'single-crystal' on sample aspect (length/width) ratio. Curve indicates probable trend

to an exponential decay for the stress irregularity at interior points. For anisotropic materials Horgan⁴ showed that this decay length was always greater than it was for an isotropic material and was of the form $\lambda = b(E/G)^{1/2}$ where b is the maximum lateral dimension of the sample, E is Young's modulus along the axis of the specimen and G the shear modulus, for shear which includes that direction, the so-called longitudinal shear modulus.

Now for isotropic materials E/G lies between 2.6 and 3.0, so λ is $\sim 1.6-1.7b$. For very anisotropic materials e.g. the microcomposite studied by Folkes and Arridge², E/G can reach values as high as 280 so that λ may be as high as $16.7b$. In such cases, therefore, neglect of the stress distribution at the points of loading becomes quite unjustifiable and only two alternatives remain. One is to determine the stress distribution for the particular method of sample clamping employed, solve the elastic equations of equilibrium and hence derive the elastic constants. The other is to choose a sample length/width ratio so large that the end effect may still be ignored.

The first alternative is extremely difficult; not only are the stresses (or displacements) difficult to determine in practice but the solution of the elastic problem for an anisotropic body is a formidable task even for simple geometries. Pagano and Halpin⁵ have considered this for tensile loading of an anisotropic material in directions at an angle to the symmetry axes and derive an explicit expression for the Young's modulus along these directions as a function of the length/width ratio of the sample. Their analysis breaks down, however, when the applied load acts along an axis of symmetry.

The second alternative seems at present the better one, provided sufficient sample material is available, which may not always be the case, for example, with minute 'whisker' crystals of inorganic or organic substances, or those samples as used in the classical measurements of the elastic constants of crystals of various symmetry classes.

EXPERIMENTAL OBSERVATIONS

In this section we report on studies of end effects in two highly anisotropic materials, one in torsion and the other in tension.

Block copolymer microcomposite

The material used for our investigations was Kraton 102, an S-B-S block copolymer, which by suitable processing can be obtained in 'single-crystal' form, consisting of a hexagonal array of polystyrene cylinders embedded in a

matrix of polybutadiene, with the cylinder axes uniaxially aligned⁶. The mechanical properties of this material have been studied in simple tension^{7,8} and torsion² and the results compared using the following approach.

If we consider the elastic properties of an anisotropic material having transverse isotropy, then the Young's modulus E_θ measured at any angle θ to the symmetry axis is given by the usual transformation equation:

$$\frac{1}{E_\theta} = S_{11} \sin^4\theta + (2S_{13} + S_{44}) \sin^2\theta \cos^2\theta + S_{33} \cos^4\theta$$

where the coefficients S_{ij} are the two-suffix compliances (see e.g. Hearmon⁹) and the symmetry axis is taken as the 3 direction.

The measured values of Young's modulus for the 'single-crystal' samples of Kraton 102 have been fitted to the above equation using the method of least squares, from which one derives values for S_{11} , S_{33} and $(2S_{13} + S_{44})$. In a previous paper⁸, it was shown on theoretical grounds that $S_{13} \sim 10^{-3}S_{44}$ and hence Young's modulus anisotropy provides values for S_{11} , S_{33} and S_{44} , the latter being inversely proportional to the longitudinal shear modulus G .

The shear modulus G can of course, be directly measured by a torsion test about the symmetry axis on a long sample². It should be noted, however, that any end effects are expected to be much less pronounced in deriving G from the tensile data in view of the fact that this quantity is primarily determined by the Young's modulus corresponding to off axis loading where the ratio E/G is much less than for loading along the symmetry axis.

Values of S_{44} or $G = 1/S_{44}$ from tensile measurements can be compared with those from torsion tests. When this is done it is found that G , derived from tensile measurements, is about one half of the value measured by a direct torsion experiment. At the time of a previous paper by the authors⁸ no explanation could be proposed for this discrepancy, but later it became apparent that end effects in torsion may mean that the usual assumptions implicit in the classical theory of torsion are unjustified. Accordingly, torsion measurements were made on samples of varying aspect (length/width) ratio up to about 120 with the results given in Figure 1. It appears from the results that the discrepancy referred to above is resolved only when very long samples are used, in fact greatly exceeding those normally used in torsion measurements.

As stated earlier, end effects are expected to persist for a length of the order of $b(E/G)^{1/2}$, which for Kraton 102 is about 16-17 sample widths from each end. Hence we would expect that the measured shear modulus should show a decrease commencing near a length/width value of about 32, as observed.

The fact that short samples give higher values of shear modulus is attributed to the constraint imposed by the sample clamping, which prevents a portion of the sample length from undergoing pure torsion. In our experiments, here, the end surfaces of the specimen were constrained to remain plane by glueing the specimens onto tufnol blocks or by inserting them in exactly matching blocks of glue so that the specimens were free to slide vertically but not able to rotate (their cross-sections were rectangular). Since Kraton 102 is a relatively soft material, this form of sample clamping is simple to arrange and gives a well defined end constraint. This may not always be possible and in fact preliminary experiments with carbon-fibre reinforced epoxy

Figure 2 Apparent tensile modulus of linear polyethylene film (draw ratio 28) as function of length/width ratio

resin specimens indicate that constraint of such materials, which can be stiffer than steel, requires very careful experimental design. More often than not, the sample clamping technique involves gripping the ends of the sample directly in the jaws of a mechanical testing machine. In this case, although the stresses still decay with a characteristic length $b(E/G)^{1/2}$, the form of the end constraint is very different.

High modulus polyethylene

End effects can also be expected in tensile and bending tests since, again, the distribution of stresses at points of application of loads does not become negligible until a length of the order of $b(E/G)^{1/2}$ is reached. Tensile specimens therefore need to be at least $2b(E/G)^{1/2}$ in length before uniformity of stress over the sample cross-section can be assumed and a three-point bend test specimen would need to be $4b(E/G)^{1/2}$ in length before the simple beam equation could be assumed correct. As stated earlier, the effect is most pronounced along the direction of highest Young's modulus. Evidence for such a slow decay in stress concentration during tensile testing is afforded by another polymeric system exhibiting a large mechanical anisotropy, represented by the ultra-high modulus polyethylene, at present the subject of extensive research in many laboratories. Figure 2 shows a plot (from ref 10) of Young's modulus versus aspect ratio for polyethylene, drawn to a draw ratio of 28, with the tensile stress applied along the symmetry axis. Sample preparation has been given elsewhere¹¹. Two important points here should be emphasized. First, it can be seen that very long samples are required before a plateau is reached on the curve and secondly the Young's modulus is seen to rise with increase in aspect ratio of sample. The latter arises from the fact that the samples were held in cylindrical collars in the jaws of the tensometer and the load is therefore applied to the sample via shear from the surface to interior points. For short samples, therefore, the load is applied to only a fraction of the sample cross-section, producing an abnormally large strain and hence under-estimating the Young's modulus for the sample as a whole. The values of Young's modulus were obtained using estimated sample strain¹⁰ assuming homogeneous stress and allowing for testing machine compliances (see Figure 9). The effect is particularly pronounced in very anisotropic materials and is supported by theoretical work using finite element methods as shown below.

If one takes the theoretical values for E and G for a polyethylene single crystal as given by Odajima and Maeda¹², then $(E/G)^{1/2} = 15.1$. This shows that the end effects should start to decrease for aspect ratios of about 30, which

is in satisfactory agreement with the experimental results in Figure 2.

Finite element calculations

The issues raised above are further illustrated in Figures 3–8 obtained using finite element models in plane strain but it should be emphasized, they are models only. Figures 3 and 4, show end effects in tension in an isotropic beam loaded at the corners only. The symbols on the diagrams represent the relative magnitudes and directions of the principal stresses. The effect of stresses introduced there is seen to approach a uniform resultant within 1–2 sample widths away from the ends. Analysis of the stresses at the centre line in these models shows, in fact, that for a length/width ratio of 5 the stress is uniform at the centre section and remains so up to 2 widths from each end. Similarly for the beam of aspect ratio 10. This is therefore consistent with the statement of St. Venant's Principle.

This is certainly not true for anisotropic beams similarly loaded, however, as Figures 5–8 show. The values of E and G used in these calculations were those calculated for polyethylene crystals by Odajima and Maeda¹². It can be seen that the applied tensile load is almost entirely concentrated in the surface layers and analysis shows that the beam has to have an aspect ratio of about 40 before the stress at the centre cross-section becomes uniform to within 1%. It is still non-uniform for about 14 widths from each end, in very good agreement with the theory of Horgan⁴, discussed earlier. Finite element calculations for beams in which the two outer surface nodes at each end and on each side are given identical displacements yield very similar results to those of Figures 5–8. This loading corresponds to the case of a soft material bonded directly on its lateral surfaces at each end to a much stiffer material.

Of great significance to the experimentalist is the fact that not until an aspect ratio of 40:1 is reached is there a region of uniform stress across the specimen. This means that not even by using strain gauges will a correct value of tensile modulus be deduced, since the surface strain is not representative of the sample as a whole. Figure 9 shows the predictions of the apparent tensile modulus deduced from the finite element model for specimens with the same degree of mechanical anisotropy as used above. One curve shows results when the movement of the points of loading is used as a measure of the sample strain while the other uses surface strain as would be measured by a suitable strain gauge. It is apparent that erroneous values will be obtained unless the specimen is long enough to ensure uniform strain at its centre. There is qualitative agreement with the experimental curve of Figure 2. Quantitative experimental results using strain gauges or other means of measuring surface strain on high-drawn polyethylene have not yet been obtained. The strains are very difficult to measure on the very small specimens available.

Evidence for a slow decay in stress concentrations due to point loads in glass-fibre reinforced material has been obtained by photoelastic means by Bold¹³, but in this material the anisotropy is much less marked, though still apparent.

CONCLUSIONS

Experimental measurements on torsion and in tension on two highly anisotropic materials show that end effects produced by various means of clamping persist further into the specimen than would be expected using the conventional

Principle of St. Venant. There is good agreement with the prediction of Horgan that such effects persist for a distance $b(E/G)^{1/2}$ and consequently specimens need to be long enough for this enhanced end effect to be ignorable.

In principle the finite element method enables calculation to be made of the stress distributions due to any system of loading. In practice this is not possible since we have no means of measuring the distribution of stresses at the points of attachment of the clamps to the specimen. The practical conclusion therefore is that measurements of any elastic moduli on anisotropic materials need to be repeated on specimens of increasing length/width ratio until consistent results are obtained. This may mean length/width ratios up to 100 for very anisotropic materials.

ACKNOWLEDGEMENT

We would like to acknowledge the assistance of Mr F. A. Lovett in the computing work.

Multi-pass Fabry–Perot spectroscopy of polymers*

S. M. Lindsay, A. J. Hartley and I. W. Shepherd

Physics Department, University of Manchester, Manchester M13 9PL, UK

(Received 25 November 1975)

The potential utility of multi-pass Fabry–Perot spectroscopy in the study of polymers is demonstrated. A triple-pass system is described and the performance is discussed. Preliminary results in three areas are presented: (1) a study of anisotropy in oriented poly(methyl methacrylate); (2) hyper-sonic viscoelastic behaviour of poly(propylene oxide) and poly(dimethyl siloxane); (3) the effect of crosslinking in poly(dimethyl siloxane) on the high frequency elastic properties and on phonon absorption.

INTRODUCTION

In this paper we wish to describe a relatively new technique, multi-pass Fabry–Perot spectroscopy (*MPFPS*), and to indicate possible applications to the study of polymers. We also present some of the early results obtained on our triple-pass equipment at Manchester.

In this work the Fabry–Perot (*FP*) is used to analyse the spectrum of laser light scattered from polymers. It is thus one of many techniques employed in scattering experiments and it is helpful to place it in context. Scattering of many types has played an important part in physics over many years, ranging in time and complication from the classical Rutherford and Compton scattering experiments to the modern work using high-flux reactors which produce intense neutron beams. These diverse experiments all have a common basis: an incident particle having momentum $\hbar\mathbf{k}_i$ and energy $\hbar\omega_i$ is scattered in the medium to emerge with changed momentum and energy $\hbar\mathbf{k}_s$ and $\hbar\omega_s$. An excitation of momentum $\hbar\mathbf{K}$ and energy $\hbar\Omega$ is created (or annihilated) in the medium. Conservation of energy and momentum requires that:

$$\omega_i - \omega_s = \pm\Omega \quad (1)$$

and

$$\mathbf{k}_i - \mathbf{k}_s = \mathbf{K} \quad (2)$$

where the positive and negative signs in equation (1) refer to creation and annihilation of an excitation. It is clear

* Presented at the Polymer Physics Group (Institute of Physics) Biennial Conference, Shrivenham, September 1975.

from these simple but basic considerations that if the incident beam is well-defined, measurement of the frequency and momentum of the scattered particle will yield information about \mathbf{K} and Ω which in turn can give information about the medium itself. Equations (1) and (2) also show that the range of momentum and energy transfer, i.e. the range of \mathbf{K} and Ω that is measurable, will depend on the incident momentum and energy. These incident beam parameters will depend on the nature of the particles, and *Table 1* and *Figure 1* show the regions of $\mathbf{K} - \Omega$ space that are covered by several different techniques. The precise shapes of the blocks in *Figure 1* are affected by experimental resolution, and in drawing the diagram criteria have been adopted that are possible to realize using modern equipment. In the interest of simplicity the range of Ω has been limited to that covered by visible light scattering, so that 'high energy' particle scattering is excluded. The most striking features of this plot are the wide open spaces not covered by any presently available techniques. In other words, this type of experiment is only grazing the surface. The second most striking features are the very wide frequency range covered by visible light scattering and the very narrow momentum range. The so-called Brillouin region, which covers the gap between Rayleigh line-width and Raman is covered by the Fabry–Perot technique. The narrow momentum range is the most serious limitation of the method, and is of course due to the fact that $|\mathbf{k}_i|$ for a visible photon is only of the order 10^5 cm^{-1} . Equation (2) then shows that the maximum $|\mathbf{K}|$ possible is $2|\mathbf{k}_i|$ or approximately $2 \times 10^5 \text{ cm}^{-1}$. This is very much less than the reciprocal of an interatomic spacing in a solid or a liquid, and so light scattering studies are effectively limited to zone centres. This limitation does not apply to the neutron, which is a massive particle for which momenta of

$|\mathbf{k}_i| \sim 10^8 \text{ cm}^{-1}$ are readily obtainable. Advantages of light scattering in general and Brillouin in particular, other than the wide energy range, are not apparent from Figure 1. They are: (a) Good sensitivity. (b) High resolution (10^7 – 10^8 Hz in Brillouin). (c) Sample preservation. Except in extreme circumstances the experiments are non-destructive. (d) Possibility of observing transient effects. Very fast pulse techniques may allow the observation of transient effects down to a time resolution of 10^{-7} sec.

Particular contributions that may be made to the study of polymers using the *FP* are suggested in Table 2. There is a somewhat arbitrary division in this Table between Brillouin scattering and low frequency Raman scattering. Historically Brillouin's name is associated with scattering from propagating pressure waves, i.e. sound waves, so the items in this column make use of the waves at hypersound frequencies to give information about the materials. The velocity of sound, v , is connected with the measured frequency shift by:

$$\frac{\Omega}{\omega_0} = \frac{2n\nu}{c} \sin \frac{\theta}{2} \quad (3)$$

where ω_0 is the incident frequency, n the refractive index and θ the angle of scatter. The width of the Brillouin peaks gives information about the attenuation or lifetime of the waves, and thus about the structure over a range of 0.1–20 μm . Where phonon-phonon scattering makes an important contribution, absorption measurements will also yield information about the high frequency (10^9 – 10^{12} Hz) dynamics of the network. The generic term 'Raman' is used for the other light scattering phenomena. The method of detection is, of course, the same in either case. Otherwise Table 2 is self-explanatory. When it is realized that the list is only a selection of possible experiments it is clear that the technique is potentially of great value.

INSTRUMENT DESCRIPTION

The spectral range we wish to cover is roughly between 10^7 and 10^{11} Hz. Visible laser sources are normally used and therefore the required resolving power is high, of the order 10^7 . The only practical possibility in these circumstances is to use a *FP* etalon which achieves high resolving power by the interference of beams multiply reflected between two highly reflecting plates. The response function¹ of the etalon for a monochromatic beam of intensity I_0 incident at 90° to the plates is given by:

$$\frac{I(\delta)}{I_0} = \frac{1}{1 + (2F_R/\pi)^2 \sin^2 \frac{1}{2}\delta} \quad (4)$$

where the phase parameter $\delta = 2d|\mathbf{k}|$; d is the plate separation and $|\mathbf{k}| = 2\pi\lambda^{-1}$ the light wavevector. F_R is the reflectivity finesse and is defined in terms of the reflection coefficient r as $\pi^{1/2}(1-r)^{-1}$. It has been assumed that the finesse is determined solely by the reflectivity. In practice other factors, such as plate flatness, can be important and decrease the finesse to an actual value F which is below the theoretical reflectivity value. The response is plotted in Figure 2 for spectral orders n and $N+1$. The parameters of experimental importance are indicated in the Figure. They are: (1) the free spectral range $\Delta\nu$, which determines the accessible region of the spectrum free of overlap between orders; (2) the instrumental linewidth $\delta\nu$, which determines the smallest measurable linewidth; (3) the contrast C , which is the ratio between the maximum and minimum intensities; (4) the resolving power $R = \nu/\delta\nu$. The free spectral range is determined by plate separation and, in frequency units, is given by $\Delta\nu = c/2d$, where c is the velocity of light. It can be adjusted between the approximate limits of 10^8 and 10^{12} Hz to suit experimental requirements. Stability problems are enhanced by the large plate separations at the lower limit and make lower values of $\Delta\nu$ extremely difficult to obtain. If it is not necessary to have an adjustable free spectral range, greater stability can be obtained by using a confocal arrangement². It is not, in general, important to increase the upper limit, because 10^{12} Hz

Figure 3 Schematic diagram of a triple-pass Fabry-Perot etalon system incorporating piezoelectric scanning and digital detection

is already well within the range of modern grating spectrometers. Under the assumption that the mirror reflectivity is the limiting factor in performance, other parameters can be expressed in terms of $\Delta\nu$ and F as $\delta\nu = \Delta\nu F^{-1}$, $C \approx 4F^2\pi^{-2}$ and $R = \nu F/\Delta\nu$. Normally finesse values of between 40 and 50 are attainable, corresponding to reflectivity of about 95% with plates flat to about $\lambda/100$. Values of C are then $\sim 10^3$, which are sufficient for samples of high optical quality that do not produce a large random scattering intensity. Unfortunately many polymers are of poor quality, and the Brillouin spectra may be unobservable because the peaks are much smaller than the minimum intensity in $I(\delta)$. This problem can be overcome by operating the etalon in a 'multi-pass' mode in which the beam is reflected back through m times, where m has experimentally optimum values of 3 or 5. In this configuration the output function is determined by raising the function in equation (4) to the m 'th power, and in this way contrasts up to 10^8 can be obtained. The effect of 'triple-passing' the instrument is indicated by the broken line in Figure 2; the important point is that the minimum is significantly suppressed. A schematic diagram of the experimental equipment is shown in Figure 3. The incident laser light from an argon ion laser ($\lambda = 5145 \text{ \AA}$) is scattered through an angle θ and

then collimated into the etalon. The beam is returned three times by corner-cube retro-reflectors and emerges through a filter to be detected by a photomultiplier tube. The signal is then recorded using multichannel scaling techniques. Line shape analysis is carried out using an off-line computer. The etalon plates are scanned piezoelectrically and Figure 3 includes a block diagram of the electronic control system. More detailed descriptions of this system can be found in refs 4 and 5.

The enormous improvements to be obtained by multi-passing are illustrated in Figure 4 where we present Brillouin spectra of a crosslinked rubber, poly(dimethyl siloxane). In Figure 4a the spectrum is shown after a single pass and the Brillouin peaks are only just visible above the background. Figure 4b shows the same system after three passes when the Brillouin peaks seem to be completely resolved and quantitative analysis of line shapes is possible. From this data it is clearly possible to determine to a high accuracy the sound velocity from the frequency shift and attenuation from the line width of the phonon bands. Finally, the limit of performance is shown in Figure 5 where the Brillouin spectra obtained by surface scattering from

Figure 4 Brillouin spectra of poly(dimethyl siloxane) rubber networks at 30°C (a) after a single pass through the etalon, $\theta = 90^\circ$ (b) after three passes, $\theta = 90^\circ$. The Landau-Placzek ratio, the ratio of the central peak intensity to the sum of the side band intensities, in this case is 3000

Figure 5 Brillouin spectra obtained by surface scattering in poly(methyl methacrylate), $\theta = 56^\circ$. The Landau-Placzek ratio is $>10^8$, showing that a contrast of at least this magnitude has been obtained.

poly(methyl methacrylate) is shown. In this case the ratio of central to side band intensities is greater than 10^8 indicating that a contrast of this magnitude has been obtained.

EXPERIMENTAL RESULTS

The data presented above have shown that extremely high contrasts of 10^8 can be obtained with a triple-pass etalon system. This implies a qualitative change in the study of polymer systems. Previously only samples of extremely high optical quality could be studied, which limited activity to clean liquids, optical quality quartz and carefully prepared poly(methyl methacrylate) blocks plus a very few other similar systems. Now, with multi-passing, samples can be chosen for study because of their intrinsic interest, and it is even possible to study entirely opaque materials by back scattering⁶. In this section we present preliminary measurements in three areas of interest.

Measurements in oriented poly(methyl methacrylate) (PMMA)

The purpose of this experiment was to measure the anisotropy of the high frequency elastic modulus in strained samples by observing the variation of sound speed as a function of the propagation direction with respect to the draw axis. This can be accomplished using Brillouin techniques with a volume resolution of 10^{-6} cm^3 . We also attempted to observe dispersion effects by varying the scattering angle and hence the sound wavelength and frequency.

Samples of ICI Perspex were drawn just above T_g and quenched. Further details of the sample preparation may be found in ref 7. The samples were then shaped into discs with the orientation axis in the plane. The scattering geometry is illustrated in Figure 6a where the incident and scattered beams, the orientation and the phonon are all in the same plane. The angle between phonon direction and orientation axis, ϕ , could be varied by rotation of the sample. Within the experimental error it appears that the phonon line width is independent of propagation direction, indicating that the phonon attenuation is independent of orientation. This is in substantial agreement with low temperature thermal conductivity studies⁸ which have found no measurable anisotropy in conductivity. The measured values of sound velocity v , as a function of ϕ are shown in Figure 6b for three different strained samples and an annealed sample. The degree of strain was characterized by the optical birefringence, Δn , and this parameter had the values -24 , -9 and -4×10^{-4} in the three cases. The func-

tional form of the data in each case is similar and follows closely the expression:

$$V(\phi) = V_0(1 - \Delta \sin^2\phi) \quad (5)$$

where V_0 is the velocity in the annealed sample, which shows no variation with ϕ , Δ is the appropriate anisotropy. It is interesting to note that the values of $V(\phi)$ are always less than V_0 , indicating that the observed sound waves are propagating in regions of high density. This contrasts with the ultrasonic work of Wright *et al.*⁹ on the same samples where considerable increase in velocity along the draw direction is observed (see Figure 8). These regions are probably separated by voids and this heterogeneity causes the large random scattering in the sample evidenced by the strong central peak that prevents such a study using a single pass system. The values of anisotropy, Δ , that give the best fit to data shown in Figure 6b are plotted as a function of birefringence, Δn in Figure 7; the dependence is apparently linear.

If the structure of the strained PMMA indeed includes regions of high density separated by voids then it may be possible to observe dispersion effects when the sound wavelength, Λ , is of the same order as the dimensions of these regions. We therefore made measurements of sound

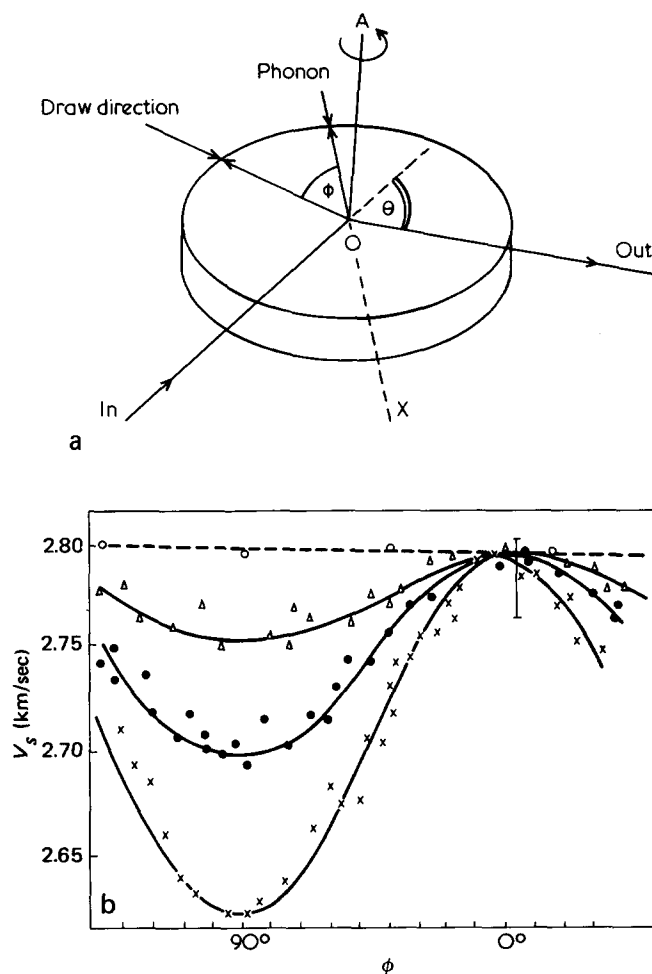

Figure 6 (a) The sample and scattering geometries for a uniaxially oriented sample (b) The measured values of longitudinal sound velocity in PMMA as a function of propagation direction ϕ relative to orientation axis. Figure 7 Values of elastic anisotropy in oriented PMMA, obtained as best fits to the data in Figure 6b, plotted against birefringence

velocity as a function of the scattering angle θ which is connected with Λ by:

$$\Lambda = \frac{\lambda}{2n} \left(\sin \frac{\theta}{2} \right)^{-1} \quad (6)$$

where λ is the incident light wavelength.

The results are shown in Figure 8 for the sample having $\Delta n = -24 \times 10^{-4}$ at ϕ values of 0 and 90° . Also shown are measurements on an annealed sample and data taken at the lower frequency of 4 MHz. No dispersive effects are observed over the range of Λ values from 0.2 to 0.8 μm . However the data taken at $\phi = 0^\circ$ at hypersonic frequency deviate significantly from the measurement at 4 MHz and this suggests that the average dimension of the structure is larger than the largest value of Λ that we have yet attained by varying θ . In fact the lowest angle of scatter we have used is $\theta = 25^\circ$ and with care it should be possible to extend the range to $\theta = 5^\circ$ and hence cover Λ values up to 5 μm . By making use of incident radiation of longer wavelength, for instance from a helium-neon laser ($\lambda = 6328 \text{ \AA}$) a further increase in Λ of 25% can be obtained and it is then very possible that the dispersion region will be reached. This would then yield valuable information about the strained structure.

High frequency relaxations in polymer fluids

The purpose of this work was to try and observe relaxations in the hypersonic frequency range and to obtain some information about the glass transition at these high frequencies. In order to conduct the experiments at a convenient temperature it is necessary to choose a polymer sample with a very flexible chain. The first choice was therefore poly(dimethyl siloxane) (PDMS) and measurements were made of sound velocity and attenuation as a function of temperature at 3.5 GHz (using the FP) and at 35 MHz (using ultrasound equipment). These data proved quite featureless. There was no sign of any relaxation over the range $240 < T < 340\text{K}$ at either frequency and the velocities at the two frequencies were identical within the experimental errors as is α/f^2 (α is the sound absorption

coefficient, f the frequency). Since it is unlikely that the α relaxation is above 340K at 35 MHz (see Figure 10) we deduce that even at 3.5 GHz the PDMS is still in a rubbery state and above the main glass transition. The fact that PDMS crystallizes at 223K makes it difficult to extend the measurements to lower temperatures and we are left with the supposition that T_g even at gigahertz frequencies is at a temperature near to, or lower than, the crystallization point for this material.

The second material chosen for this study was poly(propylene oxide) (PPO). While working on this material, of molecular weight $M_w \sim 1500$, (Shell PPG 1500), we became aware of recent work¹⁰ on a low molecular weight material ($M_w = 425$) in which a relaxation was observed at gigahertz frequencies. Our data for both sound attenuation and velocity are shown in Figure 9. A break in the gradient of the graph of V versus temperature at $\sim 187\text{K}$ is attributed¹⁰ to the glass transition. It is important to note that the value of T_g measured in this way in fact reflects changes in quasi-static parameters, such as the Gruneisen parameter, γ , and the coefficient of volume expansion, α , and does not represent a determination of T_g at hypersonic frequencies. We believe the relaxation at $\sim 310\text{K}$ to be the main α -relaxation. Accordingly this value of T_g is plotted for a frequency of 5 GHz in Figure 10 which shows the frequency dependence of the glass transition for PPO by plotting $1/T_g$ against the logarithm of frequency. Mechanical and dielectric measurements over a range of frequency from 10^{-3} to 10^7 Hz¹¹ and ultrasound measurements at 10^7 Hz as well as the present data are included. The dependence is clearly not linear implying that a single activation energy is insufficient to describe this complicated transition. The dearth of points in the high frequency region (10^7 – 10^9 Hz) can be remedied by making Brillouin measurements at low scattering angles, giving measurement frequencies in the region of 10^8 Hz. Such measurements would enable a good estimate of the activation energy appropriate to the high frequency transition to be obtained. Apart from a 50% discrepancy in the values of V our data are in reasonable agreement with the measurements of Huang and Wang¹⁰. Their measurements on a low molecular weight material did not show evidence of the secondary relaxation apparent in our data in the vicinity of 260K (Figure 9b). This is consistent with ultrasound measurements on this polymer which indicate

Figure 8 Values of longitudinal sound velocity, v , plotted as a function of sound wavelength $\Lambda = (\lambda/2n) (\sin \theta/2)^{-1}$ in strained samples with propagation direction parallel and perpendicular to the strain axis. Data is also shown for an annealed sample. \bullet , strained sample $\phi = 0^\circ$; \times , strained sample $\phi = 90^\circ$; Δ , annealed sample; \circ , ultrasound data 4 MHz. The scattering angles θ corresponding to extreme Λ values are indicated

Figure 9 (a) Longitudinal sound velocity and (b) attenuation measured at 5 GHz in poly(propylene oxide) as a function of temperature. ($M_w = 1500$). The observed dispersion is attributed to the main α -relaxation (V_∞ and V_0 are the infinite and low frequency limiting values of velocity respectively)

that low molecular weight PPO shows no specific polymeric relaxational behaviour¹². The reduced data are a reasonable fit to a two relaxational time model with $\tau_1 = 0.09 \tau_M$ and $\tau_2 = 0.002 \tau_M^5$. (τ_M is the Maxwellian relaxation time given by $\eta_s J_\infty$ where η_s is the shear viscosity and J_∞ the infinite frequency shear compliance.) Between 220 and 260K the material behaves like a non-relaxing fluid with $(\rho V^2 - k_0) J_\infty$ constant as a function of temperature (k_0 is the zero frequency bulk modulus). Between 200K and the quasi-static glass transition the material behaves like a solid with $\partial V/\partial T$ constant as a function of temperature. The measured velocity-temperature coefficient in this range corresponds to a volume expansion coefficient of 7×10^{-4} and a Gruneisen parameter of +4.5. Away from the relaxation the mechanism of phonon absorption is not understood. The value of $\alpha \lambda_s$ (~ 0.1) is consistent with that predicted for phonon-phonon scattering in long phonon lifetime limit ($\omega \tau_p \gg 1$) although estimates of phonon lifetimes from quantities such as the thermal diffusivity indicate that $\omega \tau_p \ll 1^5$.

The preliminary results of this project are encouraging. First it is extremely easy to prepare samples for multi-pass Fabry-Perot spectroscopy, and it should be possible to study a wide range of samples. Secondly, the existence of relaxation in the GHz region has already been established in one polymer (and initial measurements suggest they exist

in others), whereas only recently it was doubted that relaxations at these frequencies existed at all¹³. There should be much more information forthcoming about the α -relaxation using this technique.

Studies in rubber networks

The purpose of these studies was to investigate the constraints imposed on chain motion by crosslinking. PDMS samples of $M_w = 7 \times 10^4$ were crosslinked by γ -irradiation and the shear modulus, G , measured by the quasi-static method of ball-bearing indentation. The average crosslink density, N , was obtained from Charlesby's critical gel dose point data^{14,15} and in the samples used the average number of monomer units between crosslinks, $\langle n \rangle$, ranged from 109 to 14. The value of G increases monotonically with $\langle n \rangle^{-1}$ over the range 0.7 to 3×10^7 N/m². The extrapolated value with zero crosslinking was 0.3×10^7 N/m². and is attributed to the effect of entanglements. Values of G calculated from $G = NkT$ were an order of magnitude lower than the measured values. This disagreement may reflect uncertainty in the gel dose point due to the distribution of chain lengths between links. Measurements of the longitudinal sound velocity were made at two frequencies 5 MHz and 3.5 GHz. PDMS is in a rubbery state at these frequencies, but may sustain shear because of the crosslinks. The effective modulus is given by:

$$M = \rho V^2 = k_0 + \frac{4}{3} G \tag{7}$$

where $k_0 = \rho V_0^2$ (V_0 is the velocity in the uncrosslinked sample). Sample density increased from 9751 kg/m³ in the fluid to 9941 kg/m³ in the most highly crosslinked sample. The Brillouin and ultrasound velocity measurements are

Figure 10 A plot of $(T_g)^{-1}$ for PPO as a function of the logarithm of the frequency. The dependence is not linear, indicating that a single activation energy is insufficient to describe the relaxation. \circ , Dielectric and mechanical loss measurements (high M_w)¹¹; \blacktriangle , ultrasound measurements (M_w 400); \bullet , ultrasound measurements (M_w 4000); \blacksquare , hypersound measurements (M_w 1500) present work; \square , hypersound measurements (M_w 425)¹⁰

Figure 11 The product of density ρ and the square of the longitudinal sound velocity v^2 measured in PDMS at 3.5 GHz (●) and 5 MHz (x) versus the crosslink density $\langle n \rangle^{-1}$. —, corresponds to values of ρv^2 calculated from equation (7) using the static values of the shear modulus

Figure 12 Phonon attenuation, α , in PDMS measured at 3.5 GHz (●) and 5 MHz (x) versus the inverse of the crosslink density

summarized in Figure 11 in which ρv^2 is plotted with $\langle n \rangle^{-1}$. The solid line is calculated according to equation (7) using the measured values of G . Whilst uncertainty in the ultrasound data points precludes any comment on their crosslink density dependence the Brillouin data is a good fit to the predictions of equation (7). Clearly the elastic behaviour of the network over distances $\sim 0.3 \mu\text{m}$ mirrors the macroscopic elastic behaviour.

The absorption data show more distinct features: (a) There is a marked difference between the crosslinked and the uncrosslinked but entangled material in the ultrasound case. At Brillouin frequencies no difference is apparent. (b) Ultrasound absorption falls as a function of crosslink density above the gel point whilst Brillouin absorption rises.

These results are not understood in detail; however, it may be that the difference between the crosslinked and uncrosslinked material in the two cases reflects relaxational motions by entanglements which are 'frozen in' at Brillouin

frequencies. If this is true then the entanglements must relax with a characteristic time which lies between a microsecond and a nanosecond. At ultrasonic frequencies crosslinking below the gel point has the effect of increasing the molecular weight while leaving the chains mobile. The viscosity, and therefore the absorption, increases. Above the gel point decreasing chain mobility restricts the contributions of chain motion to the viscous loss process and so reduces acoustic losses. It may be that the increase in absorption at high crosslink density in the Brillouin case is caused by the introduction of a high frequency relaxation between crosslinks, possibly an LA mode of the free chains lengths. Extension of the experimental work to a wider range of frequencies and samples with other $\langle n \rangle^{-1}$ values is in hand.

CONCLUSION

We have suggested that the techniques of MPFPS can be used to great advantage in the study of many polymer properties and have described the construction of a triple-pass system. In addition preliminary data in three fields have been presented: (1) the study of anisotropy in strained samples; (2) the observation of the α -relaxation at hypersonic frequency; (3) the study of the constraints imposed by crosslinks on high frequency relaxations. These experiments are incomplete as yet, and in each case we are actively engaged in extending the work. However, these examples already show clearly the power of the technique in making measurements that have until now been impossible.

ACKNOWLEDGEMENTS

The authors wish to acknowledge Mr Evans of Salford University for help in preparing the PDMS rubber samples; Dr R. A. Pethrick, Department of Chemistry, University of Strathclyde and Dr Morrell of RAPRA for the use of their ultrasonic equipment; and Dr E. F. T. White of UMIST for the use of his sample preparation facilities. The work was supported by the SRC Polymer Committee.

Electric birefringence of aqueous solutions of methyl cellulose*

A. R. Foweraker and B. R. Jennings

Physics Department, Brunel University, Uxbridge, Middlesex, UK

(Received 15 December 1975; revised 16 February 1976)

Electric birefringence studies have been conducted on six samples of methyl cellulose in the molecular weight range 3×10^4 to 1.5×10^5 . Using pulsed electric fields, both the amplitudes and rates of the transient birefringence induced in these solutions have been analysed. For molecular weights below 2×10^3 , the molecules are represented by rigid rods. Above this value increasing flexibility is evident. This can conveniently be seen through reduced electrical parameters, defined herein, which are obtained from a combination of the electrical and geometrical properties of the molecules. These parameters are apparently very sensitive to flexibility in the near-rod regime. It demonstrates the utility of electro-optic experiments in which both the electrical and geometrical data are obtained simultaneously. The persistence length concept does not appear to be adequate when rotary relaxation times are interpreted through it using current equations.

INTRODUCTION

Cellulose is insoluble in water owing to its strong intramolecular hydrogen bonding. Water soluble derivatives can be produced by introducing methyl, carboxymethyl, ethyl, hydroxyethyl or hydroxypropyl groups into the cellulose molecule at one or more of the available hydroxyl groups of the cellobiose units. As the degree of etherification increases so too does the water solubility of the cellulose derivative. The products so obtained have wide commercial utility in the adhesives, cosmetics, food stuffs, oil drilling and paint industries.

In this communication we report an electric birefringence study on six different molecular weight samples of methyl cellulose in aqueous solution. The electric birefringence technique was employed in order to study both the electrical and hydrodynamical properties of the solute molecules. Measurements were made on each sample as a function of the applied field strength. The majority of macromolecules are optically anisotropic. In dilute solution, with no intermolecular interactions, each macromolecule adopts a random orientation. The bulk solution is then optically isotropic. However, on application of an electric field, any molecular electric dipoles interact with this field and cause the suspended molecules to orientate, deform and align. The bulk solution then partially exhibits the optical anisotropy of the individual molecules. It is by measuring the changes in the optical properties of the solution that we can monitor the average rotary behaviour of the constituent molecules. The *amplitude* of the changes can be interpreted in terms of the magnitudes of the electrical dipoles, whilst the *rates* of change indicate the molecular relaxation times (τ) and hence the particle sizes.

In this work, electrically induced birefringence (Δn) is measured. This is defined¹ as the difference in refractive indices parallel and perpendicular to the applied field direction for the bulk solution. It is related directly to the differences in refractive index (or optical polarizability, g) along the major axes of a molecule of cylindrical segmental symmetry. The property is measured by recording the

changes ΔI in the light intensity transmitted through an optical assembly consisting of a polarizer, a cell containing the test solution and an analyser. The electric field is applied at 45° to the azimuth of the polarizer and the analyser is crossed with the polarizer and then offset by a small angle σ . The basic theory for the birefringence of the solution in terms of the light penetrating such a system² together with details of the apparatus and its mode of operation³ have been described in detail elsewhere.

EXPERIMENTAL

All samples were kindly supplied by British Cellanese Ltd, of Spondon, Derbyshire, under their trade name Celacol. Each sample was dissolved by continuous stirring for 24 h in de-ionized water at room temperature and at a concentration of 1×10^{-3} g/ml. All optical measurements were made with light of 546 nm wavelength (*in vacuo*).

RESULTS AND DISCUSSION

The molecular orientation relaxation times (τ) were obtained by analysis of the birefringence decay rates following the termination of the applied electric field pulse. Conventional semi-logarithmic plots³ were drawn of the normalized birefringence amplitudes as a function of time and τ were evaluated from the initial slopes. Such τ values were interpreted using three molecular models, namely, the rigid rod model⁴, the weakly bending rod⁵ and the worm-like chain model⁶. The molecular parameters derived for each of these three structures are given in Table 1. The parameter L is the hydrodynamic extended length. It was calculated assuming each monomer unit to be of 0.69 nm length as indicated by X-ray data⁷. Hence, a polymer of Z degree of polymerization has $L = 0.69 Z$ nm. The equivalent rod length (l_r) is the length obtained from the experimental value of τ using the Broersma equation⁴ as for a rigid rod particle exhibiting end-over-end tumbling rotation. A parameter which has been used to indicate molecular flexibility is the 'persistence length'. This has been defined as the projection of an infinitely long molecular chain in the direction of the first segment. It can be calculated from τ using an equation for

* Presented at the Polymer Physics (Institute of Physics) Biennial Conference, Shrivenham, September 1975.

Table 1 Geometrical parameters for methyl cellulose

$M \times 10^{-3}$	Z	L (nm)	l_r (nm)	q_{WBR} (nm)	q_{WLC} (nm)
34	185	128	47	1.80	1.05
58	315	218	62	1.57	1.02
92	500	346	60	0.62	0.57
110	597	414	78	0.95	0.81
132	717	497	79	0.51	0.54
150	815	565	78	0.54	0.58

Z is the degree of polymerization for molecules of molecular weight M . The length parameters are L for an extended rod and l_r for the equivalent rod length obtained from the relaxation time as for a rigid rod. The 'persistence lengths', q , have been evaluated from the weakly bending rod (WBR) and the worm-like chain (WLC) models respectively

Figure 1 Variation of the equivalent rod length (l_r) with molecular weight calculated using a molecular diameter of 0.35 nm^{10} . ---, indicates the behaviour of the extended length (L). Data from relaxation times for solutions of $1 \times 10^{-3} \text{ g/ml}$ concentration

a weakly bending rod (WBR)⁵, hence q_{WBR} , or by using an equation for a worm-like chain (WLC)⁵, hence q_{WLC} . Under the concepts of each of the appropriate models, these two last mentioned parameters q_{WBR} and q_{WLC} should remain constant with Z or M .

In Figure 1 we compare both l_r and L as functions of the molecular weight. If the molecules were always rigid rods, then one would expect these curves to remain coincident. Departure from such behaviour shows this not to be the case. That they are coincident at low molecular weight does indicate rigid rod like behaviour for samples of low Z .

Values for q , whether obtained from the weakly bending rod or the worm-like chain equations are not constant with Z . Furthermore, they tend to assume a value which is of the order of the length of the cellobiose unit at high Z . We agree with Dev *et al.*⁸ that the concept of q ceases to be credible in such a situation. Hence, although q is often used as a flexibility parameter for samples intermediate between rigid rod and flexible coil conformations, we do not find it to be very satisfactory when derived through the relaxation time equations.

Finally, to complete the analysis of τ , we considered the modified form of Hearst's equation⁵ as presented by Tsvetkov *et al.*⁹ for slightly curved rods in the low molecular weight range. Following their procedure and incorporating

the relevant data in their equation leads to values of $\lambda = 3.0 \pm 0.2 \times 10^{-8}$ and $S = 222 \pm 15$ respectively. In the words of Tsvetkov *et al.* ' λ is the projection of the monomer unit on the direction of the molecular chain and S is the number of monomer units in a Kuhn segment'. Our values for these parameters for methyl cellulose compare well with those evaluated by Tsvetkov *et al.*⁹ for polychlorohexylisocyanates. However, we have reservations about their validity as we feel that the derivation of Tsvetkov's *et al.* equation is incompatible with that of Hearst⁵.

A typical plot of the dependence of the birefringence amplitude on field strength is shown in Figure 2. Similarly linear plots were obtained for each sample of methyl cellulose. The initial slope of these plots [$\lim_{E \rightarrow 0} (\Delta n/E^2)$] is a function of both the optical and electrical parameters of the solvent molecules. The optical polarizability difference ($g_1 - g_2$) is independent of molecular weight and molecular concentration. By using the same concentration for each sample, the initial slope as given in Table 2 was directly proportional to the molecular electrical parameters. The experimental values for each sample as listed in Table 2 are therefore taken as being directly indicative of the relative amplitudes of the electrical orientation function.

The magnitudes of the initial slope values suggest that molecular orientation is attained as a result of interaction between the applied electric field and the induced electrical polarizability anisotropy. As discussed elsewhere³ this parameter is expected to be proportional to the molecular

Figure 2 Dependence of the birefringence on the square of the applied electric field for a solution of $1 \times 10^{-3} \text{ g/ml}$ of methyl cellulose in water. For this sample, $M = 1.1 \times 10^5$

Table 2 Electrical parameters for methyl cellulose

$M \times 10^{-3}$	$\Delta n/E^2 \times 10^{15}$ ($\text{cm}^2 \text{ V}^{-2}$)	$\beta/\beta_{M \rightarrow 0}$	$\gamma/\gamma_{M \rightarrow 0}$
34	1.64	1.2	0.44
58	2.43	1.44	0.41
92	3.27	1.88	0.32
110	4.48	1.97	0.35
132	4.86	2.13	0.33
150	4.64	2.04	0.28

The parameters β and γ are given by $(\Delta n/l_r E^2)$ and $(\Delta n/L E^2)$ respectively, where Δn is the birefringence measured in an electric field of amplitude E . For a true rigid rod, the ratios in columns 3 and 4 would be equal for all rows of the Table

Figure 3 Variation of the reduced electrical parameters $\beta/\beta_{M \rightarrow 0}$ (●) and $\gamma/\gamma_{M \rightarrow 0}$ (○) with molecular weight. These parameters are defined in Table 2

length for rigid and flexible rod-like molecules. Hence in accordance with previous work^{2,3} the values obtained were reduced to unit length values and normalized to the intersection value as M approached zero. If we define the parameters β and γ as $(\Delta n/l_r E^2)$ and $(\Delta n/LE^2)$ respectively, then we have plotted the functions $\beta/\beta_{M \rightarrow 0}$ and $\gamma/\gamma_{M \rightarrow 0}$ in Figure 3 as a function of molecular weight. Here again, departure from a constant value indicates departure from rod-like behaviour with increasing molecular weight, whilst the common intercept on the ordinate indicates rod behaviour at low M .

CONCLUSIONS

- (1) The parameters β and γ are very sensitive indicators of the degree of flexibility, especially when plotted as functions of molecular weight. They indicate departure from rod-like behaviour with increasing M and may be used numerically as empirical parameters for flexibility.
- (2) At low M , methyl cellulose behaves as a rigid rod particle in an electric field.
- (3) Methyl cellulose departs significantly from such rod-like behaviour for molecular weights exceeding 2×10^3 .
- (4) That the persistence length (q) does not appear to be a satisfactory parameter for the indication of flexibility of this molecular system at least when evaluated from rotary relaxation data.

Optical anisotropy of polyisobutene*

J. V. Champion, A. Dandridge, D. Downer, J. C. McGrath and G. H. Meeten

Department of Physics, Sir John Cass School of Science and Technology, City of London Polytechnic, London EC3N 2EY, UK

(Received 19 December 1975; revised 15 January 1976)

The distribution of chemical bonds in polyisobutene results in a theoretically zero optical and electrical anisotropy of the polymer according to bond polarizability additivity principles as conventionally applied, irrespective of polymer chain conformation. Non-zero values of the segmental anisotropy ($\sim 4.4 \times 10^{-40} \text{ C}^2 \text{ m}^2/\text{J}$) derived from strain-optical birefringence on the polymer in the rubbery state have been recently reported by Liberman *et al.* who suggest qualitatively that severe crowding of the chemical groups in the polymer affects the anisotropies of the group polarizabilities and gives the observed non-zero segmental anisotropy. We have measured optical, electrical and magnetic anisotropies for the pure liquid polymer using techniques of flow birefringence, depolarized light scattering, electro-optic birefringence and magneto-optic birefringence. Segmental optical anisotropies so derived agree with those measured by Liberman *et al.* and results of the above measurements taken as a whole lead to an origin for the observed anisotropy which requires locality dependent values of optical and electrical bond polarizability anisotropies to be used in the calculation of the polyisobutene polarizability anisotropy. Our explanation of the polarizability locality dependence differs from the steric overlap suggestion of Liberman *et al.* and depends upon the electric field interaction between dipoles induced in polarizable bonds.

INTRODUCTION

Evaluation of the optical anisotropy of polyisobutene using the bond polarizability tensor additivity scheme has been made by Volkenstein¹ and Liberman *et al.*² Both calculations show that the assumption of tetrahedral bond angles produces a zero anisotropy for any conformation of the polyisobutene chain. Measurements of the optical anisotropy of the statistical segment by flow birefringence³ in polyisobutene solutions, and by strain-optical measurements^{1,2} in dry and swollen butyl rubber, have shown that an optical anisotropy exists comparable with that of polyethylene. Calculations of the segmental optical anisotropy by Liberman *et al.*², which allow for possible non-tetrahedral bond angles, give a value which is an order of magnitude smaller than measured by strain or flow birefringence. Volkenstein¹ quotes similar results.

We have made measurements of the flow birefringence, depolarized light scattering, electro-optic Kerr effect and magneto-optic Cotton–Mouton effect for low molecular weight polyisobutene ($M_n \approx 300\text{--}3000$), which is liquid at room temperature. In the molecular theories of all the above phenomena, the measured quantities can be related to some form of polymer chain optical anisotropy, each of which are examined in detail in the discussion. Meanwhile it is useful to point out that the various measurement techniques have a different effect on the molecule. Whereas strain and flow birefringence measurements involve considerable degrees of molecular strain and orientation, this does not occur in light scattering, Kerr effect and Cotton–Mouton effect measurements. The applied electric and magnetic field forces in these latter measurements have a negligible or very small effect on the molecular conformation or orientation. Hence a comparison of the optical anisotropy measured using such a range of techniques is of value in determining its origin.

EXPERIMENTAL

Materials

The polyisobutene liquids used for all measurements were derived from commercial samples donated by the Post Office Research Station (Dollis Hill), BP Chemicals Ltd and BASF Ltd. These were cleaned of dust using Millipore filters and their molecular weights, densities, viscosities and refractive indices determined. Their structure was examined by i.r. and n.m.r. spectroscopy and all samples were linear polyisobutene. No evidence was found for strongly anisotropic or dipolar impurities which could contribute disproportionately to the measured optical anisotropy. All samples were polydisperse with $M_w/M_n \approx 2$. The polymer end-groups are not uniquely defined by the polymerization process and chemical analysis showed some end-groups to possess a CC double bond.

Flow birefringence

The apparatus and techniques used have been described previously^{4,5}. For all liquids the flow birefringence Δn was positive, proportional to the velocity gradient G and the angle of extinction χ was $45^\circ \pm 0.2^\circ$. The liquid viscosities η were independent of G in the range of velocity gradients used to measure Δn . The maximum velocity gradient used for each liquid ranged from $\sim 10^4 \text{ sec}^{-1}$ for the lowest molecular weights ($\eta \approx 0.015 \text{ Pa sec}$) to 1 sec^{-1} for the highest ($\eta \approx 600 \text{ Pa sec}$).

The stress-optical coefficient $\nabla = \Delta n/\eta G$ may be related to the average optical anisotropy $\langle \Delta \alpha \rangle$ of the undisturbed polymer chain. $\Delta \alpha$ is defined as $\alpha_l - \alpha_r$ where α_l and α_r are the polarizabilities for optical wave fields parallel and perpendicular respectively to the end-to-end distance of the chain. An expression for ∇ for long chains has been developed by Peterlin⁶ and Lodge⁷:

$$\nabla = \frac{(n^2 + 2)^2}{45kT\epsilon_0 n} \langle \Delta \alpha \rangle \quad (1)$$

* Presented at the Polymer Physics Group (Institute of Physics) Biennial Conference, Shrivenham, September 1975.

Figure 1 Flow birefringence value of $\langle \Delta\alpha \rangle$ versus number-average monomer units per molecule. —, Calculated from the theory of Gotlib and Svetlov for A, 2; B, 4; C, 6 monomer units per persistence length

where n is the refractive index of the liquid, ϵ_0 is the permittivity of free space and $\langle \Delta\alpha \rangle$ is the Kuhn statistical segment anisotropy when the molecule is perturbed by the flow. For long chains:

$$\langle \Delta\alpha \rangle_\infty = \frac{3}{5} \Delta a$$

Figure 1 shows $\langle \Delta\alpha \rangle$ calculated from experimental ∇ values using equation (1), plotted with the number-average of monomer units per molecule N_n . Since the polyisobutene chains do not contain sufficient monomer units for long chain polymer statistics to be applied, equation (1) is not strictly valid; $\langle \Delta\alpha \rangle$ is not constant but tends to an asymptotic $\langle \Delta\alpha \rangle_\infty$. A plot of $\log_{10} (10^{40} \times \langle \Delta\alpha \rangle) (\text{C}^2\text{m}^2/\text{J})$ versus N_n^{-1} was found to be linear (Figure 2) from which $\langle \Delta\alpha \rangle_\infty = 2.52 \times 10^{-40} \text{C}^2\text{m}^2/\text{J}$ at $N_n^{-1} = 0$. This extrapolated value compares closely with the value $2.72 \times 10^{-40} \text{C}^2\text{m}^2/\text{J}$ derived from the results of Liberman *et al.*² who gave $\langle \Delta\alpha \rangle = (4.55 \pm 0.1) \times 10^{-40} \text{C}^2\text{m}^2/\text{J}$ measured by strain-optical birefringence in crosslinked butyl rubber. We conclude from this comparison that the origin of the optical anisotropy is the same in both short and long polyisobutene chains.

Gotlib and Svetlov's theory of flow birefringence of short polymer chains gives an expression for ∇ in terms of $\langle \Delta\alpha \rangle$ and a parameter $x = L/a$, a being the persistence length of a worm-like chain and L the polymer contour length, obtaining:

$$\nabla = \frac{(n^2 + 2)^2}{75kTn\epsilon_0} \langle \Delta\alpha \rangle \frac{x\phi_1}{\phi_2} \quad (2)$$

where ϕ_1 and ϕ_2 are complex numerical functions of x only. Figure 1 shows the fit between our experimental results and this short chain theory, obtaining $\langle \Delta\alpha \rangle$ at $N_n^{-1} = 0$ from Figure 2. A persistence length corresponding to 4 monomer units gives the closest agreement with the experimental points.

Depolarized light scattering

Measurements of the depolarized scattered light Rayleigh ratio R_{Hu} were made using a Sofica photogoniometer. The incident light was linearly polarized in the scattering plane and R_{Hu} was calculated from the total scattered intensity at 90° . For isolated anisotropic scatterers the optical anisotropy function which determines R_{Hu} is the polarizability tensor invariant:

$$\gamma^2 = \frac{1}{2} [(\alpha_1 - \alpha_2)^2 + (\alpha_2 - \alpha_3)^2 + (\alpha_3 - \alpha_1)^2]$$

where α_i are principal polarizabilities of the polymer chain about the end-to-end distance. For flexible molecules, where γ^2 depends on the molecular conformation, it may be shown⁹ that:

$$R_{Hu} = \frac{400\pi^2\rho N_A}{27\lambda^4 M\epsilon_0^2} \left(\frac{n^2 + 2}{3} \right)^2 \langle \gamma^2 \rangle \quad (3)$$

where the angled brackets $\langle \rangle$ represent the ensemble average with no externally applied perturbing forces, ρ is the density of the scatterers and M their molecular weight. Thus R_{Hu} is zero if the polyisobutene polymer is optically isotropic. For polymer chains which are closely packed as in the liquid state, angular correlations¹⁰ between nearby chains will modify $\langle \gamma^2 \rangle$ which is then not only a function of the anisotropy of an isolated scatterer, but of neighbouring scatterers also. Thus $\langle \gamma^2 \rangle$ in equation (3) is to be regarded as an effective value for a polymer chain in its liquid environment. Figure 3 shows that $\langle \gamma^2 \rangle / N_n$ calculated from equation (3) and our experimental values of R_{Hu} , is independent of N_n within experimental error. The slight increase of $\langle \gamma^2 \rangle / N_n$ with decreasing N_n is surprising since $\langle \Delta\alpha \rangle$ decreases by a factor of 2 in the same molecular weight

Figure 2 $\log_{10} \langle \Delta\alpha \rangle \times 10^{40} (\text{C}^2\text{m}^2/\text{J})$ versus N_n^{-1}

Figure 3 $\langle \gamma^2 \rangle / N_n$ versus N_n . Δ , Kerr effect; \bullet , depolarized light scattering

range. Hence it was felt necessary to use another experimental technique, the electro-optic Kerr effect, to give an alternative method of determining $\langle\gamma^2\rangle$.

Electro-optic Kerr effect

The basic measurement techniques and apparatus used for liquids having a small Kerr constant has been described previously^{11,12}. For our measurements on the polyisobutene liquids, the visual end-point determination was replaced with the Badoz photometric linear detection method¹³, increasing the apparatus sensitivity by about 100 times.

The polyisobutene birefringence Δn was proportional to the square of the applied electric field E , typical of the behaviour of small molecules or flexible polymers. The Kerr constant $B = \Delta n/\lambda E^2$ was measured over a range of molecular weights. Two major mechanisms contribute to B in non-dipolar liquids^{11,12}. One is due to the preferred orientation of anisotropically polarizable molecules, B^{an} . The other is due to hyperpolarizability, B^{hy} , and has been calculated for polyisobutene from the bond hyperpolarizability data of liquid n-alkanes¹². Thus $B^{an} = B - B^{hy}$ and B^{an} is related to $\langle\gamma^2\rangle$ by¹¹:

$$B^{an} = \frac{3\pi\rho N_A}{4\pi\epsilon_0 n \lambda M} \left(\frac{n^2 + 2}{3}\right) \left(\frac{\epsilon_r + 2}{3}\right) \left(\frac{\epsilon_r - 1}{n^2 - 1}\right) \frac{\langle\gamma^2\rangle}{45kT} \quad (4)$$

where ϵ_r is the zero frequency relative permittivity of the liquid. $\langle\gamma^2\rangle/N_n$ versus N_n is plotted with the light scattering results in Figure 3 which shows that the two sets of data are in close agreement for all polyisobutene samples. The value of $\langle\gamma^2\rangle$ derived from Kerr effect measurements includes the influence of angular correlations as in depolarized light scattering assuming that the static field induced dipole-induced dipole interaction is negligible. The anisotropy of the end-group CC double bond has a value $\Delta\alpha \approx 3 \times 10^{-40} \text{ C}^2\text{m}^2/\text{J}$. Although its effect would be negligible in high molecular weight polyisobutene, it could account for the increase of $\langle\gamma^2\rangle/N_n$ with decreasing N_n as observed.

Magneto-optic Cotton-Mouton effect

The measurement technique and apparatus used for small Cotton-Mouton constant liquids have been described⁵. A birefringence Δn was easily measurable using this apparatus with other low molecular weight polymers such as n-alkanes, poly(ethylene glycol) and poly(propylene glycol), Δn being proportional to the square of the applied magnetic field H . The smallest measurable Cotton-Mouton constant $C = \Delta n/\lambda\mu_0^2 H^2$ was about $\pm 2 \times 10^{-5} \text{ m}^{-1} \text{ T}^{-2}$ where $\mu_0 = 4\pi \times 10^{-7} \text{ H/m}$, the permeability of free space. The birefringence of polyisobutene was undetectable and hence its Cotton-Mouton constant was less than $\pm 2 \times 10^{-5} \text{ m}^{-1} \text{ T}^{-2}$. The Cotton-Mouton constant is related¹⁰ to the polymer chain magneto-optic anisotropy $\langle\gamma_m^2\rangle$ by:

$$C = \frac{(n^2 + 2)N_A\rho}{270nkT\lambda\epsilon_0\mu_0} \langle\gamma_m^2\rangle \quad (5)$$

where $2\gamma_m^2 = (\alpha_1 - \alpha_2)(\chi_1 - \chi_2) + (\alpha_2 - \alpha_3)(\chi_2 - \chi_3) + (\alpha_3 - \alpha_1)(\chi_3 - \chi_1)$ and α_i and χ_i ($i = 1, 2, 3$) are the principal values of optical and diamagnetic polarizability of a polymer chain.

Since the optical polarizability difference terms $(\alpha_i - \alpha_j)$ are not zero as shown by a finite $\langle\gamma^2\rangle$, then the near-zero

Cotton-Mouton constant implies that the $(\chi_i - \chi_j)$ terms are correspondingly small, as would result from the application of the diamagnetic bond polarizability anisotropy scheme to tetrahedrally bonded polyisobutene. An alternative explanation of $C \approx 0$ is that there is cancellation between terms of opposite sign in γ_m^2 . We regard this as unlikely since negative Cotton-Mouton constants are never found experimentally in organic liquids.

DISCUSSION

Bond polarizability additivity

The bond polarizability additivity scheme as originally proposed by Wang¹⁵ and Denbigh¹⁶ for calculating the optical polarizability of a molecule from the polarizabilities of its constituent bonds assumed that the components of the bond polarizability tensors were independent of the location of the bond within the molecule or from one molecular type to another. On this basis, tables of experimental polarizabilities for several chemical bonds have been given by Denbigh¹⁶, Vuks¹⁷, Le Fevre¹⁸ and Clement *et al.*^{19,20}. For any particular bond these tables show a large variation in the anisotropy of polarizability but when used in strongly anisotropic groups such as benzene, fair agreement is obtained. Le Fevre's results show the variation of bond polarizability anisotropy for the same bond from one molecular type to another. By contrast, the above-cited values show a good agreement for values of the mean bond polarizability. Thus it is clear experimentally that bond polarizability anisotropy may be regarded as a locality dependent quantity which varies from one environment to another, but that mean bond polarizability can be regarded as locality independent to a good approximation.

Several authors have recognized the above situation and have attempted to explain it and to examine or re-establish the rules of bond polarizability additivity.

Pitzer²¹ used the Silberstein²² model describing an anisotropically polarizable bond of two induced point dipoles having a separation r . Pitzer showed that the anisotropy of such a bond varied strongly with r but the mean polarizability was nearly constant, as found experimentally.

Matossi²³ has modified the Silberstein model by introducing screening factors to account for lack of agreement between the model and experiment. Using this model of an anisotropically polarizable bond both the anisotropy and mean polarizability would vary strongly with r unless the screening factors of the bonded atoms were equal. Matossi's modification is thus of doubtful value.

Rowell and Stein²⁴ have studied the effect of induced dipole interaction between the bonds in ethane. A considerable distortion of the electric field exists whereby the field polarizing any particular bond is the sum of the field E applied to the molecule and the field E' from the induced dipole moments of the other bonds in the molecule. They explored the range of bond polarizability tensor components which provided values of mean molecular polarizability $\bar{\alpha}$ and optical anisotropy γ^2 close to those obtained from experiment.

The CC and CH bond mean polarizabilities thus obtained were (0.54 ± 0.03) and $(0.77 \pm 0.04) \times 10^{-40} \text{ C}^2\text{m}^2/\text{J}$ respectively, where the uncertainties show the domain over which a fit between theory and experiment was possible. These values agree closely with mean bond polarizabilities listed in the tables cited above. By contrast, CC and CH bond polarizability anisotropies were not well defined and

formed a large domain of about 1 to 3×10^{-40} , and 0.3 to $8 \times 10^{-40} \text{ C}^2\text{m}^2/\text{J}$ respectively. It was thus possible to obtain consistent values of $\bar{\alpha}$ and γ^2 over a wide range of combinations of the means and anisotropies of bond polarizabilities.

Teixeira-Dias and Murrell²⁵ have calculated the polarizability tensor of methane, ethane and propane from molecular orbital theory. Using their calculated data, they show that the mean polarizabilities are bond-additive but the polarizability anisotropies are not, which they attribute to the large internal fields from bond polarizations within the molecule and also to the flow of electrons between bonds.

Mortensen²⁶ has generalized the approach of Rowell and Stein, and within the approximation afforded by the neglect of interactions between induced bond quadrupoles and higher moments has shown that the polarizability tensor of a molecule may be regarded as the sum of bond polarizability tensors. In this theory the locality independent bond polarizability tensors are replaced by a locality dependent value, wherein the apparent polarizability tensor of a bond is dependent upon the degree of distortion of the uniform applied field caused by the polarization of all other bonds in the molecule. Thus the polarizability anisotropy of a bond generally will vary according to the location of the bond within the molecule, or from one molecular type to another.

We may summarize as follows. Two effects have been neglected by most workers in deriving experimental bond polarizabilities from experimental molecular polarizability data. These are the interactions between the induced dipoles of the bonds and the flow of electrons between bonds. The former can be accounted for while still preserving bond-additivity as shown by Mortensen²⁶, where the bond polarizabilities are now locality dependent. The latter removes the identity of a bond as a polarizable unit and hence the principle of any sort of additivity. The relative proportions of these effects is not generally known. Although the molecular orbital calculations of Teixeira-Dias and Murrell²⁵ were able to reproduce mean molecular polarizabilities to within a few percent, their estimate of the optical anisotropy of ethane was a factor of four lower than experiment. Thus their anisotropy results and conclusions drawn therefrom can be regarded only as qualitative. The experimental fact of locality independent mean bond polarizabilities which are capable of being summed to give mean molecular polarizabilities to within a few percent²⁷ implies that the bond has a meaningful identity as a polarizable unit and the electron flow effect of Teixeira-Dias and Murrell is small compared with the effect of dipole or higher interactions between bonds.

Polyisobutene

The principles outlined above are applicable to polyisobutene and are capable of explaining the finite optical anisotropy and near zero diamagnetic anisotropy of this polymer.

No bond angle distortion from tetrahedral is required to explain the finite optical anisotropy of the chain. Like methane, each monomer unit possesses tetrahedral symmetry of bonds and so the locality independent bond polarizability tensor additivity scheme predicts a zero anisotropy for both. This symmetry disappears when dipole interactions are allowed between bonds. Methane remains isotropic²⁸ since its bond induced dipole interac-

tions are symmetric. The polyisobutene monomer is influenced by the polarization of the rest of the bonds in the chain, principally by those in neighbouring monomer units. This dipole interaction is not spherically symmetric and the monomer unit hence becomes anisotropic as observed.

The Cotton-Mouton constant of liquid polyisobutene is very small ($C < \pm 2 \times 10^{-5} \text{ m}^{-1}\text{T}^{-2}$) compared with other short chain hydrocarbon polymers, e.g. $C = 27 \times 10^{-5} \text{ m}^{-1}\text{T}^{-2}$ for n-tetradecane¹⁴. This result is also explicable in terms of induced dipole interactions between bonds. An electric field E induced a dipole field $E' \approx E\alpha/4\pi\epsilon_0r^3$ at a distance r from the centre of a bond of electric polarizability α . Inserting typical values: $\alpha \approx 1 \times 10^{-40} \text{ C}^2\text{m}^2/\text{J}$; $r \approx 10^{-10} \text{ m}$, gives $E' \approx E$. This shows the necessity to allow for induced dipole-induced dipole interactions in molecules. For a magnetic field, $H' \approx H\chi/4\pi r^3$ and inserting typical values: $\chi \approx 1 \times 10^{-34} \text{ m}^3$; $r \approx 10^{-10} \text{ m}$, gives $H' \approx 10^{-5} \text{ H}$. Thus for applied magnetic fields there is negligible distortion of the field at any particular bond due to the magnetic dipoles induced in nearby bonds. The diamagnetic bond tensors are thus almost locality independent and the tetrahedral symmetry of the polyisobutene molecule ensures a near-zero Cotton-Mouton constant, as observed.

The calculation of the optical anisotropy for polyisobutene could be carried out in principle by the method used for ethane by Rowell and Stein²⁴. This would be extremely complex. Accordingly, we have devised an empirical approach to this end as below.

We assign a different optical polarizability anisotropy to the skeletal and side-arm CC bonds. These are denoted $\Delta\alpha^{\text{CC}^*}$ and $\Delta\alpha^{\text{CC}}$ respectively and are assumed to differ by reason of their different locations in the chain and the consequently differing induced dipole field distortions. Simple analysis assuming tetrahedral bond angles and neglecting any difference between the skeletal and side-arm CH bond anisotropies then gives $\Delta\alpha^{\text{CC}^*} - \Delta\alpha^{\text{CC}} = \Delta\alpha_e$ for the monomer unit optical anisotropy, the polarizability tensor being diagonal for coordinate axes parallel and perpendicular to the skeletal CC bond.

Estimates of $\Delta\alpha_e$ are available from measurements of the optical anisotropy γ^2 in small molecules such as branched alkanes. A suitable molecule having no rotational isomers and similar branching to polyisobutene is 2,2-dimethylbutane for which $\gamma^2 = 2.52 \times 10^{-80} \text{ C}^4\text{m}^4/\text{J}$ as measured in the liquid state by Clement and Bothorel^{29,30}. These workers found that the measured value of γ^2 for some highly branched alkanes was larger than the value predicted by the application of the locality independent optical bond polarizability tensor additivity scheme, where the bond polarizability parameters had been derived from linear n-alkanes. We regard this discrepancy as resulting from the locality dependence of bond anisotropies and we have re-analysed the optical anisotropy of 2,2-dimethylbutane assuming that the most deeply buried CC bond has the anisotropy $\Delta\alpha^{\text{CC}^*}$. 2,2-dimethylbutane is thus $(\text{CH}_3)_3\text{C}^*\text{CH}_2\text{CH}_3$ where the asterisk denotes the CC* bond. With the assumption of tetrahedral bond angles, the addition of bond tensors gives:

$$\begin{aligned} \gamma^2 = & \Delta\alpha^{\text{CC}^*2} + \frac{8}{3} \Delta\alpha^{\text{CC}2} - \frac{8}{3} \Delta\alpha^{\text{CC}^*} \cdot \Delta\alpha^{\text{CC}} \\ & - \frac{16}{3} \Delta\alpha^{\text{CC}} \cdot \Delta\alpha^{\text{CH}} + \frac{4}{3} \Delta\alpha^{\text{CC}^*} \cdot \Delta\alpha^{\text{CH}} + 4\Delta\alpha^{\text{CH}2} \end{aligned}$$

Figure 4 Dependence of effective back-bone C-C bond anisotropy $\Delta\alpha_e$ on $\Gamma = \Delta\alpha_{CC} - 2\Delta\alpha_{CH}$

from which:

$$\Delta\alpha_e = \Delta\alpha^{CC*} - \Delta\alpha^{CC} = \frac{1}{3} \Gamma \pm (\gamma^2 - 8/9\Gamma^2)^{1/2} \quad (6)$$

where Γ is the bond polarizability parameter $\Delta\alpha^{CC} - 2\Delta\alpha^{CH}$. Figure 4 shows the positive values of $\Delta\alpha_e$ calculated from equation (6). Negative $\Delta\alpha_e$ values are ruled out by the sign of flow birefringence in polyisobutene, which was always positive. Figure 4 shows that $\Delta\alpha_e \approx 1.6 \times 10^{-40} \text{ C}^2 \text{ m}^2/\text{J}$ over the whole range of Γ existing in the literature³¹, 0.6 to $1.2 \times 10^{-40} \text{ C}^2 \text{ m}^2/\text{J}$.

No theory at present exists which realistically estimates $\langle\Delta\alpha\rangle$ or $\langle\gamma^2\rangle$ from $\Delta\alpha_e$ for polyisobutene in the liquid state. As well as the usual features of the rotation-isomeric approach¹ any theory must also include intermolecular interactions, angular correlations and the effect of the strong intramolecular steric interference between the side-groups. Conformational measurements³² and calculations³³, as well as space-filling molecular models, show that steric interference is dominant in determining polyisobutene conformation and hence conformationally dependent parameters such as $\langle\Delta\alpha\rangle$ and $\langle\gamma^2\rangle$.

However, $\Delta\alpha_e$ can be estimated from the polyisobutene flow birefringence results and a comparison made with the value of $\Delta\alpha_e \approx 1.6 \times 10^{-40} \text{ C}^2 \text{ m}^2/\text{J}$ provided by our analysis of 2,2-dimethylbutane. Tsvetkov's flow birefringence theory³⁴ relates the Kuhn statistical segment anisotropy $\langle\Delta\alpha\rangle_\infty$ to the number of monomer units per segment S by

$\langle\Delta\alpha\rangle_\infty = S\Delta\alpha_e'$ ($\Delta\alpha_e'$ is the monomer unit anisotropy referred to axes parallel and transverse to the backbone direction of the fully extended chain.) Thus $\Delta\alpha_e' = \frac{1}{2}\Delta\alpha_e$ if bond angles are tetrahedral. S is given by $2 \times$ persistence length³⁵ = 8 monomer units per segment. From our flow birefringence value of $\langle\Delta\alpha\rangle_\infty = 4.2 \times 10^{-40} \text{ C}^2 \text{ m}^2/\text{J}$ (Figure 2) this gives $\Delta\alpha_e' = 1 \times 10^{-40} \text{ C}^2 \text{ m}^2/\text{J}$ compared with $1.6 \times 10^{-40} \text{ C}^2 \text{ m}^2/\text{J}$ derived from 2,2-dimethylbutane.

CONCLUSION

The optical polarizability tensor of a bond depends on the location of that bond within the molecule due to fields set up by the polarizations of the other bonds in the molecule. The additivity of optical bond anisotropies remains valid provided that the same bonds in different locations are assigned different anisotropies. Additivity of mean optical bond polarizabilities remains unaffected to an accuracy of a few percent, as does additivity of diamagnetic bond anisotropies where the magnetic induced dipoles and dipole fields are very weak. The effect of locality dependent optical bond anisotropies may be small for strongly anisotropic molecules but will be dominant in near-symmetric cases where the molecular anisotropy is the small difference between a number of large terms such as for polyisobutene. We propose that induced dipole interactions between bonds causes the observed optical anisotropy in polyisobutene and that anisotropy calculations of weakly anisotropic molecules using locality independent optical bond anisotropies may be subject to large errors. This proposal is substantiated by the fair agreement between the polyisobutene monomer unit effective anisotropy $\Delta\alpha_e$ derived from flow birefringence data and $\Delta\alpha_e$ derived from a similarly branched small molecule 2,2-dimethylbutane.

Liberman *et al.*² propose to explain the finite observed optical anisotropy of polyisobutene by the steric overlaps prevailing in the polymer chain which alter the polarizabilities of groups or bonds, thus producing locality dependent bond polarizabilities. This suggestion would also predict a finite diamagnetic anisotropy of the chain, contrary to our results. Although we agree with the proposals of Liberman *et al.* that the finite anisotropy of polyisobutene is the result of locality dependent bond polarizabilities, we suggest that the locality-dependence arises predominantly from the electric field interaction between the dipoles induced in the bonds rather than steric overlaps between bonds.

Elastic modulus in the crystalline region of poly(*p*-phenylene terephthalamide)

R. J. Gaymans, J. Tijssen, S. Harkema and A. Bantjes

Department of Chemical Technology, Technological University of Twente, The Netherlands
(Received 13 January 1976)

Fibres from aromatic polyamides have a much higher Young's modulus than fibres from aliphatic polyamides. In order to contribute to the explanation of this observed difference we looked at one of the ultimate properties, the elastic modulus in the crystalline region in the chain direction ($E_{cr//}$). We carried out measurements on a bundle of filaments of PRD 49 fibre, which we identified by i.r. and X-ray analyses as poly(*p*-phenylene terephthalamide). With the X-ray technique we determined the lattice extensions under loading and from these data the $E_{cr//}$ was calculated. The $E_{cr//}$ was found to be 20×10^{11} dyne/cm² which is in good agreement with the calculated $E_{cr//}$, but not very different from that of nylon-6,6. The Young's modulus was found to be 11×10^{11} dyne/cm².

INTRODUCTION

Aromatic polyamides form a class of polymers which have thermal and mechanical properties that are quite different from those of the aliphatic polyamides. Fibres of aromatic polyamides have a much higher Young's modulus than corresponding aliphatic ones.

Aromatic polyamides are thought to be very good materials for reinforcing fibres¹⁻⁴. The properties of these polyamides have been reviewed by Black⁴. He states that a possible explanation for the extraordinary properties of these polymers is due to the extended orientation rather than to the high crystallinity. Since aromatic polyamide chains are much stiffer than those of aliphatic polyamides, chain folding is less likely and a fully extended chain is obtained much easier.

Both the crystallinity and the orientation seem to be very high for these aromatic polyamide fibres. Northolt and Van Aartsen⁵ suggest that poly(*p*-phenylene terephthalamide) (PpPT) has a paracrystalline structure with a long order. They did not observe any periodicity up to 250 Å with small-angle scattering.

Dulmage and Contois⁶ developed a model for the calculation of the Young's modulus from the moduli of the amorphous and crystalline phases and the degree of crystallinity, assuming the crystalline phase to be fully oriented and the amorphous phase to be unoriented.

Holliday and White⁷ have given a review on the present status of the factors governing the Young's modulus and the techniques available for measuring them.

One of these basic properties is the modulus in the crystalline region in the chain direction ($E_{cr//}$). The experimentally determined values of $E_{cr//}$ agree on the whole fairly well with the calculated values.

Fielding Russell⁸ has calculated the $E_{cr//}$ for PpPT using the method of Treloar with assumed chain dimensions and found a value of 20×10^{11} dyne/cm², which we also found with the now available cell dimensions⁵.

EXPERIMENTAL

Sample preparation

The elastic modulus was determined using an industrial fibre from Du Pont (PRD 49). In order to prepare a film

for i.r. analysis the Du Pont product was dissolved in chlorosulphonic acid and precipitated in cooled methanol (-60°C). A fine suspension of gelly particles was obtained by warming up under vigorous stirring. Filtration of the suspension gave a fairly homogeneous film. After washing and drying an i.r. spectrum of the film was taken, and compared with the spectra of poly(*p*-phenylene terephthalamide) and poly(*p*-benzamide) synthesized in our laboratory (Figure 1). As can be seen the i.r. spectra of PRD 49 and poly(*p*-phenylene terephthalamide) are identical.

The X-ray diffraction pattern of PRD 49 fibre gave the same reflections as Northolt and van Aartsen⁵ obtained on PpPT. From these results and the literature data³ we assumed PRD 49 to be poly(*p*-phenylene terephthalamide).

One filament of the fibre was too thin to obtain strong enough reflections so a bundle of 25 filaments was used. In order to be sure that all the filaments were equally well stressed both ends of the bundle were kit together while each filament was under a preload of 1.3 g. The ends were imbedded in such a way that easy clamping was possible. The length of the bundle of filaments between the imbedded areas was 4 cm.

Figure 2 X-ray intensity curve in the 00*l*-plane

Figure 3 Applied stress versus lattice extension

Figure 4 Applied stress versus macroscopic strain

Apparatus

The X-ray method was chosen for the determination of the $E_{cr//}$. Sakurada⁹ gives a detailed set-up for determining the lattice extensions. A Nonius diffractometer with a nickel filtered $\text{CuK}\alpha$ -beam was used.

We measured, at any one time, an angular range of $\theta \pm 0.12^\circ$. Reflections were scanned by steps of 0.1° with a counting time for each point of 4000 sec. From these intensities the centre of gravity of the reflection curve was calculated. The samples were loaded with dead weights and from the shifts of the gravity point the lattice extensions were calculated. Friction losses in the loading set-up were less than 5 g. The macroscopic stress-strain curve was obtained by loading a bundle of filaments and measuring the lengthening with a kathetometer. The load was increased each hour.

RESULTS AND DISCUSSION

The crystal structure of PpPT is given by Northolt and Van Aartsen⁵ as monoclinic with the cell dimensions $a = 7.87 \text{ \AA}$, $b = 5.18 \text{ \AA}$, $c = 12.9 \text{ \AA}$, and $\gamma = 90^\circ$. The space group is Pn or $P2_1/n$. For the determination of $E_{cr//}$ the reflections from the 00*l*-planes were measured. The normals of these planes are parallel to the chain axis. The intensity curve is measured from a bundle of filaments as a function of θ (Figure 2). In the intensity curve the reflections 004 and 006 can be seen. The reflections 00*l* etc., where *l* is odd, are expected extinctions. The 006 plane reflection was chosen to be measured.

It is quite important to note that in the measured region the structure factor is not very dependent on θ . Therefore the reflection maximum coincides with the lattice factor maximum so that we can use the Bragg law.

The stress-lattice extension data are given in Figure 3. The $E_{cr//}$, calculated from the slope of the curve, is $20 \times 10^{11} \text{ dyne/cm}^2$.

The macroscopic stress-strain data are given in Figure 4. Young's modulus determined from these data is $11 \times 10^{11} \text{ dyne/cm}^2$. As can be seen the calculated and the experimental $E_{cr//}$ agree very well and these values are not very different from those obtained on nylon-6,^{6,11}

So the higher Young's modulus of these aromatic polyamide fibres cannot be explained by the ultimate property, the elastic modulus in the crystalline region in the chain direction.

Coordinate polymerization of heterocycles: 1. Oligomerization of epichlorohydrin by TiCl_4

M. Kučera, A. Zahradníčková, K. Majerová

Research Institute of Macromolecular Chemistry, 656 49 Brno, Czechoslovakia

(Received 2 June 1975; revised 28 January 1976)

The polymerization of epichlorohydrin proceeds via the $\text{TiCl}_4 \cdot 2\text{EPC}$ complex provided the concentration of epichlorohydrin is twice as high as that of TiCl_4 . The oligomerization process requires supposedly the existence of a complex in which the epichlorohydrin is coordinate through a Cl—Ti bond. Diethyl ether has an inhibiting effect on the reaction. The oligomerization rate is increased in the presence of acetyl chloride, diethyl ether having no effect this time. The transformation of epichlorohydrin to polymer is always kinetically non-stationary, the number of active centres decreasing with time. Both the initiation and propagation steps proceed through a rearrangement following the coordination of monomer to the activating ligands. No polymerization active free ions have been found to be present in the system. The intermediate and final products were analysed employing spectral, chromatographic, kinetic, and conductivity measurements. The reaction mechanism of oligomerization has been suggested.

INTRODUCTION

The Ziegler–Natta polymerization of olefins can be regarded as a typical example of coordinate polymerization having considerable industrial importance. The propagating centres are almost exclusively believed to be an ‘anionic’ coordinate character^{1,2}. Epoxides can also polymerize by ‘cationic’ or ‘anionic’ coordinate mechanisms³. Cyclic ethers with more than three members in a ring can be polymerized only in the presence of strong acids. Some of these initiators facilitate the coordination of monomer prior to ring opening^{4,5}; the mechanism of these polymerizations is not well understood. The coordinate mechanism has, however, not been considered.

The character of polymerization of four- and multi-membered oxygen heterocycles strongly suggests that the ‘cationic’ coordinate polymerization might be involved. We have been interested in the nature of active centres of this kind. For this reason TiCl_4 was selected as Lewis acid for the initiation, tetrahydrofuran (THF) being the monomer. Tetrahydrofuran, however, will oligomerize in the presence of TiCl_4 only when a ‘promotor’, e.g. epichlorohydrin (EPC), is simultaneously present. We have focused our attention towards the system containing TiCl_4 and epichlorohydrin. In some cases also another promotor of THF polymerization, acetyl chloride, (AcCl), was added.

EXPERIMENTAL

Chemicals

Epichlorohydrin (a Lachema product, purissimum grade) was rectified several times, the 391.1K fraction being collected. The fraction, which was at least 99.9% pure (analysed by g.l.c.) was stored over CaH_2 in a storage bulb attached to a vacuum line.

TiCl_4 (a Fabrique de produits chimiques de Thann et de Mulhouse product) was distilled into an ampoule attached to a vacuum line. After the de-aeration, the product was

distilled into a storage bulb from where it could be transferred into a calibrated pipette. The amount required could then be transferred to a spectrometer cell or a dilatometer.

Dichloromethane (a Lachema product, analytical grade) was shaken with concentrated H_2SO_4 for several days. After washing with water until neutral the product was refluxed for 6 h in the presence of AlCl_3 , then distilled, refluxed again in the presence of P_2O_5 and rectified. The fraction containing more than 99.98% of CH_2Cl_2 was collected and stored over P_2O_5 in a storage vessel attached to a vacuum line. The connection of the storage vessel with the vacuum line was effected by a high-vacuum stainless steel valve.

Diethyl ether (Et_2O) (a Lachema product, u.v. spectroscopic grade) was dried with Na and stored over Na in a vacuum line storage bulb.

Sodium ethanolate was prepared from $\text{C}_2\text{H}_5\text{OH}$ and sodium. The stoichiometric ratio of components was selected to give a solution with a 3 mol/dm^3 concentration. This solution was stored in the dark at low temperature.

Other chemicals used (hexyl chloride, acetyl chloride) were of analytical grade.

Instruments and procedures

Polymerization: closed system. A schematic diagram of the dilatometer used for measurements is presented in *Figure 1*. The dilatometers were sealed to a vacuum line. After 1–2 days pumping the required amounts of epichlorohydrin as well as other components (dichloromethane, acetyl chloride, diethyl ether) were transferred to the dilatometer by a bulb-to-bulb distillation. The volume of each liquid component was measured using calibrated pipettes. The part containing the liquid mixture was then sealed off under vacuum. The TiCl_4 was transferred into the dilatometer using the same procedure.

Polymerizations were carried out under stirring at a constant temperature. Both dilatometer parts were first tem-

Figure 1 Vacuum dilatometer: 1, space for epichlorohydrin, dichloromethane and acetylchloride; 2, space for initiator; 3, dilatometer bulb; 4, capillary i.d. 2.53 mm; 5, break seal; 6, breaker

perature-equilibrated and then the seals were broken. After a certain time the dilatometer was opened so that the polymerization could be stopped by adding an excess of sodium ethanolate (double the quantity with regard to $TiCl_4$), an aliquot sample was taken and dried *in vacuo* to constant weight. The polymer was isolated from the residual part in the following way: approximately 1 h after the polymerization had been stopped by sodium ethanolate an excess of 1 N HCl was added, the acid-containing layer was extracted with toluene and the toluene extract was extracted with water. The solvent contained in the toluene layer was evaporated and the polymer was dried *in vacuo* at ambient temperature to constant weight. The polymer content in other layers was negligible.

Polymerization: open system. The polymerizations of epichlorohydrin in the presence of water were carried out in glass dilatometers⁶ capable of holding 13.5 and 16 ml of liquid, respectively. A millimeter scale was etched on the dilatometer capillary. The dilatometers were positioned in a cylinder which was maintained at a constant temperature of $293.0 \pm 0.1K$.

The water concentration in individual components of the polymerization mixture was determined using a coulometrically modified Fischer method⁷.

The calculated volumes of initiator ($TiCl_4$) and solvent (CH_2Cl_2) were transferred into a dilatometer flask. After reaching an equilibrium temperature, monomer and other components (epichlorohydrin, acetyl chloride, diethyl ether) were added. Neither surface nor the rate of stirring showed any influence on the polymerization. The heat due to the interaction of $TiCl_4$ with ethers was dissipated into the constant temperature bath within the first 70 sec (measured by a thermocouple). The first reading was taken 90 sec after mixing the components. The reproducibility of polymerization runs was satisfactory.

The same method as that described for the closed system was used to stop the polymerization and to isolate the polymer. The conversion achieved during each run was determined gravimetrically and tested by g.l.c.

The comparison of results from closed system with those from open system has shown that water has no significant effect upon the oligomerization even when present at concentrations as high as several hundred $mmol/dm^3$. Most of the kinetic measurements were thus performed in the open system at a constant concentration of water ($25 mmol/dm^3$) in the reaction mixture.

Each of the curves shown in the results is representative of a series of curves⁸ (e.g. at various monomer concentrations). Although all experimental curves have been interpreted and conclusions drawn, only some of the curves are presented here.

Chromatography

After the completion of the polymerization run, 5 ml of the reaction mixture were degassed on a vacuum line. The residual monomer together with low molecular reaction products were transferred into a liquid nitrogen cooled ampoule by a bulb-to-bulb distillation. The volatiles were then analysed on a Perkin-Elmer F 11 chromatograph fitted with a thermal conductivity detector; a stainless steel column 2 m long \times 3 mm i.d., was packed with Chromosorb W 60/80 mesh with 20% of silicon rubber E 301 as a stationary phase. Ar was used as a carrier gas.

Molecular weight determination

Number-average molecular weight, \bar{M}_n , was determined by the v.p.o. method using a VPO ÚMCH ČSAV instrument. The deviation method was employed, bromoform, naphthalene and diphenyl ether respectively being the standards. Acetone, dichloromethane and in some cases ethanol were the solvents used.

Conductivity measurements

The conductivity of samples was measured using a Radiometer A/S-DK-2400 Copenhagen NV-Emdrupvej 72 instrument.

In all cases the conductivity was followed as a function of polymerization time. Most of the measurements were carried out in a stopcock apparatus but no vacuum was applied. From the experiments performed in the strict absence of water under high vacuum it was established that the amount of water which can get into the open system has no significant influence upon the time dependence of conductivity changes⁸.

N.m.r. spectra

A/VMR Tesla BS 487A-80 MHz spectrometer was used to measure n.m.r. spectra. The samples were placed in ground tubes 5 mm o.d. using an external capillary standard

Figure 2 Apparatus for filling n.m.r. tubes: 1, capillary standard containing HMDS alone or in mixture with chloroform; 2, ground tube 5 mm diameter; 3, teflon rings; 4, sintered glass S 2; 5, bulb with reaction components; 6, ground joint connecting the apparatus to vacuum line. The n.m.r. tube is filled by tipping the apparatus

(hexamethyldisiloxane alone or mixed with CHCl_3 at 1:1 ratio). All the sample tubes were filled under high vacuum using an apparatus shown in Figure 2. The spectra were taken at room temperature as well as at 253 and 233K. No band shift or intensity changes were observed.

U.v. spectra

U.v. spectra were measured employing a double beam spectrophotometer Optica Milano CF-4 DR. The spectrophotometer cells (QS, $l = 1$ mm) were filled with sample under vacuum and sealed off. The differential method was used for obtaining the spectra, the samples being contained in cells shown schematically in Figure 3.

The spectrum of TiCl_4 in CH_2Cl_2 was taken first using CH_2Cl_2 in a reference beam. The break-seal separating the spectrometer cell from the storage bulb containing epichlorohydrin was then broken and the spectrum measured, using the CH_2Cl_2 solution of the same component as a reference.

I.r. spectra

The spectra were measured on an UR-10 instrument in standard cells at $308.0 \pm 0.5\text{K}$.

RESULTS

The character of epichlorohydrin oligomerization is apparent from Figure 4. At higher concentrations of diethyl ether ($>1.0 \text{ mol/dm}^3$) the polymerization of epichlorohydrin is completely inhibited. When acetyl chloride is present, however, then the contraction is increased by ether. The polymerization proceeds in a non-stationary fashion. When more epichlorohydrin is added after the end of polymeriza-

tion (provided no acetyl chloride was present) then a new, slower oligomerization commences. The addition of acetyl chloride can restart the polymerization, which had already ceased, to the full extent while further addition of TiCl_4 does not show this effect (Figure 5).

Calculated from initial rates, the oligomerization is of the first order with regard to TiCl_4 and apparently of the second order with regard to monomer. The latter value, however, is questionable because the effect of the increasing dielectric constant, this being a consequence of increasing the epichlorohydrin concentration, cannot be neglected. Since no sufficiently inert solvent possessing physical properties of epichlorohydrin is available the question of the reaction order cannot be unequivocally answered. The reaction order with regard to monomer is equal to zero in the presence of acetyl chloride. The same value with regard to acetyl chloride is equal to two. Epichlorohydrin

starts to polymerize at concentrations higher than 1 mol/dm^3 (epichlorohydrin concentration $\geq 2 [\text{TiCl}_4]$).

U.v. spectra of TiCl_4 and epichlorohydrin in dichloromethane are shown in Figure 6.

In order to judge the interaction between TiCl_4 and CH_2Cl_2 the i.r. spectrum of TiCl_4 in the mixture of CH_2Cl_2 and hexyl chloride was taken. Apart from originally present TiCl_4 (495 cm^{-1} and 615 cm^{-1}) and C-Cl (650 cm^{-1}) bands a new weak band at 625 cm^{-1} was recorded. Here the newly formed absorption band was attributed to TiCl_4 to which hexyl chloride is coordinated via chlorine atoms.

The composition of both monomer and polymer phase, concentration of components, and their structure, was determined using i.r. spectrometry and gas chromatography. The amount of monomer determined by g.l.c. was in agreement with the gravimetry. Both methods were also used for the calibration of the contraction-conversion relationship. This dependence is strictly linear in the whole interval of measurement. The conversion $([\text{EPC}]_0 - [\text{EPC}]) / [\text{EPC}]_0$ can be thus calculated by multiplying the contraction (mm) by the constant $2.75 \times 10^{-3} (\text{mm}^{-1})$.

I.r. spectra of polymers are presented in Figure 7.

Figure 8 Time dependence of electric conductivity during the polymerization of epichlorohydrin. Temperature 293.1K; concentration of components (mol/dm³): TiCl₄ = 0.5, EPC = 6.43. Curve A, EPC alone; B, AcCl = 2.5; C, AcCl = 2.5; Et₂O = 2.9; D, Et₂O = 2.9 mol/dm³

formed by interaction between epichlorohydrin and TiCl₄ or epichlorohydrin, TiCl₄ and acetyl chloride.

The conductivity measurements were carried out in a conductivity cell in which epichlorohydrin was polymerized. The results of these experiments are summed up in Figure 8. All experimental curves of ξ (specific electric conductivity) vs. t are monotonous. The highest conductivity was observed in medium in which polymerization was not proceeding. These results suggest that free ions do not play a significant role during the polymerization.

DISCUSSION

The concentration of free TiCl₄ will be practically zero in the presence of donor compounds. Thus following equilibria will be established at the beginning of polymerization of epichlorohydrin:

Epichlorohydrin starts to polymerize at concentrations that are at least twice as high as that of TiCl₄. The TiCl₄ · 2EPC complex is thus the centre to which the monomer is coordinated; TiCl₄ · EPC · CH₂Cl₂ is kinetically insignificant. Neither inhibition nor induction periods were observed; all active centres are formed immediately after mixing the components. The reaction order towards TiCl₄ is one which means that the active centre reacts with free non-complexed monomer to give polymer chain or it is deactivated to inactive derivatives and new forms of TiCl₄ capable of being activated:

The material balance of TiCl₄ can be expressed as:

$$[\text{TiCl}_4]_0 = \text{}^1\text{Ac} ([\text{CH}_2\text{Cl}_2]^2 + K_1[\text{EPC}]^2) / (K_1[\text{EPC}]^2) \quad (4)$$

If the supply of monomer to the TiCl₄ · 2EPC is faster than the propagation or deactivation rearrangement, the propagation will be of zero order with regard to epichlorohydrin. This case was observed in tetrahydrofuran oligomerization⁹. The rate of epichlorohydrin disappearance can be then expressed as:

$$-\frac{d[\text{EPC}]}{dt} = \text{}^1k_p \text{}^1\text{Ac} = \text{}^1k_p [\text{TiCl}_4]_0 (K_1[\text{EPC}]^2) / ([\text{CH}_2\text{Cl}_2]^2 + K_1[\text{EPC}]^2) \quad (5)$$

Active centres, however, also disappear in the course of polymerization. Their disappearance cannot be simply expressed as a dependence on EPC concentration according to equation (4). Judging from Figure 4, some other reaction is involved. According to equation (3) it holds:

$$-\frac{d[\text{}^1\text{Ac}]}{dt} = \text{}^1k_d [\text{}^1\text{Ac}] \quad (6)$$

When equation (5) is divided by expression (6) then the following expression results:

$$\frac{d[\text{EPC}]}{d[\text{}^1\text{Ac}]} = \frac{\text{}^1k_p}{\text{}^1k_d} \times \frac{[\text{TiCl}_4]_0 K_1 [\text{EPC}]^2}{[\text{CH}_2\text{Cl}_2]^2 + K_1 [\text{EPC}]^2} \times \frac{1}{[\text{}^1\text{Ac}]} \quad (7)$$

The actual concentration of active centres expressed as a function of EPC concentration can be obtained by integrating equation (7), assuming that $[\text{CH}_2\text{Cl}_2]^2 \ll K_1[\text{EPC}]_0 \times [\text{EPC}]$

$$[\text{}^1\text{Ac}] = [\text{}^1\text{Ac}]_0 \exp \left[-\frac{\text{}^1k_d}{\text{}^1k_p [\text{TiCl}_4]_0} ([\text{EPC}]_0 - [\text{EPC}]) \right] \quad (8)$$

Inserting equation (8) into (5) and integrating within corresponding limits the following expression is obtained:

$$[\text{EPC}]_0 - [\text{EPC}] = \frac{\text{}^1k_p}{\text{}^1k_d} [\text{TiCl}_4]_0 \ln \left(1 + \frac{\text{}^1k_d}{[\text{TiCl}_4]_0} \times [\text{}^1\text{Ac}]_0 \right) \quad (9)$$

Figure 9 The dependence of $E_0 - E$ as a function of measured variables and constants. Temperature 293.1K; concentration (mol/dm³): $\text{TiCl}_4 = 0.5$, $\text{EPC} = 6.43$. Curve A, dependence of $E_0 - E$ on $\log(1 + qt)$; $q = [^1\text{Ac}]_0 \cdot ^1k_d$; $[\text{AcCl}] = [\text{Et}_2\text{O}] = 0$; Curve B, dependence of $E_0 - E$ on B , where

$$B = \frac{[\text{TiCl}_4]_0}{^5k_d} \frac{K_2[\text{AcCl}]_0}{K_1[\text{EPC}]_0^2 + K_3[\text{Et}_2\text{O}]^2} \times \left(1 - \frac{1}{1 + [\text{AcCl}]_0 \cdot ^5k_d t} \right)$$

$[\text{AcCl}]_0 = 2.5 \text{ mol/dm}^3$; $[\text{Et}_2\text{O}] = 2.9 \text{ mol/dm}^3$

The values of K_1 , 1k_p and $^1k_d^*$ can then be calculated from equation (9) using experimental data.

Equation (9) can be plotted as a straight line (curve A in Figure 9). Experimental data presented in Figure 4 (curve B) were used for plotting.

Oligomerization of epichlorohydrin in the presence of acetyl chloride

Besides equilibria (1) and (2) the formation of complexes with acetyl chloride and diethyl ether, should also be considered. No complexes containing mixed ligands, other than Cl, were found to be formed. Therefore

* $E_0 - E = k \ln(1 + qt)$. The most suitable values of q are found by approximation of experimental values of $E_0 - E$ and t . The values of q_1 and q_2 are derived from two different values of $[E]_0$. Then K_1 can be expressed:

$$K_1 = \frac{\{[\text{CH}_2\text{Cl}_2]_2^2 - [\text{CH}_2\text{Cl}_2]_1^2\}}{[E_{01}]^2[E_{02}]^2} \left([E_{01}]^2 - \frac{q_1}{q_2} [E_{02}]^2 \right) \times \frac{q_2}{q_2 - q_1}$$

The value of K_1 is used to calculate $^1k_d [^1\text{Ac}]_0$ from equation (4) into which the initial concentration of EPC was inserted. 1k_p is then evident from the slope of the plotted function (9).

Reaction orders with regard to components together with the effect of component additions, mainly, however, the identical initial course of the oligomerization in the presence and absence of diethyl ether, suggest that out of two possible types of active centres only that type should be considered whose existence is determined by the presence of acetyl chloride. The reaction scheme of oligomerization presented in equation (3) can thus be applied for this case:

$$-\frac{d[\text{EPC}]}{dt} = ^1k_p[^1\text{Ac}] + ^2k_p[^2\text{Ac}] \approx ^2k_p[^2\text{Ac}] \quad (12)$$

The concentration $[^2\text{Ac}]$, which is kinetically manifested in form $\text{TiCl}_4 \cdot 2\text{AcCl}$, can be expressed using relationships for material balance of TiCl_4 (equations 1, 10 and 11):

$$[^2\text{Ac}] = [\text{TiCl}_4]_0 \times \frac{K_2[\text{AcCl}]^2}{[\text{CH}_2\text{Cl}_2]^2 + K_1[\text{EPC}]^2 + K_2[\text{AcCl}]^2 + K_3[\text{Et}_2\text{O}]^2} \quad (13)$$

Oligomerization of epichlorohydrin in the presence of acetyl chloride and in the absence of diethyl ether. The polymerization ceases at low conversions. Thus at first approximation the initial concentration of epichlorohydrin can be used instead of the actual one in the denominator of expression (13). Direct determinations of actual concentrations of acetyl chloride during tetrahydrofuran oligomerization have revealed that the rate of acetyl chloride disappearance depends on the value of deactivation constant k_d and time according to relationship: $[\text{AcCl}] = [\text{AcCl}]_0 (1 - [\text{AcCl}]_0 k_d t)^{-1}$ (see refs 8 and 9). The parallelism of effects caused by acetyl chloride concentration changes allows one to assume that a similar mechanism of acetyl chloride disappearance from the reaction zone is operative at oligomerization of epichlorohydrin. The n.m.r. method could not be used to measure the disappearance of acetyl chloride in epichlorohydrin medium. If the equation for the concentration of acetyl chloride is inserted into equation (13) (k_d being denoted 2k_d now) the following expression is obtained upon rearrangement and integration:

$$[\text{EPC}]_0 - [\text{EPC}] = \frac{^2k_p[\text{TiCl}_4]_0}{^2k_d[\text{AcCl}]_0} \times \frac{1}{\gamma} \times \{ \arctan \gamma (1 + [\text{AcCl}]_0 \times ^2k_d t) - \arctan \gamma \} \quad (14)$$

If donor numbers of components¹⁰ are taken into account then it can be considered that $\gamma^2 c^2 \gg 1$. In this case the following equation can be used to calculate the difference between the initial and actual concentration of epichlorohydrin:

$$[\text{EPC}]_0 - [\text{EPC}] = \frac{^2k_p}{^2k_d} \frac{[\text{TiCl}_4]_0}{[\text{AcCl}]_0} \frac{1}{\gamma^2} \left(1 - \frac{1}{c} \right) \quad (15)$$

Figure 10 Dependence of $E_0 - E$ upon values of L and P . Temperature 293.1K; concentration of components (mol/dm³): $TiCl_4 = 0.5$; $AcCl = 2.5$; $EPC = 6.43$. Curve A, dependence of $E_0 - E$ on L ;

$$L = \frac{[TiCl_4]_0}{2k_d[AcCl]_0} \times \{\arctan \gamma c - \arctan \gamma\};$$

Curve B, dependence of $E_0 - E$ on P ;

$$P = \frac{1}{\gamma^2} \frac{[TiCl_4]_0}{2k_d[AcCl]_0} \left(1 - \frac{1}{c}\right);$$

where

$$\gamma^2 = \frac{[CH_2Cl_2]^2 + K_1[EPC]_0^2}{K_2[AcCl]_0^2}; c = 1 + [AcCl]_0^2 k_{dt}$$

When the right hand sides of equations (14) and (15) are compared for the same $[EPC]_0 - [EPC]$ then the following relationship is obtained:

$$\gamma[\arctan \gamma c - \arctan \gamma] \doteq 1 - \frac{1}{c} \quad (16)$$

The values of c and γ † can be computed from equations (15) and (16) using experimental data. Subsequently the values of K_2 , $2k_p$ and $2k_d$ are obtained.

Figure 10 shows the agreement between experimental data and equations (14) and (15) containing constants calculated in the way just described.

Oligomerization of epichlorohydrin in the presence of acetyl chloride and diethyl ether. Since the sum $K_2[AcCl]^2 + [CH_2Cl_2]^2$ can be neglected with regard to other terms

† The values of $[EPC]_0$ ($t = 0$), $[EPC]_1$ (t_1) and $[EPC]_2$ (at_1) are determined from the contraction curve. At $t > 10$ min it holds that $c \approx [AcCl]_0^2 k_{dt}$. At time t , $c = c_1$ while at time at , $c = ac_1$. Thus two equations containing two unknown variables can be set up allowing one to calculate c for a given difference $[EPC]_0 - [EPC]$.

in denominator of relationship (13) the rate of disappearance of epichlorohydrin can be expressed as:

$$-\frac{d[EPC]}{dt} = 2k_p[Ac] = 2k_p[TiCl_4]_0 \times \frac{K_2[AcCl]^2}{K_1[EPC]^2 + K_3[Et_2O]^2} \quad (17)$$

Inserting the concentration of acetyl chloride $[AcCl]$ into this equation (k_d being denoted 5k_d now) and integrating, the following equation results:

$$[EPC]_0 - [EPC] = \frac{2k_p}{5k_d} [TiCl_4]_0 \times \frac{K_2[AcCl]_0}{K_1[EPC]^2 + K_3[Et_2O]^2} \times \left(1 - \frac{1}{1 + [AcCl]_0^5 k_{dt}}\right) \quad (18)$$

The insertion of known values of K_1 , K_2 and $2k_p$ allows one to calculate K_3 and 5k_d . The agreement between experimental and calculated values is shown in Figure 9 (curve B).

The values of equilibrium and kinetic constants are summarized in Table 2.

Mechanism of oligomerization

The low values of conductivity, even in a relatively polar medium indicate that no free ions are involved in the reaction. Ion-pairs are not likely to be active species in this case either, because the conductivity is not increasing with the increasing dielectric constant of the reaction medium. High concentration of $TiCl_4$, mono-molecular rearrangement of the active centre leading to higher or diminished activity, and no response towards the presence of water in the reaction mixture, are the most important observations that are suggestive of the coordinate mechanism of oligomerization.

The stability of $TiCl_4$ complexes with heterocyclic ligands coordinated to Ti atom through oxygen indicates that the polymerization of monomers bonded in this way will be difficult. If we dismiss the participation of ions in the growth reaction and assume the participation of zwitterions as a little probable one, it is very difficult to imagine the rise of a trimer and higher polymers (PO does not form high polymers in the presence of $TiCl_4$ ¹¹).

Table 2 Values of equilibrium and kinetic constants

Constant	Value	Rate constant	$k \times 10^2 [\text{sec}^{-1}]$
K_1	5	$1k_p$	4.90
K_2	1	$2k_p$	48.70
K_3	20	$1k_d$	9.33
		$2k_d$	0.17
		$5k_d$	0.08

Even though we have not succeeded in getting direct proof let us assume the existence of an equilibrium:

According to this conception the complex (I) is kinetically inactive. Only complex (II) can start the polymerization:

The active centre of propagation is very unstable. Its activity may disappear either by a change of coordination mode (equation 19) or by splitting off the growing chain

or exchanging the growing ligand for the polymeric ligand which will be coordinated to Ti via some of its oxygen atoms present in the backbone. The transfer occurs when the growing ligand is exchanged for epichlorohydrin.

This simplified picture is to be understood as a first approximation to the elucidation of the mechanism, e.g. n.m.r. spectra clearly indicate that HCl is eliminated from the epichlorohydrin molecule. The HCl thus evolved may play an important role in termination and transfer processes.

The inhibiting effect of diethyl ether can be accounted for by the coordination of the latter to Ti. Such an addition would preclude further polymerization.

The accelerating effect of acetyl chloride is probably due to the increased number of Ti-Cl-C- bonds. The coordination of acetyl chloride to Ti via chlorine atom is not excluded¹²:

This hypothesis is supported by finding the values of 2k_d lower than 1k_d and by the ability of acetyl chloride additions to restart the polymerization. When the growing ligand is detached together with Cl atom then an ester, whose presence has been detected, is formed. The other product is chlorohydrin which may be formed by the hydrolysis of the ester during the isolation of a dimer.

Coordinate polymerization of heterocycles: 2. Oligomerization of tetrahydrofuran by TiCl₄ in the presence of acetyl chloride or epichlorohydrin

M. Kučera, A. Zahradničková, and K. Majerová

Research Institute of Macromolecular Chemistry, 656 49 Brno, Czechoslovakia

(Received 2 June 1975; revised 28 January 1976)

Both acetyl chloride and epichlorohydrin facilitate the opening of the tetrahydrofuran ring in the presence of TiCl₄. Electrical conductivity and spectral measurements indicate that the process is not of a cationic character. The solvent, however, exhibits a strong influence upon the reaction. An equilibrium in the ligand field of Ti atom will be established depending on the medium; this equilibrium then determines the character of the active centre and thus its ability to polymerize tetrahydrofuran or epichlorohydrin. The kinetic analysis of polymerization was made possible by using a simple relationship between the rate and actual concentration of acetyl chloride, the latter being directly measurable by n.m.r. The values of equilibrium and rate constants have been calculated.

INTRODUCTION

The data on the polymerization of tetrahydrofuran (THF) considerably enhance our knowledge of cationic polymerization and the mechanism and the kinetics of polymerization of cyclic ethers. It is generally believed that the polymerization will proceed only if the propagating centre is in the form of a trialkyloxonium ion or a salt. This opinion is expressed explicitly in a review by Dreyfuss¹ but it occurs implicitly also in later papers². To our knowledge, the coordinate mechanism of tetrahydrofuran polymerization has not been considered to account for the observed results.

Tetrahydrofuran reacts with TiCl₄ to give a stable yellow complex. In order to enhance the fission of the tetrahydrofuran ring, promoters were added accelerating polymerization in other than TiCl₄ induced cases. Such a promoter is e.g. epichlorohydrin (EPC), which is capable of generating trialkyloxonium ion *in situ*³ or acetyl chloride (AcCl) which increases the concentration of carboxonium ions⁴.

Each of these promoters, when combined with TiCl₄, induces the tetrahydrofuran ring opening to give low molecular weight products. Employing the common methods of macromolecular chemistry we attempted to elucidate the mechanism and kinetics of oligomerization.

EXPERIMENTAL

The purity of most chemicals used, working procedures and apparatus have been presented in the first paper of this series⁵.

Tetrahydrofuran (a VEB Laborchemie Apolda product, pure) was distilled several times in the presence of metallic sodium, then in the presence of potassium permanganate to remove peroxides, until no reaction with ferrous sulphate occurred. The product was finally rectified several times using a ~4 TP column. Purity, checked by gas chromatography, was found to be better than 99.9%. 1,4-Dioxane (Lachema, analytical grade), purity checked by gas chromatography, was better than 99%.

The actual concentration of acetyl chloride during the oligomerization was determined by measuring n.m.r. spectra at various time intervals. The signals at 7.35 τ (from the methyl group in acetyl chloride) and at 8.0 τ (acetyl group in the form of acetic acid ester CH₃COOCH₂~) are typical for the spectrum. The concentration of acetyl chloride could be calculated by integrating the spectrum (*Figure 1*).

The conversion could be determined from the resonance intensity decrease of α , β hydrogens of tetrahydrofuran and from the resonance intensity increase at 8.3 τ , 6.55 τ and 5.86 τ . The agreement with conversion determined gravimetrically and by g.l.c. was satisfactory. These three methods verified that the relation between a measured contraction and an actual conversion is strictly linear. The product of an observed contraction and of a constant of proportionality yields a conversion $\pi = ([M_0] - [M])/[M_0]$.

During all experiments in the open system the concentration of water was constant (25 mmol/dm³).

RESULTS

The oligomerization of tetrahydrofuran in the presence of acetyl chloride is a strongly non-stationary process. The reaction subsides before a complete depletion of the monomer. A typical reaction course is shown in *Figure 2*, which presents a dilatometric record of contraction vs. time, the proportionality constant (mm⁻¹) being 0.175×10^{-2} for curves A, B, D, 0.33×10^{-2} for curve C and 0.55×10^{-2} for curve E. The initial rate of oligomerization is independent of concentration of water within the concentration interval $0 \leq [H_2O] \leq 0.8$ mol/dm³.

The reaction order with regard to tetrahydrofuran is low, near to zero in CH₂Cl₂ and equal to two in ether (Et₂O). The reaction is, however, strongly retarded in the presence of ether. Since, under these conditions, the diethyl ether presence made up for the decreasing concentration of tetrahydrofuran, the observed reaction rate decrease was evidently due to the increasing concentration of ether; not even CH₂Cl₂ would be inert. When 1,4-dioxane is used as a solvent then, indeed, the reaction order with regard to

Figure 1 N.m.r. spectra and their integrals measured on the system tetrahydrofuran, acetyl chloride, TiCl_4 at various time intervals. Solvent CH_2Cl_2 ; temperature 298.1K; concentration of components (mol/dm^3): $[\text{THF}]_0 = 6.1$; $[\text{AcCl}]_0 = 2.5$; $[\text{H}_2\text{O}]_0 = 0.035$. Time, t (min): A, 149; B, 69; C, 19; D, 9; E, 6; F, 150

tetrahydrofuran is unequivocally zero. The order with regard to acetyl chloride (calculated from initial rates) is ~ 2.0 and that with regard to TiCl_4 , 1.0. Neither the addition of fresh monomer nor TiCl_4 is able to restart the reaction once it has subsided. The addition of fresh acetyl chloride to such a system can, however, restart the polymerization, the latter being initiated by the second generation of active centres (Figure 3).

The concentration of acetyl chloride is therefore directly determining the concentration of active centres. N.m.r. spectra make it possible to determine the actual concentration of acetyl chloride at any stage of oligomerization. It follows from Figure 4 that the disappearance of acetyl chloride strictly obeys the relationship valid for the second-order reactions. No presence of polymerization active free ions was observed during the oligomerization; the specific electric conductivity being generally lower than in non-polymerizing systems⁵.

Differential u.v. spectra of TiCl_4 in dichloromethane (measured according to the procedure described in a previous paper⁵) are shown in Figure 5. The yellow complex $\text{TiCl}_4 \cdot 2\text{THF}$ shows an absorption at 300 nm. In the presence of EPC tetrahydrofuran is substituted in the ligand sphere of the Ti atom which results in a lowering of this absorption.

Typical oxonium ions formed in the presence of other Lewis acids, as reported by Meerwein⁶, are not formed in our case, even in the presence of acetyl chloride (Figure 6).

The infra red spectrum of a $\text{TiCl}_4 \cdot 2\text{THF}$ complex taken in the solid state is also changed by addition of a small amount of epichlorohydrin, a new band being observed at 640 cm^{-1} . The formation of other bands seen in the OH region at 3350 cm^{-1} is suggestive of the THF ring opening.

Figure 2 Oligomerization of tetrahydrofuran in the presence of acetyl chloride and epichlorohydrin, respectively. Temperature 293.1K; $[\text{TiCl}_4] = 0.5 \text{ mol}/\text{dm}^3$. Concentration of components (mol/dm^3): A, THF = 6.1; AcCl = 2.5; EPC = 0; $\text{CH}_2\text{Cl}_2 = 4.1$; B, THF = 6.1; AcCl = 2.5; EPC = 0; $\text{CH}_2\text{Cl}_2 = 1.49$; 1,4-dioxane = 2.3; C, THF = 6.1; AcCl = 0; EPC = 4.0; $\text{CH}_2\text{Cl}_2 = 2.4$; D, THF = 6.1; AcCl = 2.5; EPC = 0; $\text{CH}_2\text{Cl}_2 = 0.46$; $\text{Et}_2\text{O} = 2.9$; E, THF = 3.6; AcCl = 0; EPC = 4.0; $\text{Et}_2\text{O} = 3.9$; $\text{CH}_2\text{Cl}_2 = 0.6$

Figure 3 The second oligomerization of tetrahydrofuran induced by a fresh addition of acetyl chloride. Temperature 293.1K; concentration of components (mol/dm^3): THF = 6.1; AcCl = 2.5; $\text{TiCl}_4 = 0.5$; $[\text{H}_2\text{O}]_0 = 0.56$; after 120 min AcCl added ($2.5 \text{ mol}/\text{dm}^3$)

Figure 4 The disappearance of acetyl chloride during oligomerization. Temperature 293.1K; component concentration (mol/dm³): AcCl = 2.5; TiCl₄ = 0.5. A, THF = 6.1; Et₂O = 2.9; B, THF = 8.54; Et₂O = 0.97; C, THF = 1.83; D, THF = 6.1

Figure 5 Absorption curves of TiCl₄ and its mixture with tetrahydrofuran. Solvent CH₂Cl₂; temperature 298.1K; [THF] = 1 mol/dm³, [TiCl₄] ~ 10⁻³ mol/dm³. A, TiCl₄ in CH₂Cl₂ ~ CH₂Cl₂; B, TiCl₄ in CH₂Cl₂ with THF ~ CH₂Cl₂ + THF

The solid complex TiCl₄ · 2THF is dissolved by a greater amount of epichlorohydrin. Thus a new pronounced absorption band is seen at 615 cm⁻¹ accompanied by less intense bands at 625 and 645 cm⁻¹, instead of the original absorption due to TiCl₄ at 495 cm⁻¹. Simultaneously the maximum of OH bands is increasing at 3370 cm⁻¹.

N.m.r. spectra of the product of tetrahydrofuran oligomerization in the presence of acetyl chloride or epichlorohydrin are presented in Figures 7 and 8. I.r. spectra are shown in Figure 9.

The \bar{M}_n of oligomers formed is 230–450. Gas-chromatographic analysis⁷ together with the results of spectral measurements suggest the composition of products given in Table 1.

DISCUSSION

Oligomerization of THF in the presence of acetyl chloride.

The following equilibria should be considered to be present in the reaction system containing TiCl₄, tetrahydro-

Figure 6 U.v. spectra of TiCl₄ and its mixtures with AcCl and with acetyl chloride and tetrahydrofuran. Solvent CH₂Cl₂, temperature 298.1K; [TiCl₄] ~ 10⁻³ mol/dm³, [THF] = 0.95 mol/dm³, [AcCl] = 0.6 mol/dm³. A, TiCl₄ in CH₂Cl₂ ~ CH₂Cl₂; B, TiCl₄ in CH₂Cl₂ + AcCl ~ CH₂Cl₂ + AcCl; C, TiCl₄ in CH₂Cl₂ + AcCl + THF ~ CH₂Cl₂ + AcCl + THF

Figure 7 N.m.r. spectrum of polymer formed in the system tetrahydrofuran-acetyl chloride-TiCl₄. Temperature 293.1K, concentration of components (mol/dm³): THF = 8.54; AcCl = 2.5; TiCl₄ = 0.5. A, the spectrum taken at 323.1K; B, integral

Figure 8 N.m.r. spectra of polymer formed in the system tetrahydrofuran–epichlorohydrin. Temperature of polymerization 293.1K, temperature of measurement 298.1K; concentration of components in the polymerization system (mol/dm³): THF = 6.1; EPC = 4; [H₂O]₀ = 0

furan, dichloromethane and 1,4-dioxane or diethyl ether:

None of the reaction orders found, suggests the existence of complexes containing mixed ligands (e.g. TiCl₄ · AcCl · Et₂O). Therefore such complexes are not considered to be kinetically important species. The rate of oligomerization is directly proportional to the square of acetyl chloride concentration while the zero order with regard to the monomer indicates that the reaction of tetrahydrofuran with active centre is not the rate controlling step. Let us assume that the opening of the tetrahydrofuran ring is effected via a slow rearrangement of the active centre. The disappearance of centre activity, during which TiCl₄ is regenerated, is a competitive reaction:

It follows from the material balance ([⁵Ac] = [TiCl₄ · 2AcCl]) that:

$$[\text{}^5\text{Ac}] = [\text{TiCl}_4]_0 \times \frac{K_2[\text{AcCl}]^2}{[\text{CH}_2\text{Cl}_2]^2 + K_0[\text{THF}]^2 + K_3[\text{Et}_2\text{O}]^2 + K_7[1,4\text{-dioxane}]^2 + K_2[\text{AcCl}]^2} \quad (6)$$

The rate of tetrahydrofuran disappearance follows from scheme (5):

$$-\frac{d[\text{THF}]}{dt} = 5k_p[{}^5\text{Ac}] \quad (7)$$

The actual concentration of acetyl chloride is, according to Figure 4, expressed by the relationship:

$$[\text{AcCl}] = [\text{AcCl}]_0 / (1 + [\text{AcCl}]_0 3k_d t) = [\text{AcCl}]_0 / c \quad (8)$$

The dependence of tetrahydrofuran rate of disappearance upon measurable parameters is obtained when equations (8) and (6) are used to express equation (7). Since the oligomerization ceases at low conversions the initial

Table 1 Products of tetrahydrofuran oligomerization

System	Product	% of total
THF, AcCl	$\text{CH}_3\text{-}\overset{\text{O}}{\underset{\text{O}}{\text{C}}}\text{-(O+(CH}_2)_4)_3\text{-H}$	66
	$\text{Cl-(CH}_2)_4\text{O-(CH}_2)_4\text{-OH}$	34
THF, EPC	$\text{H-O-CH}_2\text{-CH}_2\text{-}[\text{-O-(CH}_2)_4\text{]}_n\text{-Cl}$	100

Figure 10 The dependence of difference between initial and actual concentration of tetrahydrofuran as a function of equilibrium and rate constants and time. O, data from curve A, Figure 2, processed according to equation (11) ($G = \{[\text{TiCl}_4]_0 / \alpha [\text{AcCl}]_0\} \times [\arctan \alpha c - \arctan \alpha]$); □, data from curve A, Figure 2, processed according to equation (13) ($H = \{[\text{TiCl}_4]_0 / [\text{AcCl}]_0\} \times (1/\alpha^2)(1 - 1/c)$); ⊕, data from curve D, Figure 2, processed according to equation (15) ($I = \{[\text{TiCl}_4]_0 / k_d \beta\} \times [(\arctan \beta c' / [\text{AcCl}]_0) - (\arctan \beta / [\text{AcCl}]_0)]$); ●, data from curve B, Figure 2, processed according to equation (11) (similarly to curve A) but with modified α :

$$\alpha'^2 = \frac{[\text{CH}_2\text{Cl}_2 + K_0([\text{THF}]^2 + k_7[1,4\text{-dioxane}]^2)}{K_2[\text{AcCl}]_0^2}$$

$$\left(J = \frac{[\text{TiCl}_4]_0}{\alpha' [\text{AcCl}]_0} \times [\arctan \alpha' c - \arctan \alpha'] \right)$$

concentration of tetrahydrofuran can be used instead of the actual concentration.

Oligomerization in dichloromethane. Thus to the first approximation:

$$-\frac{d[\text{THF}]}{dt} = 5k_p[\text{TiCl}_4]_0 \frac{1}{1 + \alpha^2 c^2} \quad (9)$$

$$\alpha^2 = \frac{[\text{CH}_2\text{Cl}_2]^2 + K_0[\text{THF}]_0^2}{K_2[\text{AcCl}]_0^2} \quad (10)$$

The expression for the difference between initial and actual concentration of monomer is obtained by the integration of equation (9):

$$[\text{THF}]_0 - [\text{THF}] = \frac{5k_p}{3k_d} [\text{TiCl}_4]_0 \frac{1}{\alpha [\text{AcCl}]_0} \times [\arctan \alpha c - \arctan \alpha] \quad (11)$$

Taking into account the values of donor numbers of tetrahydrofuran and acetyl chloride⁸ it holds:

$$\alpha^2 c^2 \gg 1 \quad (12)$$

Equation (9) then assumes the form:

$$[\text{THF}]_0 - [\text{THF}] = \frac{5k_p}{3k_d} \frac{[\text{TiCl}_4]_0}{[\text{AcCl}]_0} \frac{1}{\alpha^2} \left(1 - \frac{1}{c} \right) \quad (13)$$

Comparing expressions (11) and (13) the equation $1 - 1/c = \alpha(\arctan \alpha c - \arctan \alpha)$ is obtained; it consists of α and of directly measurable values $[\text{AcCl}]_0$, $3k_d$ and t ; the values of α can be calculated. Knowing K_2 (see ref 5), the value of K_0 can easily be calculated from α .

Oligomerization in the presence of diethyl ether. The values of concentrations of reactants present in the denominator of equation (6) were comparable. Since K_3 is more than an order of magnitude higher than other constants⁵ the expression for ${}^5\text{Ac}$ can be simplified:

$$-\frac{d[\text{THF}]}{dt} = 5k_p[\text{TiCl}_4]_0 \frac{K_2[\text{AcCl}]^2}{K_3[\text{Et}_2\text{O}]^2 + K_2[\text{AcCl}]^2}$$

$$= 5k_p[\text{TiCl}_4]_0 \frac{[\text{AcCl}]_0^2}{\beta^2 c'^2 + [\text{AcCl}]_0^2} \quad (14)$$

Where:

$$\beta = \frac{K_3^{1/2} [\text{Et}_2\text{O}]}{K_2^{1/2}}$$

$$c' = (1 + [\text{AcCl}]_0^4 k_d t)$$

4k_d being directly measurable (see Figure 4).

Integrating equation (14), an expression is obtained in which all values are known from previous measurements and thus it can be used for the verification of derived constants.

$$[\text{THF}]_0 - [\text{THF}] = \frac{5k_p}{4k_d} [\text{TiCl}_4]_0 \frac{1}{\beta} \times \left(\arctan \frac{\beta c'}{[\text{AcCl}]_0} - \arctan \frac{\beta}{[\text{AcCl}]_0} \right) \quad (15)$$

The observed reaction order with regard to tetrahydrofuran follows directly from equation (15). During this measurement the tetrahydrofuran concentration decrease was compensated by the increase in diethyl ether concentration. The latter is accompanied by the decrease in overall rate because of high value of K_3 .

Oligomerization in the presence of 1,4-dioxane. The sum of concentrations of tetrahydrofuran and dioxane was maintained constant. The value of denominator in right hand term of equation (6) will be constant if $K_0 \approx K_7$. The polymerization will be of zero-order with regard to monomer up to relatively high conversions. This was confirmed experimentally.

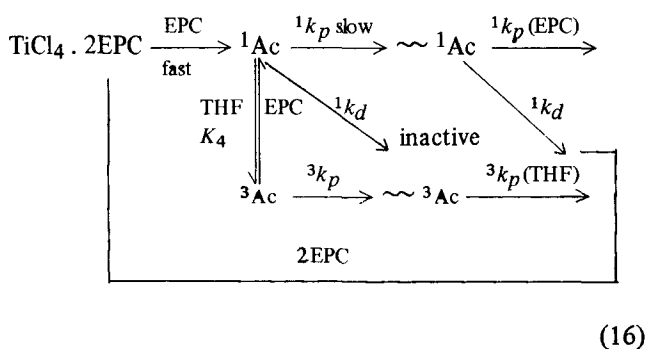

The graphical confrontation of experimental results with expressions derived here is presented in Figure 10.

Table 2 Values of equilibrium and rate constants (other constants have been taken from ref 7)

Constant	Value	Rate constant	$k_p(d) \times 10^3$ (sec ⁻¹)
K_0	1.3	3k_p	0.45
K_4	1.0	5k_p	22.67
K_7	1.3	3k_d	0.20
		4k_d	0.017

Oligomerization of THF in the presence of EPC

Only two kinds of active centres can be involved in this case: $\text{TiCl}_4 \cdot 2\text{EPC} \cdot \text{EPC}$ denoted by ${}^1\text{Ac}$ and $\text{TiCl}_4 \cdot 2\text{EPC} \cdot \text{THF}$ denoted by ${}^3\text{Ac}$. The formation of the latter should obey the following equilibria:

According to the notion ${}^1\text{Ac}$ is transformed to ${}^3\text{Ac}$ by the exchange of epichlorohydrin for tetrahydrofuran (equation 16) and *vice versa*. Therefore the consumption of tetrahydrofuran is indicative of its oligomerization on ${}^3\text{Ac}$ while the reaction of epichlorohydrin involves ${}^1\text{Ac}$. The character of ${}^1\text{Ac}$ has been known from the studies concerning the polymerization of epichlorohydrin⁵. These species are unstable, their activity disappearing with time. Judging from curve shapes in Figure 2 (curves C and E), it seems that ${}^3\text{Ac}$ centres are considerably stable. Let us assume, in the first approximation, that the value of k_d for their disappearance is zero (see also ref 5):

$$\begin{aligned}
 -\frac{d[\text{THF}]}{dt} &= {}^3k_p[{}^3\text{Ac}]_0 \\
 -\frac{d[\text{EPC}]}{dt} &= {}^1k_p[{}^1\text{Ac}] = {}^1k_p[{}^1\text{Ac}]_0 \times \\
 &\quad \exp\left(\frac{{}^1k_d}{{}^1k_p} \frac{[\text{EPC}]_0 - [\text{EPC}]}{[\text{TiCl}_4]_0}\right) \quad (17)
 \end{aligned}$$

The sum of both equations upon integration gives the relationship describing the course of oligomerization (M denotes the sum of monomers):

$$\begin{aligned}
 [M]_0 - [M] &= {}^3k_p[{}^3\text{Ac}]_0 t + \frac{{}^1k_p[\text{TiCl}_4]_0}{{}^1k_d} \times \\
 &\quad \ln(1 + {}^1k_d[{}^1\text{Ac}]_0 t) \quad (18)
 \end{aligned}$$

The expression for concentration of ${}^3\text{Ac}$ can be derived from equilibria (1), (3), (16) and (1) in ref 5 taking into account TiCl_4 balance:

$$\begin{aligned}
 [{}^3\text{Ac}] &= [\text{TiCl}_4]_0 \times \\
 &\quad \frac{K_1 K_4 [\text{THF}] [\text{EPC}]}{[\text{CH}_2\text{Cl}_2]^2 + K_0 [\text{THF}]^2 + K_1 [\text{EPC}]^2 + K_3 [\text{Et}_2\text{O}]^2} \quad (19)
 \end{aligned}$$

K_4 is the only unknown in this expression. We do not know of a direct method of its determination. If we presume that the rates of coordination of tetrahydrofuran or epichlorohydrin to the ligands are similar, than $K_4 \approx 1$. When this value is used then $[{}^3\text{Ac}]$ can be calculated from equation (19) (because of low conversions the initial concentrations of monomers can be used instead of actual ones) and 3k_p obtained from equation (18). The agreement between equation (18) and experimental results represented by curves C and E in Figure 2 is shown in Figure 11. The values of constants are summarized in Table 2.

Mechanism. The results of spectral and kinetic studies suggest the mechanism of this reaction. The coordination of acetyl chloride to TiCl_4 via chlorine is not excluded⁹. The oligomerization of tetrahydrofuran in the presence of acetyl chloride can again be visualized as a coordination of monomer to activating ligands:

 Figure 11 The dependence of $M_0 - M$ upon Z (tetrahydrofuran-epichlorohydrin system).

$$M_0 - M = ([\text{THF}]_0 + [\text{EPC}]_0) - ([\text{THF}] + [\text{EPC}]).$$

$$Z = 4k_p[{}^3\text{Ac}]_0 t + \frac{{}^3k_p[\text{TiCl}_4]_0}{{}^3k_d} \ln(1 + {}^3k_d[{}^2\text{Ac}]_0 t).$$

Temperature 293.1K; $\text{TiCl}_4 = 0.5 \text{ mol/dm}^3$; constant concentration of epichlorohydrin, 4 mol/dm^3 ; tetrahydrofuran concentration (mol/dm³): \circ , 8.54; \triangle , 6.1; \oplus , 3.66; \bullet , 1.83. Constant concentration of tetrahydrofuran, 6.1 mol/dm^3 ; epichlorohydrin concentration (mol/dm³): \blacksquare , 5; \blacktriangle , 3; \square , 2

The termination may take place when the growing ligand is split off:

or by coordination of monomer or polymer to the Ti atom via oxygen.

A similar mechanism may be suggested when epichlorohydrin is used as a promotor:

Also in this case the termination occurs probably by splitting off the growing ligand or by coordination of monomer or polymer to titanium via oxygen.

Coordinate polymerization of heterocycles: 3. Oligomerization of tetrahydrofuran induced by TiCl_4 in the presence of acetyl chloride and epichlorohydrin

M. Kučera, A. Zahradníčková, and K. Majerová

Research Institute of Macromolecular Chemistry, 656 49 Brno, Czechoslovakia

(Received 2 June 1975; revised 28 January 1976)

When a strong and a weak donor are present as promoters in the oligomerization of tetrahydrofuran then under certain conditions a pronounced stabilization of active centres occurs. The formation of centres is governed by equilibrium reactions during which the monomer and promoters are coordinated to Ti atom. The coordination ability is determined by the donor numbers. The dependence of oligomerization reaction rate on the molar fraction of tetrahydrofuran exhibits a minimum. At the concentration conditions corresponding to this minimum, especially in the presence of diethyl ether, the active centres do not lose their reactivity and the oligomerization becomes stationary to high conversions. The results suggest that the classification of coordinate polymerizations to cationic and anionic coordinate polymerizations is meaningless. Coordinate polymerizations belong to a separate group of polyreactions similarly as e.g. radical polymerizations.

INTRODUCTION

In our previous communications we analysed the oligomerization of epichlorohydrin (EPC) and tetrahydrofuran (THF) in the presence of acetyl chloride (AcCl) or epichlorohydrin. All these polymerizations are strongly non-stationary. In the presence of diethyl ether (Et_2O) and at low concentrations of epichlorohydrin the constants controlling the disappearance of activity of centres are decreasing. The question arises whether a suitable combination of conditions, namely the varying composition of the reaction mixture, cannot preclude the destruction of centres.

It is commonly believed, with a few exceptions¹ that the tetrahydrofuran ring can be opened only via a cationic process. The processes which have been shown to proceed through the coordinate mechanism are usually called cationic² or anionic (e.g. Ziegler–Natta polymerization of olefins³) coordinate processes. In the systems which we have studied so far no polymerization active free ions have been observed⁴. The strong donors which were present in the studied media would act as catalyst poisons in the case of Ziegler–Natta polymerizations.

Therefore, it seems useful to compare both cationic and anionic coordinate mechanisms and to decide how justified is the use of the attributed 'cationic' or 'anionic' in the case of coordinate polymerizations.

EXPERIMENTAL

The purification of chemicals, the method of following the course of oligomerization, measuring electric conductivity, identification of intermediates and reaction products by spectral and g.l.c. methods have been described in our previous papers⁴. The chlorine content in polymers isolated from the reaction mixture was determined by elemental analysis.

RESULTS

An example of tetrahydrofuran oligomerization in the presence of a constant amount of acetyl chloride and various concentrations of epichlorohydrin is shown in *Figure 1* where contraction is plotted against time. In all cases the contraction is directly proportional to conversion⁴. The

dependence of initial rate on the percentage of tetrahydrofuran in the mixture of monomers X_{THF} exhibits a minimum (Figure 2).

The shape of contraction curves is suggestive of a considerable influence of the reaction mixture composition upon the stationarity of oligomerization. This influence is in accordance with previous observations of the deactivation constant (k_d) changes⁴. If this influence is enhanced

by the selection of component concentration and by additions of diethyl ether then k_d may be practically zero and the oligomerization will proceed at constant concentration of centres. Such stationary oligomerizations are shown in Figure 3.

Under the conditions described above both the internal and external order of reaction with regard to tetrahydrofuran is equal to zero; the oligomerization rate is directly proportional to the concentration of acetyl chloride, being in reciprocal dependence upon diethyl ether concentration. As in previous observations⁴ the presence of polymerization active free ions in the oligomerizing system has not been detected.

The quantitative analysis of monomers has been carried out using gas chromatography. The chromatograms revealed the presence of another two components the elution times of which are identical to those of CH₃COO(CH₂)₄Cl and Cl-(CH₂)₄-OH (Figure 4).

N.m.r. spectroscopy of solid oligomerization products (Figure 5) enabled us to establish the concentration ratio of tetrahydrofuran/epichlorohydrin, the kind of monomer

Figure 4 Chromatograms of monomer phase. Concentration of components (mol/dm³): 1, THF = 6.1; EPC = 3; AcCl = 2.5; 2, THF = 3.66; EPC = 3; AcCl = 2.5; Et₂O = 2.4. Temperature: A, 313.1K (6 min); B, 413.1K

bonded to the acetyl group:

and an approximate number of bonded monomer units. The percentage of epichlorohydrin and the band intensity of C=O and -OH groups was measured by means of i.r. spectroscopy (Figure 6). The -OH groups content was determined indirectly from i.r. spectra of polymers containing additions of 1,4-chlorobutanol. There is a shift of the -OH band from 3450 cm⁻¹ towards 3350 cm⁻¹ which increases with the concentration of chlorobutanol (H-bonds). The areas of absorption bands, measured planimetrically, when inserted into the Lambert-Beer plot gave a straight line dependence. The extrapolation of the linear dependence to the origin enabled us to calculate the concentration of -OH end-groups as a percentage of added 1,4-chlorobutanol. These values were in good agreement with those obtained by elemental analysis, molecular weight measurements and n.m.r. spectroscopy.

The spectra of polymers prepared in the 'dry' system on the vacuum line were not different from those of polymers prepared in the presence of 200 mmol/dm³ H₂O. Thus the -OH groups observed in chlorohydrin were probably formed from ester CH₃CO-O- groups when alcoholic C₂H₅ONa,

containing water, was added to stop the reaction. In some cases, however, the -OH bands were observed in spite of the absence of acetyl chloride in the system. Thus the active centres containing epichlorohydrin can give -OH groups by alkaline fission of the oxirane ring taking place during the neutralization of the reaction mixture.

The approximate composition of the polymers isolated from the systems was deduced on the bases of the data presented above and is shown in Table 1.

DISCUSSION

The change in tetrahydrofuran-epichlorohydrin ratio in the presence of acetyl chloride leads to radical changes in the course of oligomerization. The oligomerization rate in the presence of a small amount of epichlorohydrin is even lower than in the absence of epichlorohydrin, the decrease of reaction rate with time being, however, small. The excess of epichlorohydrin exhibits similar effects as those observed during the polymerization of epichlorohydrin in the presence of acetyl chloride.

It follows from Figure 2 that it would be misleading to consider observed overall reaction orders in terms of molecularity. Moreover, the dielectric constant is decreasing with the increasing abscissa. Also the attempt to find a relationship describing these processes would be of no practical importance. The behaviour of systems at a certain concentration ratio of tetrahydrofuran and epichlorohydrin can, however, be analysed. At $X_{\text{THF}} = 0$ and $X_{\text{THF}} = 100$ the relationship derived in our previous papers⁴ will be valid. The most interesting, however, is the region around the minimum where the oligomerization exhibits a stationary behaviour.

In the systems containing both promoters the following centres may be present: [¹Ac], [⁵Ac], [³Ac] and TiCl₄.

EPC · AcCl, the complex from which [⁴Ac] results by a fast

Figure 6 I.r. spectra of polymers isolated from polymerization systems containing tetrahydrofuran-epichlorohydrin-acetyl chloride. Where:

addition of tetrahydrofuran. The presence of ¹Ac need not be considered in the region of the minimum because even epichlorohydrin alone does not polymerize at corresponding concentration. Therefore:

$$-\frac{d[\text{THF}]}{dt} = 5k_p[{}^5\text{Ac}] + 3k_p[{}^3\text{Ac}] + 4k_p[{}^4\text{Ac}] \quad (1)$$

The concentration of both ⁵Ac and ³Ac can be determined⁴. In order to determine the value of ⁴Ac a following equilibrium is considered:

The constant K_6 is not directly accessible. It can be estimated from the values of K_1 and K_2 ; to the first approximation the value 2×10^{-2} was used. In simple cases the ⁴Ac can be expressed as:

$$[{}^4\text{Ac}] = \frac{[\text{TiCl}_4]_0 K_1 K_6 [\text{EPC}] [\text{AcCl}]}{[\text{CH}_2\text{Cl}_2]^2 + K_0 [\text{THF}]^2 + K_1 [\text{EPC}]^2 + K_2 [\text{AcCl}]^2 + K_3 [\text{Et}_2\text{O}]^2 + K_1 K_6 [\text{EPC}] [\text{AcCl}]} \quad (3)$$

When the values of ⁵Ac and ³Ac (see ref 4) are inserted and ⁴Ac from equation (3)*, neglecting small

* At low conversions the value of [THF] can be considered as [THF]₀ and [EPC] as [EPC]₀. The actual concentration of acetyl chloride was expressed using the previously verified expression⁴: [AcCl] = [AcCl]₀ / (1 + [AcCl]₀³k_dt).

terms in denominators, then a following equation is obtained upon integration:

$$[\text{THF}]_0 - [\text{THF}] = [\text{TiCl}_4]_0 \left\{ \frac{([\text{EPC}]_0) / (K_0 [\text{THF}]_0^2 + K_1 [\text{EPC}]_0^2)}{[{}^3k_p K_1 K_4 [\text{THF}]_0 + {}^4k_p K_1 K_6 [\text{AcCl}]_0] t + [{}^5k_p K_2^{1/2} / ({}^3k_d K_0^{1/2} [\text{THF}]_0)} \right\} \left[\arctan (K_0^{1/2} [\text{THF}]_0) (1 + [\text{AcCl}]_0^3 k_d t) / (K_2^{1/2} [\text{AcCl}]_0) - \arctan (K_0^{1/2} [\text{THF}]_0) / (K_2^{1/2} [\text{AcCl}]_0) \right] \quad (4)$$

Equation (4) appears to be very complicated. All quantities are, however, known, the value of ⁴k_p being the only exception. The agreement of experimental results, represented by curves in Figure 4, with the interpretation according to equation (4) is apparent from Figure 7.

The rate of oligomerization becomes constant till high conversions when diethyl ether is present in the system (see Figure 3). The term $K_3 [\text{Et}_2\text{O}]^2$ in the denominator of equation (3) will outweigh other terms in most cases so that equation (4) assumes the form:

$$[\text{THF}]_0 - [\text{THF}] = [\text{TiCl}_4]_0 \left\{ \frac{[\text{EPC}]_0}{K_0 [\text{THF}]_0^2 + K_1 [\text{EPC}]_0^2 + K_3 [\text{Et}_2\text{O}]^2} \times [{}^3k_p K_1 K_4 [\text{THF}]_0 + {}^4k_p K_1 K_6 [\text{AcCl}]_0] t + [{}^5k_p K_2^{1/2} / ({}^3k_d K_3^{1/2} [\text{Et}_2\text{O}])] \times \left[\arctan \frac{K_3^{1/2} [\text{Et}_2\text{O}] (1 + [\text{AcCl}]_0^3 k_d t)}{K_2^{1/2} [\text{AcCl}]_0} - \arctan \frac{K_3^{1/2} [\text{Et}_2\text{O}]_0}{K_2^{1/2} [\text{AcCl}]_0} \right] \right\} \quad (5)$$

Figure 7 Dependence of $M_0 - M$ on F . $M_0 - M = ([\text{THF}]_0 + [\text{EPC}]_0) - ([\text{THF}] + [\text{EPC}])$. $F =$ right hand side of equation (4). The designation of point corresponds to Figure 1

The agreement between experimental data (Figure 3) and equation (5) is also satisfactory and is shown in Figure 8.

The analyses have revealed that more than 85% of the products were formed on ⁵Ac and ⁴Ac centres containing AcCl. The oligomerization on ⁴Ac centres is again visualized as a mutual substitution of ligands to which tetrahydrofuran is coordinated:

Another explanation accounting for the presence of products (II) and (VI) (see Table I) is offered by scheme (21) in a previous paper⁴.

The rearrangement of the complex following a relatively fast coordination of tetrahydrofuran is the rate controlling step of this reaction. The minimum reaction rate observed when changing the tetrahydrofuran–epichlorohydrin ratio (Figure 2) is due to the varying concentration of individual active centres with different rate controlling steps. The role of diethyl ether will probably lie in its ability to lower the equilibrium concentration of (⁵Ac) centres by displacing acetyl chloride from complexes. The lowering of concentration of centres whose activity is

diminishing or their complete elimination will direct the process to a kinetically stationary region. The termination of chain growth may be effected either by a detachment of the growing ligand (e.g. product (III) from Table I) or by coordination of the heterocycle or diethyl ether (or the product) to the Ti atom via oxygen. The rate constant of the rate controlling step of stationary oligomerization was determined on the basis of experimental data: ${}^4k_p = 0.04$ (sec^{-1}) at 293.1K.

It is practically impossible to meet the requirement of having only one variable when studying the behaviour of systems containing various amounts of the monomer. The quality of the medium is changing in those categories which are difficult to be assessed quantitatively (polarity, solvation ability, etc.). It is thus difficult to compare the values of k_p and k_d obtained at various concentration ratios of individual components. The dependence of k_p and k_d (obtained under a variety of conditions in this and previous works⁴) upon the reciprocal of dielectric constant indicates that such a comparison is feasible (Figure 9). It follows from the figures that: (a) the values of 4k_p and 5k_p are identical as to their magnitude and dependence on the dielectric constant; (b) the same as above will hold for 2k_d , 3k_d and 5k_d ; (c) the increasing dielectric constant causes the increase in k_p only in the case of epichlorohydrin oligomerization.

The rate of rearrangement of ⁵Ac and ⁴Ac during the oligomerization of tetrahydrofuran will be equal. Diethyl ether has no effect on the rate of disappearance of ²Ac during the epichlorohydrin oligomerization. In the polymerization of tetrahydrofuran, however, it acts as a strong retarder of centre disappearance.

CONCLUSION

The studied oligomerizations of tetrahydrofuran and epichlorohydrin are examples of coordinate polymerizations. It* seems that the different features in the reaction mech-

* In our opinion the active centre has its origin in the coordination of the monomer to activating ligands.

anism, when comparing with Ziegler–Natta anionic coordinate polymerizations³, may be accounted for by the basicity of donors (monomers). Strong donors, which act as catalyst poisons in Ziegler–Natta polymerization, may, in our case, participate in the formation of ligand sphere of the Ti atom. We believe that it is of no advantage to distinguish between ‘anionic’ and ‘cationic’ coordinate mechanism. This opinion is in agreement with conclusions of Italian authors who examined the Ziegler–Natta polymerization⁵.

According to our notions the coordinate polymerizations belong to an independent class of polymerizations comparable e.g. with the class of radical polymerizations.

Influence of intrachain double bonds on the properties of solution grown single crystals of polyethylene

C. Mancarella, E. Martuscelli and M. Pracella

Laboratorio di Ricerche su Tecnologia dei Polimeri e Reologia, CNR, 80072 Arco Felice (Napoli), Italy
(Received 1 December 1975)

The influence of intrachain *trans* double bonds, statistically distributed along a polyethylene chain, on the structure and behaviour of chain-folded single crystals has been studied. The dependence upon the percentage of double bonds of dissolution and thermal properties, external crystal habit, X-ray diffraction in the wide- and low-angle regions, of solution grown single crystals of ethylene-butadiene copolymers may be interpreted by assuming that a certain amount of $-\text{CH}_2-\text{CH}=\text{CH}-\text{CH}_2-$ units are incorporated in the lattice as defects. The results of the bromination of single crystals of a sample of ethylene-butadiene copolymers show that about the 56% of double bonds, not accessible to bromine, are situated not on the fold surface but in the inner part of the crystals.

INTRODUCTION

The effect of chemical groups statistically spaced along a polymer chain is of considerable interest. The properties of linear polyethylene may be drastically changed by introducing along the chain a small amount of units with different chemical structure. Modifications may be carried out through various chemical reactions of which chlorination and chlorosulphonation are of technological importance because the derivatives constitute a series of thermoplastic and elastomeric materials¹.

Foreign units may also be introduced along the chain of polyethylene by means of reaction of copolymerization. The properties of copolymers, obtained by reaction of ethylene and α -olefins and ethylene and carbon monoxide have been extensively studied by the authors². In a previous paper³ the effect of intrachain double bonds on the crystallization of polyethylene from the melt was investigated. *Trans* double bonds were statistically introduced in the chain of polyethylene by means of a reaction of copolymerization of ethylene and butadiene⁴. We focused our attention on copolymers with low butadiene/ethylene ratios since they can have very important technological applications different from those of linear polyethylene.

In the present paper we are mainly interested in investigating the influence of the concentration of *trans* double bonds on the crystallization of polyethylene from dilute solution; therefore the morphology, the structure, the melt properties and the bromination of solution grown single crystals of ethylene-butadiene copolymers have been examined.

EXPERIMENTAL

Materials

The experiments reported here were carried out on unfractionated samples of random ethylene-butadiene copolymers (1,4-enchainment) and of linear polyethylene (Vestolen 6013 and Marlex 6009).

The copolymers were synthesized in the laboratories of Eni-Snam Progetti, Milano (Italy) by using vanadium based catalysts. This process of polymerization leads to

samples of copolymers with a rather sharp distribution of molecular weight⁴.

The composition of the polymer samples, determined by i.r. and some melt rheological properties related to the molecular weight and to their distribution are reported in Table 1. Vestolen and ethylene-butadiene copolymers are comparable in both distribution and average molecular weight whereas Marlex has a higher average molecular weight. The presence of an appreciable number of butadiene units in *cis* configuration, in the chains of copolymers, is excluded by i.r. analysis.

Solution grown single crystals

Single crystals of linear polyethylene and of ethylene-butadiene copolymers were isothermally grown from 0.08% w/w xylene solutions. Crystallization temperatures T_c of 75°, 80° and 85°C were used. The self-seeding technique⁵ was applied throughout. The crystallization conditions used are summarized in Table 2, where precrystallization, T_{pc} , apparent dissolution T_d and seeding temperatures T_s are indicated together with the crystallization temperature T_c . For all preparations the same rate of heating to T_s and the same time of dissolution at T_s of 15 min were used. The external habit of single crystals was examined by means of a Philips EM 300 transmission electron microscope. Low-angle X-ray diffraction patterns of dried orien-

Figure 1 A, Dissolution temperature calculated according to the Flory equation (see text); B, variation of the apparent dissolution temperature of single crystals of polyethylene and of ethylene-butadiene copolymers as function of the composition

ted mats of single crystals were recorded by using a pinhole collimated Rigaku-Denki camera. The X-ray diffractions patterns, in the wide-angle region, were recorded by means of a Philips 1050/25 diffractometer using the Cu α radiation.

The density of single crystals was measured by flotation at 29 $^{\circ}$ C. Melting temperature and apparent enthalpy of fusion were determined with a Perkin-Elmer DSC-2 by using standard methods².

Bromination of single crystals

Crystals suspended in xylene were exchanged by 10 or 11 washes into CCl₄. The addition of bromine to the double bonds of sample EB4 of ethylene-butadiene copolymers was accomplished by adding 2 ml of a solution of bromine (in CCl₄, 1% by volume) to a suspension of single crystals (containing about 100 mg of polymer in 200 ml of CCl₄). The reaction proceeded in the dark at 0 $^{\circ}$ C. Time zero was taken as the instant of mixing, and samples (50 ml) were taken at appropriate intervals of time. The samples were rapidly filtered and the brominated single crystals were washed with distilled acetone to remove any traces of free bromine. The percentage of double bonds brominated was determined by i.r. absorption using a Perkin-Elmer 257 spectrophotometer.

RESULTS AND DISCUSSION

Dissolution and morphology of single crystals

The apparent dissolution temperature, T_D , of single crystals of ethylene-butadiene copolymers, defined as the clearing point of suspensions, is reported in Figure 1, where B is plotted against % butadiene. The same precrystallization temperature of 60 $^{\circ}$ C in dilute xylene and the same concentration were used for all samples. As shown in Figure 1, by increasing the butadiene content in the chains, crystals with markedly lower stability are obtained.

According to the theory of Flory⁶ the dependence of T_D on the concentration of crystallizable units in a random copolymer is given by:

$$\frac{1}{T_D} - \frac{1}{T_D^0} = -\frac{R}{\Delta H_F} \ln N \quad (1)$$

In equation (1) T_D^0 is the dissolution temperature of the pure homopolymer, N the mole fraction of crystallizable units and ΔH_F the melting enthalpy per mole of the homopolymer repeating unit. Equation (1) can be used for elucidating the dissolution temperature depression of single crystals of ethylene-butadiene copolymers. The value of T_D^0 theoretically calculated by equation (1), assuming for T_D^0 the experimental value of 98.5 $^{\circ}$ C and $\Delta H_F = 970$ cal/mol CH₂⁷, are higher than the values experimentally measured; their variation with % butadiene is shown in Figure 1, curve A. A plot of $1/T_D$ versus $-\log N$ is given in Figure 2. In our case N is the mole fraction of ethylene units. It is seen that the points for the copolymers lay fairly well on a

Figure 2 Reciprocal apparent dissolution temperature versus $-\log N$ (N = mol fraction of crystallizable units for ethylene-butadiene copolymers)

(a) Sample EB1, $\Delta T_s = 1^\circ\text{C}$; (b) EB1, $\Delta T_s = 3^\circ\text{C}$; (c) EB2, $\Delta T_s = 1^\circ\text{C}$; (d) EB2, $\Delta T_s = 3^\circ\text{C}$; (e) EB4, $\Delta T_s = 1^\circ\text{C}$; (f) EB4, $\Delta T_s = 3^\circ\text{C}$

line. The extrapolation to $-\log N = 0$ gives for T_D^0 a value of 96.5°C while the experimental value measured for Marlex and Vestolen is 98.5°C .

These results are an indication that the crystal lattice of ethylene-butadiene copolymers is somehow different from that of linear polyethylene. The difference is likely to be due to the incorporation of $-\text{CH}_2-\text{CH}=\text{CH}-\text{CH}_2-$ units in the lattice of polyethylene as defects.

In Figures 3, 4 and 5 electron micrographs of single crystals of polyethylene and ethylene-butadiene copolymers, grown at various crystallization conditions, are shown.

The crystals in all cases are truncated lozenges similar in shape to that of linear polyethylene. For the same crystallization temperature, seeding temperature and composition they result uniform in size indicating that the self-

seeding technique applies to ethylene-butadiene copolymers as well.

A slightly larger tendency to form terraced overgrowth is observed in the case of single crystals of the copolymers with higher butadiene content. The external crystal habit of truncated lozenges may be described by the quantities D , d , t , D_1 and α , defined in Figure 6 and by the thickness L of the lamellae as measured by low-angle X-ray diffraction analysis.

For a given butadiene concentration the dimensions of the crystals increases continuously increasing the seeding temperature T_s . The trend is shown in Figures 7 and 8 where the quantities $\log D$ and $\log D_1$ are plotted against $\Delta T_s = (T_s - T_D)$. It can be seen that increasing the seeding temperature $\log D$ and $\log D_1$ increases with an almost linear trend. The rate of variation as measured by the

Figure 5 Single crystals of ethylene-butadiene copolymers grown at 85°C from xylene (Electron micrographs). (a) Sample EB1, $\Delta T_s = 3^\circ\text{C}$; (b) EB2, $\Delta T_s = 3^\circ\text{C}$

Figure 6 Diagrammatic plan of a pyramidal crystal of polyethylene indicating the various sectors. The quantities D , D_1 , d , r , α , are also specified

slopes of the curves of Figures 7 and 8 is plotted versus the composition of the samples in Figure 9. The points lay on the same curve. A drastic reduction in the values of the rates $d[\log D, (D_1)]/d(\Delta T_s)$ with increasing amounts of double bonds in the chain of polyethylene is observed.

As shown in Figure 10, for single crystals of ethylene-butadiene copolymers, the values of D , measured under the same ΔT_s , and at $T_c = 80^\circ\text{C}$ monotonically decrease with % butadiene.

The effect seems to be more drastic at higher values of ΔT_s . The values of D of single crystals of linear polyethylene (Marlex and Vestolen) are also reported in Figure 10. They lay outside the curves of the copolymer points. For $\Delta T_s = 1^\circ$ and 3°C the values of D for single crystals of Marlex and Vestolen are lower than that of single crystals of samples EB1, EB2, EB3 and EB4.

Assuming that the mass of polymer crystallized at T_c is the same, we have to conclude that in the series of samples of ethylene-butadiene copolymers increasing % butadiene under the same T_{pc} , T_c , T_s and c , a larger number of nuclei are present in solution. Overgrowing effects observed on some of the single crystals with a larger concentration of butadiene units and differences in the lamellar

Figure 10 The dimensions of the crystals measured by D versus the composition of the polymer. The comparison is made under the same value of ΔT_s and at $T_c = 80^\circ\text{C}$. Marlex and Vestolen points are practically coincident. A, $\Delta T_s = 5$; B, $\Delta T_s = 4$; C, $\Delta T_s = 3$; D, $\Delta T_s = 1^\circ\text{C}$

thickness (see below) have to be taken also into consideration.

The effect of the crystallization temperature on D is shown in Figure 11 where D is plotted as function of the composition for $T_c = 85^\circ, 80^\circ$ and 75°C , at $\Delta T_s = 3^\circ\text{C}$.

The trend of the curves is the same. A slight increase in D with T_c is observed. The values of ΔT_s for growing single crystals of ethylene-butadiene copolymers with the same dimension D were found to increase linearly with increasing amounts of unsaturations. The extrapolation of these lines (see Figure 12) gives for the pure homopolymer values of ΔT_s close to zero whereas the experimental values are about 3°C .

As shown in Table 3 the values of $\tan \alpha$, measured on single crystals of polyethylene and of ethylene-butadiene copolymers, increase with the percentage of unsaturations in the chain. For Marlex we found for $\tan \alpha$ a value of 1.54 (crystallographic value 1.485) and for EB4, 1.68. This result is probably related to an expansion of the unit cell caused by the inclusion of some $-\text{CH}_2-\text{CH}=\text{CH}-\text{CH}_2-$ units as defects. This conclusion is in agreement with the

Figure 11 D versus the composition of the polymer at different crystallization temperature and for $\Delta T_s = 3^\circ\text{C}$. A, $T_c = 85$; B, $T_c = 80$; C, $T_c = 75^\circ\text{C}$

Figure 12 Dependence of ΔT_s upon the composition of the polymer to grow crystals with the same values of D . \blacksquare , $D = 6$; \square , $D = 4$

Table 3 Values of $\tan \alpha$ and of the truncation ratio for single crystals of polyethylene and ethylene-butadiene copolymers ($T_c = 80^\circ\text{C}$)

Sample	$\tan \alpha$	Truncation ratio, t
Marlex 6009	1.54 (± 0.04)	0.23 (± 0.02)
EB1	1.58	0.20
EB2	1.64	0.21
EB3	1.65	0.205
EB4	1.68	0.21

finding that, an increase of about 1% in the spacing of (200) and (110) wide-angle X-ray reflections had been found in the case of bulk EB4 copolymer.

From literature data⁸ it is well known that for single crystals of linear polyethylene the size of {100} sectors and the outline shape depends on the crystallization conditions, the sectors being more pronounced for higher polymer concentration and lower undercooling.

The truncation ratios of single crystals of ethylene-butadiene copolymers, crystallized at 80°C , range from 0.20 to 0.21 and are lower than that of linear polyethylene (0.23 for Marlex and 0.25 for Vestolen) crystallized under the same conditions and therefore at larger undercooling. The values of t are reported in *Table 3*. This last result is in contrast with the quoted literature data⁸ and seems to indicate that the chemical structure of the polymer and not only the undercooling affect the value of t . It is likely that in the case of copolymers the mobility of the chain in solution, increased by the presence of the double bonds along the chain⁹, is responsible for this behaviour, partly at least. This should indicate that the truncation phenomenon in single crystals of polyethylene cannot be simply interpreted on a crystallographic basis but perhaps better on a thermodynamics basis. The same conclusions were also reached by Pedemonte and others¹⁰ starting from different and independent observations.

Melt properties and bromination of single crystals

Density, melting temperature and apparent enthalpy of fusion of single crystals aggregates of polyethylene and ethylene-butadiene copolymers grown at 80°C are reported in *Table 4* together with the lamellar thickness measured by X-ray low-angle diffraction.

Melting temperatures of single crystals of copolymers range from 125° to 127°C and are lower than that of linear polyethylene 129.5°C . No systematic variation in the values of density and apparent enthalpy of fusion of single crystals are observed.

A significative and continuous increase with the percentage of unsaturation is found in the values of the long

spacing L . In fact, for linear polyethylene $L = 110 \text{ \AA}$ while for sample EB4 $L = 131 \text{ \AA}$. This result is in agreement with the findings of Martuscelli and others¹¹ that, under the same crystallization conditions, thicker crystals are obtained when polymers having a larger concentration of chain defects along the chains are allowed to crystallize from dilute solutions. The bromination of single crystals of sample EB4 of ethylene-butadiene copolymers was followed qualitatively and quantitatively by i.r. analysis in the wavelength region of 625 to 4000 cm^{-1} . *Figure 13* shows the intensity of the i.r. 970 cm^{-1} band, normalized with respect to the 735 cm^{-1} (*Figure 13a*) and 1475 cm^{-1} (*Figure 13b*) $-\text{CH}_2-$ bands, as function of the time of reaction. It can be seen that the absorbance due to the double bonds first drops very rapidly then a steady state is reached indicating that the reaction is terminated.

The percentage of double bonds accessible to bromine, on the fold surface of the crystals, calculated from the decay in the i.r. absorbance is about 44%.

These results are convincing evidence that a certain amount of double bonds is situated, in the core of the crystals in agreement with the findings and the experimental results reported above in the present paper.

CONCLUSIONS

The analysis of the solution properties and of some important morphological parameters shows that single crystals of ethylene-butadiene copolymers and of linear polyethylene have a different behaviour. Further a certain number of double bonds are incorporated in the crystal lattice as defects.

In the case of EB4 copolymer about 56% of double

bonds are not accessible to bromine. This should indicate that during crystallization from dilute solution a larger part of double bonds are not rejected from the crystal lattice. The decrease in the rate of crystallization and the drastic increase in the value of the free energy of formation of a nucleus of critical dimensions with increasing number of double bonds, observed when the samples of ethylene-butadiene copolymers are allowed to crystallize isothermally from the melt³, together with the different behaviour of single crystals and of their solution properties as reported in the present paper may be related to the following observations:

(a) The mobility of the chain is increased by the presence of double bonds because of the lower energy barrier that hinders the rotation around the single C-C bonds adjacent to the C=C groups⁹.

(b) The crystalline lattice of crystals of ethylene-butadiene copolymers is perturbed by the inclusions of double bond as reticular defects.

Monomer sequence distribution in butene/propylene copolymers by ^{13}C nuclear magnetic resonance

A. Bunn and M. E. A. Cudby

*ICI Plastics Division, Welwyn Garden City, Hertfordshire, UK
(Received 27 January 1976)*

We wish to report the determination of monomer sequence distribution in butene/propylene copolymers by ^{13}C nuclear magnetic resonance (^{13}C n.m.r.). This is an established technique for the measurement of stereoregularity in homopolymers¹⁻¹⁰ and the measurement of sequence distributions in copolymers¹¹⁻²¹. However, to our knowledge, the only reports of ^{13}C n.m.r. measurements of α -olefin copolymers concern the systems ethylene/ α -olefin¹⁵ and propylene/ethylene¹⁶⁻¹⁸. The proton magnetic resonances in polyolefins are severely overlapped and this limits the structural information obtainable. As the resonances in the ^{13}C n.m.r. spectra of polyolefins occur over a range of about 40 ppm we expect this technique to produce more information than proton magnetic resonance. This is indeed the situation for polypropylene⁵⁻⁷, polyethylene^{15,22,24} and propylene/ethylene copolymers¹⁶⁻¹⁸. Calculated chemical shifts from Lindeman and Adams data²³ predict that the ^{13}C n.m.r. chemical shifts in butene/propylene copolymers would be sensitive to monomer sequence distribution. In this Note, we report ^{13}C n.m.r. data on butene/propylene copolymers including random and block distributions and a copolymer which has a mixture of block and random distributions. The observed resonances are assigned to dyad, triad and tetrad monomer sequences.

The natural abundance ^{13}C n.m.r. spectra of polypropylene, polybutene and butene/propylene copolymers were measured in *o*-dichlorobenzene solution at 140°C. The 25.2 MHz spectra were recorded on a Varian XL100-15 spectrometer equipped with a proton-noise decoupler and a standard VFT-100X Fourier transform system. A 2 sec acquisition time and a 90 μsec pulse width (tip angle $\sim 70^\circ$) were used to acquire data. Field-frequency stabilization was provided by D_6 -dimethyl sulphoxide contained in a 5 mm o.d. n.m.r. tube held centrally in a 12 mm o.d. tube which contained the copolymer solution.

Figure 1 shows ^{13}C n.m.r. spectra of polybutene and polypropylene. The assignments of the resonances are also shown on the Figure. Those for polypropylene are known and those for polybutene were determined from predicted values (Lindeman and Adams data) and an off-resonance experiment. Our own work on poly(α -olefins) higher than polybutene shows that backbone methine and methylene carbon resonances are the most sensitive to tacticity changes and that in the spectra of non-isotactic polymers these resonances are broader than the remaining resonances. As the resonances in the ^{13}C n.m.r. spectra of butene/propylene copolymers examined were equally sharp and in co-

polymers with long propylene sequences the propylene α -methyl carbon resonance was a singlet and had a chemical shift the same as that found in isotactic polypropylene we feel justified in making the assumption that only a meso addition of either monomer to the polymer chain is made.

Copolymers prepared with a wide range of composition and with differing monomer sequence distributions were examined. Representative spectra of the materials are shown in Figures 2 and 3. The resonances in the ^{13}C n.m.r. spectra of these copolymers were assigned by reference to the spectra of the homopolymers, predicted values from Lindeman and Adams's data²³ and by checking that the relative intensities of the resonances were self consistent. Table 1 lists the chemical shift data of the ^{13}C n.m.r. spectra of these copolymers, our proposed assignments and the monomer sequences characterized by each resonance. The letters P and B denote propylene and butene units with any two forming a meso dyad. Thus a PPB triad would contain a

Figure 1 ^{13}C n.m.r. spectra of (a) polybutene (b) polypropylene

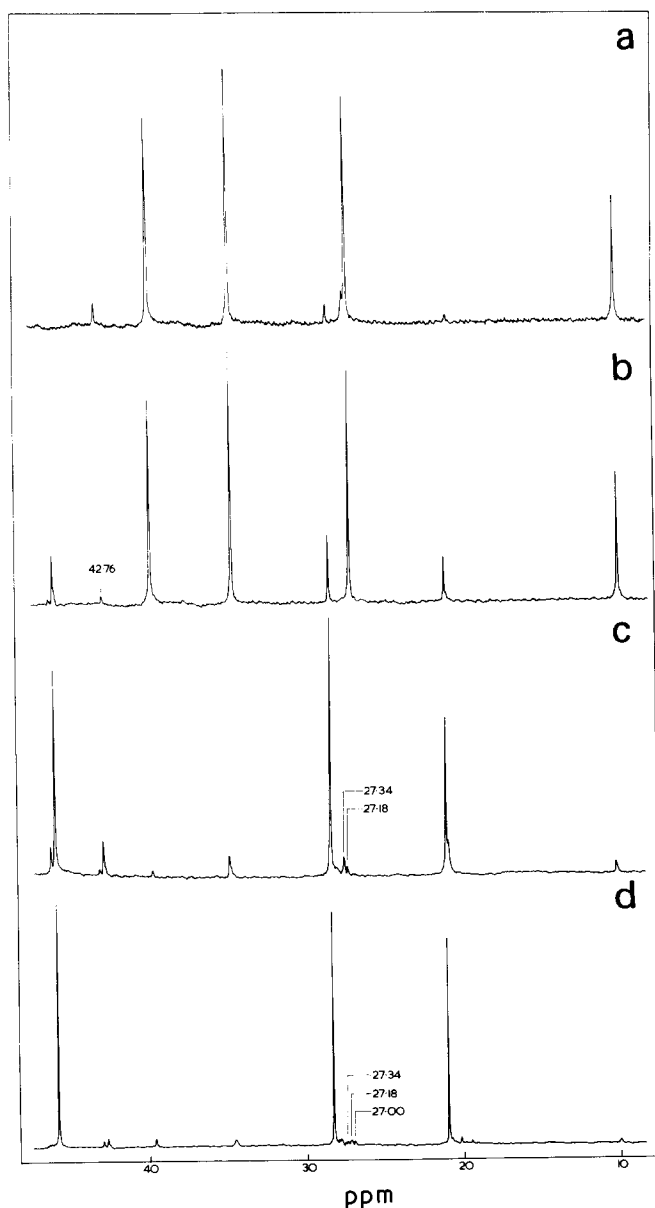

Figure 2 ^{13}C n.m.r. spectra of butene/propylene copolymers (a) 10 molar % propylene as isolated units; (b) 10 molar % propylene as propylene blocks; (c) 10 molar % butene as random copolymer; (d) 10 molar % butene with some butene blocks

PP and a PB meso dyad:

Figures 2a–2d show ^{13}C n.m.r. spectra of four copolymers denoted by A–D. Copolymer A is rich in butene and contains isolated propylene units only i.e. BPB. In contrast, copolymer B, although approximately the same overall composition as copolymer A, contains long propylene sequences. The few interchange units give rise to a resonance at 42.76 ppm from the backbone methylene carbon atom. Copolymers C and D are propylene rich and contain approximately 10 molar % butene. Copolymer C has the majority of butene units adjacent to propylene units, i.e. PBP, with the required number of adjacent butene units as is appropriate to a random monomer distribution²⁵. For copolymer D, the relative intensities of the methylene carbon reso-

nances characteristic of PP, PB and BB dyads show that there are more adjacent butene units than would be predicted for a random copolymer. The presence of three or more adjacent butene units in the copolymer chain is responsible for the 27.00 ppm resonance. The branch-methylene group carbon resonances at 27.00 ppm, 27.18 and 27.34 ppm are characteristic of BBB, BBP and PBP sequences and indicate the blockiness or otherwise of the butene units.

Figures 3a–3c show spectra of copolymers E to G. These copolymers contain roughly equal amounts of butene and propylene, E and F have spectra with resonance intensities which show that the copolymers are fairly random. The intensities of the resonances in the spectrum of copolymer G (Figure 3c) show that the copolymer does not have a random monomer distribution; this is expected, as its method of preparation would produce long sequence of adjacent propylene units. Features to note in the spectra shown in Figures 3a–3c are the resonances at 27.00 ppm, 27.18 ppm and 27.34 ppm which are characteristic of the three possible butene centred triads, and the three propylene methyl group carbon resonances around 20.7 ppm which are characteristic of the propylene centred triads i.e. PPP, PPB and BPB at 20.96 ppm, 20.74 ppm and 20.60 ppm respectively.

Tetrad sequences for propylene/propylene centred units, BPPB, PPPB, PPPP are observed from the backbone methylene carbon resonances at 45.86, 46.10 and 46.40 ppm respectively. The lack of structure on the methine carbon resonances of both butene and propylene units is somewhat surprising, especially as the butene methyl group carbon

Figure 3 ^{13}C n.m.r. spectra of butene/propylene copolymers with approximately equal amounts of propylene and butene. Copolymer G (Figure 3c) contains blocks of propylene together with random material

Note to the Editor

Table 1 Chemical shift data of the ^{13}C n.m.r. spectra of the copolymers examined

Chemical shift from tetramethylsilane (ppm)	Assignment, carbon marked with *	Polymer sequences characterized
9.92	*CH ₃ -CH ₂ -CH	BBB, BBP, PBP
20.60	*CH ₃ -CH	BPB
20.74	*CH ₃ -CH	BPP
20.96	*CH ₃ -CH	PPP
27.00	CH ₃ -*CH ₂ -CH	BBB
27.18	CH ₃ -*CH ₂ -CH	BBP
27.34	CH ₃ -*CH ₂ -CH	PBP
28.29	CH ₃ -*CH	PPP, PPB, BPB
34.47	CH ₃ -CH ₂ -*CH	BBB, BBP, PBP
39.64	-CH-*CH ₂ -CH Et Et	BBBB, BBBP, PBBP
42.76	-CH ₂ -CH-*CH ₂ -CH Et Me	PBPP
43.04	-CH ₂ -CH-*CH-CH Et Me	BBPB, BBPP and probably also PBPB
45.86	-CH-*CH ₂ -CH Me Me	PPPP
46.10	-CH-*CH ₂ -CH- Me Me	PPPB
46.40	-CH-*CH ₂ -CH- Me Me	BPPB

resonances show well defined shoulders in some of the spectra. These facts indicate to us that the origin of the chemical shift observed on the butene methyl group carbon is not a through bond effect.

In conclusion, the above data show that ^{13}C n.m.r. spectroscopy can be used to characterize butene/propylene copolymers in terms of dyad and triad sequences. Well resolved resonances were also observed for propylene/propylene centred tetrads.

Note to the Editor

Table 1 Chemical shift data of the ^{13}C n.m.r. spectra of the copolymers examined

Chemical shift from tetramethylsilane (ppm)	Assignment, carbon marked with *	Polymer sequences characterized
9.92	*CH ₃ -CH ₂ -CH	BBB, BBP, PBP
20.60	*CH ₃ -CH	BPB
20.74	*CH ₃ -CH	BPP
20.96	*CH ₃ -CH	PPP
27.00	CH ₃ -*CH ₂ -CH	BBB
27.18	CH ₃ -*CH ₂ -CH	BBP
27.34	CH ₃ -*CH ₂ -CH	PBP
28.29	CH ₃ -*CH	PPP, PPB, BPB
34.47	CH ₃ -CH ₂ -*CH	BBB, BBP, PBP
39.64	-CH-*CH ₂ -CH Et Et	BBBB, BBBP, PBBP
42.76	-CH ₂ -CH-*CH ₂ -CH Et Me	PBPP
43.04	-CH ₂ -CH-*CH-CH Et Me	BBPB, BBPP and probably also PBPB
45.86	-CH-*CH ₂ -CH Me Me	PPPP
46.10	-CH-*CH ₂ -CH- Me Me	PPPB
46.40	-CH-*CH ₂ -CH- Me Me	BPPB

resonances show well defined shoulders in some of the spectra. These facts indicate to us that the origin of the chemical shift observed on the butene methyl group carbon is not a through bond effect.

In conclusion, the above data show that ^{13}C n.m.r. spectroscopy can be used to characterize butene/propylene copolymers in terms of dyad and triad sequences. Well resolved resonances were also observed for propylene/propylene centred tetrads.

Multiple endotherms in polyepichlorohydrin

Multiple endotherms have been reported in the literature for several polymers, e.g. polyesters^{1,2}, polyethylenes (linear³, branched⁴, and extended chain⁵), isotactic polystyrene⁶, polytetrafluoroethylene⁷ and natural rubber⁸. However comparatively few investigations of multiple melting behaviour in multicomponent systems have been reported^{9,10}. This is understandable since the question of multiple melting in homopolymers itself has presented many problems in interpretation. We wish to report some preliminary investigations on multiple melting in polyepichlorohydrin (PECH) homopolymer and multicomponent systems containing crystalline PECH.

Crystalline PECH homopolymer was prepared in the laboratory according to the method of Hsieh¹¹ with a few minor changes in experimental procedure¹². Samples of homopolymer thus prepared ($T_g = -20^\circ\text{C}$, $T_m = +107^\circ\text{C}$) were heated to 200°C and kept for 10 min at this temperature to destroy previous morphology. They were then taken out of the heating chamber, the d.s.c. cell of a Du Pont 900 Thermal Analyzer, cooled to room temperature (i.e. quench cooled), allowed to crystallize for one day at room temperature and scanned in the Du Pont 900 Analyser at $30^\circ\text{C}/\text{min}$. A typical trace is shown in *Figure 1*. Two distinctly separate endotherms are noticeable. One of these with a melting peak at about 40°C was separated from the other which had a maximum peak at 100°C . This latter endotherm always showed a minor endotherm at 70°C and in addition in some batches a well-defined endotherm appeared at 90°C . (The endotherms will be designated by peak temperatures.) Experimental investigations of 70° , 90° and 100°C endotherms involving manipulation of an-

Figure 1 D.t.a. trace of crystalline polyepichlorohydrin showing multiple endotherm

nealing and rates of heating on the lines of Bell^{1,13} and Roberts¹⁴ showed that the three endotherms were not interdependent i.e. the higher melting endotherms were not formed by melting and recrystallization of lower melting endotherms during d.t.a. scanning. The following observations on the 90°C endotherm were noted. The 90°C endotherm was detected only in batches of PECH prepared under conditions such that there was initial fast polymerization¹². Batches thus prepared had to be melted in a two-roll mill and crystallized from the melt for the 90°C endotherm to be recorded. Unmilled samples crystallized from the melt or milled samples not crystallized from the melt failed to show the 90°C endotherm. Within the limits of experimental and sampling error ($\pm 10\%$) the total area (enclosed by the broken base line in *Figure 1*) of samples in which the 90°C endotherm was resolved was equal to areas of samples which failed to record this endotherm.

Crystalline PECH possessed elastomeric properties and hence multicomponent systems could be prepared by two-roll milling with other commercially available elastomers and fillers. Batches of PECH possessing the 90°C endotherm were milled with reinforcing (ISAF black, Vulcan 6—Cabot) and inert (clay, whiting) fillers. In all cases the area of the 90°C endotherm decreased with increasing filler content although the total area essentially remained constant equal to that of the unfilled homopolymer.

The effect of blending a second elastomer, without filler, on the 90°C endotherm depended on the nature of the second elastomer. Thus when natural rubber, amorphous PECH (Herclor H, Hercules) and propylene oxide rubber (Parel 58, Hercules) were used for blending, the 90°C endotherms and total areas were somewhat reduced when compared with crystalline PECH batches used but remained constant over a wide range of composition. However when more polar rubbers were used for blending, the 90°C endotherm was not recorded at the 1:1 (by weight) composition; chlorosulphonated polyethylene, nitrile and acrylic rubbers belonged to this group and blending was presumably accompanied by a very large reduction of total crystallinity.

In the case of unfilled blends, retention of the 90°C endotherm would indicate poor miscibility and compatibility as in the cases of natural rubber and the cyclic ether rubbers; disappearance of the endotherm in the blends with more polar rubbers would imply better dispersion and compatibility.

Our investigations show that observations of multiple melting in multicomponent systems could prove to be a useful diagnostic tool in the interpretation of multiple melting in homopolymer and compatibility effects in blends. Two difficulties which stand in the way of a quantitative approach need mention. One concerns difficulties in estimation of d.t.a. areas of individual endotherms; the other concerns sampling variations due to the nature of the small amount of material used in dynamic calorimetric methods.

Book Reviews

Advances in Polymer Science

Volume 17: Polymerization

Springer-Verlag, Berlin, 1975, 103 pp. \$23.00

This volume in the series covers mechano-chemical initiation of copolymerization and the polymerization of thioaldehydes, thioketones and related compounds. It would be difficult to find two more widely different facets of polymer science. The first contribution, by Casale and Porter, includes processes of commercial importance whilst the second, by Sharkey, has yet to find industrial usage. Mechano-chemistry, as the authors ably illustrate, is applicable to an extremely wide range of polymer-monomer systems which can be activated by an extensive choice of 'bond-breaking' processes. On the one hand, the coextrusion of two viscoelastic polymers can lead to high yields of block copolymers having properties differing from simple blends, whilst on the other hand, esoteric materials can be synthesized for laboratory evaluation by vibromilling or even simple solvent swelling techniques. All reported aspects of mechano-chemical reactions leading to block and graft copolymerization are discussed in depth and there are extensive references to original publications.

The synthesis of polymers by polymerization through the carbon-sulphur double bond is a very specialized field which is treated in depth by Sharkey in this book with more extensive reference to recent publications, in particular the patent literature, than the mechano-chemical section. By virtue of its specialized nature, the latter section will have a rather limited interest more or less con-

finied to production and research personnel directly involved with condensation polymerization and ring opening reactions. The first section, because of its more general nature, will appeal to practically everyone involved in the research, development, production and application of copolymers at all levels.

Apart from some missing 'free radicals' on pages 9 and 22 and a pentavalent carbon atom on page 30, the book is relatively free of typographical errors. At \$23.00 it is expensive for approximately a hundred pages but it does give a thorough review of two topics for which much of the available data is published in languages other than English. The contribution by A. Cassale, R. H. Porter and W. H. Starkey maintains the high standard which we expect from this series and it will, therefore, take its rightful place in polymer libraries throughout the world.

Reinforced Thermoplastics

W. V. Titow and B. J. Latham

Applied Science, Barking, 1975, 294 pp. £10

'Reinforced Thermoplastics' is the first book to be published on this subject and its contents well meet the aim of its authors, which is 'to present a reasonably unified account of the technology and properties' of this class of plastics materials.

The description which the book provides is essentially technological in nature but it touches on some commercial problems. Thus, it ranges from a very useful list of commercially available reinforced thermoplastics and their producers, through a discussion of their principal applications to methods of processing and to material properties and there is also an appendix devoted to relevant patents.

The book is self-contained in that it includes a description of the polymeric materials which form the basis of reinforced thermoplastics and of their properties as well as that of fibrous and particulate fillers before dealing with the two in combination. The properties of reinforced thermoplastics are dealt with primarily in terms of short term data but the importance of long term behaviour is clearly recognised. In view of the inevitable lapse of time between the completion of a manuscript and publication, the discussion of properties does not include the results of research published during the past year or two. However, it is surprising to find virtually no mention of anisotropy, even though the authors have not attempted to deal in depth with what might be termed the more scientific aspects of reinforced thermoplastics, as they clearly state in the Preface. Nevertheless, their book should be of considerable interest and of value to anyone concerned with reinforced thermoplastics.

Conference Announcement

Structure and Uses of Biopolymers

Cleveland, Ohio, USA, 11-16 October 1976

The first Cleveland Symposium on Macromolecules will be held during the week of October 11-16th, 1976 with the topic of Structure and uses of biopolymers. The week-long conference will be organized around fifteen invited international presentations in three areas: fundamental structure of biopolymers; materials properties; and medical applications, and will involve local social functions. Contributions of short papers to be presented at the meeting in the above areas are solicited. Prospective contributors, attendees and interested persons should write for further information to: Professor Alan G. Walton, Department of Macromolecular Science, Case Western Reserve University, Cleveland, Ohio 44106, USA.

Interesterification of starch with methyl palmitate

M. L. Rooney

CSIRO, Division of Food Research, Food Research Laboratory, North Ryde, New South Wales, Australia

(Received 19 December 1975)

Thermoplastic polymers derived from natural products have been prepared by interesterifying starch with methyl palmitate. The degree of substitution (*DS*) of the esters has been found to be strongly dependent upon catalyst concentration and the ratio of methyl palmitate to starch, but is largely independent of temperature and starch concentration over the range studied. Replacement of methyl palmitate with methyl esters of shorter chain acids does not appear to affect the *DS*. These observations are interpreted from the results of studies on the effect of *DS* on the solubility parameter, the nature of the interchain bonding and the specific gravity of the polymers.

INTRODUCTION

Most polymers isolated from natural products and subsequently modified retain the hydrophilic characteristic of the base polymer, whereas polysaccharide esters of long chain fatty acids have been shown to be more hydrophobic^{1,2}. Recently several authors have proposed uses for such esters. Amylose esters of a variety of fatty acids have some properties sought in dip coatings for foods², while starch esters can be used as reactive bases for polyurethane resins³ or as an artificial skin⁴. Starch esters may ultimately prove useful as low cost resins and replace some of those currently derived from petroleum.

Fatty acid esters of starch are usually prepared in the laboratory using the acid chloride-pyridine method⁵. However, this method is of little commercial value because of the cost of acid chlorides⁶. Direct esterification using the acid gives unsatisfactory yields while the anhydrides are not readily available. Interesterification has been used extensively in the preparation of biodegradable detergents from sucrose and fatty acid methyl esters⁶⁻⁸. Latetin *et al.*⁹ reacted cellulose heterogeneously with methyl stearate in dimethylformamide to a maximum degree of substitution (*DS*) of 0.38 compared with a theoretical maximum of 3. The interesterification of starch with the methyl esters of higher fatty acids has not been reported, although it is of particular interest since starch, unlike cellulose, is soluble in such solvents as dimethylsulphoxide (DMSO).

The present work was undertaken to determine the conditions under which starch could be interesterified with the methyl esters of long chain fatty acids, and to obtain data indicating the *DS* at which useful properties might be obtained. These studies include an examination of the effects of temperature, the concentrations of starch, methyl palmitate and potassium methoxide as well as the chain length of the fatty acid, on the *DS* of the resultant esters. The effects of *DS* on the specific gravity, solubility parameter and infra-red spectra of each of the esters were also determined.

EXPERIMENTAL

Materials

Wheat starch (Fielders Ltd, Sydney) was defatted and dried to a moisture content of 2.1%. The methyl esters

of palmitic, lauric and octanoic acids were greater than 98% pure and had water and free fatty acid contents less than 0.05%. Methyl n-butanoate had water and free fatty acid contents of 0.38% and 0.17% respectively. Methanolic potassium methoxide solution, 1.5 M, was used as a catalyst. Dimethylsulphoxide (Ajax Chemicals, Sydney) was dried by vacuum evaporation of 15% of its volume¹⁰.

Interesterification

The method of interesterification was similar to that used with sucrose⁷, although the starch and methyl ester solutions (dried to less than 0.02% water) were not mixed until the catalyst had been added to the starch solution and the methanol removed. The reaction was allowed to continue for 6 h after which the starch ester was precipitated with aqueous ethanol, extracted for 3 days both with boiling water and ethanol and then dried under vacuum at 80°C for 6 h.

Analyses

Water analyses were carried out using Karl Fischer reagent. Acyl contents of starch esters of palmitic and lauric acids were determined using the method of Berni *et al.*¹¹ for cellulose esters, except that after 48 h hydrolysis the starch formed was precipitated with methanol.

Aliquots (0.5 μ l) of the fatty acid salt solution were chromatographed on a Perkin-Elmer FII gas chromatograph with flame ionization detector and a column, 2 m \times 3.2 mm o.d. packed with SE 30, 5% on Chromosorb W with a nitrogen carrier flow rate of 22 ml/min. The column and injection block temperatures were 238°C and 370°C respectively, the latter being necessary to pyrolyze the quaternary ammonium salts to methyl esters. At least two samples of each ester were hydrolysed for 48 h and a minimum of four aliquots of each were chromatographed.

Acyl contents of octanoate and n-butanoate esters were determined by the alcoholic alkali method¹².

Specific gravity

The specific gravity of the polymers was measured¹³ by displacement of water and/or light petroleum ether (b.p. 100°–120°C). Water was used only for esters of *DS* greater than 0.6 while light petroleum ether was used for all esters of lower *DS* and for spot checking some esters of higher *DS*.

Table 1 Starch palmitates prepared* at various catalyst concentrations

KOHCH ₃ concentration (mol/mol starch)	DS†	Precipitation‡		Yield‡ (%)
		Alkoxide	Ester	
0.001	0.03	—	—	67
0.010	0.18	—	—	65
0.025	0.60	—	+	90
0.050	0.86	+	+	88
0.100	1.10	+	+	93
0.200	0.98	+	+	94

* Reaction Conditions: Temperature 100°C; starch/DMSO ratio 9.5×10^{-3} ; methyl palmitate/starch ratio 3.0; time 6 h

† The value 0.98 is not significantly different ($P = 0.05$) from values of 1.10 and 0.86

‡ Precipitate formed (+); no precipitate formed (—)

‡ Calculated from the weight of starch in esterified form compared with the original weight of starch

Infra-red Spectra

Films less than 20 μm thick for i.r. studies were prepared by means of a laboratory heat sealer and dried over phosphorus pentoxide. I.r. spectra were recorded using a JASCO IRA-1 spectrophotometer (Tosco, Sydney).

RESULTS AND DISCUSSION

Starch concentration

The mole ratio of starch* to DMSO was varied in four steps from 4.7×10^{-3} to 2.8×10^{-2} at 100°C, while the mole ratios of catalyst and methyl palmitate to starch were held at 0.1 and 3.0 respectively. The DS of the resulting esters was independent ($P = 0.05$) of the starch concentration and so a starch to DMSO ratio of 0.5×10^{-3} , an experimentally convenient value, was chosen for subsequent studies.

The reaction was also attempted using a dispersion of starch in pyridine⁵ but no starch ester could be isolated.

Catalyst concentration

The effects of raising the mole ratio of potassium methoxide to starch from 0.001 to 0.200 are shown in Table 1. The DS increased significantly ($P = 0.05$) with catalyst concentration up to a catalyst to starch mole ratio of 0.100. Based on the present data however, the DS value at the highest catalyst to starch ratio of 0.200 was not significantly different ($P = 0.05$) from the DS values at ratios of 0.050 and 0.100.

The reaction occurred homogeneously or partly heterogeneously depending upon the catalyst to starch ratio (Table 1). Two factors may explain both this behaviour and the effect of catalyst to starch ratio on DS. These factors are the removal of catalyst by reaction with traces of water and the insolubility of highly esterified starch.

The initial water content in each preparation was less than or equal to 0.02%, which is equivalent to one hundred times the catalyst concentration when the catalyst to starch ratio was 0.001. The very low DS value (0.03) obtained under these conditions was probably a result of catalyst destruction by water. The same probably applied to a decreasing degree as the catalyst to starch ratio was increased to 0.10, at which point the maximum possible water content equalled the catalyst concentration.

* In this report anhydroglucose, the starch repeat unit, was used as the basis for calculation of the number of moles of starch.

The precipitation of starch ester gel at catalyst to starch ratios of 0.025 or greater may be understood by reference to Figure 1a which shows the effect of DS on the Hildebrand solubility parameter (δ) obtained from measured specific gravities¹⁴. Esters of solubility parameter less than about 11 should be insoluble in DMSO¹⁵ (solubility parameter 12.93) since a difference between the solubility parameters of solute and solvent of less than 1.7 to 2 is a critical requirement for solubility¹⁶. This difference rule is probably modified by the specific reaction between DMSO¹⁷ and carbohydrates and hydrogen bonding within the polymer¹⁶. The lowest DS ester which was precipitated (Table 1) had a solubility parameter of 10 which is 2.93 less than that of the solvent.

The fact that the maximum DS obtained was 1.10 instead of 3.0 leads to the suggestion that as the DS increased the solubility parameter decreased, and in the presence of DMSO, the gel became less accessible to dissolved catalyst and methyl palmitate.

The same two factors which affected the DS also affected the yield. Removal of catalyst from solution, by means of formation of starch alkoxide immobilized on gel molecules, prevented further reaction. In this way dissolved starch did not come into contact with the catalyst and the reaction stopped. A second catalyst addition after gel precipitation might have resulted in higher yields. At low catalyst concentrations the catalyst removal by water would also have reduced yields.

Potassium carbonate was also used as a catalyst but gave results similar to those obtained using the methoxide.

Reagent ratio

The reverse reaction of methanol with starch palmitate was inhibited by distillation of the methanol formed and by increases in the ratio of methyl palmitate to starch as

Figure 1 (a) Solubility parameter of starch palmitates versus degree of substitution. (b) Specific gravity of starch palmitates versus degree of substitution: ●, petroleum spirit; ○, water; as immersion liquid

Table 2 Starch palmitates prepared* at various reagent ratios

10	1.52	71
15	1.54	67

* Reaction Conditions: Temperature 100°C; catalyst/starch ratio 0.10; starch/DMSO ratio 9.5×10^{-3} ; time 6 h

‡ Calculated from the weight of starch in esterified form compared with the original weight of starch

Table 3 Degree of substitution of starch palmitates prepared at various temperatures

Temperature (°C)	DS
80	0.71
90	0.90
100	1.08
110	0.86

shown in Table 2. The DS increased significantly ($P = 0.01$) as the reagent ratio was increased to a value of 10. Based on the present data, the DS value at the highest reagent ratio of 15 was not significantly different ($P = 0.01$) from the DS values at ratios of 5 and 10. This form of relationship is similar to those reported for cellulose stearate⁹ and sucrose palmitate⁸ formation.

Temperature

The effect of increasing the reaction temperature, from 80° to 110°C, on the DS of starch palmitate is shown in Table 3. This temperature ranged from the boiling point of DMSO at the vacuum used to the temperature above which starch degradation may become serious. All DS values were significantly different ($P = 0.05$) except those for 90° and 110°C. The differences between DS values for 100° and 110°C on the one hand and 80° and 100°C on the other are significant at $P = 0.01$. This very small effect of temperature on DS largely supports the findings of Latetin *et al.*⁹ for cellulose esterification.

Length of the fatty acid

The methyl esters of lauric, octanoic and butanoic acids were reacted with starch to establish whether or not the length of the fatty acid determined the maximum DS attainable at 100°C. The mole ratios of catalyst to starch, methyl palmitate to starch and starch to DMSO were 0.10, 9.5×10^{-3} and 5.0 respectively. Methanol was removed from the methyl butanoate reaction by means of a stream of nitrogen since the low boiling point of the methyl butanoate precluded use of refluxing under vacuum.

The DS values of the esters of octanoic, lauric and palmitic acids formed under these conditions were 1.53, 1.47 and 1.47 respectively. Such small differences could be attributed to similar relationships between solubility and DS for each of the fatty acid esters. The highest DS obtained for starch butanoate was 0.38 and this is attributed to the inadequate removal of methanol by the nitrogen stream.

This apparent independence of DS on length of the acid, at least for acids from C₈ to C₁₆, is in agreement with the

results of Gros and Feuge² for esterification using acid chlorides.

Infra-red spectra

The effect of DS on the hydrogen bonding in starch esters was studied by measurement of i.r. spectra. Esters of DS 0.6 or greater gave quite distinct spectra with many resolved bands, while the spectrum of an ester of DS 0.19 was quite similar to that of starch except for the carbonyl absorption. At DS values less than 0.19, polymer films were not prepared due to the failure of the polymers to melt.

The principal features of these spectra are the profile and wavelength of maximum absorption of the hydroxyl fundamental around 3400 cm⁻¹, as shown in Figure 2 for esters of DS 0.19, 0.64 and 1.54. This band is markedly influenced by DS, being (a) totally unresolved from that of the CH stretch at a DS of 0.19; (b) an asymmetrical band of maximum absorbance centering at 3340 cm⁻¹ at a DS of 0.64 and (c) a more symmetrical band with maximum absorbance at 3460 cm⁻¹ at a DS of 1.54. The result of partial acetylation of an ester of DS 1.52 is shown in Figure 2.

The hydroxyl absorption in the solution spectrum of an ester of DS 1.54 (0.02 M in carbon tetrachloride) was a composite of bands at 3460 cm⁻¹ and 3550 cm⁻¹. The latter band disappeared as the concentration was increased, until a saturated solution gave a spectrum similar to that of the solid polymer.

The spectral results may be interpreted as follows. As the DS increases from 0.19 to 0.54 the predominant form of hydrogen bonding changes from polymeric to dimeric¹⁸. Acetylation provides a free environment for some hydroxyls and allows mainly dimer formation for the rest. Solution in

Figure 2 Absorption frequency of hydroxyl fundamental: A, DS = 0.19; B, DS = 0.64; C, DS = 1.54; D, DS = 1.52 then acetylated

carbon tetrachloride causes disruption of interchain hydrogen bonds leading to an increased proportion of dimers on dilution. Polymeric hydrogen bonding would probably involve hydroxyls on several chains or segments whereas dimers can be formed between hydroxyls at C₂ and C₃ on adjacent anhydroglucose units.

The frequencies of maximum absorbance (ν) of the hydroxyl fundamental in the spectra of all of the esters prepared have been fitted to the equation:

$$\nu = 3238 + 135 \times DS$$

with a standard error of estimate of 14.6 and a correlation coefficient of 0.94. The scatter of the results is attributed to the flatness of the absorption band as would be expected when several closely spaced bands overlap. Thus the frequency of maximum absorbance of this band provides a measure of the *DS* of the ester. There is also a sharp band near 720 cm⁻¹ which is probably due to the methylene rocking vibration of palmitate chains. The intensity of this band increases markedly with increasing *DS* and may also offer some scope for quantitative analysis of these and related esters.

Starch octanoate of *DS* 1.53 and the laurate of *DS* 1.47 both had their hydroxyl fundamental maximum at 3405 cm⁻¹, which is more than two standard errors lower than the frequencies for the corresponding palmitates. This would be expected with shorter chain fatty acid esters which would interfere less with hydrogen bonding.

Specific gravity

Figure 1*b* shows the effect of *DS* on the specific gravity (*SG*) at 23°C of starch palmitates. The broken curve was calculated using the linear combination of specific gravities of starch and palmitic acid. The disruption of optimal packing of molecules in both of the free components is reflected in the lower specific gravity values of the esters over the range studied. This is consistent with the i.r. results which indicate disruption of interchain hydrogen bonding.

The apparent approach of the experimental results to a limiting *SG* of around 1.01 is supported by the reported value² of 1.022 (at 30°C) for amylose palmitate of *DS* 2.02. The octanoate of *DS* 1.53 has a specific gravity of 1.115 compared with 1.119 reported² for amylose octanoate of *DS* 2.25. Similarly the starch laurate of *DS* 1.47 has a specific gravity of 1.056 compared with 1.059 reported² for amylose laurate of *DS* 2.49. It appears that these esters

may also have limiting specific gravity values independent of *DS* over a range similar to that for the palmitates.

Since the specific gravity of the palmitate esters appears to be fairly constant over the *DS* range from 1 to 2 approximately, it is possible that some of the valuable properties reported² for the high *DS* esters might be found in esters of much lower *DS* also. This suggestion is supported by the nature of the solubility parameter versus *DS* curve in Figure 1*a*.

ACKNOWLEDGEMENTS

The author wishes to thank Mr E. G. Davis and Dr R. V. Holland for their helpful advice; Mr D. J. Best for carrying out statistical analyses and Mr A. J. Shorter for his valuable technical assistance.

Differential scanning calorimetric studies on phase transition of glucose and cellulose oligosaccharides

Tatsuko Hatakeyama

Research Institute for Polymers and Textiles, Sawatari, Kanagawa-ku, Yokohama, Japan

and Hiroshi Yoshida*, Chikage Nagasaki† and Hyoe Hatakeyama

Industrial Products Research Institute, Shimomaruko, Ota-ku, Tokyo, Japan

(Received 29 August 1975; revised 30 January 1976)

The phase transitions of D-glucose and an homologous series of cellulose oligosaccharides up to cello-tetraose have been studied using a differential scanning calorimeter. A detailed comparison of our experimental results with those reported by other workers has been made in order to derive precise information on melting and glass transitions of carbohydrates. Particular attention has been given to the static values of melting temperature of D-glucose and cellobiose. It has also been found that cellulose oligosaccharides which have more than three anhydroglucose units decompose below melting temperature.

INTRODUCTION

In the course of the studies of the phase transition of glucose and an homologous series of cellulose oligosaccharides in solid state, information on precise values of phase transition temperatures such as melting and glass transition temperatures are undoubtedly necessary. Pigman *et al.*¹ reported melting temperatures of D-glucose in different crystal forms. Wolfrom and Dacons² reviewed the values of transition temperatures of glucose and cellulose oligosaccharides up to celloheptaose. Alfthan *et al.*³ tried to estimate glass transition temperatures of several oligosaccharides from cellulose and xylan.

However, those values reported seem to contain some errors from the thermodynamic point of view, since the values were not obtained under carefully defined thermal conditions and time factors. Therefore, in this study, we have re-examined phase transitions of D-glucose and cellulose oligosaccharides up to cello-tetraose by the use of a differential scanning calorimeter. The isothermal melting of the carbohydrates which have melting points was carried out and attempts were made to obtain the static values of melting temperature. At the same time glass transition temperatures of glassy samples of glucose and cellulose oligosaccharides were evaluated.

EXPERIMENTAL

Sample Preparation

D-glucose monohydrate obtained commercially from Merck AG was ground to a fine powder and was dissolved into hot, absolutely dry ethanol. The solution was then placed for one night at room temperature. Anhydrous α -D-glucose separated out as crystals.

The D-glucose, above (obtained commercially) was also dissolved into water. The solution was placed for 48 h in a refrigerator. Crystals of α -D-glucose monohydrate separated out.

β -D-glucose was obtained commercially from Tokyo Chemical Industry Co. Ltd and contained 7.7% of α -D-glucose as determined from a gas chromatogram obtained under the following conditions using a Shimadzu GC-4AIT gas chromatograph: the column was a stainless tube packed with 5% silicone SE-30/Celite; temperature, 200°C; carrier gas, He 30 ml/min; TCD detector, 3 mV full scale.

Cellobiose was obtained commercially from Merck AG. The crystal forms of the above compounds were examined from X-ray diffractograms⁴⁻⁷.

According to the procedure reported by Miller *et al.*⁸, cellulose oligosaccharides containing more than three anhydrous glucose units were prepared as follows. First cellulose was acetylated with a mixture of glacial acetic acid, acetic anhydride and concentrated sulphuric acid. Then the acetylated oligosaccharides produced were separated into two portions, the anhydrous methanol soluble portion was deacetylated with sodium methylate. The free oligosaccharides obtained were separated by ethanol-water gradient elution from a chromatographic column composed of stearic acid treated mixtures of charcoal and Celite. Each separated fraction was concentrated with a rotary vacuum evaporator and dried *in vacuo*. Purification of the samples was carried out by re-chromatographic treatment and the purity examined by thin layer chromatography⁹. Characterization of the samples was carried out by measuring the molecular weight with a Hitachi model 115 molecular weight apparatus.

Amorphous glucose and cellulose oligosaccharides were prepared by freeze-drying their aqueous solution¹⁰. First small amounts of the samples were dissolved in water. The solution was then frozen quickly using liquid nitrogen as a refrigerant, and dried *in vacuo* so as to drive the solvent off. Amorphous materials obtained were dried thoroughly *in vacuo* for more than two days. Amorphous glucose was also prepared by rapid cooling from the molten state.

Measurements

A Perkin-Elmer differential scanning calorimeter, DSC-II was used throughout this experiment, low temperature equipment being attached to the DSC-II when the glass transition of D-glucose was measured. Temperature was calibrated at all scanning velocity ranges using the melting temperature of indium as a standard. At low temperature regions, melting of spectrograde benzene was used for the calibration. In both cases, the foot temperature of a melting peak observed in a differential scanning calorimetric (d.s.c.) curve was taken as the melting temperature according to the procedure recommended as a common calibration method in the manual for DSC-II¹¹.

Samples were sealed into d.s.c. pans for volatile samples as this eliminates the effect of humidity. Sample weight used as in this study was from 2 to 3 mg. Heating velocity was varied from 0.63 to $20^{\circ}\text{C}/\text{min}$. When crystalline samples were measured by dynamic method at the desired heating velocity, peak temperature was adopted as a criterion of melting for a matter of convenience¹². We mixed some samples with copper powder (1:1 in weight) and pressed into thin, small plates to increase the thermal conductivity, as the samples used were rather bulky. These mixed samples were also tested and compared with unmixed ones.

The following isothermal melting was carried out using the DSC-II, in order to measure the equilibrium melting temperatures of D-glucose and cellobiose. At first the sample was heated to the melting temperature which was roughly estimated from the value extrapolated to zero heating velocity from dynamic measurements carried out at different heating velocities. The heat change was recorded while the sample was maintained above the melting temperature. After keeping the sample at the temperature for a certain time, the sample was reheated to ascertain whether any crystals remained. The equilibrium melting temperature was thus determined by successively changing temperatures in the vicinity of the supposed equilibrium temperature.

The glass transition temperature was defined as the point when the extension of the base line intersects with a line tangent to the maximum slope of the endothermic peak.

RESULTS AND DISCUSSION

Figure 1 shows the d.s.c. curves of α -D-glucose having different crystal forms, anhydride and monohydrate; β -D-glucose and cellobiose respectively. Melting temperatures of these compounds measured at the heating velocity of $1^{\circ}\text{C}/\text{min}$ are not very different from the temperature reported pre-

viously². Melting curves of glucose and cellobiose were broad compared with those of other materials used as calibration standards such as benzene, benzoic acid and indium. The initial melting temperature of the above carbohydrates was difficult to estimate precisely from the foot temperature of a melting peak because of a gradual change in specific heat occurring from a temperature far lower than that of melting. Therefore, peak temperature was adopted in this study as a criterion of melting as described previously. In the case of cellobiose, the specific heat change was observed as a deflection in the base line of a d.s.c. curve before and after melting. Partial decomposition seems to be masked with the melting peak¹³.

Figure 2 shows the relation between the temperature of a peak and heating velocity for the samples of α -D-glucose anhydride and β -D-glucose. The melting temperature increased with increasing heating velocity. The change of peak temperatures was remarkable compared to known values of organic compounds. Similar results were also obtained in the case of α -D-glucose monohydrate and cellobiose.

Hellmuth *et al.*¹⁴ suggested that super heating was taking place after considering the special character of the structure of these organic compounds. On the other hand, Ichihara¹⁵ suggested that the heat conductivity of an organic compound could not be ignored when the heating velocity dependency was discussed even if the sample weight was very small. Iguchi¹⁶ and Hatakeyama¹⁷ obtained good agreement with the results of Ichihara¹⁵ by using extended chain-type polyoxymethylene crystal and high molecular

Figure 2 Heating velocity dependency of melting peak temperature for α -D-glucose anhydride and β -D-glucose. A, α -D-Glucose anhydride; B, β -D-glucose

Figure 3 Heating velocity dependency of melting peak temperature for α -D-glucose monohydrate. A, α -D-Glucose monohydrate; B, α -D-glucose monohydrate with Cu powder

weight polyethylene as samples. In order to clarify the effect of super heating and/or heat conductivity on the melting of carbohydrates, the melting temperature of α -D-glucose monohydrate was compared with that mixed with copper powder, as described earlier. As shown in Figure 3, the melting temperature of α -D-glucose monohydrate was affected seriously by the conditions of the sample in the high heating velocity region. This fact suggests that the heat conductivity of a sample played an important part in heating velocity dependency.

It was difficult to evaluate the melting temperature of the compounds from the data obtained by dynamic measurements, since the melting peak temperatures of glucose and cellobiose depended on heating velocity. Therefore, we tried to measure the equilibrium melting temperatures from melting curves obtained by the procedure described earlier.

Figure 4 shows the isothermal melting curves of α -D-glucose monohydrate. From this Figure, it is shown that the melting of the sample takes place over a very long time interval. The same melting behaviour was observed in the case of cellobiose. The large heating velocity dependency of glucose and cellobiose seemed due to the above features of the compounds. Isothermal melting was carried out for all samples having melting temperatures. The cellulose oligosaccharides having more than three anhydroglucose units decomposed without melting. It is possible to redraw the endotherms shown in Figure 4 into accumulation type melting curves as a function of time as shown in Figure 5. From these curves, we could estimate the half-time of melting at various temperatures. The half-time thus evalu-

ated is shown in Figure 6 for the case of α -D-glucose monohydrate.

As described above, the half-time of melting shown in Figure 6 was calculated from the isotherm of a sample which remained isothermal until it melted completely. In this case, however, if the temperature at which a sample is kept isothermally approaches an ideal equilibrium melting temperature, the time interval for melting is also expected to approach infinity, which cannot be attained in the experimental time interval. Moreover, the sensitivity of the d.s.c. is not sufficient to follow such a small amount of heat in unit time, since the transition occurs over a long period. However, the difference between the maximum and minimum temperatures where isothermal melt could occur in a sample converged within $\pm 0.5^\circ\text{C}$ by holding a

Cellobiose	505	521	335	397
Cellotriose	—		364	—
Cellotetraose	—		355	431

* In this work, T_m was determined by isothermal melting and T_g was estimated from a d.s.c. curve at the heating velocity of $10^\circ\text{C}/\text{min}$

Figure 7 D.s.c. curves of amorphous glucose, cellobiose, cellotriose and cellotetraose near the glass transition temperature. A, D-Glucose; B, cellobiose; C, cellotriose; D, cellotetraose. Heating velocity, $10^\circ\text{C}/\text{min}$

sample successively at different temperatures. The isothermal melting temperature obtained by the above method coincided well with that obtained by extrapolating values from the dynamic measurements shown in Figures 2 and 3. Table 1 shows phase transition temperatures obtained in this experiment and those reported in the literatures.

Amorphous samples of D-glucose and cellulose oligosaccharides were prepared following the method described earlier. X-ray diffractograms of the samples showed the typical amorphous pattern. It was possible for crystallization to take place by conditioning amorphous samples under an atmosphere with a very small amount of water at a suitable crystallization temperature. Crystallization of amorphous samples has been discussed in another report¹⁸. Crystallization was never observed by d.s.c. or X-ray diffraction measurement, if a sample was completely dried and handled in water free conditions. Figure 7 shows the d.s.c. heating curves of amorphous samples measured at the heating velocity of $10^\circ\text{C}/\text{min}$ near the glass transition temperatures. The specific heat change was seen clearly for all

samples. The glass transition temperatures were determined from the curves in Figure 7. The temperature errors of glass transition were within $\pm 1^\circ\text{C}$ among the runs made using different samples. No serious effects of temperature cycling was observed among the runs carried out in the temperature range from 270K to 400K.

The melting and glass transition temperatures estimated above are all listed in Table 1 together with the data obtained previously. From Table 1 it can be seen that the melting temperatures estimated in the present study are rather low as a whole compared with data reported previously. This is because the effect of time factor on phase transition process is taken into consideration.

As seen in Table 1 the glass transition temperatures of oligosaccharides increase with increasing degree of polymerization except for cellotetraose which might be contaminated by small amounts of impurities. The glass transition temperatures measured in the present study are quite different from those obtained by Alfthan *et al.*³, even after considering the different techniques used. They estimated the glass transition by torsional brake analysis and the maximum temperature of damping was adopted as the criterion of the glass transition temperature. As is well known, dynamic loss in viscoelasticity does not correspond only to the main motion but also to other phase transition, such as crystallization and local mode relaxations. On the other hand, by the thermal analysis, the glass transition is observed as the specific heat change, which is clearly distinguishable from the other first order transitions. Judging from the results obtained in this study, the glass transition temperatures reported by Alfthan *et al.*³ seem to coincide rather well with the cold crystallization temperatures which were detected in d.s.c. curves when the amorphous samples contained small amounts of water.

Interaction between carboxylic acids and the peptide group

R. M. Stephens and E. M. Bradbury

Biophysics Laboratories, Portsmouth Polytechnic, Portsmouth PO1 2QG, UK
(Received 22 September 1975; revised 26 February 1976)

The interaction between the peptide group and carboxylic acids is one of either protonation or hydrogen bonding. Both interactions will affect the vibrational frequency of the peptide group, resulting in changes in the characteristic amide vibrations. Infra-red spectroscopy has been used to examine the change in the amide I and II absorption bands of the model compound *N*-methylacetamide (NMA) when it is dissolved in deuteriochloroform and various deuteriochloroform/carboxylic acids, such as acetic, formic, dichloroacetic and trifluoroacetic acid. The results indicate that the interaction is one of hydrogen bonding except when NMA is dissolved in the strongest acid used, trifluoroacetic acid (TFA). Studies on the interaction between TFA and the peptide group of poly(L-alanine) various poly(DL-alanines) and poly(γ -benzyl-L-glutamate) show that the hydrogen bond interaction occurs, with little evidence of protonation taking place. In poly(γ -benzyl-L-glutamate) it was found that the TFA interacted both with the peptide group and the side chain carboxyl group.

INTRODUCTION

Helix-random coil transitions of polypeptides can be induced by varying the proportion of polar and non-polar components in a mixed solvent. The polar solvents are normally trifluoroacetic acid (TFA) or dichloroacetic acid (DCA) and the interaction between these acids and the peptide group are not fully understood. The interactions that can occur between TFA and the peptide group can be illustrated by examining the interaction between *N*-methylacetamide (NMA) and TFA where it can be seen that either (a) protonation or (b) hydrogen bonding can occur, (see Figure 1).

Klotz and coworkers¹⁻³ have investigated this interaction by examining the overtone region of the infra-red spectra of *N*-methylacetamide dissolved in TFA and other non-polar solvents. The first overtone of the N-H stretching vibration was observed at 6557 cm⁻¹ when NMA was dissolved in carbon tetrachloride, dioxane and water. For low concentrations of NMA in TFA two peaks were observed, one at 6620 cm⁻¹ the other at 6557 cm⁻¹ with a shoulder at 6711 cm⁻¹. The 6620 cm⁻¹ band observed for NMA in TFA was identified as that due to the overtone of the N-H group of the amide in the protonated state, and the one at 6637 cm⁻¹ due to additional hydrogen bonding between N-H groups of the protonated series and either undissociated acid or the acid anion. It was also suggested that the shoulder of 6711 cm⁻¹ observed from NMA in TFA and the band at 6734 cm⁻¹ from NMA in acetic acid was due to amide N-H hydrogen bonded to the carboxyl groups of the acid. Measurements made in the 1800 cm⁻¹ to 1500 cm⁻¹ region for NMA in TFA showed bands at 1736 cm⁻¹, 1655 cm⁻¹ and 1613 cm⁻¹. These were interpreted as being due to the C=O vibration from the COOH group in TFA, to the amide I vibrations of the peptide group and to the presence of COO⁻ ions which would have an anti-symmetric stretching vibrational frequency at about 1613 cm⁻¹. The amide II vibration which occurs at 1563 cm⁻¹ in NMA was not seen. The results obtained from the near infra-red studies of poly(L-alanine), poly(L-leucine) and poly(γ -benzyl-L-glutamate) in CHCl₃/

TFA solutions showed that as the acid concentration increased there was a decrease in absorption at 6630 cm⁻¹ with a corresponding increase in absorption of 6711 cm⁻¹ showing that the number of protonated groups increase with the proportion of acid content. Similar infra-red studies on the interaction between ethylene dichloride/DCA mixtures and the peptide group of poly(γ -benzyl-L-glutamate), poly(L-alanine) and poly(L-methionine) suggested that the interaction was one of protonation of the peptide group even at low acid concentration⁴. Volchek has investigated the interaction between DCA, TFA and the peptide group of different model amides including NMA by monitoring the changes that occur in the amide I region of the infra-red spectra for different acid/chloroform concentration⁵. The concentration of the solution was defined as $X_k = N_k(N_0 + N_k)$ where N_k is the molarity of acid in chloroform. N_0 the molarity of the model amide in chloroform was kept constant at 0.2 M. The results show that for NMA in TFA/CHCl₃ solutions, a strong absorption band occurs at the approximately 1615 cm when $X_k < 0.5$, and shifts to approximately 1632 cm⁻¹ when $X_k > 0.5$. These bands are attributed to a hydrogen bonding interaction and protonation respectively. Similar results were obtained when other model amides were dissolved in either DCA/CHCl₃ or TFA/CHCl₃ solutions and it was concluded

Figure 1 (a) Protonation; (b) hydrogen bonding

Figure 2 I.r. spectra of NMA in deuteriochloroform solutions. A, 0.2 M NMA in CDCl_3 ; B, 2 M NMA in CDCl_3 ; C, liquid NMA

that a hydrogen bonding interaction took place between the acid and the peptide group when $X_k < 0.5$ and protonation of the peptide group occurred when $X_k > 0.5$. Other investigations, using infra-red spectroscopy, of the interaction between the peptide group and TFA, concluded that the interaction was one of hydrogen bonding and not protonation^{6,7}. Mandelkern and coworkers have studied the nuclear magnetic resonance spectra obtained from poly(L-alanine) and poly(DL-alanine) NMA and *N,N*-dimethylacetamide, in TFA/ CDCl_3 solvents and concluded that whereas protonation of the peptide group occurred in the model compounds there was no evidence of a similar interaction between polypeptides and carboxylic acids^{8,9}. Quadrioglio and Urry using circular dichroism techniques also concluded that protonation did not occur in helical poly(γ -benzyl-L-glutamate) in 3.65 M DCA in CDCl_3 solution¹⁰.

The aim of this investigation is to examine and to establish the nature of the interaction between NMA and carboxylic acids having different acidities, and use the results to interpret the type of interaction taking place between several polypeptides and TFA. Infra-red spectroscopy has been used to record changes that occur in the characteristic vibrational frequencies of the peptide group when an interaction occurs between this group and other molecules; in this case carboxylic acids. If the hydrogen bonding interaction occurs the vibrational frequency of the amide I (80% C=O stretching) is lowered with little change in the amide II frequency (60% N-H in plane bending, 40% C-N stretching). If protonation of the peptide group occurs then the amide I is replaced by a new absorption band which comes from the anti-symmetrical stretching vibration of the charged carboxyl group and this occurs at a con-

siderably lower frequency. The characteristic amide II vibration will no longer occur.

EXPERIMENTAL

The concentration N_0 of water free NMA or polypeptides in deuteriochloroform was kept constant at 0.2 M and the molarity N_k of the carboxylic acid/ CDCl_3 solution of NMA was varied by adding the required amount of acid to the NMA/ CDCl_3 solution. Analar grade reagents were used and the purity of the CDCl_3 was 99.8%. The infra-red spectra of the solutions were recorded using a Grubb Parsons Spectromaster. The cells contained barium fluoride windows and had a path length of 0.05 cm. The scanning speed of the instrument was 1 $\mu\text{m}/4$ min.

RESULTS

NMA in deuteriochloroform

Figure 2 shows the infra-red spectra of liquid NMA and various solutions of NMA in deuteriochloroform (CDCl_3) at room temperature. For the pure liquid NMA the amide I occurs at 1663 cm^{-1} with a broad shoulder at 1649 cm^{-1} . The amide II also shows asymmetry with a peak at 1566 cm^{-1} and shoulders on the low frequency side. The amide I vibration is due mainly to carboxyl stretching and the amide II to N-H in plane bending and C-N stretching, and the pronounced asymmetries are due to hydrogen bonding, between NMA molecules involving the peptide group. For a dilute solution of 0.2 M NMA in CDCl_3 the amide I and II sharpen considerably and occur at 1672 cm^{-1} and 1536 cm^{-1} , indicating that very little hydrogen bonding is taking place. As the concentration of NMA in CDCl_3 increases the amide I shifts to a lower frequency and broadens and the amide II moves to a higher frequency. At 4.0 M NMA in CDCl_3 the amide I and II bands occur at 1653 cm^{-1} and 1570 cm^{-1} with very little asymmetry in either band. This indicates that very strong hydrogen bonding is taking place at this concentration.

NMA in acetic acid/deuteriochloroform

For NMA in dilute acetic acid/deuteriochloroform ($\text{CH}_3\text{COOH}/\text{CDCl}_3$) solution two distinct amide I absorption bands are seen at 1670 cm^{-1} and 1651 cm^{-1} with a broad amide II at $\sim 1537\text{ cm}^{-1}$ (Figure 3). At the higher acid concentration of 2.0 M only two bands can be seen, one at 1649 cm^{-1} , the other at 1558 cm^{-1} . If there was another higher frequency band present it could not be observed due to the intense background from the acid peak. Examination of the solvent spectra for this acid concentration shows that there is no strongly absorbing band at 1558 cm^{-1} and thus the 1558 cm^{-1} is due completely to the amide vibration. Therefore it seems likely from the intensity and position of the peaks observed for 0.2 M NMA in 2.0 M $\text{CH}_3\text{COOH}/\text{CDCl}_3$ that the interaction between acetic acid and NMA is one of hydrogen bonding.

NMA in formic acid/deuteriochloroform

For NMA in formic acid/deuteriochloroform solution, the amide I absorption occurs at 1670 cm^{-1} with a shoulder at 1643 cm^{-1} which becomes well resolved in 0.1 M formic acid (Figure 4). The amide II band is broad and centred about 1538 cm^{-1} . These results indicate that hydrogen bonding is taking place. However, at 0.75 M formic acid the amide I is broad with a peak at 1639 cm^{-1} .

Figure 3 I.r. spectra of 0.2 M NMA in acetic acid/ CDCl_3 solutions. A, NMA in 0.2 M acetic acid in CDCl_3 ; B, NMA in 0.7 M acetic acid in CDCl_3 ; C, 2 M acetic acid/ CDCl_3 solvent; D, NMA in 2.0 M acetic acid in CDCl_3

The amide II occurs at 1558 cm^{-1} with a shoulder at 1565 cm^{-1} , and may have lost some of its intensity. If this region of the spectrum is compared with the corresponding solvent spectrum it is seen that there are no solvent peaks present. Thus there may be two different interactions between formic acid and NMA; hydrogen bonding and a small amount of protonation at the higher acetic acid concentration.

NMA in dichloroacetic acid/deuterochloroform

When NMA is dissolved in dichloroacetic acid/deuterochloroform ($\text{Cl}_2\text{CHOOH}/\text{CDCl}_3$) at an acid concentration of 0.1 M the amide I is sharp and occurs at 1670 cm^{-1} , the amide II absorbs at 1544 cm^{-1} and 1559 cm^{-1} , and the interaction band occurs at 1628 cm^{-1} (Figure 5). At an acid concentration of 0.2 M, the interaction band increases in intensity, and is accompanied by a decrease in intensity of the amide I band. At the higher acid concentration of 1.0 M, the interaction band has shifted to 1610 cm^{-1} and the amide I absorption band is not observed. In the amide II region there is a band at 1565 cm^{-1} but when the spectrum of the solvent is examined it is seen that there is an absorption band present near this position, indicating that the amide II absorption band has greatly reduced intensity. This suggests that protonation of the peptide group in NMA is occurring at 1.0 M DCA in CDCl_3 .

NMA trifluoroacetic acid/deuterochloroform

With NMA dissolved in trifluoroacetic acid/deuterochloroform ($\text{CF}_3\text{COOH}/\text{CDCl}_3$) and interesting effect is observed. Below an acid concentration of 0.25 M and above a concentration of 7.5 M the solution of NMA and TFA/ CDCl_3 is clear but between these two acid concentrations the solution is cloudy at room temperature, but can be made transparent by gentle heat. The infra-red spectrum at the high acid concentration (Figure 6), shows a strong interaction band at 1620 cm^{-1} with asymmetry on the high frequency side, and a band at 1558 cm^{-1} . Examination of the solvent spectrum at this acid concentration shows that the band at 1558 cm^{-1} is due to solvent, and thus the amide absorption band has disappeared indicating that only one interaction is taking place between NMA and TFA at this concentration. For the 0.25 M acid solution the interaction band occurs at 1610 cm^{-1} with a pronounced shoulder on the high frequency side, and absorption band at 1560 cm^{-1} . As the acid concentration is 30 times lower than previously this band must be due to the amide II vibration. Its intensity however, is low, similar to that observed for the 1.0 M DCA in CDCl_3 solvent which

Figure 4 I.r. spectra of 0.2 M NMA in formic acid/ CDCl_3 solution. A, NMA in 0.05 M formic acid in CDCl_3 ; B, NMA in 0.1 M formic acid in CDCl_3 ; C, 0.75 M formic acid in CDCl_3 solvent; D, NMA in 0.75 M formic acid in CDCl_3

Figure 5 I.r. spectra of 0.2 M solutions of NMA in DCA/CDCl₃ solution. A, NMA in 0.1 M DCA in CDCl₃; B, NMA in 0.2 M DCA in CDCl₃; C, 1 M DCA in CDCl₃ solvent; D, NMA in 1 M DCA in CDCl₃

suggests that at 0.25 M TFA in CDCl₃ two interactions are taking place between the NMA and TFA. If deuterated TFA is used, the interaction band occurs at 1620 cm⁻¹ at an acid concentration of 0.25 M (Figure 7). This is 10 cm⁻¹ higher than the corresponding band when the hydrogenated acid interacts with NMA and the intensity of the band at 1566 cm⁻¹ is lower than that observed using ordinary TFA. This additional decrease in the intensity of the amide II is due to deuteration of the amide hydrogen but as the acid concentration (0.25 M) is similar to the NMA concentration (0.2 M) only 50% of the amide hydrogens are deuterated. At the higher deuterated acid concentration (7.5 M) the interaction band occurs at 1636 cm⁻¹. If the interaction at this high acid content were due to hydrogen bonding between the amide carboxyl group and the acid, deuteration of the hydrogen bond would shift this interaction band to a slightly lower frequency (due to the fact that the interaction band would arise from a modified carboxyl stretching vibration).

POLYPEPTIDES IN TRIFLUOROACETIC ACID/DEUTEROCHLOROFORM

Poly(L-alanine) in TFA/CDCl₃

To see if hydrogen bonding or protonation occurs between the acid and the peptide group for poly(L-alanine) in TFA/CDCl₃ solutions its infra-red spectra have been examined. Figure 8 shows the spectrum of a solution of poly(L-alanine) in 5.4 M TFA in CDCl₃. It can be seen that the amide I and II bands occur at 1658 cm⁻¹ and 1556 cm⁻¹ respectively, and that an interaction band of almost the same intensity as the amide I occurs at 1623 cm⁻¹. For the same polymer in 5.4 M deuterated TFA in CDCl₃ the amide I occurs at 1653 cm⁻¹ and due to deuteration of the amide hydrogen, the amide II has shifted to a much lower frequency. The interaction band occurs at 1621 cm⁻¹ and is 2 cm⁻¹ lower than that which was observed when the polymer was dissolved in the hydrogenated acid. It is unlikely from these results that protonation is taking place at this acid concentration as the intensity of the amide II is lower when the acid is deuterated (as would be expected when hydrogen bonding takes place). O.r.d. results have shown that poly(L-alanine) in 5.4 M TFA in CDCl₃ is mainly helical²⁰.

Poly(DL-alanines) in TFA/CDCl₃

To see if a similar interaction takes place between TFA and randomly coiled polyalanine, the infra-red spectra of solutions of various poly(DL-alanines) in 7.4 M TFA in CDCl₃ were recorded. It can be seen from Figure 9 that when L/D = 39 a strong acid interaction band is present at

Figure 6 I.r. spectra of 0.2 M NMA in TFA/CDCl₃ solutions. A, NMA in 0.05 M TFA in CDCl₃; B, NMA in 0.25 M TFA in CDCl₃; C, 7.5 M TFA in CDCl₃ solvent; D, NMA in 7.5 M TFA in CDCl₃

Figure 8 I.r. spectra of 0.2 M solutions of poly(L-alanine) in A, 5.4 M deuterated TFA in CDCl₃; B, 5.4 M TFA in CDCl₃

1626 cm⁻¹ which is absent when L/D = 1.25. In the latter case the amide I band is broad and occurs at 1637 cm⁻¹ indicative of the acid solvated random coil form. For the polymer with L/D = 39 the amide I occurs at 1656 cm⁻¹ indicating that this polymer is helical. The conformations of the poly(DL-alanines) in 7.4 M TFA in CDCl₃ has been confirmed using o.r.d. techniques²⁰. However, irrespective of the ratio of L:D i.e. the helicity of the polymer the intensity of the amide II band remains almost constant with the result that very little protonation is taking place.

Poly(γ -benzyl-L-glutamate) in TFA/CDCl₃

Figure 10 shows the infra-red spectra of solutions of poly(γ -benzyl-L-glutamate) in TFA/CDCl₃. It can be seen that at an acid concentration of 0.34 M TFA two changes have occurred in its infra-red spectrum compared with that obtained from the polypeptide in deuteriochloroform. The first is the appearance of a weak band at 1613 cm⁻¹ which is in a similar position to the interaction band that is seen when poly(L-alanine) is dissolved in TFA/CDCl₃ solution. Secondly the intensity of the ester C=O at 1736 cm⁻¹ has diminished with the appearance of a new band at 1713 cm⁻¹. It can be seen that as the acid concentration increases the intensity of the band at 1713 cm⁻¹ increases steadily and the one at 1736 cm⁻¹ decreases, until at an acid concentration of 2.0 M only a band at 1713 cm⁻¹ can be seen. Meanwhile the intensity of the weak band at 1610 cm⁻¹ has reduced as the acid concentration increased and as the conformation of the polymer changed from helical to random coil as indicated by the changes in the amide I and II bands.

DISCUSSION

Infra-red spectroscopy has been used to investigate the type of interaction taking place between carboxylic acids

Figure 9 I.r. spectra of 0.2 M solutions of poly(DL alanine) in 7.4 M TFA in CDCl₃. A, poly(L-alanine); B, L:D 39; C, L:D 9; D, L:D 1.25

and the peptide group of NMA and various polypeptides. The interaction may be either (a) hydrogen bonding or (b) protonation. The former causes a reduction in the stretching frequency of the affected group whilst the latter gives rise to the presence of a charged COO^- stretching vibration accompanied by the disappearance of the amide II vibration.

This investigation of the interaction between NMA and various carboxylic acids, show that two types of interaction may occur. For relatively weak acids like acetic or formic acids, $K_a = 1.75 \times 10^{-5}$ and 1.77×10^{-4} respectively, hydrogen bonding between the acid and NMA is present at quite high acid concentrations, with possibly only a little protonation occurring. Protonation is only likely to occur with the stronger carboxylic acids.

When hydrogen bonding is taking place between the acid and NMA the frequency of the interaction band occurs between 1651 cm^{-1} and 1649 cm^{-1} for acetic acid ($MW 60$) and between 1645 cm^{-1} to 1639 cm^{-1} for formic acid ($MW 46$). The frequency of the hydrogen bonded interaction band should depend to some extent upon the mass

of the hydrogen bonded molecule. Thus the fact that the interaction band frequencies are lower for the lowest molecular weight acid (formic acid) indicates that the hydrogen bonding is stronger in formic acid than in acetic acid. This is to be expected when one compares the magnitude of their acidity constants K_a . The fact that the hydrogen bonded interaction band is at 1649 cm^{-1} for pure liquid NMA ($MW 73$) means that the hydrogen bonding interactions between NMA molecules is weaker than between these carboxylic acids and NMA. Any hydrogen bonding occurring between DCA ($K_a = 5 \times 10^{-2}$) and NMA is likely to be stronger than that for acetic and formic acid. Consequently the frequency of the hydrogen bonded carboxyl stretching band should be even lower than that observed when formic acid hydrogen bonds to NMA. The interaction band for low dichloroacetic acid concentrations (0.1 M) is broad and has a peak at 1628 cm^{-1} . It sharpens and occurs at 1620 cm^{-1} when the acid concentration is 1 M. The amide II vibration is present at the lowest acid concentration but absent at the higher one. Thus when DCA/ CDCl_3 is used as a solvent for NMA it appears that the interaction is mainly one of hydrogen bonding at low acid concentration but with increasing amounts of protonation as the acid concentration increases.

For NMA dissolved in 0.05 M TFA in CDCl_3 the amide I and II absorption bands are present and a weak interaction band occurs at 1610 cm^{-1} . In 7.5 M TFA in CDCl_3 only two bands can be seen one at 1620 cm^{-1} the other at about 1555 cm^{-1} . This latter band is due to absorption from the solvent, indicating that the amide II absorption is absent. It appears then that at an acid concentration of 7.5 M the interaction is one of almost complete protonation. In 0.05 M TFA in CDCl_3 the interaction between the acid and NMA is likely to be hydrogen bonding. Even so protonation cannot be ruled out as the acid concentration is low and any observable effect would be small.

In view of the above conclusions, that complete protonation of NMA only occurs with high concentration of TFA and not with the weaker acids, the interactions between polypeptides and carboxylic acids has been restricted to that between polypeptides and TFA.

With poly(L-alanine) in 5.4 M TFA in CDCl_3 the infrared spectra show that an interaction band occurs at 1623 cm^{-1} with amide I and II bands at 1658 cm^{-1} and 1555 cm^{-1} respectively. When deuterated TFA is used the interaction band occurs at a slightly lower frequency and it appears likely that hydrogen bonding takes place between TFA and helical poly(L-alanine). From the studies made on various poly(DL-alanines) at an acid concentration of 7.4 M in CDCl_3 , hydrogen bonding occurs between the peptide group and TFA when $L/D = 39$ (as the interaction band occurs at 1626 cm^{-1} and the amide II band is present). When $L/D = 1.25$ the resultant spectrum is indicative of the acid solvated random coil form.

When the interaction between TFA and the polypeptide containing an ester group [poly(γ -benzyl-L-glutamate)] is examined, two interaction bands occur which were not present when the polypeptide was dissolved in deuteriochloroform. For an acid concentration of 0.34 M, apart from the expected amide I, II and ester $\text{C}=\text{O}$ stretching vibration absorption bands, two weak bands occurred at 1610 cm^{-1} and 1713 cm^{-1} . As the acid concentration increased, the polypeptide becomes more random (as indicated by the shape of the amide bands), the band at 1610 cm^{-1} remained practically unchanged in intensity, whilst the band at 1713 cm^{-1} increased in intensity. When the acid concen-

tration is 2.0 M TFA in CDCl_3 the spectrum is that from the acid solvated random coil form of poly(γ -benzyl-L-glutamate) with the interaction band at 1610 cm^{-1} absent and the one at 1713 cm^{-1} very strong. Thus it seems that the main interaction occurs between TFA and the side chain ester group in poly(γ -benzyl-L-glutamate), and is one of hydrogen bonding. Very few TFA molecules appear to interact with the peptide group of this polypeptide.

CONCLUSIONS

The results above indicate that protonation of NMA occurs when strong carboxylic acids such as DCA and TFA are used as solvents. Hydrogen bonding occurs between NMA and weaker carboxylic acids (acetic and formic acid) and at low acid concentrations of NMA in DCA/ CDCl_3 solutions. Protonation of the peptide group is not observed for the polypeptides studied when they are dissolved in TFA/ CDCl_3 solutions; the interaction is one of hydrogen bonding between the peptide group of helical polymers and the acid. If the polypeptide contains an ester group in its side chain, such as poly(γ -benzyl-L-glutamate), there is good evidence that the carboxylic acid will hydrogen bond to the side chain ester group.

These conclusions are in agreement with the experimental and theoretical studies which support the ideas of a hydrogen bond interaction^{5-7,9,12-19}, and disagree with previous studies supporting protonation¹⁻⁴. The different conclusions may be due to the difficulty in characterizing

changes that were observed in the overtone region of the infra-red spectrum.

Viscosity-molecular weight concentration relationships beyond the critical region in polymer solutions and melts

N. M. Chaurasia, Anil Kumar and Santosh K. Gupta

Department of Chemical Engineering, Indian Institute of Technology, Kanpur-208016, India

(Received 23 December 1975)

A multivariate regression analysis of viscosity—molecular weight—concentration data is presented which is superior to the methods currently used. Four sets of data from the literature are analysed to show the efficacy of the method.

INTRODUCTION

The flow properties of concentrated polymer solutions and melts are of great importance in the study of their processing characteristics and molecular structure. A considerable amount of experimental work has been reported in the literature¹⁻⁷ on the dependence of the zero shear viscosity, η_0 , of polymer solutions and melts on the molecular weight of the polymer, M , and its concentration, c , or density, ρ . The experimental data show a dependence of η_0 on $M^{3.4}$. However, the dependence of η_0 on the concentration appears to vary from system to system. Graessley⁸ has recently reviewed the theoretical developments^{3,8-11} in this area but most of the theories seem to be in contradiction with experimental behaviour.

It has been found empirically that log-log plots of η_0 versus M at different c and η_0 versus c at different M are superimposable by horizontal shifts and on this basis the following equation has been suggested for regions beyond the critical point⁸:

$$\eta_0 = Kc^\alpha M^\beta \quad (1)$$

where K , α and β are constants. Several methods have been used in the literature to evaluate α and β . In the first method¹², α and β are assumed to be 5.0 and 3.4 respectively (i.e. $\beta/\alpha = 0.68$) and a plot of $\log \eta_0$ versus $(3.4 \log M + 5.0 \log c)$ is made. The deviation of experimental points from a straight line of slope unity at high values of the abscissa indicate deviations from equation (1). This method has the drawback in that excessive experimental scatter does not indicate whether the functionality in equation (1) is wrong or whether incorrect values of α and β have been chosen. The same experimental data have been replotted¹³ and β/α has been found to be 0.54 instead of 0.68 assumed earlier. Recently a variation of this method has been used⁷ and $\log \eta_0$ has been plotted as a function of $\log (cM^{0.625})$ as well as $\log (cM^{0.68})$. Analysis of data on polystyrene in toluene reveals that it is impossible to decide which of the two exponents, 0.625 and 0.68, is really applicable. A similar insensitivity has been reported by Graessley⁸ who shifted $\log \eta_0$ versus $\log (cM)$ and $\log \eta_0$ versus $\log (cM^{0.68})$ plots vertically.

Plots of $\log \eta_0$ versus $\log M$ for various values of c as well as $\log \eta_0$ versus $\log c$ for various values of M have been made¹³ and these curves shifted horizontally to super-

pose on any reference concentration, c_0 , or molecular weight, M_0 . The shift factors $a_c (\equiv \log c/c_0)$ and $a_m (\equiv \log M/M_0)$ are related to β and α as:

$$a_c = -\frac{\beta}{\alpha} \times a_m \quad (2)$$

and a plot of a_c versus a_m gives β/α . This method has the drawback that the superposition of plots by visual methods leads to a loss of precision. Besides, this method is far too cumbersome to use.

The insensitivity of the various methods of analysing experimental viscosity data and the loss of precision by visual shifts necessitates a more reliable method of analysis. In this paper, a multivariate regression analysis is suggested and some representative data existing in the literature are analysed to give the 'best-fit' values of K , α and β in equation (1). This method has the advantage of being amenable to computer calculations.

METHOD OF ANALYSING DATA

Above the critical region, equation (1) can be written as:

$$\log \eta_0 = \log K + \alpha \log c + \beta \log M \quad (3)$$

or, in simplified notation:

$$y = A + \alpha x_1 + \beta x_2 \quad (4)$$

A multivariate regression analysis for the case of two independent variables leads to a set of three simultaneous algebraic equations in the three unknowns, A , α and β ¹⁴:

$$\begin{aligned} An + \alpha \sum x_{1,i} + \beta \sum x_{2,i} &= \sum y_i \\ A \sum x_{1,i} + \alpha \sum x_{1,i}^2 + \beta \sum x_{1,i}x_{2,i} &= \sum x_{1,i}y_i \\ A \sum x_{2,i} + \alpha \sum x_{2,i}x_{1,i} + \beta \sum x_{2,i}^2 &= \sum x_{2,i}y_i \end{aligned} \quad (5)$$

where n is the number of data points, $x_{1,i}$, $x_{2,i}$ and y_i are

Table 1 Values of $\log K$, α and β for viscosity data obtained using the regression analysis

the values of $\log c$, $\log M$ and $\log \eta_0$ for the i th data point and the summations are over all values of i from 1 to n . Cramer's rule can now be used to obtain the three best-fit values for the parameters.

Figure 2 η_0 vs. $cM^{\beta/\alpha}$ for PMMA in DEP¹⁶ at 30°C (Curve B) and at 60°C (Curve C): \square , $c = 0.226$; \circ , $c = 0.113$. Curve D represents η_0 vs. $cM^{\beta/\alpha}$ for PVAc in DEP¹⁵: \bullet , $c = 0.171$; \triangle , $c = 0.26$; \square , $c = 0.325$

DISCUSSION

The multivariate regression analysis has been applied to four sets of data beyond the critical region, taken from the current literature¹⁵⁻¹⁷. *Table 1* lists the values of K , α and β for the cases studied. It is observed that there is a considerable variation in the values of α . Such variations have already been reported¹⁸⁻²⁰. The values of β are all found to be around 3.4 except in the case of PMMA. *Figures 1* and *2* show plots of $\log \eta_0$ as a function of $\log (cM^{\beta/\alpha})$ using the values of β/α listed in *Table 1*, along with the best-fit lines.

This method of analysis of data does not have the drawback of insensitivity nor does it require any visual shifts of data which would lead to loss of precision. Moreover, the regression analysis minimizes the standard deviation.

It should be mentioned here that workers in this area usually plot $\log \eta_0$ versus $\log M$ and $\log \eta_0$ versus $\log c$ for different c and M and obtain β and α from the slopes of these plots above the critical region, respectively. As few as four to five points are normally used in the evaluation of β and α . As opposed to this, in the regression analysis presented here, the number of data points used is much larger because data for different M and c can be used simultaneously.

Brillouin scattering study of gelatin gel using a double passed Fabry-Perot spectrometer

D. S. Bedborough and D. A. Jackson

Physics Laboratory, University of Kent, Canterbury, Kent CT2 7NR, UK

(Received 4 November 1975; revised 16 February 1976)

The Brillouin spectrum of gelatin gels has been recorded at room temperature as a function of concentration of gelatin, using a double passed Fabry-Perot spectrometer. It was found that both the Brillouin shifts and line-widths increase linearly with concentration. In the case of the line-widths it was shown that the rate of increase was sensitive to the thermal history of the gels, being greater for gels cooled slowly. Explanation of the results in terms of a relaxation phenomenon is improbable. The observations can however be explained in terms of the structure of the gel. Expressing this structure as a number density of crosslinks, which is dependent on the concentration of gelatin, the increase in Brillouin shift is consistent with the change in bulk properties. The increase in line-width is shown to be caused by the crosslinks scattering the sound waves in the gel.

INTRODUCTION

A common form for a polymeric material is that of a gel. This state is characterized by a low but finite rigidity and high incompressibility. These properties are directly related to the gel structure which usually incorporates both high and low molecular weight material. The high molecular weight material forming a semi-rigid three-dimensional network with the low molecular weight material (usually a liquid) pervading this network. An important part of the elucidation of the nature of a gel is the determination of the structure of the crosslinks between the polymer molecules forming the network. Another interesting feature of gels concerns the dynamics of the network. Both of these problems have been investigated by light scattering. Information on the structure is obtained by conventional elastic light scattering¹ and on the dynamics by the more recent technique of analysis of the quasi-elastic scattered light (Rayleigh line) by correlation and spectrum analysis methods². Raman scattering from molecular vibrations has also given information on the crosslinking structure³. However, to our knowledge the technique of Brillouin scattering, which measures the frequency and damping of sound waves in a system, has not been applied to the study of gels.

BRILLOUIN SCATTERING THEORY

Brillouin scattering⁴ arises when light is scattered with a change in frequency by sound waves in the system under study. Physically we may picture this as the sound wave giving rise to a spatially periodic compression and rarefaction of the medium which then acts as a moving diffraction grating; the frequency shift, essentially a Doppler shift, arises from the motion of the sound wave.

In the quantitative evaluation of Brillouin scattering experiments two central results are needed. One relating the wavelength of the sound wave (λ_p) being studied to the geometry of the experiment i.e.:

$$\frac{2\pi}{\lambda_p} = 2\nu \times \frac{2\pi}{\lambda_i} \sin \frac{\theta}{2} \quad (1)$$

where λ_i is the wavelength of the incident light, ν the velocity of sound in the medium under study and θ the angle between incident and observed light.

The equation (2) relates the change in frequency of the scattered light (ω_p) to the velocity of sound in the medium:

$$\omega_p = 2 \times \frac{n\nu}{c} \omega_i \sin \frac{\theta}{2} \quad (2)$$

where ω_i is the frequency of the incident light, n the medium refractive index and c is the velocity of light in vacuum.

More important than the frequency shifts in this work are the widths of the Brillouin lines (Γ_B) which are related to the lifetime of a phonon before it is scattered or absorbed. If we view the sound wave as spatially damped according to $\exp(-\alpha x)$ then the Brillouin width at half height in Hz is given by:

$$\Gamma_B = \frac{\alpha\nu}{\pi} \quad (3)$$

In many fluid systems (although we believe not in our case) a viscous mechanism is responsible for the line width⁵. However, we speculate below that the crosslinking regions of the gel under study, scatter the sound waves travelling in the liquid of the gel and give rise to broader Brillouin lines.

EXPERIMENTAL

Light scattering system

A conventional experimental system consisting of a Coherent Radiation Laboratories 52B Laser operated at a single frequency and 200 mW power, piezoelectrically scanned Fabry-Perot⁶ spectrometer plus d.c. detection of the light scattered at 90° was used except for one important feature not hitherto applied to polymer systems. This feature, made fairly standard in semi-conductor physics⁷, consists of passing the scattered light through the Fabry-

Figure 1 Typical Brillouin Spectra of gels of low gelatin concentration. The upper trace is a single pass Fabry-Perot (98% mirrors) and the lower spectra obtained by the double pass technique

Perot twice. This enables the weak scattered light to be detected in the presence of very much stronger elastically scattered light, i.e. it increases the contrast of the Fabry-Perot.

The reflectivities of the Fabry-Perot mirrors were chosen as 92% at the exciting wavelength of 5154 Å. The free spectral range⁶ of the instrument was 8.66 GHz which with a finesse of ~40 gave a resolution of 200 MHz. A typical spectrum is shown in Figure 1 along with a single passed spectrum taken using higher reflectivity plates (~98%) in the Fabry-Perot (contrast increases with plate reflectivity⁶). These spectra clearly demonstrate the need for a multipassed system. It is not clear whether the Tyndall light is inherent in the nature of the gel or merely due to impurities such as dust etc. In obtaining the line-widths, allowance was made for the convoluting effect of the instrument function.

Gels

The gelatin gels in this study were made from Eastman Gelatin (purified pigskin). A range of gels were made by dissolving appropriate quantities in 0.15 M NaCl solution which had been previously made using distilled water. The salt solution was used because it is known^{1,8} that the nature of a gel is dependent upon the ionic nature of the solvent and the presence of a significant amount of NaCl should make the effects of impurities less important.

The solutions were prepared by heating to not more than 60°C. The samples were then allowed to cool naturally to room temperature at a rate of ~0.5°C/min or transferred directly from the water bath at 60°C to a bath at 0°C (quenched samples).

RESULTS

The shift and width of the Brillouin lines were measured at room temperature (~20°C) for eight concentrations between zero and 0.2 g/cm³. The first set of results were taken from gels cooled slowly to room temperature (~1°C/

min). During an attempt to study the time dependent behaviour of the Brillouin spectra while a sample gelled, it was noted that the line width of the final sample was significantly lower. In view of the expected structure of the gel (see Discussion) and known phenomena of crystallization of polymers (crystalline regions decrease in size with increasing cooling rate) it was speculated that this change in line width was due to the rate at which the gel was cooled. Thus eight more samples were prepared and quenched in ice water and a significant drop in Brillouin line width was noted. The shifts and widths are displayed for the two cooling rates in Figures 2 and 3.

In view of the fact that the changes in the Brillouin Spectrum on gelling for the low concentrations are small and that the higher concentrations gel relatively rapidly it was found necessary to delay a dynamic study of the gelling process to a later date.

DISCUSSION

There are two possible interpretations to the observed Brillouin spectra. One phenomenological explanation is that changes in the spectra are brought about by the change

Figure 2 The graph of Brillouin shifts versus concentration of gelatin. X, gel cooled slowly (0.5°C/min); ●, gels quenched cooled to 0°C

Figure 3 The graph of Brillouin line width versus concentration of gelatin. X, gels quench cooled slowly (0.5°C/min); ●, gels quenched to 0°C; □, line-width of the gel in the molten state

in concentration affecting the relaxation frequency of the gel and the other that the structure of the gel scatters the thermal phonons in the gel and therefore affects their frequency and lifetime. We briefly consider first the relaxational interpretation.

Relaxational interpretation

There are essentially two effects observed in these experiments, the small (~20%) increase in velocity of sound in the medium (*Figure 2*) and the large (~300%) increase in the widths of the Brillouin lines (*Figure 3*) which in turn mean a large decrease in the life-time of the sound wave.

Considering the equations describing Brillouin scattering in a relaxing medium⁴ under the very common approximation of a single relaxation time necessary to make the equations tractable, we investigate the possibility of the above two features being explained by a relaxational model.

It was found, however, that the only parameters physically variable in such a model i.e. the low frequency elastic modulus and the relaxation time, had to change in a physically unrealistic manner. The modulus for instance had to decrease with increasing gel concentration. Therefore it was concluded that a relaxational mechanism is very unlikely to be responsible for the observed effects.

However, stronger evidence against relaxational interpretation can be inferred from the effect on the Brillouin line-width of changing the exciting line from 5145 Å to 4880 Å. If a relaxation mechanism is present a decrease in line-width should be observed after correction for the inverse quadratic dependence of Γ_B on λ . However, on performing this experiment the width increases significantly. An accurate quantitative estimation of the dependence of width on frequency was not attempted since the resolution of the Fabry-Perot decreased with wavelength because of the nature of mirror coatings.

Structural scattering

Since a relaxational process would not appear to explain the experimental observations we investigate an alternative mechanism which might be responsible for the observed Brillouin line-widths i.e. that of the scattering of phonons by stationary objects.

Scattering interpretation

Taking as our model for the structure of the gel one in which the crosslinks between the polymer molecules are the triple helices⁹ of the parent collagen molecule we consider the regions of helices as cylindrical scattering entities. In this case the problem of the scattering of sound waves by such a system is closely analogous to that of the propagation of sound in a fog¹⁰. In the case of fog the scattering entities are spherical water droplets whereas in the gel they are the triple helix of a portion of the native collagen molecule which are cylindrical in shape. In principle it should be possible to interpret the Brillouin shifts and widths in terms of expressions derived from scattering from finite cylindrical scattering centres. Unfortunately, it appears that this problem has not been treated theoretically, however, it is justifiable to use the expression derived for spherical scatterers to demonstrate an order of magnitude for the effect.

Brillouin shift

The velocity of sound in a system of N spheres of radius a_n embedded in a medium is given by¹⁰:

$$v^2 = \frac{1}{K_R \rho_R} \quad (4)$$

$$K_R = K_0 + \sum_{n=1}^N \frac{4}{3} \pi a_n^3 (K_n - K_0) \quad (5)$$

$$\rho_R = \left[\frac{1}{\rho_0} + \sum_{n=1}^N \pi a_n^3 \left(\frac{1}{\rho_n} - \frac{1}{\rho_0} \right) \right]^{-1}$$

where K_R and ρ_R are the appropriate mean compressibility and density of the total system. The density and compressibility of the spheres and medium are ρ_n , K_n and ρ_0 , K_0 respectively. We know from our results that K_R and ρ_R increase only slightly. Therefore we may consider the effect of such small changes on equation (4) we have:

$$\frac{dv}{v} = -\frac{1}{2} \left| \frac{d\rho}{\rho} + \frac{dK}{K} \right|$$

Evaluating $d\rho/\rho$ and dK/K from (5) using ρ_n and K_n , 1.3 g/cm³ and $K = 10^{-11}$ cm² dyne¹¹ respectively and approximating the scattering centre as a sphere of radius 25 Å we calculate the value of N required to give the observed 10% increase in Brillouin shifts. This yields a value of $N \sim 10^{20}$ cm⁻³ which gives a value for inter-crosslink distance of the order 20 Å. This value would appear to be rather low but probably should not be interpreted too literally since equation (5) is derived assuming the interparticle distance is greater than the wavelength, and this would not appear to hold. It is worth noting however, that the above figures would predict approximately a 50% solution of gelatin, which is of the same order of magnitude as that used.

Brillouin widths

The expression for Brillouin widths arising from the scattering of phonons by the spheres can be derived from $\Gamma_B = \alpha v/\pi$ using a value of α . This can be shown to be¹⁰ $N\Sigma_s$ where Σ_s is the scattering cross-section of one of the spheres and is given by:

$$\Sigma = \frac{4}{3} \pi a^2 (\kappa a)^4 \left[\left| \frac{K_n - K_0}{K_0} \right|^2 + \left| \frac{\rho_n - \rho_0}{2\rho_n - \rho_0} \right|^2 \right]$$

Using the above values of K , ρ , n etc., and equation (3) to related spatial decay rate of a sound wave to Brillouin line width the calculated line width is ~100 MHz, giving a good order of magnitude agreement with observation. Thus it would appear that the Brillouin spectrum of the gel may be explained in terms of the scattering of sound waves by the structure of the gel, i.e. the crosslinking regions.

A further test that presents itself is the behaviour of the line width when the gel is melted. Melting the gel destroys the network and thus the line widths should decrease. We see from the single point of the graph, *Figure 3*, that this did in fact occur which further supported the scattering interpretation.

Correlation with ultrasonic results

An alternative experimental method of probing the properties of a gel using sound waves is by ultrasonic methods. However only scant data appears to be available. Koinito¹² reports no change in absorption on gelling at a frequency of 1 MHz. Mikhailor and Tarutina¹² report an increase in absorption up to a concentration of 3% and thereafter a constant absorption. This observation is consistent with the scattering interpretation since the wavelength (λ) of sound in ultrasonic experiments is very much larger than that in Brillouin scattering. For λ very much larger than the inter-crosslink distance the scattering is expected to be small in agreement with Koinito's results at high concentration. If the inter-crosslink distance decreases with increasing concentration then the behaviour described by Mikhailor and Tarutina may be expected. A convincing test would be effectively to increase the wavelength of the sound giving rise to the Brillouin scattering until it overlapped that of Mikhailor and Tarutina, however, this requires an unattainably small scattering angle.

Variation of line width and thermal treatment

An interesting result obtained from the Brillouin scattering measurements is the way that different thermal treatments affect the line-width. Quench cooling always resulting in a reduction in this width. These results are indicated in *Figure 3*.

If the increase in line width of the gel over that of water is accepted as due to scattering by the crosslinks in the gel then the explanation of the difference between slow cooled and quenched gel can be indicative of (a) differences in the size (probably the length) of the scattering units or (b) differences in the concentration of the scattering units. In reality, both probably occur and it is difficult, on the basis of the present inelastic light scattering data to distinguish between the two.

CONCLUSIONS

We have reported what we believe to be the first Brillouin scattering investigation of material of biological origin. This

was made possible due to the high contrast available from multipassed Fabry-Perot techniques. The results have been interpreted in terms of scattering of sound waves by the structure of the gel under study and parameters inferred from the study are in good agreement with the accepted structure of the gel.

A sonic pulse propagation study of phase separation in certain block copolymers

A. Beamish and D. J. Hourston

Department of Chemistry, University of Lancaster, Bailrigg, Lancaster LA1 4YA, UK
(Received 20 January 1976)

A pulse propagation technique has been used to measure the longitudinal sonic velocities (C_L) of both linear ABA and 4-arm star block copolymers of styrene and butadiene. When homo-polystyrene and homo-polybutadiene are added to vary the styrene content a plot of C_L against vol % polystyrene (V_G) results in a smooth curve whose equation can be represented empirically as $C_L = 6.9 \times 10^{-2} + 9.95 \times 10^{-4} V_G^{1.4}$. It is found that neither the star copolymer nor ABA poly(styrene-*b*-isoprene) lie on this curve. The latter material appears to give a lower and approximately parallel curve. The experimental curve cannot so far be predicted by equations of mixing including that attributed to Urick.

INTRODUCTION

A considerable number of papers concerned with the internal structures resulting from phase separation in ABA block copolymer systems, where A is a glassy and B a rubbery block, have now been published¹⁻⁵. Meier⁶⁻⁸ has deduced theoretically all the morphological possibilities. Part of this work has been devoted to the study of the influence of processing temperature¹ or casting solvent⁹ on the resulting structure, showing that both of these variables can influence the internal structure considerably.

To date the two techniques which have dominated morphological studies of this kind are electron microscopy and low-angle X-ray diffraction. The deduction of structure by both of these techniques is somewhat time consuming and, in the case of electron microscopy, some skill is also required in the sectioning of these rubbery materials. This latter difficulty is sometimes avoided by solvent-casting the polymer onto electron microscope grids, but as it is known that both the solvent, as already mentioned, and the evaporation rate⁹, at least for certain solvents, can influence the structure, it is an unsatisfactory approach if information on bulk structure of heat processed material is required.

As a more rapid method of achieving even only qualitative information about composition, structure and orientation in these systems would be welcome, a sonic pulse propagation technique has been applied in an attempt to achieve this end. This paper is a preliminary report on this work.

This technique has been applied to both homogeneous and heterogeneous polymer systems for some considerable time^{10,11}, but has mainly been used with semi-crystalline materials¹⁰⁻¹² often in an attempt to measure orientation in the amorphous phase^{12,13} which has a lower sonic velocity than the crystalline phase. In the case of styrene-butadiene-styrene and styrene-isoprene-styrene copolymers the individual homopolymers which comprise the blocks also have widely differing sonic velocities so that it would seem very probable that both copolymer composition and bulk structure should markedly influence the overall sonic velocity. For example, a system where the two phases are continuous should differ substantially in terms of sonic velocity from a system of the same compo-

sition where the glassy blocks are regularly dispersed as spheres in a rubbery matrix.

Craver and Taylor¹⁴ have discussed the theory of propagation of plane longitudinal sound waves through materials. In the case of a planar isotropic body, the sonic modulus (E_s) is related to the longitudinal wave velocity (C_L) by equation (1):

$$E_s = \rho C_L^2 (1 - \mu^2) \quad (1)$$

where ρ is the density of the sheet and μ is the Poisson's ratio.

The equivalent expression for the sonic shear modulus (G_s) is given by equation (2):

$$G_s = \rho C_T^2 \quad (2)$$

where C_T is the transverse sonic velocity. By the combination of equations (1) and (2), plus the relation $E_s = 2G_s(1 + \mu)$, the following expression for Poisson's ratio is obtained:

$$\mu = 1 - \left(\frac{2C_T^2}{C_L^2} \right) \quad (3)$$

Thus, by the measurement of longitudinal and transverse velocities it is possible to calculate Poisson's ratio and sonic moduli so long as the sample is isotropic.

Composition as well as structure should influence sonic velocity, but the form of such a dependence for this type of system is not known. The following equation for mixtures which is due to Urick¹⁵ has been applied as has a simple mixing equation, but neither fits the observed results:

$$C_L = \frac{1}{(\rho_0 K_0)^{1/2}} = \left\{ \frac{1}{[\rho_2 \beta + \rho_1 (1 - \beta)] [K_2 \beta + K_1 (1 - \beta)]} \right\}^{1/2} \quad (4)$$

where ρ_0 and K_0 , ρ_1 and K_1 and ρ_2 and K_2 are the density

EXPERIMENTAL

The four linear tri-block copolymers used in this study were unfractionated commercial polymers (Cariflex) manufactured by Shell Chemical Company. Both ABA poly(styrene-*b*-butadiene) (SBS) and ABA poly(styrene-*b*-isoprene) (SIS) were included. Two samples of a styrene-butadiene star copolymer (4 arms) were kindly supplied by Phillips Petroleum-UK Ltd. Details of these materials and of the polystyrene and polybutadiene homopolymers used in the compositional study are given in Table 1.

A Mechrolab Membrane Osmometer (Model 501) was used to determine number-average molecular weight and the configurational analysis was achieved by means of 220 MHz proton n.m.r.

All the systems investigated were fabricated into sheet by casting onto glass plates using re-distilled toluene as solvent. The rate of evaporation was kept low so that it could be eliminated as a factor influencing morphology.

A Morgan Dynamic Modulus Tester (PPM-5R) supplied by H. M. Morgan Co. Inc., Cambridge, Massachusetts, USA was used to measure sonic velocity. This instrument transmits a pulse of sound at a frequency of around 10 kHz from one piezoelectric transducer to another and directly measures the time elapsed between transmission and reception of the pulse. By changing the orientation of both transducers by 90° it is possible to measure the longitudinal and transverse sonic velocities.

Samples for electron microscopy were cast from very dilute toluene solutions onto a clean mercury surface and collected on nickel grids. The samples were stained by suspending the grids over a 1% aqueous solution of osmium tetroxide. The grids were examined using a Siemens Elmiskop 1A electron microscope.

RESULTS AND DISCUSSION

Applicability of the technique

The data in Table 2, which are for sheet prepared by hot pressing, show that the technique is sensitive to structural anisotropy. It was found that when these polymers were cast from toluene the resulting sheet was isotropic. The sonic velocity values for solvent cast samples of SBS-1 and SIS-2 were 0.161, 0.162 and 0.157 km/sec and 0.111, 0.109 and 0.111 km/sec respectively in the three previously

defined directions. For these cast samples, as shown in Table 3, Poisson's ratio was found to be close to 0.5. At low strains this is the expected result for a structure where the glassy phase is discontinuous and embedded in a rubbery matrix. This structure has been shown to be the correct one (see Figure 1a). This clearly shows a spherical or possibly a cylindrical polystyrene domain structure in a rubbery matrix.

Influence of polystyrene content on C_L

Figure 2 shows the influence of vol % polystyrene on C_L , indicating that when various amounts of polystyrene and polybutadiene homopolymers were added to SBS-1 a smooth curve (A) which also passes through the point representing pure polybutadiene results. Furthermore, it was found that the data for SBS-2 and SBS-2 with added polystyrene also fitted the same curve, but that the data for SIS-1 and SIS-2 did not fall on the curve, but seem to lie on a lower, and, approximately parallel, curve. In the case of the two styrene-butadiene star polymers the sonic velocities lay considerably above curve A.

Figure 1 (a) Electron micrograph of SBS-1 cast from toluene. Magnification: 71 500x; (b) electron micrograph of SBS-1 plus 10% (w/w) added polystyrene (light areas). Cast from toluene. Magnification: 56 000x; (c) SBS-1 plus 50% (w/w) added polystyrene (dark areas). Magnification: 0.57x; (d) electron micrograph of Star-2 polymer cast from toluene. Magnification: 72 000x

The polystyrene added to the SBS rubbers had a considerably higher molecular weight than that of the end-blocks. A consequence of this, which was recognized in advance, was that some or even the bulk of the added homopolymer would not be accommodated in the domains,

but would rather form macrodomains of pure polystyrene. Such occluded polystyrene macrodomains were observed for all levels of added polystyrene. Figure 1b shows a typical structure which also shows that the regularity of domain structure is largely retained. If the volume per-

Figure 2 Longitudinal sonic velocity (C_L) versus vol % polystyrene. Curve A: \circ , SBS-2 and SBS-2 plus added polystyrene, \times , SBS-1 and SBS-1 plus added polybutadiene or polystyrene; Δ , polybutadiene. Curve B, equation (5). Curve C, equation (4)

centage of polystyrene exceeded $\sim 40\%$ the result was phase separation on a massive scale (see Figure 1c).

The polybutadiene which was added to lower the polystyrene content had a very similar microstructure and molecular weight to that of the mid-blocks of both SBS-1 and SBS-2, and would certainly be located in the matrix. The fact that all the points lie on a smooth curve would seem to a first approximation to indicate that the overall sonic velocity is sensitive only to the volume percent of the glassy phase and not to whether it is all incorporated into the pre-existing glassy domains or whether macrodomains result. In either case it is assumed that the polystyrene phase remains discrete. This tentative conclusion will be tested by using polystyrene of much lower molecular weight.

It has been reported¹⁶ that styrene-butadiene star copolymers have higher elastic moduli than their equivalent linear counterparts. As the densities of the two systems are very similar an inevitable consequence of this is that the sonic velocities will also be higher. In the case of Star-1 where the vol % polystyrene was 34.6, the sonic velocity was 0.540 km/s. The result for Star-2 is shown in Figure 2. Figure 1d shows that although the domains are somewhat less regular for the cast star polymer the rubbery phase is the continuous one.

Because of the non-linearity of curve A (Figure 2) simple equations of mixing such as equation (5) cannot be expected to fit the observed data precisely.

$$C_L = \nu_G C_G + (1 - \nu_G) C_R \quad (5)$$

Where ν_G is the volume fraction of glassy polymer and C_G and C_R are the longitudinal sonic velocities of the glassy and rubbery phases respectively. However, in fact, expressions of this type result in very poor fits as is illustrated by curve B (Figure 2). An experimentally determined value of 0.069 km/sec was used for the longitudinal sonic velocity

of polybutadiene. It is now clear that in such systems there will be boundary regions¹⁷ where an admixture of polystyrene and polybutadiene coexist. By considering this third phase it should be possible to improve, somewhat, the fit of such equations of mixing. At the moment however, it is not clear what composition should be used for this mixed phase.

The curve predicted by Urick's equation (equation 4) is shown as curve C (Figure 2), and, again, this curve bears no relation to the observed results. In the calculation of this curve the densities of the glassy and rubbery phases were taken as 0.899 and 1.05 g/cm³ respectively, whilst Poisson's ratios for these two phases were assumed to be 0.33 and 0.49 respectively. The bulk compressibilities were calculated from experimental values of dynamic storage modulus. This relation is very sensitive to the values chosen for Poisson's ratio for the rubber, but changes in this parameter, and, also the addition of a third mixed phase, only results in somewhat lower, and parallel, curves.

At this stage of the work it is necessary to resort to the empirical equation shown below.

$$C_L = 6.9 \times 10^{-2} + 9.95 \times 10^{-4} V_G^{1.4} \quad (6)$$

where V_G is the vol % polystyrene.

In conclusion, it can be stated that equation (6) relates C_L to vol % polystyrene specifically for linear SBS systems, and, that a similar relation will probably hold for SIS polymers. Acceptance of such relations would allow rapid estimation of polystyrene content.

Microstructure of directionally solidified poly(ethylene oxide)

Andrew J. Lovinger, Chi-Ming Lau and Carl C. Gryte

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York 10027, USA

(Received 17 December 1975; revised 18 March 1976)

Poly(ethylene oxide), zone solidified within a temperature gradient, has been examined by electron microscopy and X-ray diffraction. Longitudinal fracture replicas show the lamellae to be oriented parallel to the direction of solidification, with no observable order in the transverse direction. These results are also substantiated by X-ray diffraction. In contrast to a drawn fibre, the crystallites are not oriented in a single direction, but rather parallel to the $\{100\}$ planes. This is consistent with growth on the $\{120\}$ faces. These are inclined by 45° with respect to the a^* axis, which is parallel to the direction of solidification and to the direction of the temperature gradient.

INTRODUCTION

During the past two decades, the zone solidification technique¹ developed by Pfann² has found widespread applications in the production of single crystals of metals³ and inorganic⁴ and organic⁵ compounds, in the oriented growth of alloys⁶, and in the purification of chemical substances^{7,8}. This technique involves passage of a rod of the material at a steady state through a zone heater where the temperature is high enough to cause melting. The melt–solid interface is steady, so that crystallization proceeds at a constant growth rate equal to the velocity of the rod.

This method has also been used to produce directionally oriented polymer crystals from the melt in the works of Fujiwara^{9,10} and Crissman^{11,12} on polyethylene and polypropylene, as well as Stein *et al.*¹³ on films of poly(butene-1). A review of these and other methods^{14,15} of inducing uniaxial growth of polymers has been given elsewhere¹⁶.

The microstructure of uniaxially crystallized material is expected to be similar to that in a narrow radial sector of ordinary spherulites. The divergence of the radii from a nucleation point requires a certain branching, but that does not affect the nearly parallel growth of adjacent fibrils. Price and Kilb¹⁷ have confined poly(ethylene oxide) (PEO) in a small capillary, and have in fact used the resulting morphology as a model for spherulitic microstructure. Also, the diffraction pattern of a small sector of a type III polypropylene spherulite, as shown by use of a micro-X-ray beam¹⁸, is very similar to that of a zone solidified sample¹⁰.

Poly(ethylene oxide) rods have been directionally solidified¹⁶ to produce uninterrupted lamellae that extend throughout the full length of the material. The morphology, as determined by polarizing optical microscopy, indicates a spherulitic macrostructure in the form of an uninterrupted matrix of parallel lamellar fibrils practically devoid of primary nuclei. These large specimens are thus ideally suited for microstructure evaluation by electron microscopy of fracture surfaces and by X-ray diffraction. It is the purpose of this report to use these techniques to determine the orientation of the PEO lamellae within a zone solidified rod, and to indicate their organization in planes parallel and normal to the direction of oriented growth.

EXPERIMENTAL

Poly(ethylene oxide), (Union Carbide WSR-205, molecular weight 600 000), was injection moulded to produce cylindrical rods, 10 cm in length and 1 cm in diameter. The rods were then placed into glass tubes that were subsequently evacuated, filled with dry nitrogen, and sealed. Zone solidification of the polymer was effected by passing the rods through an annular heater and cooler, as has previously been described¹⁶. The temperature gradient between these was substantially linear at $3^\circ\text{C}/\text{mm}$, and the solid–melt interface was observed to remain stationary during the procedure. At speeds below $400\ \mu\text{m}/\text{min}$, the directionally solidified sample was composed of spherulites slightly elongated in the direction of motion. When rates below $15\ \mu\text{m}/\text{min}$ were employed, the initially nucleated spherulites extended into the entire length of the polymer rod, and birefringence indicated that fibrils were oriented in the longitudinal direction, parallel to the cylinder axis¹⁶.

From the zone solidified samples, longitudinal and transverse sections, 1–2 mm thick, were cut to be used for X-ray studies. The same procedure was carried out on randomly crystallized rods, as well as on fibres; these were used for comparison purposes. As PEO is water soluble, the samples were stored under vacuum in a desiccator.

Diffraction patterns were recorded on X-ray film (Kodak Type AA-2) using a well collimated beam from a $\text{CuK}\alpha$ source. A lead beam stop was placed on the film, which was at a distance of 5.56 cm from the sample.

Electron micrographs were made of replicas produced from fracture surfaces in both the longitudinal and transverse directions of the rods. Clean breaks could be made only after cooling the samples to liquid nitrogen temperatures. As ordinary carbon replicas showed very little contrast, gold shadowing at an angle of about 30° was used prior to carbon deposition. The replicas were then isolated by dissolution of the polymer in water, and placed on 200-mesh grids or bar grids for bright field studies.

RESULTS AND DISCUSSION

Electron microscopy

Poly(ethylene oxide) crystallizes in the form of lamellae

Figure 1 Fracture surface from a longitudinal section of directionally solidified PEO. Zone velocity = 15 $\mu\text{m}/\text{min}$

Figure 2 Fracture surface from a transverse section of directionally solidified PEO. Zone velocity = 15 $\mu\text{m}/\text{min}$

about 100 Å thick and several microns in lateral dimensions¹⁹. The clear lamellar structure of this polymer is seen in *Figure 1*, obtained from a surface replica in the longitudinal direction of a sample zone solidified at 15 $\mu\text{m}/\text{min}$. A distinct orientation of the lamellae from left to right is evident. Of course, the high magnification and consequent narrow field do not permit any general conclusions regarding overall orientation to be reached from a single micrograph. However, it has been conclusively observed by use of numerous electron micrographs taken from different areas of each replica, as well as from other longitudinal sections of the same and of similar samples, that for any given rod all lamellae are indeed oriented in the same direction. Use of bar grids has shown that this also coincides with the direction of zone solidification.

Examination of the transverse cross-section can be made on the electron micrograph of *Figure 2*. In order to be able to observe the overall structure, the magnification has been reduced so that the field of view is now about eight times larger than in *Figure 1*. Here, no unique orientation is apparent; practically all possible directions are represented in this micrograph. Similar results obtained from other transverse sections indicate that there is indeed no overall orientation normal to the direction of solidification. These observations are consistent with the optical birefringence data¹⁶ on the same materials, for which the transverse sections were found to be birefringent but without orientation when viewed between crossed polarizers.

Nevertheless, despite the lack of overall orientation, adjacent fibrils, as seen in small regions of *Figure 2*, do

adopt parallel directions. This is due to the space filling requirement of efficient packing of individual lamellae within the fibrillar texture. This is seen more clearly in *Figure 3*, which presents a part of the preceding photograph at a higher magnification. In addition, a number of very thin links are observed to connect many adjacent lamellae. Such links have been absent in all longitudinal replicas. These void-like areas may be caused by dimensional changes of the material during zone solidification. Their absence in the longitudinal direction would then be due to the fact that in this case all crystal boundaries are parallel to that direction.

X-ray diffraction

Figures 4a and *4b* show the diffraction patterns obtained from bulk crystallized PEO and from a drawn fibre of this polymer. By use of such diffraction patterns, several investigators^{17,20-24} have determined the unit cell parameters. In this study, the most recent values of Takahashi and Tadokoro²⁴ were used, postulating a monoclinic unit cell ($a = 8.05 \text{ \AA}$, $b = 13.04 \text{ \AA}$, $c = 19.48 \text{ \AA}$, $\beta = 125.4^\circ$) with a considerable distortion from the D_7 helical symmetry that had been previously observed.

Figures 5a and *5b* contain the diffraction patterns shown by two longitudinal sections of the directionally crystallized PEO, while the major inner reflections are indexed in *Figure 5c*. In all cases the direction of solidification is vertical. The sample of *Figure 5a* was zone solidified at 200 $\mu\text{m}/\text{min}$, forming numerous spherulites, all distinctly elongated in the direction of motion¹⁶. The full circles seen in the bulk crystallized specimen of *Figure 4a* now begin to partly break up into arcs, indicating the start of limited orientation. A much more highly oriented structure is exhibited in the diffraction pattern of *Figure 5b*, where very distinct arcs are now apparent. This photograph was obtained from a sample crystallized at 15 $\mu\text{m}/\text{min}$, representing uninterrupted growth of PEO lamellae in a temperature gradient.

When the X-ray beam is directed parallel to the sample axis through a transverse cross-section, the pattern of *Figure 5d* is obtained. Full circles are again formed, indicating the lack of any preferred orientation normal to the direction of oriented growth of the spherulitic fibrils. The molecular chains thus adopt all possible directions about the rod axis.

Comparison of the diffraction patterns from the bulk crystallized sample (*Figure 4a*) and from the transverse section (*Figure 5d*) shows a striking difference. Although

Figure 3 Higher magnification of the fracture surface of *Figure 2*

Figure 4 X-Ray diffraction patterns of PEO. (a) Bulk crystallized sample; (b) drawn fibre; fibre axis vertical

the strong outer ring of *Figure 4a* (composed chiefly of the 032 and $\bar{1}32$ reflections) is also present in *Figure 5d*, the strongest individual reflection, i.e. the 120 seen as the intense inner ring in *Figure 4a*, is almost totally absent in *Figure 5d*. This implies that orientation in the transverse cross-section is not totally random, since in no case do the $\{120\}$ planes adopt a Bragg angle of 9.6° required for their reflection.

The treatment of Sisson²⁶ regarding the various types of orientation can be used to explain the differences in the diffraction patterns of *Figures 4b* and *5b*. The former is the ordinary type of axial orientation²⁵ (or fibre formation) obtained by mechanical drawing, in which case the *c*-axes lie parallel to the fibre direction. In the zone solidified sample of *Figure 5b*, the crystallites lie parallel to a transverse plane¹⁶, but can otherwise have all possible directions on this plane.

In this case the X-ray photograph shows row lines parallel to a rotation axis. Layer lines are absent since the principle planes of the reciprocal lattice are now inclined with regard to the equator²⁵. Such row lines are clearly seen in *Figure 5b* and *5c* in the vertical direction. In these *Figures* the reflections on each specific row line have identical *k* indices. A transformation of the row lines using a Bernal diagram²⁷ indicates equatorial spacings of $13.1 \pm 0.2 \text{ \AA}$ which are indeed characteristic of the length of the *b*-axis of the PEO unit cell. Small individual deviations occur in each row line (e.g. in the 020 and the 021 reflections) when the *l* values of the reflections are different. In this case the *c*-axes to which these indices correspond are inclined with respect to the axis of rotation in the monoclinic cell.

A similar diffraction pattern was obtained by Price and Kilb¹⁷ from a PEO spherulite grown isothermally within a very fine capillary. They found crystal orientation consistent with rotation about the (401) plane normal, while Walter and Reding²⁸ had previously concluded that rotation occurs about the *b*-axis of the unit cell. However,

indexing of the diffraction pattern of *Figure 5b* shows that Price and Kilb¹⁷ are right in rejecting the *b*-axis. Nevertheless, the *b*-axis is still a very special direction within the unit cell; it is perpendicular to both the *a* and *c*-axes, as well as to the true rotation axis of the zone solidified polymer.

The present data tend to question also the $[401]^*$ axis proposed by Price and Kilb¹⁷. It is true that their axis is consistent with the experimental data, and the interplanar angles as calculated from the formula for monoclinic unit cells are in close agreement with those predicted from the observed azimuthal angles (see *Table 1*). However, it is equally true that this axis is physically awkward, resulting in an anomalous growth mode. This is seen in *Figure 6*, a perspective drawing of the PEO unit cell, and in *Figure 7*, which depicts two sections of this cell, viewed along the (010) and $(10\bar{4})$ plane normals. The $[401]^*$ axis is inclined at an angle of 4.6° with respect to the normal to the (100) plane, causing the *c*-axes of the unit cell to be positioned at an angle of 85.4° away from the $[401]^*$ direction.

A much more attractive choice for a rotation axis is the $[100]^*$, i.e. the *a** axis, which is normal to the *c*-axis, allowing the molecular chains to crystallize perpendicular to the growth direction and parallel to the melt–solid interface (see *Figures 6* and *7*). Not only is this axis also consistent with the diffraction pattern of *Figure 5b*, but a comparison of the observed and calculated interplanar angles gives a closer agreement for the $[100]^*$ axis than for the $[401]^*$, as is seen in *Table 1*.

The precise growth front is most likely composed of parallel lamellae, growing on their $\{120\}$ faces in a manner similar to that depicted in *Figure 8*. There is substantial evidence in the literature that the (120) is by far the favoured growth plane in the PEO crystals²⁹. Investigations of the unit cell structure^{17,20–24} show that the $\{120\}$ planes are the most closely packed in the lattice. In fact, the latest unit cell proposed by Takahashi and Tadokoro²⁴ causes the $\{120\}$ planes to be even more closely packed than had pre-

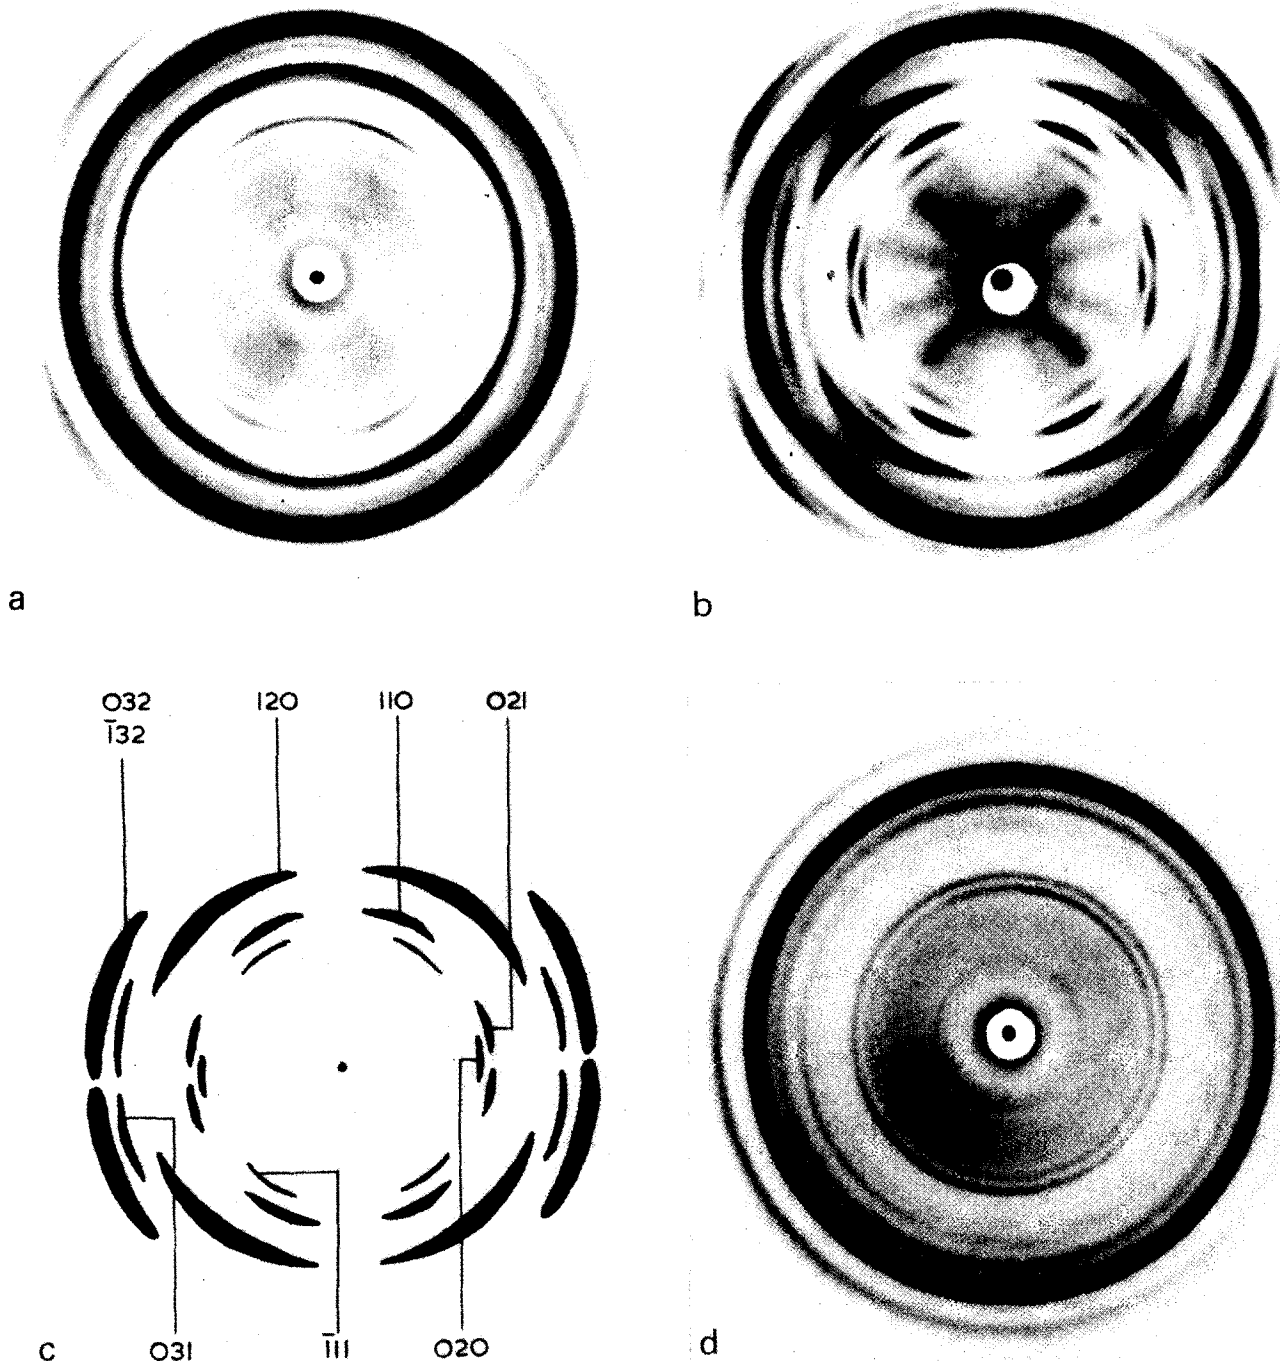

Figure 5 X-Ray diffraction patterns of zone solidified PEO. (a) Longitudinal section; axis vertical; zone velocity = 200 $\mu\text{m}/\text{min}$; (b) longitudinal section; axis vertical; zone velocity = 15 $\mu\text{m}/\text{min}$; (c) indices of the major inner reflections of Figure 5b; (d) transverse section; zone velocity = 15 $\mu\text{m}/\text{min}$

viously been thought. Barnes and Price¹⁹ have observed growth spirals and terraces typical of (120) growth on single crystals of PEO. Lotz and Kovacs³⁰ have isolated single crystals of PEO, which in most cases appear as nearly perfect squares whose four sides are (120) planes, while their diagonals are parallel to a^* and b^* . Thus, the above growth model also accounts for the striking absence of the strongest single reflection from the diffraction pattern of the transverse section in zone solidified PEO (Figure 5d). As this reflection is caused by the {120} planes which are inclined at a constant angle of 45.4° to the proposed $[100]^*$ axis (see Figure 6), the 9.6° Bragg angle required for reflection

can never be attained. As seen from the above discussion, this type of growth results in a conical orientation of the {120} planes. The base of the cone is a common (100) plane, and its axis is $[100]^*$ or a^* , which coincides with the direction of the oriented growth and the temperature gradient.

It should be noted that the model proposed is not in disagreement with the branching of spherulitic fibrils reported in the treatment of Keith and Padden³¹. However, as is also seen in Figure 1, directional growth geometrically constrains the extent of the branches produced, and thus the X-ray pattern should show no significant orientation other than around the rotation axis.

Differential refractometry and light scattering on nylon-6 and poly(methyl acrylate) in mixed solvents

M. B. Huglin and R. W. Richards*

Department of Chemistry and Applied Chemistry, University of Salford, Salford M5 4WT, UK
(Received 21 January 1976; revised 23 February 1976)

Investigations have been made of solvent systems for potential use in characterizing nylon-6/poly(methyl acrylate) copolymers. To this end, measurements involving differential refractometry (at constant composition and also constant chemical potential of solvents) and light scattering have been conducted on solutions of nylon-6, poly(methyl acrylate) and a mixture of these two polymers. From refractometric and solubility considerations the most suitable solvents are binary mixtures of *o*-chlorophenol (*o*-CP) and 2, 2', 3, 3'-tetrafluoropropanol. In particular, the binary solvent containing 73% (by volume) of *o*-CP yields the molecular weight of the nylon-6 constituent of the polymer mixture directly, since the light scattering from the other polymer constituent is thereby eliminated. Preferential adsorption of *o*-CP occurs to both polymers, the maximum extents corresponding to 1 mol *o*-CP/1.4 segments nylon and 1 mol *o*-CP/5.7 segments poly(methyl acrylate). This is attributed to a breakdown of intramolecular hydrogen-bonding in *o*-CP and subsequent formation of hydrogen bonds with the carbonyl groups in the polymers.

INTRODUCTION

Previous communications¹⁻⁵ have been devoted to the kinetics of the γ -radiation initiated grafting of acrylic acid to nylon-6. A continuation of this work is the correlation of these kinetics with the chain lengths of the grafts and of the nylon/poly(acrylic acid) copolymer produced, the latter being freed from homopolymer and ungrafted substrate⁶. From solubility considerations it is found convenient to handle the grafts in their methylated form⁶, i.e. as poly(methyl acrylate). In the present communication we investigate the potentialities of some solvent systems with a view to optimizing a future characterization of methylated copolymers. To obviate any possible confusion it should be noted that no data on copolymers are reported here, and the measurements relate solely to solutions of nylon-6, poly(methyl acrylate) and a mixture of these two polymers.

CONDITIONS, UNITS AND ABBREVIATIONS

The temperature for all measurements was 303K and the wavelength of light *in vacuo* for refractometry, differential refractometry and light scattering was 436 nm. SI Units are used throughout so that molecular weights are quoted in kg/mol, these values consequently being smaller by a factor of 10^3 than those expressed more conventionally in the non-SI units of g/mol. These considerations apply equally to the heterogeneity parameters *P* and *Q*. The following abbreviations and symbols are adopted:

NY (also subscript A) nylon-6,
PMA (also subscript B) poly(methyl acrylate),
subscript AB mixture of polymers A and B,
o-CP (also subscript 1) *o*-chlorophenol,

2, 2', 3, 3'-tetrafluoropropanol, true weight-average molecular weights of polymers A and B, true and apparent weight-average molecular weights of mixture comprising polymers A and B, true *z*-average mean square radii of gyration of polymers A and B, apparent *z*-average mean square radius of gyration of mixture comprising polymers A and B, weight fractions of A and B in mixture comprising polymers A and B, refractive index of pure or mixed solvent, volume fraction of solvent 1 in mixed solvent comprising solvents 1 and 2, notation for specific refractive index increment in general (also denoted commonly elsewhere by $d\tilde{n}/dc$), specific refractive index increments at constant composition and constant chemical potential respectively, limiting viscosity number, wavelength of light *in vacuo*.

EXPERIMENTAL

Materials

NY film was Soxhlet extracted with methanol for 24 h, dissolved in freshly distilled *m*-cresol and precipitated in chilled diethyl ether. After filtering and washing, the powder was dried at 313K under vacuum.

* Present address: Department of Chemical Engineering and Chemical Technology, Imperial College of Science and Technology, London SW7 2AZ, UK.

PMA was prepared at 323K by polymerizing under nitrogen a solution of freshly distilled methyl acrylate in acetone (60% w/w) using azobisisobutyronitrile (0.4% w/w) as initiator. Reaction was carried out for 100 min (~10% conversion) and the PMA was isolated by precipitation in petroleum ether (b.p. 333–353K). The polymer was then dissolved in methyl ethyl ketone, reprecipitated as before and dried at 313K under vacuum. *o*-CP, as well as the methyl ethyl ketone required for physico-chemical measurements, were dried over anhydrous MgSO₄ and distilled at atmospheric pressure, the boiling points being 448.0 and 352.7K respectively.

Samples of TFP, obtained from three different commercial sources, were combined; the major portion (~90%) was an Eastman Kodak product. Purification was effected according to the procedure recommended by the Du Pont de Nemours Company⁷, viz. the crude TFP was mixed with 1/5 of its volume of water and 1/20 of its weight of sodium metabisulphite, left to stand for 24 h and then distilled rapidly at atmospheric pressure. Sufficient anhydrous lithium chloride was added to the distillate to saturate its aqueous portion and to thereby salt out the TFP as a lower layer. This separated layer was distilled, the residual water in it being removed as an azeotrope* with 71% (v/v) TFP at 366–368K. After isolation of more portions of TFP by salting out and distillation, all the products were combined, dried over anhydrous magnesium sulphate and redistilled through a Hempel Column. The major fraction distilling within the range 365–383K was retained, utilized and referred to in subsequent sections as TFP. The yield of product of reported* b.p. 380K would have been very low. In view of the boiling point range taken, the final product must certainly have contained impurities such as other fluorinated alcohols of similar physical properties. Reported values⁸ at 298K and $\lambda_0 = 546$ nm for \bar{n}_0 and $\nu_{\phi A}$ in the mixture LiCl/TFP/H₂O are 1.3217 and 0.185 dm³/kg respectively. The characteristics of the TFP used in the present work are b.p. 365–383K, $\bar{n}_0 = 1.3247$ and specific refractive index increment ($\nu_{\phi A}$) of NY in TFP = 0.186 dm³/kg, the last two quantities relating to 303K and $\lambda_0 = 436$ nm. When the solvent was reclaimed after use for further experiments, the procedure outlined was adhered to exactly (after removal of polymer present) and the properties quoted above were taken to characterize the reclaimed TFP.

Refractometry

Refractive indices of pure and mixed solvents were measured with a Pulfrich refractometer fitted with an external circulatory thermostat. Specific refractive index increments were measured in a Brice Phoenix differential refractometer maintained similarly at constant temperature. Values of ν_{ϕ} were obtained in pure and mixed solvents. Values of ν_{μ} for polymers in mixed solvents were measured at dialysis equilibrium of solution with mixed solvent of the same composition. This condition was achieved by the use of simple dialysis cells described previously⁹. However, to obtain good reproducibility, the dialysis bags were not allowed to dry, the water in the Visking tubing being extracted by repeated rinsing with methanol, which was then removed by successive washings with the mixed solvent. The time for dialysis equilibrium was 24 h.

Light Scattering

Measurements were made on a Sofica photometer maintained at constant temperature as above and calibrated with highly purified toluene, taking $R_{90} = 58.1 \times 10^{-4} \text{ m}^{-1}$ for this calibrant, as calculated from the Einstein–Cabannes equation¹⁰. Solutions and solvents were clarified by centrifugation at 1600 rev/min followed by filtration through Gelman ‘Solvinert’ filters. Data were analysed via Zimm plots. The molecular weights of the PMA and NY samples were determined separately using methyl ethyl ketone as solvent for the former and a mixture⁸ of TFP/LiCl/H₂O as solvent for the latter. Measurements were also made on solutions comprising a NY–PMA mixture in which $W_A = 0.573$ (to correspond to the composition of a copolymer, which it is intended to study later). These solutions were made up by weighing NY and PMA individually into graduated flasks and then adding the desired mixed solvent.

RESULTS

Refractive index increments and selection of solvent medium

In principle, light scattering measurements on a solution of a binary polymer system can be used to obtain its molecular parameters. For a copolymer comprising species A and B these parameters are the molecular weight (M_{AB}) of the copolymer as well as the molecular weights (M_A and M_B) of the A-portion and the B-portion. When the solute consists of a mixture of two polymers A and B, the derived quantities M_{AB} , M_A and M_B signify respectively the molecular weights of the mixture and of the separate polymers A and B. In practice, however, complications arise due to compositional heterogeneity of the sample, the effect being particularly pronounced for a mixture. This is manifested by an observed dependence of the molecular weight of the copolymer or mixture on the refractive index of the solvent. Hence the measured quantity has an apparent value (M_{AB}^*), only, and special procedures are necessary to evaluate the true molecular weights.

Among these is the expedient of conducting separate experiments using solvents of different indices, which in turn afford values of ν_A , ν_B and ν_{AB} that vary according to the solvent. The expression relating the experimental quantities M_{AB}^* , ν_A , ν_B and ν_{AB} to the desired molecular parameters of the systems can then be solved via simultaneous equations. Since there are three desired parameters (i.e. molecular weights), it is necessary to obtain data relating to at least three different solvent media. Alternatively, it is often possible to cover a larger range of values of the experimental quantities by using several solvents, which encompass a wide span of refractive indices. In this case the previously mentioned expression is not solved, since it is simpler to treat it graphically. The appropriate plot of the expression is parabolic and the desired parameters may be located on it from a knowledge of certain fixed co-ordinates. The form of the expression as well as full details of the procedures are given later.

These comments, directed at the general reader rather than the specialist, have been included to emphasize the necessarily more complex procedure involved when using light scattering to determine the molecular weight of a copolymer compared with that required for a polymer. In particular it will be evident that, in order to obtain true molecular parameters of a binary polymer system (co-

* We are indebted to Dr P. Kratochvíl (Institute of Macromolecular Chemistry, Prague) for this procedure.

Figure 1 Specific refractive index increment at constant solvent composition as a function of refractive index of solvent. ●, ▲ single solvents; ○, △ binary *o*-CP/TFP solvent mixtures of composition indicated on upper abscissa scale. Curve A, NY; B, PMA

polymer or polymer mixture), certain criteria have to be met with regard to the values of the specific refractive index increments of species A and B. For maximum sensitivity of the molecular weight determinations, the following convenient summary of the optimum conditions has been proposed by Tuzar *et al.*¹¹:

$$|\nu_A| = |\nu_B| \text{ and both large, to obtain } M_{AB} \quad (1)$$

$$|\nu_A| \text{ large and } \nu_B = 0, \text{ to obtain } M_A \quad (2)$$

$$|\nu_B| \text{ large and } \nu_A = 0, \text{ to obtain } M_B \quad (3)$$

Since the refractive indices of NY and PMA are markedly different (~ 1.61 and 1.49 respectively), it is clear that condition (1) in terms of ν_ϕ cannot be realized. This is demonstrated also in Figure 1, where values of $\nu_{\phi A}$ and $\nu_{\phi B}$ in pure and mixed solvents are plotted as a function of \tilde{n}_0 . (Some of the data for PMA in single solvents were obtained here by Mr K. Harvey and have been included elsewhere^{12,13} as part of a compendium of ν_ϕ values for polymers). Condition (2) holds, although $\nu_{\phi A}$ is only moderately large ($0.069 \text{ dm}^3/\text{kg}$) when $\nu_{\phi B} = 0$. Interpolation shows that in order for condition (3) to hold (i.e. for $\nu_{\phi A} = 0$), the corresponding $\nu_{\phi B}$ would be moderately large in value ($\sim -0.077 \text{ dm}^3/\text{kg}$), but the appropriate solvent would have to be one of the few liquids having a high refractive index (~ 1.60).

The expedient of using mixed solvents and the resultant values of ν_μ can often induce changes which are sufficiently great to accommodate relationships (1)–(3). However, the refractometric nature of the solvent must be coupled closely with considerations of polymer solubility. Thus, whilst several solvents exist for NY and PMA individually, exploratory tests revealed only three liquids capable of dissolving NY–PMA copolymers, viz. TFP, dichloroacetic acid and molten chloral hydrate. The last two of these were

discounted on the grounds of possible degradation^{14,15} of the NY portion. The value of \tilde{n}_0 for TFP is very low (1.325) and hence the second component of a mixed solvent must be of extremely high refractive index (≥ 1.61). The inclusion of a large proportion of 1-bromonaphthalene ($\tilde{n}_0 = 1.69$), whilst suitable in principle, was not found to be feasible in practice, since addition of this liquid at low concentration to a solution of NY–PMA copolymer in TFP caused instantaneous precipitation of polymer. Consequently, recourse was made to the use of *o*-CP ($\tilde{n}_0 = 1.578$) in conjunction with TFP as mixed solvent. These two liquids are completely miscible and allow solubility of copolymer or polymer mixture over the whole range of solvent composition. As already noted from values of ν_ϕ for NY and PMA in such mixtures, the refractive index of *o*-CP is still not high enough to allow condition (3) to be fulfilled, but measurements of ν_μ were made to ascertain if a favourable change could be induced at constant chemical potential of mixed solvent.

In Figure 2 the values of ν_μ as a function of ϕ_1 (and \tilde{n}_0) are shown for solutions of NY and PMA in *o*-CP/TFP mixtures. In no case is condition (1) realized. Relation (2) does hold at $\phi_1 = 0.73$ (i.e. in a mixed solvent of $\tilde{n}_0 = 1.497$) and here, when $\nu_{\mu B} = 0$, the value of $\nu_{\mu A}$ is $0.100 \text{ dm}^3/\text{kg}$, which is rather larger than the corresponding value of $0.069 \text{ dm}^3/\text{kg}$ found for $\nu_{\phi A}$. However, even at the highest concentration of *o*-CP ($\phi_1 = 0.90$), the value of $\nu_{\mu A}$ is still not reduced to zero and hence condition (3) remains unfulfilled.

For PMA, $|\nu_{\mu B}| > |\nu_{\phi B}|$ except for the one mixture in which these two quantities are equal in magnitude. For NY, $|\nu_{\mu A}| > |\nu_{\phi A}|$ over most of the composition range, this relation being reversed only at high contents of *o*-CP, that is, at ϕ_1 greater than ~ 0.80 . Comparison of refractive increments at constant composition and constant chemical potential in mixed solvents is, in fact, one of the methods available for quantifying selective adsorption of one of the solvent components. Although they are of secondary importance to the main theme of selecting the most suitable solvent medium, we report also the findings on preferential adsorption. The fact that in general ν_ϕ is not equal to ν_μ

Figure 2 Dependence of specific refractive index increment at constant chemical potential of solvents on composition of *o*-CP/TFP mixed solvents. ▲, △ represent values relating to constant solvent composition for solutions in pure *o*-CP and pure TFP. Curve A, NY; B, PMA

Figure 3 Parameter characterizing selective adsorption of *o*-CP as a function of composition of *o*-CP/TFP, mixed solvent. Refractive index of solvent indicated on upper abscissa scale. Curve A, NY; B, PMA

indicates finite values of the preferential adsorption coefficient γ_1 in equation (4)^{16,17}:

$$\gamma_1 = (\nu_\mu - \nu_\phi) / (d\tilde{n}_0/d\phi_1) \quad (4)$$

Here, $d\tilde{n}_0/d\phi_1$ expresses the dependence of the refractive index of the mixed solvent on the volume fraction ϕ_1 of *o*-CP in it. Measurements of the refractive index of *o*-CP/TFP mixtures over a range of composition showed a linear variation, thus:

$$\tilde{n}_0 = 1.325 + 0.253\phi_1$$

Hence the value of $d\tilde{n}_0/d\phi_1$ is 0.253 for all values of ϕ_1 . Values of the selective adsorption coefficient γ_1 have been calculated via equation (4) from experimental values of ν_μ and ν_ϕ for each of the two polymers in *o*-CP/TFP mixtures. The dependence of γ_1 on ϕ_1 is shown in Figure 3, where there is seen to be positive adsorption of *o*-CP to NY and to PMA except in solvents very rich in *o*-CP.

Light scattering

Estimation of molecular parameters from light scattering measurements is made via the following two equivalent expressions¹⁸ (equations 5 and 6), which have been referred to in general terms:

$$M_{AB}^* = (\nu_{\mu A} \nu_{\mu B} / \nu_{\mu AB}^2) M_{AB} + [\nu_{\mu A} (\nu_{\mu A} - \nu_{\mu B}) / \nu_{\mu AB}^2] \times \\ W_A M_A - [\nu_{\mu B} (\nu_{\mu A} - \nu_{\mu B}) / \nu_{\mu AB}^2] (1 - W_A) M_B \quad (5)$$

$$M_{AB}^* = M_{AB} + 2P[(\nu_{\mu A} - \nu_{\mu B}) / \nu_{\mu AB}] + \\ Q[(\nu_{\mu A} - \nu_{\mu B}) / \nu_{\mu AB}]^2 \quad (6)$$

In equation (6), P and Q are parameters characterizing the heterogeneity in composition of an A-B copolymer or, as in the present instance, a mixture of polymers A and B. The maximum heterogeneity is attained in a mixture. When using mixed solvents, as in the present situation, the appro-

priate refractive increments are those relating to constant chemical potential of solvents. Kratochvíl and coworkers¹¹ have demonstrated the validity of equations (5) and (6) expressed in terms of ν_μ instead of the ν_ϕ terms adopted in single solvents. To afford a range of ν_μ values, measurements were made using mixed solvents in which $\phi_1 = 0.1, 0.5$ and 0.7 . In each case the solute was the polymer mixture of previously quoted composition, and the values of $\nu_{\mu AB}$ were calculated from equation (7):

$$\nu_{\mu AB} = \nu_{\mu A} W_A + \nu_{\mu B} W_B \quad (7)$$

Solution of expressions (5) and (6) by simultaneous equations yielded values of M_{AB}, M_A, M_B, P and Q . An additional experiment was conducted in the mixed solvent of $\phi_1 = 0.73$ since, as already noted, the scattering due to PMA is thereby eliminated and equation (5) reduces to equation (8):

$$M_{AB}^* = (\nu_{\mu A}^2 / \nu_{\mu AB}^2) W_A M_A \quad (8)$$

As a means of comparison, directly measured values of M_A and M_B are available. Insertion of these into equation (9) allows M_{AB} for the mixture to be calculated:

$$M_{AB} = M_A W_A + M_B W_B \quad (9)$$

Similarly, if the directly measured values of M_A and M_B are inserted into equations (10), the parameters P and Q may be estimated¹⁸:

$$P = W_A W_B (M_A - M_B) \\ Q = W_A W_B (M_A W_A + M_B W_B) \quad (10)$$

All measured and calculated data are reported in Table 1.

The plot according to equation (5) is given in Figure 4. Included in this are the data points corresponding to the known values of M_A and M_B as well as that of M_{AB} calculated from equation (9). Thus¹⁸, for abscissae of $0, 1/W_A$ and $-1/W_B$, the corresponding ordinates are $M_{AB}, M_A/W_A$ and M_B/W_B . These points fall smoothly on the parabola

Figure 4 (a) Plot according to equations (5) and (6) for the polymer mixture in *o*-CP/TFP binary solvents. ●, experimental data; ○, points corresponding to known molecular weights of the individual polymers and the polymer mixture. (b) Enlargement of the section for positive values of abscissa

together with the four experimental data points. Because the abscissae do not extend to high enough positive values, it is not possible to locate the minimum of the curve with any degree of certainty. At the minimum the ordinate and abscissa correspond to $(M_{AB} - P^2/Q)$ and $(-P/Q)$ respectively¹⁸. The values of P and Q derived from the estimated minimum, in conjunction with the value of M_{AB} calculated from equation (9), are included in Table 1.

In addition to yielding an apparent molecular weight of the polymer mixture, light scattering gives an apparent value, $\langle S_{AB}^2 \rangle$, for the mean square radius of gyration in each mixed solvent. The relevant equation differs in form from that for a copolymer and is expressed by^{18,19}:

$$M_{AB}^* \langle S_{AB}^2 \rangle = (M_A \langle S_A^2 \rangle / W_A) y^2 + (M_B \langle S_B^2 \rangle / W_B) (1 - y)^2 \quad (11)$$

where $y \equiv W_A \nu_{\mu A} / \nu_{\mu AB}$

The plot of the left-hand side of equation (11) as a function of y should be parabolic and of upward curvature. Since W_A remains constant in value at 0.573, variations in y are effected solely via changes in solvent composition, i.e. effectively through differences in the refractive index increments. The situations $y = 1$ and $y = 0$ correspond to NY and PMA respectively and the values of $\langle S_A^2 \rangle$ and $\langle S_B^2 \rangle$ were measured individually for each of these samples. Consequently these constitute two additional points on the curve (Figure 5). Similarly, the minimum value of the ordinate, y_{\min} , can be calculated readily and, from equation (12), it is clear that this value must lie between 0 and 1:

$$y_{\min} = 1 / [1 + (M_A \langle S_A^2 \rangle W_B) / (M_B \langle S_B^2 \rangle W_A)] \quad (12)$$

The value of y_{\min} calculated from equation (12) and the corresponding minimum ordinate $M_{AB}^* \langle S_{AB}^2 \rangle$ obtained thereby from equation (11) are 0.99 and $4.2 \times 10^{-14} \text{ m}^2 \text{ kg/mol}$ respectively. The minimum of the smooth curve through the four experimental data points relating to *o*-CP/TFP solvent mixtures indicates values of 0.97 and $8.1 \times 10^{-14} \text{ m}^2 \text{ kg/mol}$ for these quantities. A value of 0.97 is actually obtained for y_{\min} from equation (12), if errors of $\pm 5\%$ and $\pm 10\%$ are assumed for the constituent molecular weights and mean square radii of gyration respectively, the signs of the errors being selected so as to maximize the

denominator in equation (12). However, under these conditions, the resultant minimum value of $M_{AB}^* \langle S_{AB}^2 \rangle$ is not significantly different from 4.2×10^{-14} (actually $4.3 \times 10^{-14} \text{ m}^2 \text{ kg/mol}$).

Further discussion is deferred to the next section. With regard to Figure 5 we wish to emphasize here that (1) the curve is of the form predicted theoretically and (2) the points relating to the two individual polymers alone ($y = 0$ and $y = 1$) do not fall on the curve.

DISCUSSION

Refractive index increments and selective adsorption

Assuming the value of $d\tilde{n}_0/d\phi_1$ to be subject to negligible error, the accuracy of γ_1 calculated via equation (4) is dictated solely by the errors in ν_{μ} and ν_{ϕ} . If the minimum absolute error in each of these is taken as $\pm 0.001 \text{ dm}^3/\text{kg}$ and the sign of each error is selected to maximize the total error, then the coefficient of selective adsorption is $\gamma_1 \pm (0.002/0.253)$, i.e. approximately $\gamma_1 \pm 0.01$, where γ_1 is the reported uncorrected value. This order of error in each datum point has a virtually undetectable effect on the curves in Figure 3. However, if the prime concern had been the absolute values of each adsorption coefficient, then the relative errors in γ_1 would have been reflected in a less favourable light, viz. ranging from $\sim 1\%$ (for high γ_1) to $\sim 20\%$ (for low γ_1).

Figure 5 (a) Plot according to equation (11) for the polymer mixture in *o*-CP/TFP binary solvents. ●, experimental data; ○, points corresponding to known molecular weights and radii of gyration of the individual polymer. (b) Enlargement of the section for $y = 0.7-1.0$

With reference to equation (4), it is apparent that maximum or minimum values of γ_1 occur when $d\gamma_1/d\phi_1 = 0$, that is, when:

$$d\nu_\mu/d\phi_1 = d\nu_\phi/d\phi_1 \quad (13)$$

For both NY and PMA, comparison of the constant Gladstone–Dale slope in *Figure 1* with the various slopes in *Figure 2* indicates that:

(a) Relation (13) holds in the mixed solvent for which ϕ_1 is approximately 0.2–0.3, which is actually the region of maximum γ_1 in *Figure 3*.

(b) There is unlikely to be an abrupt change in the form of γ_1 versus ϕ_1 in the region $\phi_1 = 0$ to $\phi_1 = 0.1$, i.e. where there are no experimental data.

(c) The observed minimum in γ_1 versus ϕ_1 for solutions of NY suggests that there must be a value of ν_μ (in the region $\phi_1 = 0.9$ –1.0), which is of smaller magnitude than the lowest value obtained experimentally (i.e. at $\phi_1 = 0.9$).

Selective adsorption may be envisaged more readily when expressed in terms of the number (n_1) of *o*-CP molecules adsorbed preferentially per segment of polymer, thus¹⁶:

$$n_1 = \gamma_1 M_0 / \bar{V}_1 \approx \gamma_1 M_0 / V_1 \quad (14)$$

Here, M_0 is the molecular weight of the polymer segment and \bar{V}_1 and V_1 are respectively the partial molar volume and molar volume of *o*-CP. The maximum extents of selective adsorption are calculated from equation (14) to be equivalent to 1 molecule *o*-CP/1.4 segments NY and 1 molecule *o*-CP/5.7 segments PMA. The one negative value of γ_1 observed for NY indicates a preferential adsorption of TFP with a selective adsorption coefficient γ_2 , where $\gamma_2 = -\gamma_1$. In this situation equation (14) becomes

$$n_2 \approx -\gamma_1 M_0 / V_2$$

where V_2 is the molar volume of TFP and n_2 is the number of molecules of TFP adsorbed per segment of NY. This yields a selective adsorption of 1 molecule TFP/21 segments NY, when the solvent medium is very rich in *o*-CP ($\phi_1 = 0.9$).

The curves of preferential adsorption coefficient versus composition of mixed solvent (*Figure 3*) are of a similar form to those observed for other systems^{16,20,21}. Expressions have been derived^{16,22,23} for γ_1 in terms of ϕ_1 , but these involve the Flory–Huggins interaction parameters χ_{ij} , the values of which are not available for the present systems. In certain instances²⁴ the approach of calculating the values of the χ_{ij} terms from Hildebrand–Scott solubility parameters has met with some limited success, but here again the relevant values are not known. Consequently, we restrict our comments to a purely phenomenological discussion of the selective adsorption of *o*-CP.

Apart from the molecular weight²⁵ and the structure^{26,27} of the polymer, the most critical factor affecting the sign and magnitude of γ_1 is the nature of the two liquids comprising the binary solvent, as exemplified by their solvent power, polarity, associative capacity and molecular size. In the present system the two liquids exhibit similar solvent power for NY. Thus the values of $[\eta]$ (m^3/kg) in *o*-CP and TFP are 0.14 and 0.18 respectively. Moreover for PMA solutions, $[\eta] = 0.31$ for both solvents. A simple molecular size effect can be discounted, because V_1 and V_2 are of a very similar magnitude (0.093 and 0.104 dm^3/mol respectively).

Combela *et al.*²⁸ have studied the preferential adsorption by polyacryloylpiperidine of trifluoroethanol in admixture with carbon tetrachloride; hydrogen bonding between the alcoholic –OH groups and the $>\text{C}=\text{O}$ groups in the polymer was proposed. More recently Chaufer *et al.*²⁹ and Lety-Sistel *et al.*³⁰ have discussed selective adsorption in systems already reported, and they have themselves made a comprehensive investigation involving light scattering and infra-red analysis of selective adsorption occurring in the systems poly(vinyl pyrrolidone)/halogenated solvent/proton donating solvent. Dependent on the solvent composition, adsorption of either of the solvents was observed. In the case of preferential adsorption of the proton donating liquid, hydrogen bonding to the $>\text{C}=\text{O}$ group of the polymer, followed by further induced auto-association of the proton donor, was proposed. A rationale was also afforded for the preferential adsorption of the halogenated solvent. No such detailed infra-red analysis has been performed on the present system, but it is reasonable to infer that hydrogen-bonding prevails here also. The situation is complicated, however, by the facts that (a) *o*-CP, as opposed to the halogenated hydrocarbon, is itself capable of hydrogen-bonding and (b) consequently, the known hydrogen-bonding tendencies of *o*-CP and TFP separately may alter, when one liquid is in the presence of the other. Discussion is confined to some qualitative observations.

Infra-red spectra of *o*-CP and TFP reveal that there is intramolecular³¹ bonding between adjacent –OH and Cl groups, whereas in the latter there is intermolecular³² bonding between –OH groups. If entropic effects are neglected and realization is made about the uncertainty in reported values³³ of hydrogen-bond enthalpies (ΔH), then the following simplified picture emerges. The value of ΔH between –OH groups in alcohols is 21 kJ/mol, but the same amount of energy is liberated on reforming these bonds with $>\text{C}=\text{O}$ groups in the polymer chain (NY or PMA); hence there is no net decrease in energy. In contrast, the value of ΔH for intramolecular bonding in *o*-CP is –16 kJ/mol. Rupture of this bond followed by bonding between the –OH group in *o*-CP and $>\text{C}=\text{O}$ groups in the polymer would yield a net energy change of $(+16 - 21) = -5$ kJ/mol, i.e. a fall in energy, which would render bonding between polymer and *o*-CP more favourable than bonding between polymer and TFP. Moreover constructions with molecular models of a molecule of *o*-CP and a segment of NY suggest that the bonding may well be yet more energetically favourable. Thus, when the –OH group in *o*-CP is made to coincide with the $>\text{C}=\text{O}$ group in the polymer, the Cl group in *o*-CP coincides with the $>\text{NH}$ group separated by five carbon atoms. Hence it is feasible, at least, to envisage two forms of bonding of *o*-CP to NY with a net energy change of $(+16 - 21 - 16) = -21$ kJ/mol. This accords with the observed, higher values of γ_1 for NY than for PMA.

Light scattering

We consider now the parameters listed in *Table 1*. Although the three values obtained for M_A via different routes are in excellent agreement, this may be fortuitous to some extent in view of the errors which can be reasonably expected in light scattering. Of course, accuracy can rarely be ascertained for a molecular weight determination, since there is no basis for comparison in absolute terms. Hence it is more correct to indicate the good consistency and to note that the use of a mixed *o*-CP/TFP solvent of $\phi_1 = 0.73$

would be a reliable means of obtaining the molecular weight of the NY portion of a NY/PMA copolymer. The difference of ~17% between the directly measured value of M_B and the one derived indirectly via the use of three solvents exceeds the error expected from a single molecular weight determination. This large difference arises from the cumulative effect of the operations involved in solving simultaneous equations coupled with the errors in the molecular weights and refractive index increments contained therein. The accord among the values for M_{AB} may be considered satisfactory.

The parameter P correlates the molecular weight of the mixture with its composition and, although there are no limits to its numerical value, it must be of negative sign here, as follows from the definition in equations (10). The more commonly adopted ratio P/M_{AB} ranges slightly in magnitude from -0.47 to -0.50 depending on whether the values of P and M_{AB} taken together are those obtained experimentally from measurements in three solvents or are estimated from the known individual values of M_A and M_B .

The parameter Q quantifies the heterogeneity in composition of the mixture, and is expressed commonly per unit molecular weight as Q/M_{AB} . The value of this ratio is zero for a completely homogeneous sample, whereas the maximum value attainable for a mixture is $W_A W_B$, as seen in equations (10). As before, the value obtained for Q/M_{AB} depends on whether the values of Q and M_{AB} taken together are those determined experimentally in three solvents or are estimated from known individual values of M_A and M_B . In the former and latter instances respectively, Q/M_{AB} is 0.29 and 0.32, both of which exceed the theoretical maximum of $0.573 \times 0.427 = 0.245$. The expedient of combining the experimental $Q (=101)$ with the calculated $M_{AB} (=389)$ reduces Q/M_{AB} to a more acceptable value of 0.26. Effectively, this is equivalent to regarding the calculated value of M_{AB} as the correct one. This approach has been adopted by others such as Kratochvíl and coworkers who obtained the following experimental (and theoretical) values for mixtures in which the magnitudes of W_A and W_B were similar to those here: 0.25 (0.24) for poly(ethylene glycol methacrylate) + poly(methyl methacrylate)¹¹; 0.22 (0.25) for polystyrene + polybutadiene³⁴. The inherent errors mentioned in the determination of M_B apply equally to Q , when data relating to three solvents are employed. The value of Q/M_{AB} determined here would seem to be as accurate as allowed by this particular technique.

With regard to the minimum values of γ and $M_{AB}^* \langle S_{AB}^2 \rangle^*$ (equation 12 and Figure 5), the uncertainty in these is quite considerable, because in the present system $M_B \gg M_A$ and γ is generally very large. Moreover, the error in $\langle S_A^2 \rangle$ must be greater than that normally encountered when estimating the mean square radius of gyration from a limiting slope (at zero concentration) in a Zimm plot; indeed, it was a matter of some surprise that we were actually able to determine the value of $\langle S_A^2 \rangle$ in view of the low molecular weight of the NY sample (a molecular weight of ~200 kg/mol is considered³⁵ as an approximate lower limit for this purpose). The fact that the data points for the individual polymers fall outside the curve in Figure 5 is not disturbing, since the solvents used in the determination of $\langle S_A^2 \rangle$ and $\langle S_B^2 \rangle$ were different from each other and also different from those used for the solutions of the polymer mixture.

In connection with future work on graft copolymers of NY/PMA, the anticipated heterogeneity should be lower than that deliberately introduced here for the mixture. Consequently, any over-estimate in the value of Q will be

of greater relative significance. We note that such over-estimates in copolymer heterogeneity have been discussed in detail by Vorlíček and Kratochvíl³⁶, who concluded that a meaningful measure of Q in a copolymer is only possible by light scattering provided that certain critical conditions be fulfilled with respect to molecular weight and $|\nu_A - \nu_B|$.

Branched poly(ethylene terephthalate) correlations between viscosimetric properties and polymerization parameters

P. Manaresi*, P. Parrini, G. L. Semeghini and E. de Fornasari

Montedison Spa, Centro Ricerche Ferrara, 44100 Ferrara, Italy

(Received 13 October 1975; revised 20 January 1976)

Samples of poly(ethylene terephthalate) (PET) modified with small amounts of trimesic acid groups and hence containing long chain branching have been prepared. From the content of trifunctional modifier and from the experimental value of the extent of reaction, the weight-average molecular weight \bar{M}_w and branching density \bar{B}_w have been calculated, assuming that all the end-groups are equally reactive and intramolecular reactions are absent. The values of \bar{M}_w and \bar{B}_w have been correlated with the experimental values of intrinsic viscosity $[\eta]$ and the Newtonian melt viscosity η_0 . General relations of the following type have been obtained:

$$f_1([\eta], \bar{M}_w, \bar{B}_w) = 0; \quad f_2(\eta_0, \bar{M}_w, \bar{B}_w) = 0;$$

$$f_3(\eta_0, [\eta], \bar{B}_w) = 0; \quad f_4(\eta_0, [\eta], \bar{M}_w) = 0$$

In particular, $[\eta]$ and η_0 increase on increasing \bar{M}_w and decrease on increasing \bar{B}_w , but, at equal $[\eta]$ values, η_0 increases with \bar{B}_w . Through the last relation, the reliability limits of which should be experimentally checked, and from measurements of $[\eta]$ and η_0 , it is possible to calculate \bar{M}_w of a branched PET.

INTRODUCTION

One problem that is most frequently met in the technological development of polymers is obtaining slight property variations after carrying out operations on the structural parameters. Among them long chain branching, together with the molecular weight and chemical structure, are some of the most important.

In the case of a polycondensate, branching may easily be obtained by using a comonomer having functionality higher than two: this may lead to the formation of a tri-dimensional network. The basic theoretical concepts concerning polyfunctional polycondensation and the criteria for gel formation were established several years ago by Carothers¹, Flory²⁻⁵ and Stockmayer^{6,7}. In recent years the topic has been studied thoroughly and partly revised, especially from a theoretical point of view⁸⁻¹⁷. However, apart from patent literature, no data have been published on branched poly(ethylene terephthalate) (PET) even though this polymer is quite important for the production of fibres.

Therefore we thought it interesting to prepare PET samples modified with small amounts (<2%) of a trifunctional comonomer, and to examine the relationships between the various viscometric quantities as a function of the extent of reaction and the content of modifier. This study was carried out in the light of theories concerning polyfunctional polycondensation and the influence of long chain branching on properties.

EXPERIMENTAL

Preparation of PET samples

PET samples were prepared from dimethylterephthalate and ethylene glycol with the desired amount of trimethyl-trimesate as the trifunctional modifier. The reaction was carried out in two consecutive steps, ester-interchange and polycondensation, according to the general procedure described in a previous paper¹⁸. After the ester-interchange step, only one type of functional group remains, the OH groups of glycolic esters, i.e.

and polycondensation proceeds with evolution of ethylene glycol.

Viscometric measurements

Intrinsic viscosity was measured in *o*-chlorophenol at 25°C. Melt viscosity was measured at 280°C by the capillary method¹⁸. The values of the flow gradient being low, the melt viscosity measured by this method practically corresponds to the Newtonian one.

Determination of the extent of reaction

Conversion *p* (extent of reaction) was obtained by separately determining the number of OH and COOH end-

* Istituto Chimico, Facoltà di Ingegneria, Università di Bologna, Bologna, Italy.

groups, the latter being present in small amounts. Carboxyl content was determined according to Pohl¹⁹, using freshly distilled aniline (instead of benzyl alcohol) as solvent. Hydroxyl content was determined according to the Conix method²⁰. E_{OH} and E_{COOH} being the number of equivalents of OH and COOH end-groups per 10⁶ g of polymer, the sum of the two $E = E_{OH} + E_{COOH}$ was considered in order to calculate p .

Conversion is given by:

$$p = 1 - \frac{E}{10^6} \left[\frac{M_b}{2} - \rho \left(\frac{M_b}{2} - \frac{M_t}{3} \right) \right]$$

The significance of ρ , M_b and M_t is given below (in this particular case $M_b = 192.17$ and $M_t = 249.20$).

THEORETICAL

Polyfunctional polycondensation

In the case considered here after the first reaction step there is only one type of functional group, and the polymerization may be shown schematically as follows:

Let ρ be the composition parameter, i.e.:

$$\rho = \frac{\text{number of groups of initial trifunctional units}}{\text{number of total initial functional groups}} = \frac{3N_t}{3N_t + 2N_b} \quad (1)$$

where N_t = number of initial trifunctional molecules and N_b = number of initial bifunctional molecules.

By assuming that all functional groups have the same reactivity and by neglecting the intramolecular reactions, Flory² obtained for the branching coefficient α :

$$\alpha = \frac{p\rho}{1 - p(1 - \rho)} \quad (2)$$

where p is the extent of reaction. For $\alpha = 0.5$ gelation becomes possible; at this point the extent of reaction (critical value) is $p_c = 1/(1 + \rho)$.

The number-average degree of polymerization \bar{x}_n will be given by:

$$\bar{x}_n = \frac{N_t + N_b}{(N_t + N_b) - (3N_t/2 + N_b)p}$$

where the second term of the denominator represents the number of bonds formed. By introducing equation (1) we obtain:

$$\bar{x}_n = \frac{3 - \rho}{3 - \rho - 3p} \quad (3)$$

The number-average molecular weight is given by:

$$\bar{M}_n = \bar{x}_n M_0$$

where M_0 is the molecular weight of the average monomeric unit. If M_b and M_t are the molecular weights respectively of the bi- and tri-functional monomer units (in this case 192.17 and 249.20), then:

$$M_0 = \frac{M_b N_b + M_t N_t}{N_b + N_t} = \frac{3M_b + \rho(2M_t - 3M_b)}{3 - \rho}$$

Hence:

$$\bar{M}_n = \frac{3M_b + \rho(2M_t - 3M_b)}{3 - \rho - 3p} \quad (4)$$

Therefore \bar{M}_n depends on the extent of reaction and to a lower extent on the trifunctional units content: the latter, instead, extensively affects \bar{M}_w . In the case considered here, the distribution function obtained by Stockmayer⁶ is:

$$m_{n,l} = 3N_t \rho^{(n-1)} (1 - \rho)^l p^{(n+l-1)} (1 - p)^{(n+2)} \times \frac{(2n + l)!}{n! l! (n + 2)!} \quad (5)$$

where $m_{n,l}$ is the number of polymeric molecules consisting of n trifunctional units and of l bifunctional units. From the definition of \bar{M}_w :

$$\bar{M}_w = \frac{\sum_{n,l} m_{n,l} (M_b l + M_t n)^2}{N_b M_b + N_t M_t}$$

and from equations (1) and (5) is obtained:

$$\bar{M}_w = \frac{6(1 - p)^2}{p(2\rho M_t + 3M_b - 3\rho M_b)} \times \sum_{\substack{n,l=0 \\ (n+l \geq 1)}}^{\infty} \left\{ (M_b l + M_t n)^2 \times \frac{[p\rho(1 - p)]^n [p(1 - \rho)]^l (2n + l)!}{n!(n + 2)! l!} \right\} \quad (6)$$

[if the trifunctional group is absent, the usual relations are valid: $\bar{M}_n = M_b/(1 - p)$; $\bar{M}_w = M_b(1 + p)/(1 - p)$].

With the help of a computer the summation in equation (6) may be evaluated; since such a calculation must be generally carried out to very high values of l , we have applied the equation in a form that may be easily drawn from the previous one, i.e.

$$\bar{M}_w = \frac{6(1 - p)^2}{p(2\rho M_t + 3M_b - 3\rho M_b)} \times \sum_{\substack{n,l=0 \\ (n+l \geq 1)}}^{\infty} \left\{ (M_b l + M_t n)^2 [p\rho(1 - p)]^n [p(1 - \rho)]^l \frac{(l + 1)(l + 2) \dots (l + 2n)}{n!(n + 2)!} \right\} \quad (7)$$

NC = not calculated, as $\alpha > 0.5$ ($\rho > \rho_c$).

From equation (7) it is possible to calculate the summation terms as long as the values of n are not too high. For values of n higher than 30, the equation has been transformed, through the Stirling approximation formula, into the following equation of easier use:

$$\bar{M}_w = \frac{3e^2(1-p)^2}{\pi p(2\rho M_t + 3M_b - 3\rho M_b)} \times \sum_{n,l} \left\{ \left(\frac{M_b l + M_t n}{n+2} \right)^2 \frac{1}{[n(n+2)]^{1/2}} \times \left[\frac{p\rho(1-p)e^2}{n(n+2)} \right]^n [p(1-\rho)]^l (l+1)(l+2) \dots (l+2n) \right\} \quad (8)$$

Table 1 shows the results of such calculations, carried out in some cases to values of $n = 300$ and $l = 30\,000$: when the extent of reaction gets near to the critical value p_c , \bar{M}_w rapidly approaches infinity, whereas \bar{M}_n stays relatively low.

Number of branches

The number of branches may also be theoretically deduced and may be quite significant for a correlation with

the experimental data. The number-average branching density, i.e., the average number of branches per molecule \bar{B}_n , is given by:

$$\bar{B}_n = \frac{N_t}{(N_t + N_b) - (3N_t/2 + N_b)p} \quad (9)$$

From equation (1) it follows:

$$\bar{B}_n = \frac{2\rho}{3 - \rho - 3p} \quad (10)$$

It is often more useful to consider the so-called weight-average branching density \bar{B}_w . The value of \bar{B}_w is related to that of \bar{B}_n and to the molecular weight distribution; in polycondensates, if the Stockmayer statistical distribution is assumed, the relation:

$$\bar{B}_w = \frac{3}{2} \bar{B}_n \bar{M}_w / \bar{M}_n \quad (11)$$

was proved to be valid²¹. While \bar{B}_n simply 'counts' the branches, \bar{B}_w 'weights' them in the larger molecules more than in the smaller ones. Evidently \bar{B}_w approaches infinity when p gets near to the p_c value.

Figure 1 Dependence of the melt viscosity on intrinsic viscosity for various PET. —, linear PET; ●, $\rho = 0$ (linear PET); X, $\rho = 0.00748$; ▲, $\rho = 0.01121$; ■, $\rho = 0.01493$; ○, $\rho = 0.02233$

Analysis of the viscometric data

As is well known, the intrinsic viscosity of branched macromolecules is lower than that of linear ones with the same molecular weight, the volume of the former in solution being smaller^{22,23}.

The ratio $[\eta]_b/[\eta]_l$ between the intrinsic viscosities of the branched polymer and of the linear one, of the same molecular weight, has been frequently used as an experimental index of the degree of branching. In a θ solvent such a ratio should be a function of g only, i.e. of the corresponding ratio of the mean-square radii of gyration.

In the practical case of branched and polydispersed polymers, a comparison among intrinsic viscosities should be made, using convenient average quantities taking into account the 'viscosity exponent' in the Mark-Houwink equation^{21,24}. Semi-empirically and for sake of simplicity we chose to consider the \bar{M}_w values, the intrinsic viscosity being nearly a weight-average quantity. Our choice has also

been supported by the remarks reported in literature²⁵ according to which a correlation curve between $[\eta]$ and \bar{M}_w constitutes one of the most sensitive methods for evidencing the presence of branches.

The Newtonian melt viscosity also extensively depends on the presence of long branches. Their influence may be quite complex, but in general the final result is a decreased viscosity²⁶⁻²⁸. Therefore, even in that case, the ratio $\eta_{0,b}/\eta_{0,l}$ between Newtonian viscosities of branched and linear polymers, at the same value of \bar{M}_w , may supply an experimental index of the degree of branching.

RESULTS AND DISCUSSION

Table 1 shows the experimental values of ρ , $[\eta]$ and η_0 for linear PET's and those branched with different amounts of trimethyltrimesate. In this Table are also reported the calculated values of \bar{M}_n , \bar{M}_w , α and \bar{B}_w . Evidently, as the polymerization is statistical, the values of the conversion high and the trifunctional comonomer contents low, branches are few and long.

Correlations have been attempted between $[\eta]$, η_0 and \bar{M}_w : an approximate linearity on a bi-logarithmic scale was observed (Figures 1, 2 and 3). In all branched polymer, at equal \bar{M}_w values, $[\eta]$ and η_0 are significantly lower and, at equal $[\eta]$ values, η_0 is significantly higher than in the linear ones.

Figure 2 Dependence of the intrinsic viscosity on \bar{M}_w for various PET. ●, $\rho = 0$ (linear PET); X, $\rho = 0.00748$; ▲, $\rho = 0.01121$; ■, $\rho = 0.01493$; ○, $\rho = 0.02233$

Figure 3 Dependence of the melt viscosity on \bar{M}_w for various PET. ●, $\rho = 0$ (linear PET); X, $\rho = 0.00748$; ▲, $\rho = 0.01121$; ■, $\rho = 0.01493$; ○, $\rho = 0.02233$

For the linear PET, the following relations have been obtained:

$$\log \eta_{0,1} = 4.36 + 4.78 \log [\eta]_1 \quad (12)$$

$$\log [\eta]_1 = -3.62 + 0.74 \log \bar{M}_w \quad (13)$$

$$\log \eta_{0,1} = -12.96 + 3.54 \log \bar{M}_w \quad (14)$$

in agreement with previous results by the authors¹⁸ and Gregory¹⁹.

Using relations (13) and (14) we calculated, for each branched sample, the values of $[\eta]_1$ and $\eta_{0,1}$ (at equal \bar{M}_w values), and then the ratios $[\eta]_b/[\eta]_1$ and $\eta_{0,b}/\eta_{0,1}$ reported in Table 1. These ratios, always below unity, decrease on increasing the trifunctional unit content and the extent of reaction, and a good correlation exists among them.

Since such 'viscosity indexes' must be related to the parameters that theoretically define the amount of branching, attempts have been made to correlate them with α , \bar{B}_n and \bar{B}_w . A satisfactory linear correlation has been obtained on a semi-logarithmic scale especially in the case of \bar{B}_w , apart from a few points corresponding to polymers with very high ρ values. The following equations have thus been derived:

$$\log [\eta]_b/[\eta]_1 = -0.06 \bar{B}_w \quad (15)$$

$$\log \eta_{0,b}/\eta_{0,1} = -0.25 \bar{B}_w \quad (16)$$

By combining equations (15) and (16) with (13) and (14) respectively, we obtained the following equations:

$$\log [\eta] = -3.62 + 0.74 \log \bar{M}_w - 0.06 \bar{B}_w \quad (17)$$

$$\log \eta_0 = -12.96 + 3.54 \log \bar{M}_w - 0.25 \bar{B}_w \quad (18)$$

Finally, by combining equations (17) and (18), two further ones are obtained:

$$\log \eta_0 = 4.36 + 4.78 \log [\eta] + 0.037 \bar{B}_w \quad (19)$$

$$\log \eta_0 = 2.13 + 4.17 \log [\eta] + 0.456 \log \bar{M}_w \quad (20)$$

All these relations are valid for both branched and linear PET. In Figures 4 and 5 curves corresponding to these equations are compared with experimental data: the relationships are valid for all values of ρ and p .

Thus both viscosities decrease, at equal \bar{M}_w values, on increasing \bar{B}_w , while the melt viscosity increases, at equal $[\eta]$ values, on increasing \bar{B}_w . This essentially occurs independently of the single values of ρ . Through equation (20) it is possible to calculate the value of \bar{M}_w for a branched (as well as linear) PET from solution and melt viscosity measurements.

Figure 4 Melt viscosity as a function of intrinsic viscosity and branching density for various PET. —, corresponds to equation (19); ●, $\rho = 0$ (linear PET); X, $\rho = 0.00748$; ▲, $\rho = 0.01121$; ■, $\rho = 0.01493$; ○, $\rho = 0.02233$

Figure 5 Melt viscosity as a function of the intrinsic viscosity and \bar{M}_w for various PET. —, corresponds to equation (20); ●, $\rho = 0$ (linear PET); X, $\rho = 0.00748$; ▲, $\rho = 0.01121$; ■, $\rho = 0.01493$; ○, $\rho = 0.02233$

Similar results had been obtained by Peticolas and co-workers^{30,31} and by Schreiber and coworkers³² in the case of polyethylenes with long branches. They found that η_0 at fixed temperature and given \bar{M}_w appears to be primarily a function of long branching, and they give for unfractio-nated polyethylenes relationships of the same form as equation (18)

More recently Ram and Miltz³³, by a careful character-ization of several samples of commercial free-radical poly-ethylenes, found that by using the variable $([\eta]_b/[\eta]_l)^2 \bar{M}_w$ most rheological parameters can be correlated into single straight lines on a bi-logarithmic scale. From Ram's data it is possible to obtain a general relation between η_0 , \bar{B}_w and \bar{M}_w of the same form as equation (18).

Finally, it must be noted that the values of \bar{M}_w have been calculated from those of p and ρ , by assuming that all end-groups have the same reactivity and intramolecular reactions are absent: it is certain that this last condition is no longer valid in proximity of the gel point. The most recent theories on gel formation, such as the stochastic graph theory, instead, suggest that this is due to the formation of cyclic structures as a result of intramolecular reactions¹³. Hence, in our opinion, one of the most important results achieved by this work is that the existence is suggested, with regard to branched (and linear) PET, of a general relation between η_0 , $[\eta]$ and \bar{M}_w such as equation (20). The reliability limits of such a relation should be checked by direct experimental measurements of \bar{M}_w .

Equilibrium ring concentrations and the statistical conformations of polymer chains: 14. Calculation of the concentrations of medium sized cyclics in poly(dimethyl siloxane) equilibrates

L. E. Scales* and J. A. Semlyen

Department of Chemistry, University of York, Heslington, York YO1 5DD, UK
(Received 29 December 1975; revised 10 February 1976)

Theoretical molar cyclization equilibrium constants K_x for dimethyl siloxane cyclics $[(CH_3)_2SiO]_x$ in undiluted poly(dimethyl siloxane) equilibrates are calculated for values of x in the range $7 < x < 13$. The Jacobson and Stockmayer theory is used for the calculations and K_x values are computed by finding the statistically weighted fraction of the 3^{2x-3} conformations [defined by the Flory, Crescenzi and Mark (FCM) rotational isomeric state model of poly(dimethyl siloxane)] that have terminal atoms in close proximity for ring formation. The FCM model gives theoretical K_x values in good agreement with experiment for $x = 8, 9, 10$ but yields a K_{11} value that is nine times greater than that found experimentally. This result is discussed in terms of the molecular structure of dimethyl siloxane chains. The effect on the calculated K_x values of modifying the FCM model by assigning a smaller value to the Si–O–Si bond angle is explored.

INTRODUCTION

It has been customary in developing theories in polymer science to assume that random-coil linear macromolecules obey Gaussian statistics. These statistics were established by Kuhn and others¹⁻⁴ over forty years ago and they have been applied to interpret a wide range of polymer properties and behaviour. However, it has always been realized that Gaussian statistics would not necessarily apply to flexible random-coil molecules of finite length. In general, as the lengths of molecules decrease, deviations from Gaussian behaviour would be expected to become greater.

Until recently, experimental data providing a close insight into the relationship between the statistical properties of chain molecules and their chain lengths have not been available. However, in the past few years experimental data have been obtained⁵ that give a unique opportunity of assessing the deviations from Gaussian statistics shown by chains of finite length. In particular, experimental molar cyclization equilibrium constants K_x have been measured with a considerable degree of precision for dimethyl siloxane cyclics $[(CH_3)_2SiO]_x$ with eight to as many as five hundred skeletal bonds⁶⁻⁸. Measurements were carried out for ring-chain equilibration reactions in the bulk polymer^{7,8} as well as in solution in toluene^{6,8} and in diglyme⁸. Plots of $\log K_x$ against $\log x$ exhibit well defined minima in the region $x = 12$ and these minima are followed by definite maxima located at values of $x \cong 15$.

One of the aims of this paper is to find a theoretical explanation for these experimental observations. To this end, the molar cyclization equilibrium constants for dimethyl siloxane rings have been calculated using the

Flory, Crescenzi and Mark⁹ rotational isomeric state model for poly(dimethyl siloxane). The computational procedures involve finding the statistically weighted fraction of the 3^{2x-3} conformations of the open chain molecules $[(CH_3)_2SiO]_x$ defined by the rotational isomeric state model that have terminal atoms in juxtaposition for ring formation. The calculations have been carried out for cyclics containing up to twenty four skeletal bonds. They are an extension of some calculations which were carried out for smaller dimethyl siloxane cyclics in an earlier study¹⁰.

ROTATIONAL ISOMERIC STATE MODEL OF POLY(DIMETHYL SILOXANE)

The rotational isomeric state model of poly(dimethyl siloxane) was set up by Flory, Crescenzi and Mark (FCM model)⁹. It was based on a critical examination of all the available molecular structure data. Their model takes each skeletal Si–O bond to be of length 1.64 Å, each Si–O–Si skeletal bond angle to be 143° and each O–Si–O skeletal bond angle to be 110°. The FCM model assigns each skeletal bond to one of three rotational isomeric states at $\phi = 0^\circ$ (*trans*), 120° (*gauche*⁺) and 240° (*gauche*⁻) positions. The statistical weight matrix U' that takes account of the mutual interdependence of adjacent pairs of skeletal bonds centred on silicon atoms is as follows:

$$U' = \begin{matrix} & \begin{matrix} t_i & g_i^+ & g_i^- \end{matrix} \\ \begin{matrix} t_{i-1} \\ g_{i-1}^+ \\ g_{i-1}^- \end{matrix} & \begin{bmatrix} 1 & \sigma & \sigma \\ 1 & \sigma & 0 \\ 1 & 0 & \sigma \end{bmatrix} \end{matrix} \quad (1)$$

* Present address: The Computer Laboratory, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK.

The corresponding statistical weight matrix U'' that takes account of the mutual interdependence of adjacent pairs of skeletal bonds centred on oxygen atoms is:

$$U'' = \begin{matrix} & t_{i+1} & g_{i+1}^+ & g_{i+1}^- \\ \begin{matrix} t_i \\ g_i^+ \\ g_i^- \end{matrix} & \begin{bmatrix} 1 & \sigma & \sigma \\ 1 & \sigma & \delta \\ 1 & \delta & \sigma \end{bmatrix} \end{matrix} \quad (2)$$

The parameters σ and δ of the FCM model were assigned values so as to reproduce the experimental characteristic ratio $\langle r^2 \rangle_0 / nl^2$ of linear poly(dimethyl siloxane) and the temperature coefficient $d(\ln \langle r^2 \rangle_0) / dT$ (where $\langle r^2 \rangle_0$ is the mean-square end-to-end distance of the unperturbed chain of n bonds each of length l in the limit $n \rightarrow \infty$)^{11,12}. The statistical weight parameters σ and δ are Boltzmann factors $\exp(-\Delta E / RT)$ where ΔE is the difference in energy between its associated conformation and the all-*trans* conformation, and R is the gas constant. At the temperature of 383K that is relevant to the calculations to be described here, the values of the FCM model parameters are $\sigma = 0.327$ and $\delta = 0.082$.

As will be discussed below, the greatest uncertainty in the assignment of a structural parameter in the FCM model is probably the value of 143° for the Si-O-Si skeletal bond angle. In the direct computations of cyclic concentrations to be described here, an alternative assignment was made for this bond angle. The statistical weight parameters were adjusted accordingly so as to reproduce the experimental values for the characteristic ratio and the temperature coefficient $d(\ln \langle r^2 \rangle_0) / dT$ of poly(dimethyl siloxane).

CALCULATION OF MOLAR CYCLIZATION EQUILIBRIUM CONSTANTS

Experimental and theoretical molar cyclization equilibrium constants

The equilibrium between ring and chain molecules of poly(dimethyl siloxane) may be represented thus:

This equilibrium can be set up in the bulk polymer^{7,8}, or in solution in toluene^{6,8} or diglyme⁸. In all these cases, there is a most probable distribution of chain lengths. It follows that the molar cyclization equilibrium constants K_x for cyclic dimethyl siloxanes are related to the extent of reaction of functional groups in the chain polymers p by:

$$K_x = [(\text{CH}_3)_2\text{SiO}]_x / p^x \quad (4)$$

In this paper, experimental K_x values used to compare with theory refer to undiluted equilibrates at 383K. Similar K_x values are found in diglyme⁸ but substantially larger K_x values were obtained for the smallest cyclics in toluene up to cyclics with $x < \sim 8$. These higher K_x values for the small rings have been discussed elsewhere^{7,8}.

The Jacobson and Stockmayer theory^{13,14} provides the following expression for K_x values (in mol/dm³) for cyclics produced by the forward step of equation (3):

$$K_x = \bar{W}_x / 2N_A x \quad (5)$$

where \bar{W}_x represents the density of end-to-end vectors \mathbf{r} in the region $\mathbf{r} \cong 0$ (in molecules/dm³) for an x -meric chain and N_A is the Avogadro constant.

As in the previous study¹⁰, no account is taken of the expected correlations between terminal bonds in the intramolecular cyclization processes, and K_x values are calculated using equation (5) by simply computing the statistically weighted fraction of the total number of conformations that have the centres of terminal atoms within small spheres of radius r . In this connection it is noted that there is no molecular structural information available as yet which could be used to define a solid angle within which the termini of siloxane chains must meet to form a bond.

Calculation of molar cyclization equilibrium constants for cyclic dimethyl siloxanes

In the previous paper¹⁰, molar cyclization equilibrium constants K_x for small cyclic dimethyl siloxanes $[(\text{CH}_3)_2\text{SiO}]_x$ were calculated using the FCM rotational isomeric state model by determining the statistically weighted fraction of the 3^{2x-3} discrete conformations of the corresponding open chain molecules which adopt highly coiled conformations corresponding to ring formation. The chains were assumed to be unperturbed by excluded volume effects and the calculations were carried out for cyclics with $x = 4-9$. Excellent agreement between experiment and theory was found for the cyclic octamer and nonamer. Furthermore, the failure of the FCM model to predict K_x values for the smaller cyclics and in particular the cyclic tetramer, pentamer and hexamer was rationalized by making a small but necessary adjustment to the FCM model so as to make it applicable to the calculation of the K_x values of small siloxane rings¹⁰.

The close agreement between experimental K_x values for the smaller cyclic siloxanes and those predicted by the FCM model has encouraged the calculations reported here, whereby K_x values for cyclics with $x > 9$ are computed. As will be seen, such an extension of the calculations has made it possible to explore the $\log K_x$ values in the region $x \cong 12$, where there is a well defined minimum rising to a maximum at $x \cong 15$ before the values decrease again (see Figure 1 for the experimental K_x values).

The calculations were carried out as before¹⁰. Probability densities \bar{W}_x required by equation (5) were calculated by dividing the sum z_r of the statistical weights for all chain conformations with their terminal atoms separated by less than r Å, by the volume $(4/3)\pi r^3$ and by the total sum Z of the statistical weights of all 3^{2x-3} conformations. Z is the conformational partition function of the x -meric chain and is given by:

$$Z = [1 \ 0 \ 0] (\mathbf{U}' \mathbf{U}')^{x-2} \mathbf{U}'' \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} \quad (6)$$

and

$$\bar{W}_x = z_r / Z (4/3)\pi r^3 \quad (7)$$

The value of r , the radius of the sphere within which termini of siloxane chains meet to form a bond, is treated as an adjustable parameter. This radius is expected to be small but finite and in previous calculations it was assigned

Figure 1 Theoretical molar cyclization equilibrium constants K_x for cyclic dimethyl siloxanes at 383K calculated by the direct computational method using the FCM model and assuming that $r = 2 \text{ \AA}$ (\bullet). They are compared with the experimental K_x values for an undiluted poly(dimethyl siloxane) equilibrate (\circ)

the value 3 \AA . For the calculations to be described here, smaller values have been assigned to r . In this connection it is noted that as the chains are built up and calculations of end-to-end distances are carried out, tests can be made at shorter chain lengths to discover whether the ends of the full length chain can ever fall within the volume of radius r . If they cannot, there is no further need to continue adding further skeletal bonds. Naturally, the smaller the value of r the greater will be the saving of computational time. Provided that r is not too small, the values of \bar{W}_x are found to be relatively insensitive to its precise value and the general conclusions reached in this paper are not dependent on the values chosen for r in particular calculations.

In Figure 1, K_x values for cyclics with $x = 8-11$ calculated by equations (5)–(7) using the FCM model and with $r = 2 \text{ \AA}$ are compared with experimental values for an undiluted poly(dimethyl siloxane) equilibrate at 383K. It is found that there is a close correspondence between experimental and theoretical K_8, K_9 and K_{10} values but a complete failure of the FCM model to calculate the experimental K_{11} value. Thus, the calculated K_8, K_9 and K_{10} values agree within experimental error with the corresponding experimental values, whereas the calculated K_{11} value is nearly nine times greater than the experimental value.

The reason for the sharp increase at $x = 11$ may be appreciated if the chain geometry is considered. The

poly(dimethyl siloxane) chain consists of a regular alternation of bond angles of unequal magnitude centred on silicon and oxygen atoms. Consequently, the planar all-*trans* conformation will correspond to a closed loop after a definite number of monomer units. For the bond angles chosen by Flory, Crescenzi and Mark⁹ chain closure occurs at eleven monomer units (see Figure 2). Hence, for $x = 11$ there are a total of 1 162 261 467 conformations and 296 357 of these have the centres of their terminal atoms within 2 \AA . The total statistical weight of these highly coiled conformations is approximately 17.4 and the all-*trans* conformation alone contributes a statistical weight of unity. Hence, the FCM model does predict a well defined minimum in the $\log K_x$ versus $\log x$ plot for dimethyl siloxane cyclics as is found experimentally but this minimum is not centred at $x = 12$. In the section to follow the FCM model is modified in order to explore whether even better correspondence between experiment and theory can be achieved.

Modification of the FCM model

The structural parameter of the poly(dimethyl siloxane) chain that is open to most doubt in the FCM model is the Si–O–Si bond angle. The value of 143° assigned to it is that observed in the cyclic tetramer $[(\text{CH}_3)_2\text{SiO}]_4$. Now, the Si–O–Si bond angle is known to be flexible and to adopt different values in different silicone and silicate structures¹⁵. For example, a bond angle of $130 \pm 10^\circ$ has been observed in hexamethyl disiloxane $[(\text{CH}_3)_2\text{Si}]_2\text{O}$ ^{16,17}. Hence a new value of 138° was assumed for the Si–O–Si bond angle, 5° less than that in the FCM model. This value corresponds to the first appearance of a planar all-*trans* cyclic conformation at $x \cong 13$. The statistical weight parameters of the FCM model were assigned new values of $\sigma = 0.22$ and $\delta = 0.10$ at 383K so as to reproduce the experimental characteristic ratio of poly(dimethyl siloxane) and the temperature coefficient of its unperturbed dimensions. The $\log K_x$ versus $\log x$ plot obtained using this

Figure 2 Diagram of the dimethyl siloxane chain in the planar, all-*trans* conformation

Figure 3 Theoretical molar cyclization equilibrium constants K_x for cyclic dimethyl siloxanes at 383K calculated by the direct computational method using the modified FCM model and assuming that $r = 1 \text{ \AA}$ (▲) and $r = 2 \text{ \AA}$ (●). They are compared with the experimental K_x values for an undiluted poly(dimethyl siloxane) equilibrate (O)

modified model predicts a minimum in the region $x \cong 10$ followed by a sharp increase at $x = 12$ (see Figure 3). Less complete calculations showed that the K_x value for $x = 13$ is also considerably higher than the experimental value. Furthermore, Monte Carlo calculations for even larger cyclics suggest that theoretical K_x values decrease as x increases. Hence a good rationalization of the experimental K_x values has been obtained.

CONCLUSIONS

The main conclusion of this study is that the FCM model gives a good qualitative understanding of the molar cyclization equilibrium constants for dimethyl siloxane cyclics but it does not predict K_x values for all the individual rings.

A small modification of the model by making a 5° decrease in the Si—O—Si bond angle moves the minimum in the $\log K_x$ versus $\log x$ plot but gives K_{12} and K_{13} values that are much higher than those observed experimentally.

These calculations provide a most exacting test of the FCM rotational isomeric state model and it is believed that it is the discrete nature of the model (with fixed bond angles and only three rotational isomeric states about each bond) that is responsible for the failure to predict theoretically the smooth changes in the $\log K_x$ versus $\log x$ plot that are observed experimentally.

Institut für Physikalische Chemie der Universität Wien, A-1090 Wien, Austria (Received 8 December 1975; revised 26 February 1976)

Light scattering measurements for two samples of polystyrene (I, $M_w = 2.15 \times 10^5$; II, $M_w = 2.5 \times 10^6$) were performed in the iso-refractive mixed solvent dimethoxymethane–diethyl ether. For sample I the temperature dependence of the second osmotic virial coefficient A_2 was determined for three constant compositions of the mixed solvent. In the range -30° to $+25^\circ\text{C}$ the three curves run practically parallel and exhibit a maximum at approximately -10°C . For the volume fraction of 0.7 diethyl ether in the mixed solvent, an endothermal theta-temperature θ_+ was found at $-27.0^\circ \pm 1.5^\circ\text{C}$ and θ_- , the exothermal theta-temperature, at $-5.0 \pm 1^\circ\text{C}$. The investigation of sample II in the above-mentioned solvent confirmed the observed θ_- -temperature and displayed a higher exothermicity compared with I. Similarly to the temperature variation of A_2 , the chain dimensions of II, determined from the angular dependence of the scattered light, run through a maximum. The unperturbed dimensions in the mixed solvent are found to be: $r_w = 448 \pm 5 \text{ \AA}$ at $\theta_+ = -27^\circ\text{C}$ and $r_w = 443 \pm 5 \text{ \AA}$ at $\theta_- = -5^\circ\text{C}$, as compared with $r_w = 420 \pm 10 \text{ \AA}$ at $\theta_+ = +33^\circ\text{C}$ in cyclohexene. The inter-relation of the chain expansion coefficient and A_2 is quantitatively described by the Zimm–Stockmayer–Fixman equation over the entire range of heats of dilution.

INTRODUCTION

A lot of work has been dedicated to the question of whether the unperturbed dimensions of dissolved polymers, as determined by light scattering, depend on the particular conditions under which pseudo-ideality is achieved^{1–7}. Practically all systems studied so far were more or less endothermal and only in a few rare exceptions exothermal theta conditions were investigated^{8,9}. The quintessence of these studies is that when a polymer is examined in a series of endothermal solvents, showing different θ -temperatures and different heats of dilution, the unperturbed dimensions normally do not differ widely and there is no systematic dependence on either of these two parameters or on the chemical nature of the solvent.

To our knowledge no attempt has hitherto been made to compare the unperturbed dimensions of a given polymer for positive and negative heats of dilution and to eliminate chemical influences by using a solvent which exhibits both, endothermal and exothermal theta conditions. The present work is therefore concerned with this problem.

The requirement that the two θ -temperatures should lie within the normal operation range of a light scattering instrument is rarely met by a binary polymer–solvent system. From our investigation on mixed solvents for polystyrene^{10,11} it was clear, however, that a mixture of diethyl ether and a proper second component should serve the purpose, since the ether exhibits its maximum solvent power, which still does not mean complete miscibility, at approximately -10°C ¹². By adding a suitable amount of a better solvent, the desired θ_+ ($< -10^\circ\text{C}$) and θ_- ($> -10^\circ\text{C}$) condi-

tions^{13,14} could then be realized. For the determination of the unperturbed dimensions by means of light scattering measurements, the solvent had to meet a second condition, namely iso-refractivity with diethyl ether (DEE). Fortunately dimethoxymethane (DMOM) not only fulfills this requirement* in addition its mixing behaviour with DEE deviates only slightly from ideality, as can be seen from vapour pressure measurements¹⁵.

The system DMOM/DEE/PS is thus highly suited for a study of the purely thermodynamic influences on chain dimensions of dissolved polymers.

EXPERIMENTAL

Materials

Both samples of PS were anionically prepared. The low MW product is the main fraction of the lot S 111 provided by the Dow Chemical Co. The molecular weight of the main fraction prepared according to Breitenbach and Streichsbier¹⁶ was found to be $M_w = 2.15 \times 10^5$ as determined from its intrinsic viscosity and the viscosity–molecular weight relationship¹⁷. Its non-uniformity $U = M_w/M_n - 1$ is less than 0.1¹⁶. The corresponding values for the high molecular weight product, which was a commercial sample from the Pressure Chemical Co., are $M_w = 2.5 \times 10^6$ and $U \sim 1.0$; these results, which have been confirmed by measurements in different solvents (cyclohexane and

* We are grateful to our previous coworker J. K. Rigler for drawing our attention to this iso-refractive system and its possibilities.

Figure 1 Evaluation of the light scattering data according to equation (2) for $\bar{M}_w = 2.15 \times 10^5$ and 66.6 vol % DEE (20°C) in the mixed solvent OTMF/DEE; $P^{-1}(90) = 1.08$. A, -30° ; B, -26° ; C, -20° ; D, -14° ; E, -7.5° ; F, 2.5° ; G, 9° ; H, 15° ; I, 21° C

t-decalin) and by different experimentalists are in disagreement with the data given by the producers, namely $M_w = 2.0 \times 10^6$ and $U \sim 0.2$.

The solvents were p.a. products, which we merely dried before use. The refractive indices n (at 15°C , 435.8 nm) of DMOM and DEE are 1.36356 and 1.36375, respectively and their thermal expansion coefficients at 0°C , $1.49 \times 10^{-3} \text{K}^{-1}$ and $1.52 \times 10^{-3} \text{K}^{-1}$ respectively.

Apparatus and procedure

Since DEE and DMOM are very volatile compounds, we had to construct special closed cells which are sealed by means of a spherical grind and teflon foils. The clasps by which the two parts of the grind are pressed together are made entirely of brass and fit exactly into the holding device of the commercially available light scattering instrument Sofica PGD 42000 in order to prevent the entrance of external light. A further consequence of the high volatility of our solvents was the necessity to clear the solutions by filtration instead of centrifugation. The use of relatively tight teflon coated cellulose filters, produced by Millipore Corp., Mass. USA (diameter $0.5 \mu\text{m}$), was possible because of the low viscosity of the solutions even at the working temperature of 0°C .

The light scattering apparatus itself also had to be adapted for low temperatures, since small ice particles forming in the bath result in a strong increase in light scattering, and water condensing on the window transmitting the light into the bath disturbs the geometry of the primary beam. The first difficulty was overcome by using a bath liquid miscible with water; the only substance meeting the additional requirement of approximately the same refractive index as glass (in order to keep the errors introduced by reflection small) was α -methylpyridine. The second problem was

solved by ventilating the window with a stream of dried nitrogen. For very low temperatures we had to stir the bath in order to prevent the formation of temperature gradients. All measurements were performed with unpolarized light of 435.8 nm.

EVALUATION

In order to avoid the laborious measurement of refractive index increments for polystyrene in our mixed solvent, we have used the evaluation procedure described by Kirste and Schulz¹⁸. Instead of the well known equation (1) of Debye:

$$\frac{K_\lambda c}{R} = \frac{1}{P(\theta)M_w} + 2A_2c + \dots \quad (1)$$

we start from the modified expression (2):

$$\frac{K_\lambda^* c}{i_\theta} = \frac{1}{P(\theta)M_w} + 2A_2c + \dots \quad (2)$$

in which i_θ , the difference in the galvanometer reading between solution and solvent observed at the angle θ replaces the Rayleigh-ratio R_θ . Consequently K_λ^* comprises the geometric constants of the apparatus and the correction for the reflected light in addition to the refractive index and refractive index increment (and some other quantities, constant for one measuring series) already contained in K_λ .

Zimm-like diagrams can now be constructed on the basis of equation (2), by plotting c/i_θ vs. $\sin^2 \theta/2 + \text{constant } c$. For known molecular weight M_w of the polymer, the constant K_λ^* is accessible from the twofold extrapolated ratio:

$$\left[\frac{c}{i_\theta} \right]_{\substack{c=0 \\ \theta=0}} = \frac{1}{M_w K_\lambda^*} \quad (3)$$

since $P(\theta) = 1$ for $\theta = 0$; once K_λ^* is known, the rest of the evaluation can be performed in the usual manner.

RESULTS AND DISCUSSION

Second osmotic virial coefficients

Figures 1–3 give the results for three different ratios of solvent and non-solvent. The evaluation of these data according to the procedure described in the experimental section, yields the temperature dependence of A_2 depicted in Figure 4.

For the highest DEE content the curve runs below $A_2 = 0$ over the entire temperature range. When the content of DMOM is increased a practically parallel shift towards higher A_2 -values is observed. For a volume fraction of $\phi_{\text{DEE}} \sim 0.71$ in the mixed solvent the maximum of the temperature dependence of A_2 would touch the abscissa at approximately -10°C , i.e. a theta condition would be created for the first time. Because $\partial A_2/\partial T$ becomes zero as well as A_2 , the corresponding θ -temperature belongs to an athermal heat of dilution.

For still higher DMOM contents of the mixed solvents the above mentioned athermal θ -temperature separates into an endothermal (θ_+) and an exothermal (θ_-) theta-temperature which drift apart as the mixed solvent becomes richer in the solvent component. The corresponding composition dependence of the θ -temperatures looks similar

Figure 2 Evaluation of the light scattering data according to equation (2) for $\bar{M}_w = 2.15 \times 10^5$ and 70 vol % DEE (20°C) in the mixed solvent OTMF/DEE; $\bar{P}^{-1}(90) = 1.08$. A, -22°; B, -90°; C, 0°; D, 6.5°; E, 14°; F, 21°C

Figure 3 Evaluation of the light scattering data according to equation (2) for $\bar{M}_w = 2.15 \times 10^5$ and 75.0 vol % DEE in the mixed solvent OTMF/DEE; $\bar{P}^{-1}(90) = 1.08$. A, -22°; B, -18°; C, -12°; D, -8°; E, 1°; F, 6°; G, 12°; H, 20°; I, 25°C

to the binodal edges determined from phase equilibria¹¹, in fact it constitutes the critical line for infinite molecular weight of the polymer ($c_{pol} = 0$).

To our knowledge the present system is the first for which the complete transition from endothermal to exothermal θ -conditions could be followed by light scattering. It was thus interesting to check whether the theoretically calculated character of the interdependence of entropy and enthalpy contributions to the second osmotic virial coefficient¹⁹, hitherto only comparable to a limited range of heats of dilution¹⁹, is experimentally substantiated.

The required subdivision of A_2 into its enthalpy contribution $A_{2,H}$ and its entropy contribution $A_{2,S}$ ²⁰:

$$A_2 = -\frac{\Delta G_1^E}{RTc_2^2V_1} = -\frac{\Delta H_1}{RTc_2^2V_1} + \frac{\Delta S_1^E}{Rc_2^2V_1}$$

$$= A_{2,H} + A_{2,S} \quad (4)$$

was performed by means of its temperature dependence according to:

$$A_{2,H} = T \left(\alpha A_2 - \frac{\partial A_2}{\partial T} \right) \quad (5)$$

where α denotes the thermal expansivity of the solvent. Figure 5 shows the thus obtained interdependence of $A_{2,S}$ and $A_{2,H}$, which confirms the picture given by the Prigogine-Patterson theory¹⁹. In a diagram such as Figure 5, θ -conditions correspond to points on the diagonal, and it is clear that at a proper constant composition of the mixed solvent some curve should run through the origin of this graph. One could think that a perfect solution is created under these conditions ($\Delta S_1^E = \Delta H_1 = 0$), but this is not the case because of a non-zero ΔV_1 value, which must be anticipated from our pressure experiments on the similar system acetone/DEE/PS²¹.

For one mixed solvent ($\phi_{DEE} = 0.7$) the molecular weight influence on A_2 was also investigated. The corresponding results, as obtained from several Zimm-plots (an example of which is shown in Figure 6) are entered in Figure 4. Owing to the limits of experimental error (A_2 can be determined with an accuracy of approximately $\pm 5 \times 10^{-6} \text{ cm}^3 \text{ mol/g}^2$

Figure 4 Temperature dependence of the second osmotic virial coefficient A_2 for the indicated molecular weights and compositions of the mixed solvent. ---, calculated according to the equations (6)–(8) as described in the text; \circ , $\bar{M}_w = 2.15 \times 10^5$; \triangle , $\bar{M}_w = 2.5 \times 10^6$. Curve A, $\phi_{DEE} = 0.666$; B, $\phi_{DEE} = 0.7$; C, $\phi_{DEE} = 0.7$; D, $\phi_{DEE} = 0.75$

Figure 5 Interdependence of the enthalpy and the entropy contributions to the second osmotic virial coefficient for the indicated compositions of the mixed solvent for $\bar{M}_w = 2.15 \times 10^5$ with increasing temperature from left (endothermal) to right (exothermal) on the curves: A, $\phi_{DEE} = 0.66$; B, $\phi_{DEE} = 0.7$; C, $\phi_{DEE} = 0.75$

in the present case) there is some uncertainty as to the precise shape of the curve below -15°C . There is however no doubt that the temperature dependence of A_2 on the two molecular weights under investigation cross at θ_- and that the higher molecular weight sample exhibits the *more exothermal* heat of dilution. Since it is well established on the other hand, that a similar common point of intersection exists at θ_+ , which, however, is characterized by the fact that the higher MW sample exhibits *less endothermal* behaviour²², one should conclude, that the $A_2(T)$ functions intersect in the region $A_2 > 0$ and that a given solvent reaches its maximum solvent power for different molecular weights of the polymer at different temperatures.

As is generally known, a theoretical description of the temperature dependence of A_2 explaining the occurrence of θ_+ and θ_- in the same system, must in some way or other include free volume effects. In the application of all these theories at least one parameter is adjustable, we have thus chosen the simplest method for the calculation of the dependence of the Flory-Huggins interaction parameter χ on the variables of state. This is equation (6) which was introduced by Patterson and Delmas²³:

$$\chi = -\frac{\tilde{U}_1}{\tilde{T}_1} a + \frac{\tilde{c}_{p1}}{2} b \quad (6)$$

In this equation tildes, $\tilde{}$, indicate reduced quantities and the index 1 stands for the solvent. U represents the internal heat of vaporization and c_p its temperature derivative. The latter two quantities are calculated using Flory's equations of state²⁴:

$$\tilde{U} = -\tilde{V}^{-1} \quad (7)$$

and

$$\tilde{T} = \tilde{V}^{-1} - \tilde{V}^{-4/3}; \tilde{p} = 0 \quad (8)$$

Although, the system specific parameters a and b can in principle be calculated theoretically, a is normally adjusted

to the experiment. Since in addition, equation (6) constitutes an excellent analytical expression for the reproduction of measured dependencies, when both system specific parameters are adjusted^{21,25}, it seemed interesting to check, whether this equation can describe $A_2(T)$, when a and b are determined from the fact that according to:

$$A_2 = \left(\frac{1}{2} - \chi \right) \frac{1}{\rho_2^2 V_1} \quad (9)$$

χ must become 0.5 at θ_+ and θ_- , respectively.

Treating the mixed solvent (which shows negligible preferential solvation¹⁵) as one component, whose reduction temperature and reduction volume is calculated from the corresponding thermal expansivity to be:

$$T^* = 4070\text{K}, \text{ and } V^* = 72.2 \text{ cm}^3,$$

we arrived at the dependence shown in Figure 4 by the broken line.

Similar to the previous findings the dependence calculated from equations (7) and (8) is very close to the measured one even at relatively large distances from the points of adjustment. It is also noteworthy that the observed influences of molecular weight on A_2 cannot be explained theoretically by equations (6)–(9), unless either the θ -conditions are treated to be slightly dependent on molecular weight or the equations (6) and (9) are modified.

Radii of gyration

Chain dimensions as a function of temperature were determined for $M_w = 2.5 \times 10^6$ in the mixed solvent containing 70 vol% DEE (at 20°C). Under these conditions the unperturbed dimensions can be observed at $\theta_+ = -27^\circ \pm 2.5^\circ\text{C}$ and at $\theta_- = -5^\circ \pm 1^\circ\text{C}$. As an example for the Zimm-plots obtained, Figure 6 gives the result for -11°C , at which temperature the solvent power of the mixed solvent achieves its maximum.

The z-average of the radius of gyration was obtained from the initial slope of P_θ^{-1} vs. $\sin^2 \theta/2$ (which is found to be constant in the whole range in agreement with theoretical prediction for values of the non-uniformity near unity²⁶) according to²⁷:

$$P_\theta^{-1} = 1 + \frac{16\pi^2 r_z^2}{3\lambda^2} \sin^2 \frac{\theta}{2} + \dots \quad (10)$$

Figure 6 Evaluation of the light scattering data according to equation (2) for $\bar{M}_w = 2.5 \times 10^6$, 70.0 vol % DEE (20°C) in the mixed solvent OTMF/DEE and -11°C . A, $c = 0$; B, $c = 0.489 \times 10^{-3}$; C, $c = 0.813 \times 10^{-3}$; D, $c = 1.24 \times 10^{-3}$; E, $c = 1.6 \times 10^{-3}$; g/ml; F, $\theta = 142.5^\circ$; G, $\theta = 135^\circ$; H, $\theta = 120^\circ$; I, $\theta = 105^\circ$; J, $\theta = 90^\circ$; K, $\theta = 75^\circ$; L, $\theta = 60^\circ$; M, $\theta = 45^\circ$; N, $\theta = 37.5^\circ$; O, $\theta = 0^\circ$

Figure 7 Temperature dependence of the radius of gyration for $M_w = 2.5 \times 10^6$ and 70.0 vol % DEE (20°C) in the mixed solvent OTMF/DEE. The shaded areas mark the limits of experimental reproducibility in the determination of the unperturbed dimensions

Figure 8 Dependence of the chain expansion coefficient α_e on the second osmotic virial coefficient A_2 for $M_w = 2.5 \times 10^6$. \circ, \square correspond to endothermal solutions; \blacktriangle , exothermal and endothermal points coincide; —, calculated from the theoretical equation (12); \blacktriangle, \square DMOM/DEE/PS; \circ , cyclohexane/PS

where $\lambda (= \lambda_0/n)$ is the wavelength of the light in the medium and r_z the z -average $r_z = (\overline{r_z^2})^{1/2}$ of the radius of gyration.

The conversion of r_z to the weight-average radius of gyration $r_w = (\overline{r_w^2})^{1/2}$ was performed by means of the relation given by Schulz²⁸:

$$r_w = r_z \left(\frac{1+U}{1+2U} \right)^{1/2} \quad (11)$$

The obtained values of r_w are on average in better agreement than $\pm 1.5\%$ with the results obtained by the evaluation of the corresponding dissymmetry data by means of tables²⁹, directly yielding r_w .

Figure 7 shows how r_w depends on temperature. As is immediately obvious from the shaded areas, the unperturbed dimensions in the endo- and exothermal solution are identical within experimental scattering i.e.:

$$r_w = 448 \pm 5 \text{ \AA at } \theta_+ = -27^\circ\text{C:}$$

$$r_w = 443 \pm 5 \text{ \AA at } \theta_- = -5^\circ\text{C}$$

Since it seems interesting to compare this value with that obtained for the same polymer sample in a conventional one component (with a much larger heat of dilution) θ -solution, we also determined the unperturbed dimensions in cyclohexane and arrived at $r_w^{\text{CH}} = 420 \pm 10 \text{ \AA}$ at $\theta_+ = +33^\circ\text{C}$. This result lies within the normal scattering of the unperturbed dimensions in different single solvents.

The conclusion can therefore readily be drawn that the enthalpy conditions as such stay inconsequential on the chain dimensions resulting for a pseudo-ideal Gibbs free energy of dilution of the solvent ($A_2 = 0$).

Chain expansion and second osmotic virial coefficient

The observed correlation of the chain expansion coefficient $\alpha_e = r/r_\theta$ with the second osmotic virial coefficient A_2 was compared with the theoretical expression reported in literature. Best agreement is obtained when the Zimm–Stockmayer–Fixman³⁰ equation:

$$A_2 M_w^{1/2} = 4N_L (\pi K'_\theta)^{3/2} a_1^{-1} (\alpha_e^2 - 1) \quad (12)$$

with the experimentally determined value $K'_\theta = r_{w,\theta}^2/M_w = 7.9 \times 10^{-18} \text{ (cm}^2\text{mol/g}^2\text{)}$ and $a_1 = 134/105$ is inserted.

Other theoretical equations give deviations up to 40%. The dependence of α_e on A_2 , calculated from equation (12), is shown in Figure 8 together with the experimental points. It is noteworthy that equation (12) is equally suited for the representation of slightly endo- and exothermal conditions of the mixed solvent and of the highly endothermal solution of PS in cyclohexane.

The fact that the K'_θ value for the mixed solvent is in good agreement with the mean value of 7.9×10^{-18} for several single solvents⁴ and in particular with the value of 7.2×10^{-18} obtained for our polymer in cyclohexane is a further indication that the mixed solvent really behaves like one component.

CONCLUSION

Because it is possible to tailor the thermodynamic quality of a solvent by selecting the proper ratio of its components, the entire typical dependence of A_2 on temperature could be followed. It was thus possible to compare the unperturbed dimensions r_θ for endothermal and exothermal conditions without changing the system. The observed independence of r_θ on the particular thermodynamic conditions under which pseudo-ideality of the solution is achieved, indicates that the variations of r_θ reported in literature are exclusively the result of some local, solvent specific interactions which influences the stability of the different conformers and/or temperature.

In addition, the abnormal molecular weight dependence encountered in the vicinity of the exothermal theta conditions makes it once more clear that the theoretical concept of the dimensionless intermolecular excluded volume function $h(z)$ must at least be modified, to cover all thermodynamic facts existing.

Studies on the curing of a loaded unsaturated polyester binder

R. M. V. G. K. Rao* and A. Pourassamy*

Propulsion Division, National Aeronautical Laboratory, Bangalore-17, India
(Received 2 February 1976)

Experimental studies were made to determine the effect of loading and particle size on the gel-time of an unsaturated polyester binder filled with crystalline potassium chloride powder. The filler chosen was found to exhibit neither absorbing nor catalytic effect on the curing system in the time scale of these studies. While the gel-time decreased with increased solid (filler) loading and with decreased particle size, the gel-temperature essentially remained constant. A surface area mechanism is proposed to explain the observed results.

INTRODUCTION

Filler behaviour in thermosetting formulations is different from that with thermoplastic resins. While the thermoplastics render themselves processible through a physical change (e.g. melting, solidification etc.) thermosets do so through a chemical reaction resulting in the extension and crosslinking of the molecular chains. The filler, then has a direct effect on the curing parameters such as gel-time and gel-temperature, in a manner that depends on whether it has a tendency to absorb or adsorb the resin or whether it has any catalytic effect on the system. Curing in the presence of an absorptive filler presents all the complexities of a bulk process, while in the case of an adsorptive filler, the resin is taken up over a few layers of the filler giving rise to a surface mechanism. In such a case increased filler loading or decreased particle size for the same loading, means an increase in the surface area of the curing mass. Further, when the chosen filler is non-catalytic, the curing reaction becomes based on the surface area of the filler and the concentration of the chosen curing agents (catalyst and accelerator). This analysis was applied to explain the observed behaviour, as the chosen filler was found to exhibit no absorptive and catalytic effects on the system within the time scale of these experiments.

EXPERIMENTAL

General purpose polyester resin (Grade HSR 8111) was employed in these experiments in combination with the catalyst (methyl ethyl ketone peroxide) and the accelerator (cobalt naphthanate), all supplied by Bakelite Hylam (India) Ltd. The filler chosen was white crystalline potassium chloride powder (Analar grade) and it was classified into three different particle sizes, viz. 74, 53 and 44 μm . All the studies were conducted at a constant room temperature of $25 \pm 1^\circ\text{C}$.

In each experiment 50 g of resin were cured using 1 cm^3 of accelerator and 1 cm^3 of catalyst (2 $\text{cm}^3/100$ g resin). The time-temperature history was noted, from the instant of complete addition of solids, the reaction mass having been continuously stirred.

Gel-time was noted as the point, when the reaction mass became just rubbery enough and the corresponding temperature was defined as gel-temperature. This procedure was repeated for loadings ranging from 10–100 phr

and for three different particle sizes, viz. 74, 53 and 44 μm . The results have been presented in *Figures 1* and *2*.

RESULTS AND DISCUSSION

The relationship between gel-time and the filler loading for various particle sizes is shown in *Figure 1*.

Any curve in the diagram can be divided into three regions as marked in the Figure at a loading of 5 and 80 phr. The steep decline in gel-time from a value of 18.5 min for the unfilled resin to its value of 5 phr loading, occurs because of the sudden availability of surface area for the curing mass as a result of the incorporation of the first batch of the filler. Then there is further decrease in gel-time with increased loading upto 80 phr. The change, however, is gradual, since the resin/filler ratio decreases with progressing filler loading, leading to a resin-lean condition. Between the values of 80 and 100 phr the change in gel time is small, probably because all the resin is adsorbed by the filler and additional loading results only in a resin-deficient formulation. A similar effect is observed for different particle sizes, but for a particular loading. Here again, the gel-time decreases as the particle size diminishes.

Thus the occurrence of the same effect in both cases viz. increased filler loading and decreased particle size, both resulting in an increased surface area available to the curing mass, indicates the effect on the curing rate, of the surface area as evidenced by the decreased gel-times in these cases.

Referring to *Figure 2*, it can be seen that a steep rise in the slope of the curves beyond a value of 30°C occurs in all three cases, indicating the onset of gelling. This is characterized by a sudden change in the specific volume, temperature and viscosity of the mass. The onset of gelling is advanced with the increased filler loading as shown in the Figure. This is again a consequence of the surface area increase due to increased filler content.

The more or less constant temperature of gelling (33°–34°C) in all the cases tells us something about the relation between the heat release and the proportionality between the curing rate and the surface area. Thus, it may be expected that with an increase in the surface area of the filler, the curing rate increases, decreasing the gel-time, in order to give rise to a constant heat release.

CONCLUSIONS

Gel-time decreases with increased surface area of the non-absorbing and non-catalytic filler, as a result of progressive loading or decreased particle size for the same loading. Studies made on the system chosen indicate no absorbing or catalytic tendency of the filler towards the polymeric binder.

Curing rate increases with the increased surface area of the filler. Curing essentially occurs at a constant temperature in all cases indicating some constancy in the heat release, and this appears to explain why the gel-time decreases with increased curing rates.

In view of the problems associated with mixing at higher solid loadings, as experienced in these experiments, it seems desirable as far as possible to work with lower filler loadings but with finer filler particles.

A more comprehensive study would involve investigation of the effects of the filler's shape and its cohesive and adhesive tendencies, and the particle size distribution which affects the surface area change phenomenon under the above situation.

ACKNOWLEDGEMENTS

The authors are very grateful to the Head of Propulsion Division and the Director of this laboratory for providing the facilities to conduct the experiments and forwarding the paper.

Polymerization of ethylene by n-butyl lithium

J. N. Hay, D. S. Harris and M. Wiles*

Department of Inorganic and Physical Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, UK

(Received 5 January 1976)

The polymerization of ethylene with butyl lithium activated with tetramethyl ethylene diamine (TMEDA) has been investigated, and the mechanism proposed by McCabe *et al.* substantially vindicated. The active initiating species is considered to be free monomeric butyl lithium, unchelated to TMEDA, and the mechanism of propagation of olefin insertion between the metal-carbon bond, probably involving an intermediate π -complex between olefin and metal alkyl.

INTRODUCTION

The addition of metal alkyls to olefins is an important source of polymerization reactions, originally being studied as models of the heterogeneous coordination anionic catalyst, but also in their own right. They have been used to:

(1) initiate the anionic polymerization of dienes and α -olefins¹

(2) study the coordination anionic catalyst²,

By analogy, aluminium triethyl dimers and 1:1 complexes have been studied in their reactivity to α -olefins;

(3) oligomerize olefins³⁻⁶ by the insertion reaction:

n-Butyl lithium has been observed to polymerize ethylene³ by an insertion mechanism, but high molecular weight polymer is produced only at high ethylene pressures. This is due to the competition of an elimination with the insertion reaction, and the polymerization is also inhibited by association of butyl lithium (hexamer) since only the monomer is reactive to addition, i.e.

(this dissociation equilibrium is certainly over-simplified).

Polyethyl lithium species are also associated, but unassociated species in general are reactive to further addition:

Various chelating agents have been found to have startling effects on the reactivity of n-butyl lithium. In particular, Eberhardt and Butte⁷, found that certain tertiary diamine, e.g. tetramethyl ethylene diamine and sparteine would telomerize ethylene in the presence of aromatic hydrocarbons. The following mechanism was proposed:

Later work⁸, in n-octane as solvent, was interpreted in terms of a 1:1 chelate polymerizing ethylene to a linear product. Langer^{9,10} has extended this to consider the effect of a number of bifunctional agents on the polymerization of ethylene with butyl lithium, and established that *N,N,N',N'*-tetramethyl ethylene diamine (TMEDA) was the most effective. Molecular weights up to 10^5 were reported at pressures of 5×10^3 lbf/in².

McCabe *et al.*^{11,12} have studied the kinetics of the ethylene polymerization and established that although the dominant species in solution is the 1:1 complex at BuLi:TMEDA molar ratios below 1:1, the rate of polymerization is independent of the chelate concentration over a wide molar ratio range. Accordingly the 1:1 complex could not be the active polymerizing species. It was suggested that the action of the chelating agent was to reduce the degree of association of the butyl lithium, encouraging the formation of unchelated butyl lithium monomer. Zero-order in chelating agent followed if it were required to reduce the association, and it complexed with the monomer,

It has been suggested that this mechanism is inconsistent since it would require the chelating agent to act as an

inhibitor for the polymerization¹³. Instead, an ionic mechanism was postulated in which the presence of the chelating agent encourages the formation of loose ion-pairs.

Accordingly, it is interesting to reconsider this ethylene polymerization further, particularly in the light of the three mechanisms, anionic, complex formation and monomer insertion, invoked previously.

EXPERIMENTAL

De-aromatized *n*-hexane and tetramethyl ethylene diamine (TMEDA) were used after distilling *in vacuo* from *n*-butyl lithium. Ethylene (Cambrian Chemical Co. Ltd) was used after drying; mass spectroscopic and g.l.c. analyses indicated that it was at least 99.5% pure.

Polymerizations were carried out in all glass apparatus with ethylene pressures up to 3 atm, and in a stainless-steel reaction vessel up to 100 atm. The extent of reaction, in the latter, was followed with a pressure transducer. Polymerization characteristics are listed in Table 1.

Low molecular weight hydrocarbon products were analysed by gel permeation chromatography, using a Waters Associates Model 100, with ten columns of crosslinked polystyrene gels with permeabilities in the range 13–15 nm. 1.6% w/v solutions in tetrahydrofuran, stabilized with 2,6-di-*t*-butyl-*p*-cresol, were used at a flow rate of 1 cm³/min at 295K.

Number-average molecular weights, \bar{M}_n , of the polyethylene samples in the range 500–10 000, were determined by ebulliometry using *p*-xylene as solvent. *n*-Tetracontane and naphthalene were used as calibrants. Higher molecular weights were determined by temperature drop turbidimetry.

RESULTS

Lower pressure studies

Rate measurements. McCabe *et al.*^{11,12} have studied the kinetics of polymerization from the overall ethylene pressure change. They established that a constant rate of ethylene uptake occurred only after an initial period of more rapid uptake of ethylene. The excess volume of ethylene absorbed in this period, over that absorbed at constant rate, corresponded with one mole of ethylene per mole of butyl lithium irrespective of the molar ratio of BuLi:TMEDA.

The nature of this initial rapid uptake of ethylene was further investigated by following pressure changes over a time scale consistent with first 2% conversion (moles of ethylene/moles of BuLi) of the slower constant rate of polymerization. The system was then degassed, ethylene re-admitted and the uptake of ethylene recorded as before. This was repeated (4 to 5 times) and in each case the ethylene uptake was the same. This adsorption was 25 times larger than ethylene solubility and corresponded to one mole per mole of *n*-butyl lithium present.

The initial rapid adsorption of ethylene was clearly reversible and dependent on butyl lithium concentration to first-order, consistent with McCabe's^{11,12} conclusions of a π -complex, i.e.:

Analyses of the products of the addition reaction indicated that little or no insertion of ethylene had taken place, and clearly metallation of the ethylene must be excluded since it cannot account for the reversible nature of the adsorption, i.e.:

The constant rate of ethylene consumption was first order in ethylene and butyl lithium and zero order in TMEDA. In the absence of TMEDA no reaction took place, at least below 330K, and at atmospheric pressure, even in the presence of tertiary amines. The effect of molar ratio was investigated over the range 100:1 to 1:30 (BuLi:TMEDA) from the observed rate constant, k :

$$-d/dt[\text{C}_2\text{H}_4] = kK_s p_{\text{C}_2\text{H}_4} [\text{BuLi}]_0$$

where K_s is the solubility constant of ethylene in hexane, and $p_{\text{C}_2\text{H}_4}$ the partial pressure of ethylene. At ratios above 100:1 no reaction was observed. With increasing TMEDA concentrations the observed rate constant increased to a value which remained constant over the range 10:1 to 1:10; at higher ratios the rate constant decreased (Figure 2).

Molecular weight changes. The molecular weight distributions of the products of the reaction broadened with increasing conversion, which is also with increasing time (see Table 2). Soluble products, up to chain lengths of 20, were monodispersed, and so termination or transfer reactions were not considered important. At higher chain lengths the polymerization became heterogeneous and the rate decreased. The broadening of the dispersities was not

Figure 2 Effect of BuLi:TMEDA ratio on polymerization rate

inconsistent with the heterogeneous nature of the polymerization.

Number-average molecular weights of the products were greater than calculated assuming no transfer (or termination) and each mole of BuLi initiating. Indeed, based on these assumptions BuLi was 30–50% efficient, but decreased with conversion (which is also molecular weight) (see Figure 1). Extrapolation to low conversion did not exceed 50%, and there is evidence of catalyst decreasing in activity with time.

The 50% efficiency cannot readily be explained unless growth proceeds from both ends of the chain. Accordingly the number of active sites per chain was determined by terminating with excess benzoyl chloride and determining the phenyl ketone by the u.v. absorption band at 240 nm. 1.1–1.2 end-groups per chain were detected, (see Table 3). Hydrogen was also used to terminate the polymerization. Langer has shown that the 1:1 complex of BuLi:TMEDA reacts with hydrogen with the precipitation of lithium hydride. With a molar ratio of BuLi:TMEDA less than 1:2, 1 mole of hydrogen was absorbed per mole of BuLi initially present. Accordingly there was no loss of alkyl lithium bonds on initiation of the ethylene polymerization, although half the bonds were involved in initiating. McCabe *et al.*^{11,12} have also shown that polyethyl lithium will initiate the polymerization of butadiene, but with the same 50% efficiency in producing the block copolymer. Block lengths were consistent with this efficiency.

Polymerizations at higher pressure

Polymerizations were carried out in a stainless-steel vessel agitated by rocking. Despite this polymer was observed to form a crust on the liquid surface, and agitation was not sufficient to prevent the rate of solution of the ethylene determining the rate of polymerization. The observed kinetic parameters were considered atypical and experiments were restricted to a study of initiator activity.

In general, the yield of polymer increased with pressure, time and concentration of BuLi. Some of the scatter in experimental results was due to a part of the BuLi being used to purge the reaction system.

Langer^{9,10} studied the polymerization at similar ethylene pressures, and concluded that a more reactive initiator was formed on ageing by a slow reaction of polyethyl lithium and TMEDA to produce a $\sim\text{CH}_2-\text{N}(\text{CH}_2)_2\text{Li}^+$

species. This new initiator produced a higher molecular weight product. Langer's experiments were repeated by ageing (*in vacuo*) the TMEDA:BuLi (2:1 molar ratio) complexes for varying periods up to a week, before being used to polymerize ethylene for a fixed period of time at a constant ethylene pressure. The weight of polymer decreased with ageing period, (Table 4). Higher molecular weight materials were obtained, but this was considered more appropriate to a reduced initiator concentration, in that the rate of dissolution of ethylene became less rate controlling, and there was a decrease in competition between propagating centres for the available ethylene in solution, (see Table 4). The initiator decomposed to inactive material rather than to more reactive material (see Table 4).

Polymerizations carried out over an extended period exhibited a similar decrease in initiator efficiencies (see Figure 2 and Table 4).

DISCUSSION

Langer⁹ has interpreted the reactivity of butyl lithium in the presence of TMEDA to the formation of a 1:1 complex, i.e.

particularly since the n.m.r. chemical shift of the α -protons of the butyl lithium increased progressively up to this ratio. Indeed, molecular weight studies¹² in cyclohexane indicate a progressive decrease in association of butyl lithium, such that it is monomeric at a ratio of 1:1. If the reactivity can then be attributed to the decreased association and the increased ionic character of the Li-alkyl bond complex to TMEDA, maximum reactivity would then be achieved at a molar ratio of 1:1. This was observed by Langer^{9,10} in the hydrogenolysis of butyl lithium. Efficiencies studies also indicate that the same species is not involved in the hydrogenolysis and ethylene polymerization reactions. McCabe *et al.*¹⁴ have also shown, in the anionic polymerization of butadiene and isoprene, that a 1:2 molar ratio is required for maximum efficiency. This involved the propagating species, $\text{CH}=\text{CH}-\text{CH}_2\text{Li}^+(\text{TMEDA})_2$. No simple relationship between molar ratio and catalyst efficiency exists in the present polymerization studies; indeed a constant maximum polymerization rate is observed over the molar ratio 10:1 to 1:10, which covers the molar ratios required for all the predicted BuLi/TMEDA complexes, i.e. 4:1; 2:1; 1:1; 1:2, etc.

McCabe *et al.*¹² have argued that since the polymerization rate is first order in BuLi concentration, monomeric butyl lithium is involved in the initiating species. Also, by analogy TMEDA cannot be involved, other than to break up the degree of association. They invoked Zeigler's mechanism³ of olefin insertion into alkyl metal bond which is inhibited by association of the alkyl metal, since monomer is alone active, i.e.

TMEDA accordingly accelerates the lithium alkyl reaction by reducing the degree of association, and increasing the stationary concentration of monomeric butyl lithium.

Allen *et al.*¹³ have indicated that this mechanism cannot be correct since chelating agents, e.g. cyclic ethers, will inhibit the addition reactions of aluminium triethyl, i.e.

By analogy TMEDA should inhibit the reaction of BuLi monomer. While this indeed may be the case for a simple dimer/monomer equilibrium, it is by no means proved for a hexameric/monomer one, since:

$$[\text{BuLi}] = K^{1/n} [(\text{BuLi})_6]^{1/n}$$

where K is the overall dissociation constant, and n is 6 or a lower integer

$$[\text{BuLi}] = K_2 [\text{BuLi} + \text{TMEDA}] / [\text{TMEDA}]$$

If $K_1^{1/n} \ll K_2 / [\text{TMEDA}]$ the reaction will be accelerated over that of $(\text{BuLi})_6$.

These reactions are oversimplified; there is clear evidence for several BuLi:TMEDA complexes^{7-12,14}, and for each of these one can envisage the general reaction:

which assist the formation of BuLi monomer, so

$$[\text{BuLi}] = \sum_{x=1}^6 K_x \frac{[(\text{BuLi})_x \text{TMEDA}]}{[(\text{BuLi})_{x-1} \text{TMEDA}]} \quad (1)$$

The presence of these equilibria would have the effect of buffering the inhibition by TMEDA, until it is present in large excess. With a large excess of TMEDA there is indeed a decrease in rate. The presence of TMEDA complexes on either side of the equilibria will reduce the dependence of dissociation on its concentration, and so account for the apparent zero-order dependence. If on the average $x = 2$, the 50% efficiency may be explained.

Allen *et al.*¹³ have further proposed that the reactive species is a TMEDA-BuLi complex and the presence of TMEDA increases the concentration of looser (more reactive) ion-pairs, thereby increasing the overall reaction rate. If this were the case, the reaction would not be inhibited at higher TMEDA concentrations. It would appear that the reactive species is the unlikely monomeric BuLi, uncomplexed. BuLi:TMEDA complexes will form π -complexes to ethylene,

in a reversible equilibrium, which must have an effect on the dissociation reactions.

Stereospecific anionic polymerization and copolymerization of 1, 1-diphenylethyl methacrylate

Heimei Yuki, Yoshio Okamoto, Yoshiki Shimada, Koji Ohta and Koichi Hatada

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka, Japan
(Received 26 January 1976)

1,1-Diphenylethyl methacrylate (DPEMA), which is a new methacrylic ester, was synthesized and polymerized by *n*-butyllithium (*n*-BuLi) in toluene and THF. The triad tacticity of the polymers was determined from the n.m.r. spectrum of poly(methyl methacrylate) (PMMA) which was derived from them. A highly stereoregular polymer was not formed either in toluene or in THF by *n*-BuLi between -78° and 30° C. In toluene, the tacticity depended very much on the polymerization temperature, and unexpectedly, the polymer obtained at -78° C was rich in syndiotacticity. The polymers obtained in THF were atactic regardless of the temperature. A highly isotactic polymer was formed with Grignard reagents. DPEMA (M_1) was also copolymerized with methyl methacrylate (MMA), diphenylmethyl methacrylate (DPMMA), and trityl methacrylate (TrMA) (M_2) in toluene and THF with *n*-BuLi; the tacticity of the copolymers was determined. Generally, the stereoregularity of the copolymers was lower than those of the M_2 homopolymers. In the copolymerization with MMA monomer reactivity ratios were also determined.

INTRODUCTION

Stereospecific polymerizations of methyl and other methacrylates have been studied extensively and the effect of ester groups on the tacticity of polymers has been reported by many authors. Radical polymerizations of methacrylates have been investigated by Sakaguchi *et al.*¹, Niezette *et al.*², and Matsuzaki *et al.*³, who showed the relationship between the bulkiness of ester groups and the syndiotacticity of polymers. Since the stereoregulation in the anionic polymerizations of methacrylates is influenced by many factors such as propagation species, counter-ion, ester group and penultimate unit, there still exist several unresolved problems in the polymerization.

In a previous paper⁴, we reported the stereospecific polymerizations of very bulky methacrylates, diphenylmethyl methacrylate (DPMMA) and trityl methacrylate (TrMA), which formed quite different tactic polymers with *n*-BuLi in THF. The former gave a highly syndiotactic polymer, while the latter gave a highly isotactic one.

In the present study, a new monomer, 1,1-diphenylethyl methacrylate (DPEMA) was synthesized and polymerized by using *n*-BuLi in toluene and THF in order to clarify the steric effect of the ester group on the tacticity of the polymer. The bulkiness of the ester group of this monomer lies between those of the above two monomers. The stereoregularity of the copolymers of DPEMA with MMA, DPMMA, and TrMA was also investigated.

EXPERIMENTAL

Materials

DPEMA was prepared from silver methacrylate and 1,1-diphenylethyl chloride in diethyl ether. The chloride was produced by the reaction of equimolar amounts of diphenylmethylcarbinol (50 g, 0.25 mol) and HCl gas in benzene-petroleum ether (1:1) mixture (350 ml) at 0° C⁵. The chloride contained 1,1-diphenylethylene which was formed simultaneously, but was used without the separation of the olefin as the separation was found to be diffi-

cult. The yield of the chloride was found by n.m.r. analysis to be 69% (0.17 mol). The chloride and silver methacrylate (39 g, 0.20 mol) were allowed to react in 500 ml of diethyl ether for 3 h under reflux. Etheral solution was separated from precipitates by filtration, and ether, methacrylic acid, and 1,1-diphenylethylene were removed by distillation under reduced pressure. The residues contained DPEMA, the carbinol, 1,1-diphenylethylene, and a small amount of polymer which was produced thermally during the above treatment. These were poured into a large amount of petroleum ether in order to separate the polymer by filtration. The filtrate was then left at $\sim -20^{\circ}$ C for a few days to crystallize the monomer. The crude monomer thus obtained was recrystallized from petroleum ether; yield 11 g, 17%; m.p. 34.0° – 35.0° C. Found for $C_{18}H_{18}O_2$: C, 81.03%; H, 6.73%; calculated: C, 81.17%; H, 6.81%. The monomer is decomposed at $\sim 100^{\circ}$ C to give 1,1-diphenylethylene and methacrylic acid.

TrMA was prepared from silver methacrylate and trityl chloride in diethyl ether⁶; m.p. 102° – 104° C (literature value⁶ 101° – 103° C).

DPMMA was prepared by the reaction of methacryloyl chloride with diphenyl carbinol in the presence of triethylamine in diethyl ether; m.p. 80° – 82° C (literature value⁴ 78° – 79° C).

MMA was purified in the usual way and stored over CaH_2 . It was redistilled under vacuum just before use.

Toluene was purified and dried over sodium. The solvent was mixed with a small amount of *n*-BuLi and redistilled under high vacuum just before use. Tetrahydrofuran (THF) was purified in the usual way and was distilled onto lithium aluminium hydride, where it was stirred and redistilled under reduced pressure just before use. *n*-BuLi was prepared from *n*-butyl chloride and lithium metal in *n*-heptane.

Phenylmagnesium bromide (PhMgBr), cyclohexylmagnesium bromide ($C_6H_{11}MgBr$), and isobutylmagnesium bromide (iso-BuMgBr) were prepared from the corresponding bromides and magnesium in diethyl ether and most of the ether was replaced with toluene by distillation. Diethylaluminium diphenylamide (Et_2AlNPh_2) was prepared by

the reaction of triethyl aluminium and diphenylamine in toluene at 60°C⁷.

Polymerization

The polymerization was carried out in a dry glass ampoule. The solid monomer was first placed in the ampoule under dry nitrogen. The ampoule was then evacuated and flushed with nitrogen gas. This procedure was repeated at least twice. Then, a solvent and a liquid comonomer, if necessary, were added with hypodermic syringes. A catalyst solution was added with a syringe to the ampoule which had been placed in a thermostat bath.

Monomer reactivity ratio

Monomer reactivity ratios were calculated by use of Fineman–Ross equation for the initial copolymer.

Conversion of poly(1,1-diphenylethyl methacrylate) to PMMA

Poly(1,1-diphenylethyl methacrylate) (DPPEMA) was completely hydrolysed to poly(methacrylic acid) (PMAA) by refluxing in methanol containing a small amount of hydrochloric acid. However, the DPPEMA obtained by the Grignard reagents was not completely hydrolysed under the above condition. These polymers and a copolymer of DPPEMA with DPMMA were converted to PMAA by the reaction with hydrogen bromide in toluene solution. The PMAA thus obtained was converted to PMMA with diazomethane in benzene–diethyl ether solution. The triad tacticity of the original polymer was determined from the n.m.r. spectrum of PMMA thus derived. In the hydrolysis of the copolymer of DPPEMA and MMA by hydrochloric acid in methanol, only the DPPEMA unit was hydrolysed quantitatively.

Measurement

N.m.r. spectra were obtained with a JEOL (JNM–MH–100) spectrometer at 100 MHz. The spectrum of PMMA was measured in 8–10% CDCl₃ solution at 60°C using tetramethylsilane as an internal reference. The copolymer composition was calculated from a n.m.r. spectrum of the copolymer which was measured in a 10% CCl₄ solution at 60°C using tetramethylsilane as an internal reference. The composition of the copolymer of MMA and PMAA derived from copolymer MMA/DPPEMA by hydrolysis was determined from an n.m.r. spectrum in a 10% pyridine-*d*₅ solution at 100°C using hexamethyldisiloxane as an internal reference.

The solution viscosity of a polymer was measured in toluene ($C = 0.5$ g/dl) at 30.0°C by using an Ubbelohde type viscometer.

RESULTS

Homopolymerization of DPPEMA

The polymerizations of DPPEMA by n-BuLi were carried out in toluene and THF. The results are shown in Table 1. Surprisingly, the DPPEMA obtained in toluene at -78°C was rather syndiotactic. This result is very unexpected, so the polymerization was repeated under the same reaction conditions taking care that there was no contamination from polar substances. However, the polymer obtained still had the same tacticity. The tacticity of the polymer was influenced by the polymerization temperature in toluene; i.e. syndiotactic at -78°C, isotactic at -40°C and atactic at 30°C, although the differences in tacticities were not remarkable. At -78°C the addition of twice as much THF as n-BuLi (mol/mol) did not induce a considerable change in tacticity, but the yield of the polymer was much greater than that in the absence of THF. However, the highest syndiotacticity was attained by adding ~10% THF to toluene. In THF atactic polymers were formed regardless of the temperature.

In Table 2 are shown the results of polymerizations by PhMgBr, C₆H₁₁MgBr, iso-BuMgBr, Et₂AlNPh₂, and AIBN in toluene. Highly isotactic polymers were obtained with Grignard reagents regardless of the organic moiety. The isotactic polymers were not completely hydrolysed to PMAA by methanolic hydrochloric acid, probably because of the highly regular structure. It is known that the polymerizations of methacrylates by Et₂AlNPh₂ usually produce syndiotactic polymers^{7,8}. DPPEMA also gave a syndiotactic polymer by this catalyst, although the syndiotactic content was low. The radical polymerization by AIBN gave an atactic polymer.

Anionic copolymerizations of DPPEMA (M₁) with MMA, TrMA, and DPMMA (M₂)

Monomer reactivity ratios, r_1 and r_2 were determined in the copolymerizations of DPPEMA (M₁) with MMA (M₂) by n-BuLi in toluene and in THF at -78°C. The copolymer composition curves are shown in Figure 1. The monomer reactivity ratios were found to be $r_1 = 0.56 \pm 0.36$ and $r_2 = 7.45 \pm 1.53$ in toluene, and $r_1 = 1.62 \pm 1.00$ and $r_2 = 1.13 \pm 0.35$ in THF.

Anionic copolymerization of equimolar DPEMA and MMA was carried out for a prolonged time in toluene and THF with n -BuLi at various temperatures. The results are summarized in Table 3. In toluene the yield of the copolymer was highest at 0°C and lowest at -78°C . The composition of the copolymer obtained at -78°C was rich in MMA unit as expected from the r_1 and r_2 values. When the copolymers obtained in toluene were hydrolyzed in methanol containing a small amount of hydrochloric acid, methanol soluble and insoluble parts were separated. The results are summarized in Table 4. The methanol-insoluble part was

almost the homopolymer of MMA and the soluble part contained nearly equal amounts of MMA and DPEMA. The tacticity of the copolymers prepared in toluene was rich in isotactic triad and independent of the polymerization temperature. On the other hand, the copolymers obtained in THF at higher temperatures were rich in DPEMA unit. As the temperature increased, the syndiotacticity slightly decreased.

The polymerizations of DPEMA (M_1) with equimolar amounts of TrMA and DPMMMA (M_2) were also carried out in toluene and THF with n -BuLi at -78°C . The results are shown in Table 5. In the Table, besides the tacticity of the copolymers, that of the M_2 homopolymers prepared under the same reaction conditions is also shown. The reactivity of DPEMA in toluene was comparable to that of TrMA and much lower than that of DPMMMA. The stereoregularity of all the copolymers was much lower than that of the corresponding M_2 homopolymers and a great deal different from that of PDPEMA shown in Table 1.

DISCUSSION

It is well known that MMA forms an isotactic polymer by n -BuLi in a non-polar solvent at low temperatures⁹⁻¹¹. Various alkyl methacrylates and some acrylates whose α -position were substituted with alkyl or phenyl group also gave isotactic polymers under the same reaction conditions^{12,13}. The polymerization of DPEMA may be the first example which yielded a polymer rich in syndiotacticity by n -BuLi in a non-polar solvent.

The values of $4IS/H^2$ from which the penultimate effect in the polymerization can be estimated¹⁴ are given in Table 1. The values in toluene at low temperatures deviated from unity, indicating that the process of the polymerization cannot be explained by the Bernoulli trials.

The tacticity of PDPEMA was compared with those of PTrMA and PDPMMMA which have similar ester groups to PDPEMA (Table 6). It has already been observed that TrMA formed a highly isotactic polymer with n -BuLi not only in toluene but also in THF and DPMMMA gave a highly isotactic polymer in toluene and a syndiotactic one in THF⁴. In the polymerization of DPEMA a highly stereoregular polymer was not obtained either in toluene or THF by n -BuLi. On the other hand, these monomers behaved in quite a different manner in the polymerizations with PhMgBr in toluene. DPEMA formed a highly stereoregular polymer, DPMMMA gave an atactic polymer, and TrMA formed no polymer⁴. These results indicate that the small difference in ester group has a large influence on the tacticity of the polymer and the effect of the ester group can be varied a great deal by the nature of the counter-ion.

In the polymerization of MMA in toluene by n -BuLi it is postulated that the lithium counter-ion can coordinate with

the carbonyl oxygen of the penultimate monomer unit in the growing chain and the resulting cyclic intermediate dominates the conformation of the incoming monomer toward the lithium cation to give an isotactic polymer^{15,16}. It is expected from a molecular model that in the polymerization of TrMA, the bulkiness of a trityl group may prevent the syndiotactic placement and the monomer prefers to take the isotactic placement with a helical conformation⁴. This may be one of the reasons why TrMA forms an isotactic polymer even in THF. The very low stereoregularity of PDPEMA obtained by *n*-BuLi probably demonstrates that the bulkiness of the ester group is not enough to force the monomer to take the isotactic configuration, and the coordination to lithium ion may be weakened by the bulky ester group.

In previous papers^{17,18}, we reported the copolymerizations of various methacrylates (M_1) and MMA (M_2) with *n*-BuLi at -78°C , and the relative reactivity of the methacrylates towards MMA^- anion was correlated with the electron density on the β -carbon, accordingly the polar effect of the ester group of monomer. The plots of $\log(1/r_2)$ vs. the $^{13}\text{C}_\beta$ or $^1\text{H}_a$ (*cis* to carbonyl) n.m.r. chemical shifts of the monomers are shown in Figures 2 and 3, respectively.

The $\log(1/r_2)$ values in toluene and THF were practically identical for many methacrylates and many were situated near the straight line. However, the plots for DPMEA as well as TrMA and dimethylbenzyl methacrylate in toluene were quite different from those in THF because of the extremely low reactivity of those monomers in toluene. It

has been found that in the cases of TrMA and dimethylbenzyl methacrylate, not only the copolymers containing nearly equal amounts of M_1 and M_2 , but isotactic MMA homopolymers were also formed^{17,19}. Similar results were

Figure 2 Plots of $\log(1/r_2)$ vs. $^{13}\text{C}_\beta$ chemical shift of methacrylates; ●, in toluene; ○, in THF. A, diphenylmethyl; B, trityl; C, benzyl; D, α -methylbenzyl; E, α,α -dimethylbenzyl; F, ethyl; G, isopropyl; H, *t*-butyl

obtained in the hydrolysis of the copolymers of MMA with DPEMA, as shown in Table 4. These results suggest that there exist, at least, two kinds of propagating species, one which predominantly polymerizes MMA and the other which yields a copolymer. Consequently, the monomer reactivity ratios determined in toluene should be taken as mean values for these two propagating species; one leads to $r_1 = 0, r_2 \gg 1$ and the other leads to $r_1 \approx r_2 \approx 1$. In THF, however, only the species forming the copolymer may exist. This is probably one of the reasons for the extremely low reactivity of these monomers in toluene, and this suggests that the bulky tertiary ester monomers cannot add to the growing MMA chain end with subsequent long MMA sequences in toluene because of steric hindrance.

The isotacticity of the copolymer DPEMA/MMA obtained in toluene by *n*-BuLi lies between those of PMMA and PDPEMA obtained under the same conditions (Table 3). Similar results have been found in the copolymerizations of MMA with various methacrylates²⁰. The tacticity of the copolymers of DPEMA with TrMA and DPMMA obtained in THF seems to be close to the mean values of those of the homopolymers (Table 5). However, the isotacticity of the copolymer DPEMA/TrMA obtained in toluene was very low. Since this copolymer consists of equal amounts of DPEMA and TrMA, the distribution of the monomers in the copolymer may be rather at random. The isotacticity of the copolymer DPEMA/DPMMA prepared in toluene was also

rather low judging from the copolymer composition. It seems that DPEMA lowers the stereoregularity in the copolymerizations with these bulky monomers in toluene.

ACKNOWLEDGEMENTS

The authors are very grateful to Mr H. Okuda for the measurements of ^{13}C n.m.r. spectra. Part of this work was supported by the Grant-in-aid for scientific research from the Ministry of Education.

Transition metal impurities in crystalline conjugated polymers

G. C. Stevens*, D. J. Andot†, D. Bloor and J. S. Ghotra

Department of Physics, Queen Mary College, London E1 4NS, UK
(Received 26 January 1976)

Two disubstituted diacetylene monomers and their corresponding polymers were found to contain transition metal impurities, the presence of which may be associated with the observation of anomalous e.s.r. absorption spectra. Copper complex impurities are considered responsible for the observed paramagnetism which is thought to arise from their inclusion at specific sites within the monomer crystal.

INTRODUCTION

Anomalous magnetic properties, including the occurrence of broad line e.s.r. absorption spectra, have been observed in natural macromolecules^{1,2} and synthetic conjugated polymers^{3,4}. The observed e.s.r. absorption lines were asymmetric, exceedingly broad ($\Delta H_{pp} \sim 500$ to 1500 Gauss; 1 Gauss = 10^{-4} Tesla) and of high integrated intensity; many spectra contained zero-field absorptions and *g*-values ranged from 2.1 to 3.0. Three possible explanations were proposed⁵ viz.: (a) presence of ferromagnetic inclusions; (b) presence of paramagnetic ions participating in collective interactions mediated by the hosts crystal and electronic structure and (c) unusual properties of unpaired electrons, a consequence of specific chemical and structural features of organic systems.

It soon became clear that these observations could be attributed to transition metal impurities, particularly iron⁶. Conjugated polymers prepared so as to minimize these impurities were found to contain 10 to 500 ppm of iron and one to three orders of magnitude less of cobalt, nickel and chromium⁶. The chemical nature of the impurities was not clear and the presence of ferromagnetic oxides in interstitial or colloidal form was invoked to explain the observations.

This problem has not been considered very important until recently when the possibility of preparing crystalline conjugated polymers by solid state polymerization⁷⁻⁹ required that it be reconsidered. These polymers allow the fundamental properties of the conjugated polymer chain, free from major morphological defects, to be investigated. The presence of transition metal impurities may be significant in this situation, not only in producing impurity e.s.r. absorption spectra but also by the unknown effects of these impurities on other physical properties, e.g. electrical conductivity. The impurities will be introduced during the growth of monomer crystals from solution and the degree of impurity inclusion can be assessed by a number of techniques¹⁰. Under these circumstances it is the purity of this initial monomer solution which is important in determining the final impurity content of the polymer.

EXPERIMENTAL

Two disubstituted diacetylene monomers were chosen for this study: 2,4-hexadiyne-1,6-diol (HD) and the diester, bis(*p*-toluenesulphonate) of 2,4-hexadiyne-1,6-diol (TSHD), derived from it. HD polymerizes to an amorphous polymer¹¹ in contrast to TSHD which retains its complete crystal structure during solid state polymerization^{10,12}. The monomer and polymer molecular structures of HD and TSHD are shown in *Figure 1*.

HD, 'Purum' grade (Fluka AG), was purified by recrystallization from redistilled 'Aristar' grade toluene (BDH Chemicals), the latter having a specified assay of less than 0.01 ppm for iron, cobalt, manganese and nickel and less than 0.02 ppm for cadmium, copper, lead and zinc. Purification was also achieved by vacuum sublimation. 'Pure' TSHD monomer was prepared by the Wegner method¹³ using diol as purified above and 'Analar' grade reagents (BDH Chemicals). 'Ultra-pure' TSHD monomer was prepared by the same method, using the following reagents: diol, purified as above; *p*-toluenesulphonyl chloride, 'Puriss' grade (Fluka AG), minimum assay 99% (typically 35 ppm iron, 5 ppm copper, other transition metals absent); tetrahydrofuran, 'Analar' grade (BDH Chemicals), minimum assay 99.5%; acetone, 'Aristar' grade (BDH Chemicals), general metal impurities ≤ 0.1 ppm; potassium hydroxide, 'Aristar' grade (BDH Chemicals), general metal impurities ≤ 250 ppm; demineralized water (resistivity $> 4 \times 10^5 \Omega \text{ cm}$).

Samples of 'pure' TSHD for e.s.r. measurements were prepared by repeated freezing and melting of 'Analar' acetone solutions under vacuum and oxygen free argon to remove oxygen; polycrystalline samples of both TSHD and HD were placed in quartz sample tubes and evacuated to less than 10^{-3} Torr¹⁴. Monomer single crystals of 'ultra-pure' TSHD were grown from seeds by sub-ambient cooling of saturated 'Aristar' acetone solutions in an argon gas atmosphere.

Metallic ion impurity analysis was carried out by atomic absorption spectroscopy using a Pye Unicam SP-1950 machine, which allowed detection of required metallic ions to an accuracy of $\pm 2\%$, with sensitivities as shown in *Table 1*. E.s.r. spectra were recorded with a Varian E-9, X-band spectrometer incorporating an E-101 microwave bridge, as described previously¹⁴.

RESULTS AND DISCUSSION

2,4-Hexadiyne-1,6-diol

Iron and copper content varied in the 'as received' commercial HD; in most cases copper was absent or present in small traces with cobalt, chromium, manganese and nickel below the limits of detection. Typical iron concentrations for a single HD batch subjected to recrystallization and sublimation are shown in *Table 2*. A single recrystallization gave the best reduction in iron content; indeed, with care, single recrystallized samples were obtained with as little as 1 ppm concentration of iron.

The increase in impurity content on subsequent recrystallizations is unusual. 'As received' HD always contained some polymer which was extracted prior to recrystallization so that the first recrystallized monomer solution is essentially polymer free. Polymerization is slow and subsequent monomer solutions may contain small dispersed quantities of low molecular weight polymer. These chains may absorb or react with impurity species and be included in growing crystals allowing impurities to accumulate with repeated recrystallization.

E.s.r. observation of HD polycrystalline monomer samples taken from a single batch containing 1 ppm of iron by analysis did not reveal any spectra directly attributable to iron. This is to be expected since the corresponding impurity spin concentration of about 10^{16} spins per gram of

monomer would be difficult to detect in 50 mg samples and spectral linewidths of the order of 10^3 Gauss (*Figure 2*). However, monomer-batch impurity analysis can be misleading if the impurities are not homogeneously distributed. This is illustrated by the iron and copper content of an HD polymer sample, exhibiting no impurity e.s.r. absorption, from the high purity monomer-batch after thermal polymerization at 373K. The monomer-batch and polymer-sample iron contents were 1 and 54 ppm respectively; the copper levels were 0 and 18 ppm respectively. This variation in monomer-polymer impurity concentration will be discussed further below.

Bis(*p*-toluenesulphonate) of 2,4-hexadiyne-1,6-diol

Figures 2a and *2b* illustrate some typical broad impurity e.s.r. absorption spectra with $g \approx 2$ and $g \neq 2$ respectively for samples of 'pure' polycrystalline TSHD. For all samples observed it has been found that the impurity absorption spectra are present in the monomer and do not change in intensity, shape or position during thermal polymerization. The narrow $g = 2$ absorptions in *Figure 2* arise during polymerization and have been associated with defect centres in the 'as formed' polymer¹⁴. Some polycrystalline monomer-batch and resultant e.s.r. polymer-sample iron and copper impurity concentrations are listed in *Table 3*; all other common transition metals were absent. The polymer-sample impurity spin concentrations $N_s(\text{Fe})$ and $N_s(\text{Cu})$, calculated assuming one spin per impurity atom, may be compared with the observed spin concentration N_{OBS} , calculated from the observed first derivative spectra by double numerical integration and comparison with a Varian strong pitch reference standard ($3 \times 10^{15} \pm 15\%$ spin/cm)¹⁴.

^aspins/g of sample.

Inspection of *Table 3* indicates the inconsistent nature of the monomer-batch and polymer-sample impurity results. It is clear that both decreases and increases in individual impurity atom content occur in comparing the monomer-batch and polymer-sample results. This suggests that inhomogeneous impurity distribution occurs, post-recrystallization contamination is unlikely in view of the precautions taken during sample handling. However, the very large variation in polymer-sample impurity content is not reflected in the observed spin concentration which is typically about 3×10^{18} spins per gram of polymer sample. This result suggests that only a part of the total metallic impurities present actually contribute to the observed e.s.r. absorption; the TSA1 polymer-sample result suggests also that there is not necessarily a single spin per impurity atom contribution to the observed spectrum.

The above results and the need to investigate purer TSHD single crystals led to the preparation of an 'ultra-pure' monomer, as described earlier. Analysis of the monomer-batch sample revealed iron and copper concentrations of 34 ppm each, all other common transition metals being absent. In comparison, typical impurity concentrations of TSHD single crystals grown from this monomer were, copper between 50 and 120 ppm, with iron and all other common metals absent. E.s.r. observations of four single crystals gave no absorption spectra which could not be accounted for from other sources, e.g. sample tube.

However, anomalous e.s.r. absorptions do occur in polycrystalline TSHD samples with only copper contamination. *Figure 3* illustrates two very intense low field absorptions obtained from two polycrystalline samples, TSA4 and TSA9, whose monomer-batch analysis was that of TSA1 and TSA10 respectively. Both polymer samples contained only copper impurities, TSA4 approximately 168 ppm and TSA9 150 ppm. The strong zero-field absorptions in *Figure 3* are in agreement with the results of Blumenfel'd et al.³. They found that complexes of polyaminoquinones with copper gave broad absorption spectra and increasing copper content increased the intensity of the broad absorption already present and induced a strong zero-field absorption also. Thus, in associating the observed e.s.r. absorption spectra with a metallic or a corresponding metallic complex impurity, the results indicate, in the case of TSHD, that it is probably copper.

The formation of a copper-monomer complex involving the acetylenic bonds, such that unpaired electrons occupy the ground state of the complex, seems reasonable. However, the constancy of N_{OBS} in *Table 3* and the absence of absorption spectra in copper-containing single crystals require explanation. Two factors are important in determining impurity content of the monomer crystals. These are: (a) crystal morphology and (b) the presence of oligomeric species. Crystal morphology has a strong influ-

ence on impurity inclusion. For slow crystal growth, well faceted monomer single crystals are obtained containing minimal included impurity. Polycrystalline samples will contain some crystallites with irregular non-crystallographic facets which are much less effective in rejecting impurities¹⁰. Impurity inclusion at such faces may be either into the crystal lattice or into voids containing impurity rich solvent. In addition more of the final impurity rich solution will be trapped in the spaces between crystallites in polycrystalline samples. We can also conclude from the behaviour of HD, reported above, that repeated recrystallization as used in preparing polycrystalline samples leads to an enhancement of impurity content, possibly by the formation of impurity oligomer complexes which are included in the monomer crystal. These factors contribute to the large variations in impurity content from sample to sample. Our observation of a nearly constant e.s.r. spin density in spite of these variations can be explained in terms of diamagnetic impurity complexes some of which become paramagnetic by inclusion at particular sites, i.e. the close proximity of the complex to surrounding monomer or oligomer molecules with a specific geometry favours a reaction whose product is paramagnetic.

The results are not conclusive but it is suggested that explanation (b) in the introduction is the most acceptable

**Figure 3** TSHD impurity anomalous e.s.r. absorption spectra. A, TSA9; B, TSA4

for TSHD at the present time. However, the variety of e.s.r. absorption spectra observed for polycrystalline samples prohibit a more complete interpretation, in which the roles of copper and iron impurity complexes are clearly displayed. The degree of impurity control in diacetylene polymers is much greater than in most other polymer systems and this should allow more selective experiments, such as doping, to be pursued in conjunction with other techniques capable of identifying the impurity complex unambiguously.

ACKNOWLEDGEMENTS

We thank Mr S. Adams for performing the atomic absorption experiments. This work was supported by a Science Research Council grant and one of us (G.C.S.) thanks the Science Research Council for a studentship.

Crack growth in plastic panels under biaxial stress

P. S. Leever, J. C. Radon and L. E. Culver

Department of Mechanical Engineering, Imperial College, London SW7 2BX, UK
(Received 12 January 1976; revised 18 February 1976)

It is commonly considered by theoreticians and practitioners of fracture mechanics that the behaviour of a crack is determined only by loads causing a stress singularity at its tip. However, evidence is accumulating which indicates that this may not be entirely so, and that stresses parallel to the crack can affect fracture toughness and cyclic propagation rates. More extensive investigation of these effects involves experimental difficulties. Testing equipment described in this article offers the solution of these problems in a simple way without any significant sacrifice in experimental accuracy. Preliminary tests on poly(methyl methacrylate) are described to demonstrate the machine itself and the phenomena which it is being used to investigate; the results suggest that, for this material at least, the effects of transverse stresses are indeed slight.

INTRODUCTION

The concepts and techniques of fracture mechanics are now widely used for predicting and analysing the behaviour of flawed components. The mathematical and physical models of the fracture process which are in common use generally concentrate on uniaxial-stress situations, in which the crack propagates normally to the applied load. Within the last ten years or so considerable effort has been directed towards the problem of the 'angled crack'¹, whose behaviour is significantly modified by superposed remote shear stresses. Situations in which the crack is subject to additional direct stress along its line have been much less widely investigated; if any consequent change in fracture behaviour is admitted at all, it is usually considered to be negligible.

This may be an optimistic over-simplification. Experiments and analyses have variously suggested that tensile transverse stresses can enhance^{2,3}, reduce⁴ or have no effect⁵ on fracture toughness; increase⁶, reduce⁷ or have little effect³ on fatigue crack growth rates; can cause instability of the path direction of the crack⁸, and can change slow-crack-growth rates in viscoelastic materials⁹. These effects are of obvious importance. Flaws in most service structures may be expected to initiate and propagate continuously along a minor principal stress trajectory^{10,11}, but the ratio between the two principal stresses can vary considerably during propagation. Since this is also the situation in many fracture specimen geometries, a parameter such as the stress intensity factor K may be inadequate to characterize the testing environment.

Clearly the field offers considerable scope for further investigation. Two interacting deterrents have contributed to its neglect: the lack of a substantial theoretical framework within which to treat data, and experimental difficulties. If conventional tensile and fatigue testing machines were equipped or readily adaptable for biaxial loading, much more data would be available; since they are not, investigators are required to design and construct their own. A recent publication¹² has described the development of a purpose-built biaxial fatigue testing rig. Capable of a wide range of biaxiality ratios, cyclic waveforms and frequencies, this type of system would be eminently suitable for

biaxial fracture testing. Unfortunately, it is correspondingly complex and expensive. For their own work in this field, the present authors have designed and constructed a system which represents a simple and cheap solution to the requirements of the planned test programme: a series of biaxial-stress static-load and fatigue fracture tests on various polymers. The essential features of the system are described in the present paper and results are presented from a series of exploratory tests, designed to demonstrate the suitability of the machine and the general character of the phenomena which it is being used to investigate.

SPECIMEN AND MACHINE DESIGN

Specimens and loading shackles

The logical starting point in the design of such a system is the selection of a suitable specimen geometry for biaxial-stress testing. Most previous examples of these are rendered unsuitable by the special requirements of a fracture mechanics approach, which weight the choice in favour of a conventional pre-cracked flat plate type, for which material is normally readily available. Of these, the classical centre notched (CN) configuration offers the advantages of a long usable propagation path which can vary freely in direction, and along which K can be assessed from existing analyses. Furthermore, a significant quantity of data from uniaxial-stress tests on such specimens is available for comparative purposes.

Some modifications to this simple geometry are required to maintain acceptably uniform stress biaxiality and symmetry in the working area. These have been specially investigated elsewhere^{13,14} and are implicit in an arrangement previously used¹⁵ for biaxial creep testing; the design arrived at for the present work (*Figure 1*) derives partly from all three sources. Load is applied to the central region, which is considered for analysis to be a square plate of 190 mm width under uniform normal boundary stresses, through four longitudinally-slotted extensions on each side. The longer and more laterally compliant these extensions are, the less will strain along the side affect the applied stress

Figure 1 Biaxial-stress fracture specimen design

normality, and the less will the difference between uniform-load and uniform-displacement boundary conditions affect the crack tip stress field. However, a practical limit is imposed by material and machining costs. A convenient compromise can be achieved by the use of 'whipple-tree' loading shackles, which can accommodate extensive deformation or initial misalignment of the loading points on the specimen while maintaining equal and normal loads on them.

Figure 2 shows a specimen mounted in its shackles on the straining frame to be described below. The uniformity of the central stress field was checked *in situ*, using a full-size 6 mm thick Araldite CT200 replica of the specimen and a specially built photoelastic bench. Photographs of representative isochromatic fringe patterns for uniaxial and biaxial loading are shown in Figure 3. Analysis of isochromatics and isoclinics showed that within a central square of 75% of the plate width w , the local biaxiality ratio varied by less than 5% and principal plane directions were within 3° of the centrelines. These conditions in the uncracked specimen justify the assumption that cracks of lengths normally used in fracture testing (less than $0.5w$) will behave similarly to those in a square plate of width w under uniform, normal stresses on its boundaries.

Fatigue loading rigs: the design alternatives

The specimen and shackle design, having been adopted, constituted the primary constraint on the machine design. A system was required to apply two normal in-phase loads of independently-variable magnitude and ratio, either constantly or varying monotonically or cyclically with time. Easy visual access to the specimen was necessary for crack monitoring and transmission photoelastic work. Most important, simplicity, reliability and low cost were to be maintained.

A few investigators whose technical requirements have been similar have devised rigs of widely varied sophistication. Arrangements for transverse dead-weight loading have been added to conventional fatigue machines^{3,10}. In this situation the non-singular part of the crack-tip stress field varies cyclically and, if the crack path curves, so might the singular part, rendering analysis difficult. True biaxial fatigue fracture tests have been accomplished by eliminating transverse strain in a uniaxially fatigued *CN* plate³; the biaxiality ratio was therefore immutably equal to the Poisson ratio.

In a purpose-built rig¹⁶ for testing Mönch-Galster type specimens under static biaxial stresses, load was applied by two pairs of opposed hydraulic rams, each pair backed by an independent hydraulic system. This is a difficult arrangement to modify for in-phase fatigue loading. A similar straining frame has been used¹⁷ for strain cycling cruciform specimens by interconnecting the hydraulic systems to eliminate phasing errors, but thereby restricting load biaxiality ratios to 1, 0 and -1.

The same machine has subsequently been extensively developed¹² to overcome this difficulty. In its current form, each pair of hydraulic jacks is controlled by a servo-hydraulic valve, which forms part of a closed control loop working from load or strain feedback. Capable of a wide range of frequencies, cyclic waveforms and biaxiality ratios, this machine represents an ideal for the fracture tests which are now envisaged; unfortunately this flexibility demands a high capital outlay. The machine to be described below offers performance of a standard suitable for fracture testing at a fraction of the cost and complexity.

A simple biaxial fatigue machine

The machine applies in-phase tensile loads to both axes of the specimen, using a single hydraulic actuator; load biaxiality is stepwise variable. The output of two 15 kN capacity strain gauge load cells is used to measure (on an x/y plotter) and control (using a limit switching device) the load cycle. The electro-hydraulic interface is a direct solenoid-operated direction control valve, which implements an essentially triangular load/time characteristic whose rise and fall rates are independently controlled by flow control valves. The entire system is outlined schematically in Figure 4.

Mechanical system. The straining frame is constructed on a substantial welded *I*-beam base. As can be seen in Figure 2, the specimen is freely accessible, and there is

Figure 2 General view of specimen in straining frame

Figure 3 Isochromatic fringes in fracture specimen. Mercury vapour arc light, circularly polarized. (a) $B = 0$ (uniaxial), $P_y = 7.85$ kN, 4th order fringe at centre; (b) $B = 2.06$, $P_y = 7.60$ kN, 2nd order fringe at centre

ample room to fit a temperature controlled cabinet if required. One of each facing pair of shackles is connected to the frame via a pin-jointed load cell, and the two moving shackles are linked (in one case through a right-angle crank) to the ends of a single crosshead about 350 mm long. The point of load application on this crosshead determines the load biaxiality ratio B , defined as transverse load P_x divided by normal load P_y . In the present arrangement one of a limited number of nominal ratios B_n (0, 1, 1.5, 2, 3, 4) is selected by moving the hydraulic cylinder, but a similar system allowing infinite variability is clearly feasible.

The mechanical system is mounted in the horizontal plane. This takes the weight of the numerous pin-jointed linkages off the specimen, allowing their free self-alignment. Where necessary, heavy moving parts (e.g. the crosshead) are supported on rollers.

Electronic control system. Each load cell consists of a full strain gauge bridge (four TML type PL-3 120 Ohm foil gauges) mounted on a waisted tubular core of En24 steel. Calibration indicated 2% linearity in both cells up to 15 kN; 0.1% unbalance in each active gauge corresponded to 8.03 and 8.22 kN load. A.c. excitation and output signal amplification are achieved by a twin channel transducer converter (SE Labs Ltd, type SE 905), which has the useful ability to propagate a calibration step, corresponding to 0.1% change in active gauge resistance, through the control system.

The x/y plotter (Bryans Ltd, type 201 080/8) is calibrated on this basis to indicate both orthogonal loads, P_x and P_y , simultaneously. Alternatively, it can be used to plot the load/time characteristic, so that loading rates and the cyclic waveform can be accurately monitored at the frequencies of which the machine is capable (0.05 to 0.5 Hz).

The control loop is closed by a limit switching millivoltmeter. In the form used here (Messcontactor type 2023/P542, made by Gossen GMBH of West Germany), this is a 600 mV meter on whose scale two movable pointers set the desired cyclic maximum and minimum readings. Travel of the indicating pointer beyond each limit is sensed inductively and triggers a corresponding relay; this latches a simple relay bistable in the appropriate hydraulic direction control valve solenoid circuit. Since similar units are available with up to eight separate limit pointers, the system can be extended to apply programmed loading.

Hydraulic circuit. In essence, the hydraulic circuit is a simple meter-out configuration controlling flow from each side of an area-balanced double-acting cylinder. Line pressure, as set by the relief valve V3 (Figure 4), can be temporarily reset to tank pressure by operation of the tank return valve V1. This is operated by overtravel limit switches on the crosshead tracks, or from a control panel push-button, via a relay latch circuit. The solenoid-operated direc-

Figure 4 Biaxial-stress fatigue rig and operating system

tion control valve V4 reverses flow through the actuator at pre-set load limits; forward and reverse flow rates are set by pressure and viscosity compensated flow control valves V5 and V6.

The second actuator, A2, was connected in parallel with the first after initial performance inadequacies had been noted. The high stiffness of the machine reduced oil flow rates to levels which were difficult to control. Loading rates were erratic and the valves tended to jam with oil impurities; furthermore, transient leakage through the flow valve compensating spools at flow reversal caused shock unloading of the specimen at the peak point (Figure 5a) which was considered highly detrimental to valid testing. These problems were alleviated by increasing the hydraulic compliance of the load. Actuator A2 (identical to A1) acts against a 400 kN/m spring, raising flow rates by at least fifteen times, the factor depending on the degree of biaxiality. This has virtually eliminated sensitivity to hydraulic line shock, oil impurities and specimen stiffness variations, and has softened the machine response, as can be seen by the plateau at each load cycle limit (Figure 5b). These are significant advantages in a load-cycling testing machine.

MACHINE EVALUATION AND EXPLORATORY TESTS

The rig described above is initially to be used for measurement of fracture toughness, fatigue crack growth rates and fracture path stability in polymers under varying stress biaxiality. To assess the general character of these problems and the suitability of the machine for their investigation, some exploratory tests have been carried out on

poly(methyl methacrylate) (PMMA). This quasi-brittle thermoplastic, used here in the form of 6.35 mm thick ICI Perspex sheet, has been the subject of extensive previous work; much data on its fracture behaviour in established testing modes is therefore already in existence (see, for example, reference 10).

Figure 5 Oscillograms of load cycle waveform. Frequency = 0.1 Hz. Upper trace P_x , lower trace P_y . (a) without additional hydraulic accumulator; (b) with additional hydraulic accumulator

Figure 6 Cyclic traces of P_y versus P_x . Frequencies 0.1 to 0.5 Hz. Characteristic values of load biaxiality ratio B are shown for loading and unloading, for comparison with the nominal value B_n : A, 4; B, 2; C, 1; D, 1.5; E, 3

If the stress intensity factor K characterizes crack tip strain components, its true derivative dK/dt governs strain rates. For materials as highly strain-rate sensitive in their fracture behaviour as polymers^{18,19}, it seems desirable to compare results from different loading environments on a basis of similar time dependence of the governing conditions at the crack tip. A feature of the planned programme of tests, which involves only linear or triangular load/time (and hence, at constant crack length, K/time) histories, is therefore to be the adoption of a fixed value of dK/dt . Implementing this condition in fatigue tests involves increasing the cycle time linearly with ΔK , so that the frequency must be appropriately reduced as the crack propagates across the plate under a constant load range.

To gauge the effects, if any, of this variation in frequency on the shape of the cyclic crack growth rate da/dn versus ΔK curve, comparative tests have been performed at constant frequency (0.1 Hz) and at constant dK/dt ($0.2 \text{ MN}^{3/2}/\text{sec}$). These are convenient values for the particular material and for the machine. Using the same value of dK/dt , monotonic-load fracture toughness tests were performed at various biaxiality ratios.

Fatigue tests

30 mm long symmetrical centre cracks were produced by cutting 25 mm notches with a hacksaw and forcing a razor blade into each tip. Uniaxial fatigue loading for 1 or 2 kcycles was then used to straighten the crack fronts before the first readings were taken. A simple method of crack length measurement was devised to cover cases in which the crack path would curve, making the use of a travelling microscope difficult. A 100 mm square measuring grid, graduated in millimetre divisions, was cut from self-adhesive pre-printed acetate sheet (Letraset Letratone type LT159) and fixed centrally to one face of the specimen. Location of the crack tips on this grid by eye was judged to be accurate to ± 0.1 mm, and the accuracy of the sheet itself is better than 1%. The former error hardly affects crack growth curves for paths tens of millimetres long, while the latter is insignificant in comparison with the nor-

mal scatter band for this kind of test, and is correctable by grid calibration.

Fatigue tests were carried out at constant frequency and constant dK/dt at a load range of 3.5 kN, at a stress ratio of 0.1 and under uniaxial and equibiaxial stress ($B_n = 0$ and 1). Figure 6 shows an x/y plotter trace of P_x versus P_y during fatigue cycling at various nominal biaxiality ratios. It can be seen that the true-load biaxiality ratio B is affected by friction in the transverse loading linkage, mainly in the crank pivot, a PTFE-lined bush on a mild steel shaft. On the loading edge of the cycle B is constant up to the peak load, this being the point for which a characterizing value is defined. After load reversal friction elevates B , an upper-shelf value being attained at 60–70% of the load amplitude and then maintained downwards. Since the maximum and minimum values of B are not symmetrically disposed about B_n , geometrical errors in the linkage are indicated; viscous or inertial effects, however, appear to be negligible, the same plot being characteristic of a range of frequencies from 0.1 to 0.5 Hz.

The machine ran continuously for periods of up to 100 h during which the cycle time, at a constant frequency of 0.1 Hz, was maintained to within 5% on the initial flow valve settings. The response speed of the limit switching equipment and solenoid valve was found to be 0.2 sec; this caused limit overshoot. In variable frequency tests adjustments were necessary to maintain the required load limits of 0.4 and 3.9 kN (± 0.05 kN as measured on the x/y plotter) each time the frequency was adjusted, at about 1 mm crack growth increments.

Crack lengths at very high growth rates were measured from striations on the exposed surface after specimen fracture; these cycle-by-cycle measurements were then matched with those previously taken at intervals with a corresponding cycle counter reading. Figure 7 shows da/dn versus ΔK curves for PMMA in the high growth-rate region for the various conditions tested. It is clear that within the rather narrow range of conditions investigated, neither modification of the frequency nor superposition of in-phase transverse stress noticeably affects growth rates.

Figure 7 Fatigue crack growth rates: PMMA in air. \circ , $B = 0.9$, $dK/dt = 0.2 \text{ MN}^{3/2}/\text{sec}$; \bullet , $B = 0.9$, $f = 0.1 \text{ Hz}$; \square , $B = 0$, $f = 0.1 \text{ Hz}$

Figure 9 Fracture toughness, K_{Ic} , of PMMA in air, as a function of stress biaxiality B

Quasi-static tests

For these tests, the length of the initial crack was about 40 mm. For eleven of the thirteen specimens used, no attempt was made to straighten the crack tips by fatigue extension, since it is customary to base fracture toughness calculations on the crack length at the initiation of fast fracture, at which point slow crack extension has already taken place. A further two specimens, which were uniaxially fatigued prior to testing, showed similar toughness and path stability characteristics. The resulting fracture trajectories in all cases were straight at low stress biaxiality ratios and S-shaped (or, in one case, arch-shaped) at higher ones (Figure 8). No particular orientation was observed relative to the machine, the paths tending to veer off in the direction of the initial crack tip angle. The general shape of

these trajectories does not, however, seem to be so strongly influenced by the initial tip misorientation as by the biaxiality ratio. The possibility of correlating these path geometries with the stress biaxiality ratio will be discussed in a forthcoming paper.

Crack growth normally followed a smooth path from the initial crack tip, through a slow-growth region, and into fast fracture; only occasionally (more often at low transverse stress levels) was an 'angled crack' type path discontinuity observed. When this did occur, slow growth was generally suppressed, suggesting that perhaps the other tip had already reached the free surface before the first began to move. Fast fracture toughness values, K_{Ic} , for cracks in which preliminary slow growth had occurred are shown in Figure 9 as a function of stress biaxiality, which does not appear to exert any powerful influence. K_{Ic} was evaluated using the horizontal crack length after slow growth; curvature of the slow growth path was always less than 10° . Although the data is too scarce to support firm conclusions, a slight decrease in fracture toughness due to tensile transverse stress is indicated, rather than the large increase (up to 25%) previously reported³.

NOMENCLATURE

a	half crack length,
da/dn	rate of half-crack growth per cycle,
B	biaxiality ratio (P_x/P_y),
B_n	nominal value of B ,
f	fatigue loading frequency,
K	Mode I stress intensity factor,
K_{Ic}	value of K at initiation of unstable fracture,
ΔK	cyclic variation in K ,
P_x	load on specimen parallel to crack,
P_y	load on specimen normal to crack,
w	effective width of specimen.

Association of stereoregular poly(methyl methacrylates): 3. Thermal behaviour and composition of stereocomplex

A. de Boer and G. Challa

Department of Polymer Chemistry, State University of Groningen, Groningen, The Netherlands
(Received 14 January 1976)

Stereocomplexes of isotactic and syndiotactic poly(methyl methacrylate) (i- and s-PMMA) were prepared by mixing dilute i- and s-PMMA solutions in acetone or DMF at different temperatures. At 50°C the rate of complex formation is larger than at 20° or 70°C. Differential scanning calorimetry and X-ray powder diffraction measurements were performed on the material crystallized from mixed solutions. The thermograms showed 3 endotherms at temperatures not depending on the i-/s-PMMA ratio of the sample. The endotherm at ~280°C is caused by degradation of PMMA, the maximum at ~210°C by melting of the stereocomplex and the endotherm at ~185°C by melting of solvent stabilized s-PMMA. By comparing X-ray powder diffraction patterns of s-PMMA crystallized from borderline solvents with those of stereocomplexes of i-/s-PMMA with different drying histories it is concluded that the reflection at $2\theta = 4^{\circ}10'$ belongs to a solvent stabilized s-PMMA structure. Partial association of i- and s-PMMA chains in an i-/s-PMMA ratio of about 1:1 and crystallization of solvent rich s-PMMA is proposed as a mechanism for the complex formation under the present conditions.

INTRODUCTION

In 1958 Fox *et al.*¹ reported for the first time that gelation occurred by mixing solutions of isotactic and syndiotactic poly(methyl methacrylate) (i- and s-PMMA). This gelation process can be explained by the formation of stereocomplexes of i-/s-PMMA. Stereocomplex formation may be regarded as a general property of stereoregular polymers. The driving force in the complex formation of i- and s-PMMA is the structural complementarity of both tactic polymers. This has also been proven by the template polymerization of MMA in the presence of i-PMMA, resulting in the formation of s-PMMA².

Basic questions concerning the composition and structure of the formed stereocomplexes remained unanswered. The stereocomplex formation of i- and s-PMMA has been investigated by viscometry and turbidimetry³⁻⁶, light scattering^{7,8}, high resolution and broad line n.m.r.^{9,10}, sedimentation in an ultracentrifuge^{8,11}, calorimetry^{12,13}, and by dynamic mechanical^{13,14} and dielectric measurements¹⁵.

Viscosity and turbidity measurements in dilute solutions have pointed out that complex formation of i- and s-PMMA can occur at concentrations far below that with homogeneous segmental distribution³. As the solvents have different influence on complex formation we divided them into three types: (a) strongly complexing; (b) weakly complexing, and (c) non-complexing solvents. Buter *et al.*¹⁶ and Gons *et al.*¹⁷ found that the effect of solvent on the stereochemistry and kinetics of the template polymerization of MMA in the presence of i-PMMA is in line with its complexing ability. The heats of complex formation of i- and s-PMMA as reported by Biroš *et al.*¹² are also in agreement with this classification.

N.m.r. measurements⁹ showed that the mobility of the methoxy protons of stereocomplexes is strongly decreased by mixing concentrated i- and s-PMMA solutions in CCl₄ or CD₃CN. Pyrlík *et al.*¹⁴ also found by dynamic mechanical measurements that complex formation can occur in very

concentrated solutions. In a previous paper¹³ we concluded from calorimetric and dynamic mechanical measurements that complex formation of i-/s-PMMA can even occur in bulk. We found that the complex formation rate was maximal at 140°C and that within a few minutes, more than half of the complex has been formed. From the fact that annealed and non-annealed samples had the same value of the storage modulus (G') above the glass transition temperature, we concluded that the main process taking place in bulk during annealing comprises growth of complex crystallites. Liquori *et al.*¹⁸ have proposed a model for the stereocomplex in the form of 5₁ helices of i-PMMA in the grooves of which the flat chains of s-PMMA lie so that the α -methyl groups of both macromolecules become situated at van der Waals distance from each other, stabilizing the stereocomplex in polar solvents by hydrophobic interaction. In this model the syndiotactic chains are tilted ~60° with respect to the isotactic helical chain. We find it difficult to understand the phenomena of the template polymerization of MMA in the presence of i-PMMA using this model. In this case one would expect that the isotactic and syndiotactic chains are aligned parallel to one another in some way. Moreover, we have shown that samples obtained by template polymerization behave like material crystallized from mixed dilute solutions of i- and s-PMMA³.

The most frequently quoted composition of the stereocomplex is an i-/s-PMMA ratio of 1:2, but other results have been presented^{4,6} in favour of an i-/s-PMMA ratio of 1:1 and lately also a ratio of 1:1.5^{9,12}. On the other hand, Chiang *et al.*⁸ concluded from ultracentrifuge measurements that complex formation of i- and s-PMMA does not proceed necessarily in a fixed stoichiometric ratio.

In order to elucidate the structure of the stereocomplex of i-/s-PMMA, it is necessary to know the real i-/s-PMMA ratio of the associated regions. Therefore we prepared stereocomplexes by mixing very dilute solutions of i- and s-PMMA in the strongly complexing solvents DMF or acetone at dif-

ferent i/s-PMMA ratios. The results of calorimetric, X-ray and n.m.r. measurements on the crystallized material are described and discussed in this paper.

EXPERIMENTAL

The polymers i- and s-PMMA were prepared according to known procedures^{19,20}. The data of the polymers used are summarized in Table 1. The tacticities of PMMA were measured on 5 wt% solutions in *o*-dichlorobenzene at 160°C²¹ by 60 MHz n.m.r. spectroscopy with a Jeol C-60 HL apparatus. Values of $[\eta]$ for the PMMA samples were determined in chloroform at 25°C. For the calculation of \bar{M}_v we used the relationship²² $[\eta] = 4.8 \times 10^{-5} \bar{M}_v^{0.8}$. Stereocomplexes were prepared by mixing 0.2 wt% i- and s-PMMA solutions in DMF or acetone. The mixed solutions were kept in thermostatically controlled baths at 20° and 50° ± 0.1°C for 20 days. At 70°C no complex formation could be observed after 20 days. Therefore the solutions were kept 70 days at 70°C. The solvents DMF and acetone (Merck) were used without further purification. The crystallized material was separated from the solution in a centrifuge with an acceleration of 25 000 × *g* and then dried *in vacuo* at 70°C for 64 h.

The melting behaviour of i- and s-PMMA and their stereocomplex was studied with a differential scanning calorimeter (Perkin-Elmer DSC 1B). The temperature scale was calibrated with high purity metal standards. Normally a heating rate of 8°C/min and sealed pans were used, unless otherwise indicated.

Thermogravimetric measurements were performed with a Mettler DTA/TGA apparatus with a heating rate of 10°C/min. X-ray powder diffraction patterns were recorded by a Philips diffractometer with a scan speed of 0.5°/min and angle aperture of 1/2 or 1/6°. Ni-filtered CuK α radiation was applied. Triad contents of the crystallized material were measured in the same way as described for the PMMA samples. It is known^{3,14,23} that the stereocomplex is completely dissociated at 160°C.

RESULTS

Crystallization of i- and s-PMMA

For a better understanding of the thermal behaviour and structure of the stereocomplex we required first data on crystalline i- and s-PMMA. For i-PMMA the crystal growth in bulk showed a maximum rate at 120°C and produced a substantial melting endotherm at 155°C after 5 days²⁴. For s-PMMA only data are reported on crystallization from borderline solvents^{1,25-27}. We were also unsuccessful with bulk crystallization of s-PMMA and tried to achieve crystallization by cooling hot solutions of s-PMMA in borderline solvents. The precipitates isolated from heptanone-4 or methyl isobutyrate solutions at room temperature showed an endotherm at ~190°C in the d.s.c. and a reflection at $2\theta = 4^\circ 30'$ in the X-ray powder diffractogram. After drying at 70°C this reflection disappeared, while the melting endotherm was lost after drying at higher temperatures, e.g. 150°C *in vacuo*. The same phenomena were observed with the needle-like crystals of s-PMMA grown from toluene at -20°C. So, it seems that some crystalline structure of s-PMMA is stabilized by solvent and is destroyed by drying. Careful drying of a toluene solution in a desiccator above paraffin for 2 months at room temperature produced s-PMMA with an endotherm at about 200°C, which did not disappear after prolonged drying.

Stereocomplex of i/s-PMMA

In Figure 1 the yield of crystallized material is plotted versus wt% s-PMMA for DMF solutions at 20° and 50°C. Complex formation from acetone produced a similar picture. The results of DMF solutions at 70°C are not presented in this Figure because in this case the material was separated only after 70 days.

From n.m.r. measurements it appeared that the gross composition of the material crystallized from DMF or acetone at 20°C is about the same as the composition of PMMA in the starting solution.

Thermograms of crystallized material with different i/s-PMMA ratios obtained from DMF solutions at 20°C are represented in Figure 2. The peak temperatures of the

Figure 3. Relative area of the endotherm at $\sim 185^{\circ}\text{C}$ (T_{m1}) versus wt% s-PMMA for samples crystallized from DMF and acetone at 20°C (A) or 50°C (B), relative area = $T_{m1}/(T_{m1} + T_{m2})$

Figure 4. Area of the endotherm at $\sim 285^{\circ}\text{C}$ (T_{m3}) recorded by d.s.c. versus heating rate for samples crystallized from mixed solutions of i- and s-PMMA in DMF with i-/s-PMMA ratios of 1:2 or 1:1

endotherms at about 185° , 210° and 280°C are designated as T_{m1} , T_{m2} and T_{m3} respectively. In Table 2 values of T_{m1} and T_{m2} are compiled for products isolated from PMMA solutions with different i-/s-PMMA ratios in acetone and DMF at 20° , 50° and 70°C . T_{m1} could not be observed in samples obtained from DMF solutions at 70°C . In Figure 3 the relative area of the endotherm at 185°C (T_{m1}) is plotted versus wt% s-PMMA for products obtained

from acetone and DMF at 20° and 50°C . These Figures show that the relative area of the endotherm at T_{m1} increases with increasing s-PMMA content and is much larger for material prepared at 20° than at 50°C .

In Figure 4 the area under the endotherm at T_{m3} is plotted versus heating rate in the d.s.c. We see a strong decrease of transition heat with increasing heat rate, whereas the peak temperature T_{m3} itself increases from 270° to 335°C . These phenomena are less important for our present study of stereocomplex formation and can be explained by thermal depolymerization of PMMA. According to thermogravimetric analysis the weight loss started at 280°C , so that the volatile monomer can escape from the nonsealed pans at T_{m3} . At a lower heating rate more monomer can diffuse out of sample and pan at a given temperature which leads to the increase of the area and lowering of the peak temperature. When a sample is kept at 240°C for 10 min a fully amorphous X-ray powder diffraction pattern results. This also indicates that T_{m3} is not related to the stereocomplex.

X-ray powder diffraction patterns for different i-/s-PMMA ratios are presented in Figure 5. This Figure shows that the reflection in i-PMMA at $2\theta = 8^{\circ}10'$ which is a (110) or (200) reflection²⁸ is not present in the stereocomplex. The intensity of the reflection at $2\theta = 4^{\circ}10'$ which is a (hko) reflection¹⁸ increases with increasing s-PMMA content. As mentioned above this reflection also occurs in solvent stabilized 'crystalline' s-PMMA. The effect of drying on the X-ray powder diffractogram of a sample with an i-/s-PMMA ratio of 1:2 crystallized from DMF at 70°C is shown in Figure 6. A strong decrease of intensity of the reflection at $2\theta = 4^{\circ}10'$ is observed, but in this case the reflection does not fully disappear after prolonged drying. Samples crystallized at 20°C behave like s-PMMA and lose the reflection completely.

DISCUSSION

From Figure 1 it is clear that more crystalline material has been formed at 50° than at 20°C . By measuring the yield after 10 days, it was observed that the complex formation rate in a solution with i-/s-PMMA ratio of 1:1 is higher at 50° than at 20°C .

Spěvák and Schneider²⁹ have shown by n.m.r. measurements that self-association may occur in i-PMMA solutions. However, by varying the dissolution temperature of i- and s-PMMA in DMF no influence could be established on the amount and quality of the material crystallized from the mixed solutions at 20° and 50°C . Hence, the difference between the amounts of crystalline material formed at 20° and 50°C shown in Figure 1 cannot be ascribed to self-association and has to be explained in terms of a complex

Figure 5 X-ray diffraction intensity (I) versus diffraction angle 2θ (degrees) for samples with different *i*-/*s*-PMMA ratios: A, 100:0; B, 60:40; C, 50:50; D, 33:67; E, 20:80; F, 0:100. Curve F relates to *s*-PMMA containing some solvent

formation which is closer to the equilibrium state at 50°C than at 20° or 70°C. The broadening of the yield curve at 50°C in Figure 1 towards lower *s*-PMMA contents indicates that *i*- and *s*-PMMA do not form stereocomplexes in a fixed stoichiometric *i*-/*s*-PMMA ratio of 1:2.

Figures 2 and 3 showed that the relative area of the endotherm T_{m1} increases with increasing *s*-PMMA content. The same trend is observed for the intensity of the reflection at $2\theta = 4^\circ 10'$ (Figure 5). From Figure 6 it is clear that the material crystallized from mixed solutions of *i*- and *s*-PMMA exhibits in some way the same behaviour as solvent stabilized 'crystalline' *s*-PMMA. Hence we conclude that the endotherm at about 185°C (T_{m1}) as well as the reflection at $2\theta = 4^\circ 10'$ can be attributed to solvent stabilized 'crystalline' *s*-PMMA. Experiments carried out with *s*-PMMA 119 showed that the molecular weight of *s*-PMMA does not affect the thermal behaviour and X-ray powder diffraction pattern of the crystallized material.

So far we have attributed T_{m3} to thermal degradation and T_{m1} to *s*-PMMA, leaving T_{m2} as the melting point for the stereocomplex. By partial scan and the effect of scan speed on T_{m2} ³⁰ we have shown that this endotherm is an independent one and does not result from the endotherm at T_{m1} by recrystallization. From the foregoing we derive the following mechanism: isotactic and syndiotactic PMMA chains partly associate in an *i*-/*s*-PMMA ratio of about 1:1. When these associates crystallize from the solution, non-associated isotactic and syndiotactic chains are dragged from the solution and the *s*-PMMA chains crystallize in a

solvent stabilized 'crystalline' structure. Indeed it appeared also possible to crystallize *i*-PMMA chain segments. Annealing a sample crystallized from an acetone solution with an *i*-/*s*-PMMA ratio of 1.5:1 for 5 days at 120°C an extra endotherm arose at about 170°C and the reflection at $2\theta = 8^\circ 10'$ could also be detected with the X-ray diffractometer. We know that the growth rate of *i*-PMMA crystals is maximal at 120°C²⁴ and that the rate of complex formation in bulk equals zero at this temperature¹³.

The proposed mechanism is partly in accordance with that of Miyamoto and Inagaki³¹ who performed ultra centrifuge and thin layer chromatography measurements on the complex formation of *i*- and *s*-PMMA in acetone. According to these authors a primary complex formation occurs yielding stereocomplexes with an *i*-/*s*-PMMA ratio of 1:1. In a second step these complexes are transformed in stereocomplexes with an *i*-/*s*-PMMA ratios of 2:1 or 1:2. However, Table 2 shows that the *i*-/*s*-PMMA ratio has no influence on the melting temperature (T_{m2}) of the stereocomplex. The melting temperature (T_{m2}) depends only on the temperature T_c of complex formation. So, in our opinion it is more likely that complex formation occurs

Figure 6 X-ray diffraction intensity (I) versus diffraction angle 2θ (degrees) for a sample crystallized at 70°C from a DMF solution with an *i*-/*s*-PMMA ratio of 1:2 subsequently dried at 70°C *in vacuo* for 64 h (A); at room temperature for 3 months (B); at 150°C *in vacuo* for 19 h (C); and at 150°C *in vacuo* for 120 h (D)

only in an i-/s-PMMA ratio of 1:1 and that at the same time some liquid induced crystallization of s-PMMA occurs. Under the prevailing conditions of solvent and temperature s-PMMA has a stronger tendency to crystallize than i-PMMA. This may explain why the yield curves in *Figure 1* are shifted towards higher s-PMMA content.

Finally, we have estimated the degree of crystallinity of the stereocomplex from X-ray powder diffraction patterns applying the method proposed by Challa *et al.*³². Stereocomplexes with an i-/s-PMMA ratio of 1:2 obtained from DMF at 70°, 50° and 20°C showed a crystallinity of 40, 30 and 15% respectively. In our opinion this is in line with our view that association of stereoregular PMMAs occurs only partially.

Instituto de Energia Atômica, Setor de Radiobiologia, Cidade Universitaria, São Paulo, Brazil
(Received 9 December 1975; revised 23 February 1976)

The amino-acid sequence of crotamine, a toxin found in the venom of the south Brazilian snake *Crotalus durissus terrificus* was recently determined by Laure¹. It is a miniprotein with 42 amino-acid residues and a minimum molecular weight of about 5000. This molecule contains among others, 6 half-Cys, 2 Trp, 1 Tyr and 2 Phe residues which can contribute to the behaviour of the optical rotatory dispersion measured in the ultraviolet region of the spectra.

The present communication reports studies on the ultra-violet o.r.d. of crotamine and the effect of denaturants on the protein. The pure protein used in the experiments was obtained from the snake venom purified on a column of SP-Sephadex G-25 with a gradient of 0.5 to 3.0 M NaCl in 0.05 M ammonium formate, pH 3.2, after gel filtration in Sephadex G-75 with 0.05 M ammonium formate buffer pH 3.4. The purified material showed only a single component by disc electrophoresis in polyacrylamide gel².

O.r.d. measurements of the pure toxin, were carried out in a Fica Spectropol I Spectropolarimeter with a thermostated cell and the reduced mean residue rotation values, $[m']$, were expressed in degrees cm^2/dmol .

The infra-red spectrum of crotamine was obtained with a Perkin-Elmer Model 225 Spectrophotometer in a pressed potassium bromide disc.

Figure 1 shows the o.r.d. curve of native crotamine dissolved in unbuffered distilled water pH 5.5 over a wavelength range of 197 to 325 nm. This anomalous spectrum is due to several Cotton effects caused by the

Figure 1 Optical rotatory dispersion of crotamine dissolved in unbuffered distilled water pH 5.5 at 25°C. The $[m']$ values from 325 to 237 nm are the average of those obtained for 0.25, 0.50, 0.75, 1.00, 1.25, and 1.50 mg/ml of protein using a 0.1 dm quartz cell, and those below 237 nm were obtained from 0.025 and 0.050 mg/ml of protein concentration using a 0.05 dm quartz cell

protein chromophores. The positive band found between 283 to 325 nm shows a peak at 293 nm which is related to the Trp residue. Besides the peak, a shoulder at 285 nm appears to the Tyr Cotton effect³. The very asymmetric negative band from 240 to 283 nm has two troughs centred at 263 and 242 nm. The first trough, indicates the participation of Phe³, and disulphide bridges⁴ in the anomalous o.r.d. spectrum of crotamine. The other one, can be related to β -II structure⁵. It is very

difficult, if not impossible to determine which chromophores of the toxin are responsible for each Cotton effect found below 283 nm, mainly below 235 nm through the o.r.d. spectrum. Nevertheless, the presence of disulphide bridges can perturb some of the other Cotton effects of the protein⁶.

Evidence of the presence of β -structure was obtained through the infra-red spectrum of the protein as shown in Figure 2. The peaks found at 1625 cm^{-1} of amide-I band and at 1533 cm^{-1} of amide-II band can be regarded as due to the presence of this structure in the molecule^{7,8}. The $[m']$ values of +400 at 199 nm shown in Figure 1, and of -1460 at 232 nm of Figure 3, are not enough to postulate significant helical content in this macromolecule, despite the fact that sodium dodecyl sulphate at the concentration of 6.5×10^{-3} M changes the very anomalous o.r.d. curve to one characteristic of helical like structure with a trough at 232 nm (Figure 3, curve A).

The effect of chemical denaturant urea at a concentration of 8 M on the crotamine spectrum is shown in Figure

Figure 2 Infra-red spectrum of crotamine measured from 1.16×10^{-3} to 1.76×10^{-3} cm^{-1} . The spectrum was obtained using a pressed disc of 4 mg of protein with 200 mg of potassium bromide

Figure 3 Effect of denaturants on the conformation of crotonamine. O.r.d. measurements of crotonamine solution with a concentration of 1 mg/ml in 6.5×10^{-3} M sodium dodecyl sulphate were carried out between 230 and 360 nm (curve A) and of the same concentration of protein in 0.1 M acetate buffer pH 5.5 containing 8.0 M urea, between 230 and 350 nm (curve B)

3, curve B. There are no significant changes in the spectrum from 235 to 350 nm which indicates a high resistance of the protein molecule to urea denaturation. The o.r.d. spectrum remained the same, even when a solution of crotonamine in 0.1 M acetate buffer pH 5.5 containing 8 M urea was left at room temperature for twenty days and then heated at 60°C for two hours. However, the protein must have significant tertiary structure, since the reduction of the disulphide bridges by 2-mercaptoethanol in the presence of 8 M urea in 0.1 M tris-HCl buffer pH 8.6 abolishes the anomalous o.r.d. spectrum of the molecule between 250 and 320 nm.

The high resistance to conformational modifications of crotonamine in the presence of concentrated urea solution combined with a very low intrinsic viscosity of 1.2 ml/g at pH 5.5, indicates that at tertiary structure level, the mini-protein is maintained very compact having an axial ratio close to the unity.

ACKNOWLEDGEMENTS

The authors thanks Dr Aida Hasson Volloch from the Instituto de Biofísica da UFRJ, for the use of the Spectropolarimeter, and Dr M. M. Vozári-Hampe for the critical analysis of the manuscript.

Structure of a compatible mixture of two polymers as revealed by low-angle neutron scattering

This letter reports results of a brief investigation made, using low-angle neutron scattering measurements, of the extent of segregation and dimensions of polymer molecules in a compatible mixture of two polymers. In recent years, the technique of low-angle neutron scattering has been developed to study molecular dimensions in amorphous polymers in the solid state¹⁻⁴. This method relies on the large difference in the coherent scattering length for neutron diffraction between hydrogen and deuterium atoms to provide the required contrast. For example, the neutron scattering pattern from a perdeutero polymer tagged with say 5% protopolymer, depending on molecular weight, may be compared with the scattering from a perdeutero polymer blank. Using this technique it is possible to examine the size of the molecules and, at the same time, check that the tagged molecules are statistically distributed within the sample and not clustered together. The technique has also been applied to semi-crystalline polymer systems both in the melt^{5,6} and solid state⁷ as well as to studies of polymer solutions^{8,9}. In addition, Kirste *et al.*⁸ have reported an initial result for an incompatible mixture of two homopolymers, poly(methyl methacrylate) and poly(α -methylstyrene). They deduce from the scattering results that, for this system, the poly(α -methylstyrene) formed spherical aggregates each containing about sixteen molecules (weight-average). However, as yet nothing is known about the distribution or dimensions of polymer molecules in an apparently compatible mixture: do the molecules adopt their unperturbed configuration as in an amorphous homopolymer or are the dimensions of the molecules affected by neighbouring unlike molecules? Are the molecules statistically distributed or is there any clustering of like molecules? The purpose of the experiments reported here was to attempt to elucidate the structure in a compatible polymer mixture.

The polymer system selected for

this investigation was polystyrene/poly(α -methylstyrene). At high molecular weights this system is reported to be incompatible but, in the lower molecular weight region we have used, compatible mixtures have been observed¹⁰. In addition, calculations made using the procedure described by Krause¹¹, based upon the Flory-Huggins theory of polymer solutions, have indicated that the polymer mixtures described below should be compatible.

The neutron scattering samples were prepared using polymers produced by anionic polymerizations: molecular weights obtained by gel permeation chromatography and compositions of the mixtures are shown in *Table 1*. The polydeuterostyrene was 98% deuterated. The concentration of tagged molecules, polyprotostyrene, in the samples was restricted to 5% which was low enough to ensure 'dilute solution' scattering behaviour¹². Mixtures were prepared by dissolving in chloroform and precipitating into methanol.

Each mixture appears to be a compatible system according to the differential scanning calorimetry data shown in *Table 1*. These data were obtained at a heating rate of 20°C/min. The

mixtures showed only broad transitions with no detectable transition corresponding to any of the homopolymers.

Low-angle neutron scattering experiments were performed at Jülich using a sample to detector distance of 3 m and a neutron wavelength of 7.2 Å. Guinier plots were constructed from the corrected scattering patterns obtained for each tagged sample and the intercept and slope used to derive the weight-average molecular weight, \bar{M}_w and the z-average radius of gyration, $\langle s^2 \rangle_z^{1/2}$, respectively. Both tagged samples gave a value for the polyprotostyrene \bar{M}_w of $54\,000 \pm 5000$ and for $\langle s^2 \rangle_z^{1/2}$ of 61 ± 2 Å. It will be seen from *Table 1* that the weight-average molecular weight derived from neutron scattering is identical with the g.p.c. datum. Because of this excellent agreement, a Zimm plot procedure was not considered necessary. This result clearly shows that in a compatible mixture of two polymers the molecules are statistically distributed. This contrasts with Kirste's result for an incompatible system where clustering was observed.

The weight-average radius of gyration, $\langle s^2 \rangle_w^{1/2}$, obtained from neutron scattering after correction for polydis-

Table 1 Compositions and d.s.c. data for polymer mixtures used in neutron scattering experiments

Polymers	G.p.c. \bar{M}_w	T_g (°C)	
		Onset	Finish
A Polyprotostyrene	54 000	103	110
B Polydeuterostyrene	128 000	102	109
C Poly(deutero- α -methylstyrene)	32 000	170	178

Mixtures	Composition (wt %)			T_g (°C)	
	A	B	C	Onset	Finish
6 (blank for 7)		10	90	155	172
7	5	5	90	154	173
8 (blank for 9)		5	95	156	171
9	5		95	162	174

persity was $54 \pm 2 \text{ \AA}$. This may be compared with a value of $63 \pm 3 \text{ \AA}$ calculated for an unperturbed system using $\langle s_0 \rangle_w^{1/2} = 0.660 \bar{M}_w^{1/2} / (6)^{1/2}$. The measured radius of gyration is thus near to, or slightly less than, the unperturbed value. If the uncertainties in the measurements are as low as indicated there is a small reduction in radius of gyration below that of the unperturbed value. Similar behaviour has been both observed¹³ and described theoretically¹⁴ for a single phase polymer solution in a poor solvent below the theta-temperature, when the second virial coefficient will be negative.

The main conclusion from the results of this work is that it is possible to produce a truly compatible mixture of two polymers in which the molecules are statistically distributed. This result may be used to clarify what is meant by the term 'polymer compatibility' and to impose a new criterion for establishing compatible polymer systems.

Optically active vinyl polymers containing fluorescent groups: 1. Synthesis and properties of copolymers of *N*-vinylcarbazole with optically active monomers

Introduction

Chiroptical properties of copolymers of vinylaromatic monomers with optically active α -olefins¹⁻³ have been useful in helping to define the conformational requirements of aromatic moieties inserted in a regular conformational environment. Studies of the same properties in copolymers of *N*-vinylcarbazole with optically active monomers could, in principle, permit a valuable approach to the correlation of luminescence and photoelectrical properties of poly(*N*-vinylcarbazole) with the stereochemical arrangement of monomeric units. In the present paper we report preliminary results of copolymerization experiments of *N*-vinylcarbazole (NVC) with optically active monomers (α -olefins, alkyl vinyl ethers, acrylates and methacrylates) in the presence of different catalytic systems.

Results and Discussion

Copolymerizations of NVC with optically active comonomers have been carried out in the presence of various catalytic systems which are capable of polymerizing NVC and/or the selected comonomers. In Table 1 data are collected for those reactions giving poly-

mer yields in excess of 10%. In all cases regular linear enchainment of monomeric units is substantiated by n.m.r. and i.r. spectroscopy which show the presence of bands characteristic of only unsubstituted carbazole rings. By using a conventional cationic catalyst (EtAlCl_2) and experimental conditions which are claimed to give stereoregular poly(alkyl vinyl ethers)⁴ and poly(*N*-vinylcarbazole)⁵, three different alkyl vinyl ethers having an asymmetric carbon atom in the β -position with respect to the double bond (BVE, TPVE, MVE) and one (MBVE) having the chiral centre γ to the double bond, have been copolymerized with NVC (Runs C1-C5). In one case (Run C6) a complex catalyst based on $\text{Al}(\text{iso-C}_4\text{H}_9)_3$ and H_2SO_4 was used⁶. (Full structures of the alkyl vinyl ether monomers are given later.)

Moderately high molecular weight polymers ($\bar{M}_n < 2 \times 10^4$) were obtained and, in the runs where the overall conversion is lower than 90%, the polymerization rate of NVC is always larger than that of alkyl vinyl ethers except Run C1 where BVE is polymerized more quickly than NVC. The solubility characteristics of the copolymerization products (polymers con-

taining appreciable amounts of NVC units are soluble to an extent greater than 90% in cyclohexane, which is a very poor solvent for poly(*N*-vinylcarbazole) as well as measurements of optical rotation and differential dichroic absorption ($\Delta\epsilon$) indicate the formation of copolymer macromolecules. In fact in all cases c.d. spectra show the presence of two complex dichroic bands at about 300 and 260 nm having practically the same rotatory strength ($\theta \approx 5 \times 10^3/\text{mol NVC unit}$), and it is particularly interesting that no dichroic band can be observed corresponding to the u.v. band at 350 nm associated with the ${}^1L_b \leftarrow {}^1A$ transition in the carbazole ring⁷.

Copolymerization of NVC with (*S*)-4-methyl-1-hexene, in the presence of the $\text{Al}(\text{iso-C}_4\text{H}_9)_3/\text{TiCl}_4$ catalytic system, which is claimed to polymerize NVC^{8,9} as well as α -olefins¹⁰ by an anionic coordinated mechanism, yielded only a mixture of the two homopolymers, supporting previous conclusions¹¹ that these types of monomers polymerize by independent routes. Therefore earlier assumptions of polymerization of NVC by an anionic coordinated mechanism seem to be questionable.

persity was $54 \pm 2 \text{ \AA}$. This may be compared with a value of $63 \pm 3 \text{ \AA}$ calculated for an unperturbed system using $\langle s_0 \rangle_w^{1/2} = 0.660 \bar{M}_w^{1/2} / (6)^{1/2}$. The measured radius of gyration is thus near to, or slightly less than, the unperturbed value. If the uncertainties in the measurements are as low as indicated there is a small reduction in radius of gyration below that of the unperturbed value. Similar behaviour has been both observed¹³ and described theoretically¹⁴ for a single phase polymer solution in a poor solvent below the theta-temperature, when the second virial coefficient will be negative.

The main conclusion from the results of this work is that it is possible to produce a truly compatible mixture of two polymers in which the molecules are statistically distributed. ^aDetermined by n.m.r. spectroscopy and/or elemental analysis; ^bby vapour pressure osmometry in benzene at 37°C; ^cin CHCl₃ ($c = 1-5$ g/dl); ^devaluated for homopolymer mixture having the same composition as the corresponding copolymerization product; ^erelated to the fraction extracted with cyclohexane containing 88% of NVC monomeric units; ^fintrinsic viscosity in benzene at 25°C

In the presence of a conventional radical initiator (AIBN) NVC has been copolymerized with menthyl acrylate and methacrylate. The relative polymerization rate of the comonomers seems to be very similar, and formation of copolymers was established on the basis indicated above.

Finally in the presence of a conventional anionic catalyst (C₆H₅MgBr) both the comonomer mixtures gave polymers in very poor yield (conversion $\leq 5\%$), and which at the present have not been further characterized.

Studies are in progress to prepare copolymers of NVC with optically active alkyl vinyl ethers, acrylates and methacrylates in order to investigate the correlations between physico-optical properties on the one hand, with chemical composition, distribution of monomeric units, and stereoregularity of the copolymerization products.

Conclusions

Copolymers of optically active alkyl vinyl ethers, menthyl acrylates or methacrylates with *N*-vinylcarbazole can be obtained by copolymerization in the presence of conventional cationic catalyst or radical initiator respectively. Extraction of the polymeric products with boiling solvents, as well as their optical rotation and differential dichroic absorption demonstrates the formation of copolymer macromolecules rather than mixtures of homopolymers.

Attempts to copolymerize NVC with α -olefins, menthyl acrylate or methacrylate in the presence of anionic coordinated or anionic catalysts were unsuccessful.

Experimental

Monomers. (*S*)-4-methyl-1-hexene

(4 ME), $[\alpha]_D^{25} - 2.82$ (neat), optical purity 93.0%¹² was prepared according to the procedure already described¹².

[(*S*)-1-methylpropyl]-vinyl ether (BVE), $[\alpha]_D^{25} + 12.5$ (neat), optical purity 87.1%¹³; [(*S*)-2-methylbutyl]-vinyl ether (MBVE), $[\alpha]_D^{25} - 5.82$ (neat), optical purity 100%¹⁴; [(*S*)-1,2,2-trimethylpropyl]-vinyl ether (TPVE), $[\alpha]_D^{25} - 8.00$ (neat), optical purity 78.0%¹⁵ and (-)-menthyl vinyl ether (MVE), $[\alpha]_D^{25} - 73.6$ (neat), optical purity 100%^{13,16} have been prepared by transvinylolation¹⁷ starting from the corresponding optically active alcohols.

(-)-Menthyl acrylate (MA), $[\alpha]_D^{25} - 89.9$ (benzene), optical purity 97.0%¹⁸ was prepared by the reaction of methyl acrylate with menthoxymagnesium bromide¹⁹. (-)-Menthyl methacrylate (MMA), $[\alpha]_D^{25} - 91.8$ (neat), optical purity 99% was prepared as already reported¹⁵.

N-vinylcarbazole (NVC) (commercial grade purity) was purified by crystallization from *n*-hexane (m.p. 65°C)²⁰.

Catalysts. AIBN and TiCl₄ analytical grade purity were used without further purification. EtAlCl₂ and Al(iso-C₄H₉)₃ were distilled at reduced pressure prior to use. Al(iso-C₄H₉)₃/H₂SO₄ catalyst was prepared by adding H₂SO₄ (100%) dropwise to a solution of Al(iso-C₄H₉)₃ in *n*-heptane [Al(iso-C₄H₉)₃/H₂SO₄ = 4.5 mol/mol^{6,21}].

Copolymerization of NVC with (*S*)-4-methyl-1-hexene. The run was carried out in a glass vial under dry nitrogen. Equimolecular comonomer mixture was added at 0°C to the catalytic slurry obtained by reacting TiCl₄ with Al(iso-C₄H₉)₃ in toluene, comonomers/

TiCl₄ = 50 mol/mol, [Al(iso-C₄H₉)₃/TiCl₄ = 3 mol/mol]⁸. The run which was stopped after 70 h by addition of methanol, gave a polymeric product (68.4% yield evaluated as weight of polymer/weight of the starting comonomer mixture) constituted mainly (95%) of poly(*N*-vinylcarbazole).

Copolymerization of NVC with (-)-menthyl acrylate and methacrylate. Both runs were carried out in vials sealed under vacuum in the presence of AIBN at 70°C. 1 M solutions of comonomers in benzene were used and the polymerization were interrupted after 6 h.

Copolymerization of NVC with alkyl vinyl ethers. The copolymerization runs were carried out in glass vials at -78°C and -15°C when EtAlCl₂ and Al(iso-C₄H₉)₃/H₂SO₄ catalyst was used respectively. 1 M toluene solutions of comonomers were used.

Characterization of copolymerization products. The crude polymeric products, after reprecipitation from methanol, were characterized as unfractionated materials, but in some cases were fractionated by extraction with boiling solvents under nitrogen in Kumagawa extractors²² by using methanol, acetone, cyclohexane, and toluene or chloroform in that order. Chemical compositions of polymeric products were determined by elemental analysis and/or n.m.r. spectroscopy using a Varian T60 or a Jeol JNM-PS-100 spectrometer. Optical rotatory measurements were performed on a Perkin-Elmer Model 141 with sensitivity $\pm 0.003^\circ$ using chloroform solutions having a concentration in the range 0.5-5 g/dl. C.d. and u.v. spectra were measured for solutions in the range 240-400 nm using a Jouan II dichrograph and a Cary Model 14 Spectrophotometer.

Novel synthesis of 2-vinylanthraquinone

Introduction

We have recently concentrated some attention on the synthesis, characterization and evaluation of various potentially intrinsically useful polymers. One system which appears to offer particular promise concerns poly(2-vinylanthraquinone). Earlier syntheses^{1,2} of a vinyl polymer containing the anthraquinone system were aimed at the production of materials containing redox groups and generally took the form of 2-vinylanthraquinone/styrene/divinylbenzene crosslinked networks. However, in recent years, the photochemistry and the stereochemistry of polymers containing large pendant π -systems has gained much interest. *N*-vinylcarbazole deserves particular mention in this respect³. Our interest in 2-vinylanthraquinone concerns its role as an intermediate in the synthesis of polymers having both novel and useful characteristics including intrinsic colour.

More recent syntheses of 2-vinylanthraquinone involve the use of high temperatures and catalysts, and require that the reacting species be in the vapour phase^{4,5}. Consequently yields are irreproducible and the products difficult to purify. Using this type of procedure Manecke⁶ has reportedly achieved yields of 2-vinylanthraquinone of the order of 83%. We have not been able to obtain yields at this level and

the reaction product composition was found to be un-reproducible as were the final yields.

Fernandez-Refojo *et al.*⁷ have devised an alternative route to 2-vinylanthraquinone which involves synthesis of anthraquinone-2-aldehyde, conversion to the 2-acrylic acid derivative which is subsequently decarboxylated to the vinyl compound (yield 25.7%).

Here we report details of an alternative, novel and reproducible route to 2-vinylanthraquinone, which results in significantly higher yields of the monomer, and involves forming the vinyl derivative from the aldehyde via the Wittig reaction.

The reaction of anthraquinone-2-aldehyde with the ylid, produced from methyl-triphenyl phosphonium bromide and phenyl lithium, did not give the corresponding expected 2-vinylanthraquinone but instead gave a stable blood-red complex. This was probably an ion-pair formed from interaction between the intermediate betaine and lithium bromide which is produced in the synthesis of the ylid⁸. Subsequently the stronger base, potassium *t*-butoxide (as a 1:1 complex with *t*-butanol in tetrahydrofuran) was employed. The reaction gave 2-vinylanthraquinone in high purity and allowed recovery of the unreacted aldehyde. This was then available for use in subsequent syntheses, thus ensuring mini-

mal losses of important intermediates.

Experimental

For ease of replication, full experimental details are presented.

Reagents. *t*-Butanol was distilled from fresh sodium. Tetrahydrofuran (THF) previously stored over sodium, was freshly distilled from lithium aluminium hydride prior to use. Benzene was dried over sodium after distillation from sodium. With the exception of potassium *t*-butoxide, which was stored in the cold, organic solids were dried to constant weight in a vacuum oven at 50°C. Nitrogen (oxygen-free) was dried by passing through sulphuric acid and calcium chloride.

Synthesis. A vigorously stirred suspension of 4.47 g (0.0135 mol) of methyl-triphenyl phosphonium bromide in 100 ml of benzene under a nitrogen atmosphere was treated to slow addition of a THF solution of 1.66 g (0.0148 mol) potassium *t*-butoxide complexed with 1.03 g (0.0148 mol) of *t*-butanol. The mixture was allowed to stand for 3/4 h, filtered and the filtrate added dropwise (over 2 h) to a refluxing, stirred solution of 3 g (0.135 mol) of anthraquinone-2-aldehyde in 80 ml of benzene under an atmosphere of nitrogen (the aldehyde was prepared, following the method of Fernandez-Refojo⁷ *et al.*, in 48% yields). The solution volume

Novel synthesis of 2-vinylanthraquinone

Introduction

We have recently concentrated some attention on the synthesis, characterization and evaluation of various potentially intrinsically useful polymers. One system which appears to offer particular promise concerns poly(2-vinylanthraquinone). Earlier syntheses^{1,2} of a vinyl polymer containing the anthraquinone system were aimed at the production of materials containing redox groups and generally took the form of 2-vinylanthraquinone/styrene/divinylbenzene crosslinked networks. However, in recent years, the photochemistry and the stereochemistry of polymers containing large pendant π -systems has gained much interest. *N*-vinylcarbazole deserves particular mention in this respect³. Our interest in 2-vinylanthraquinone concerns its role as an intermediate in the synthesis of polymers having both novel and useful characteristics including intrinsic colour.

More recent syntheses of 2-vinylanthraquinone involve the use of high temperatures and catalysts, and require that the reacting species be in the vapour phase^{4,5}. Consequently yields are irreproducible and the products difficult to purify. Using this type of procedure Manecke⁶ has reportedly achieved yields of 2-vinylanthraquinone of the order of 83%. We have not been able to obtain yields at this level and

the reaction product composition was found to be un-reproducible as were the final yields.

Fernandez-Refojo *et al.*⁷ have devised an alternative route to 2-vinylanthraquinone which involves synthesis of anthraquinone-2-aldehyde, conversion to the 2-acrylic acid derivative which is subsequently decarboxylated to the vinyl compound (yield 25.7%).

Here we report details of an alternative, novel and reproducible route to 2-vinylanthraquinone, which results in significantly higher yields of the monomer, and involves forming the vinyl derivative from the aldehyde via the Wittig reaction.

The reaction of anthraquinone-2-aldehyde with the ylid, produced from methyl-triphenyl phosphonium bromide and phenyl lithium, did not give the corresponding expected 2-vinylanthraquinone but instead gave a stable blood-red complex. This was probably an ion-pair formed from interaction between the intermediate betaine and lithium bromide which is produced in the synthesis of the ylid⁸. Subsequently the stronger base, potassium *t*-butoxide (as a 1:1 complex with *t*-butanol in tetrahydrofuran) was employed. The reaction gave 2-vinylanthraquinone in high purity and allowed recovery of the unreacted aldehyde. This was then available for use in subsequent syntheses, thus ensuring mini-

mal losses of important intermediates.

Experimental

For ease of replication, full experimental details are presented.

Reagents. *t*-Butanol was distilled from fresh sodium. Tetrahydrofuran (THF) previously stored over sodium, was freshly distilled from lithium aluminium hydride prior to use. Benzene was dried over sodium after distillation from sodium. With the exception of potassium *t*-butoxide, which was stored in the cold, organic solids were dried to constant weight in a vacuum oven at 50°C. Nitrogen (oxygen-free) was dried by passing through sulphuric acid and calcium chloride.

Synthesis. A vigorously stirred suspension of 4.47 g (0.0135 mol) of methyl-triphenyl phosphonium bromide in 100 ml of benzene under a nitrogen atmosphere was treated to slow addition of a THF solution of 1.66 g (0.0148 mol) potassium *t*-butoxide complexed with 1.03 g (0.0148 mol) of *t*-butanol. The mixture was allowed to stand for 3/4 h, filtered and the filtrate added dropwise (over 2 h) to a refluxing, stirred solution of 3 g (0.135 mol) of anthraquinone-2-aldehyde in 80 ml of benzene under an atmosphere of nitrogen (the aldehyde was prepared, following the method of Fernandez-Refojo⁷ *et al.*, in 48% yields). The solution volume

was reduced by 50% by distillation and the residue allowed to reflux for 1 h. By this time the blood-red colour of the betaine intermediate had almost disappeared. The resulting mixture was poured slowly into a 3 fold excess of ligroin (60°–80°C) and the precipitate of triphenyl phosphine oxide separated. Residual solvents were removed and the yellow residue (aldehyde–vinyl anthraquinone mixture) partly dissolved in benzene/ligroin (3:1). The insoluble residue of unreacted aldehyde was recovered for recycling. The crude 2-vinylanthraquinone was purified by column elution with 4:1 ligroin/benzene. Recrystallization from 3:1 benzene/methanol gave pale yellow needles, melting point 176°–177°C, in 61% yield. Such yields have been maintained on repeated preparations. Analysis calculated for C₁₆H₁₀O₂: C, 82.05; H, 4.30. Found: C, 82.08; H, 4.50. The infra-red spectrum was found to be identical with the product

of the method of Manecké^{1,2}.

In forming vinyl compounds from aldehydes using the Wittig reaction the more customary addition of the aldehyde had to be reversed in order to reduce reaction at the 9,10-quinone positions. Any reaction in the 9,10-quinone positions of the anthraquinone nucleus gives 9,10-dimethylanthracene derivatives as highly fluorescent and unwanted side-products. It is the production of vinyl compounds, from a precursor containing both aldehyde and ketonic groups, by making use of the greater reactivity of the aldehyde group, which gives this preparation its originality, within the present context and creates a route for the production of many similar compounds.

Work is at present being carried out by one of us (A. J. G.) concerning the γ -ray, thermal, chemical and ionic routes to polymers based on vinylanthraquinones and their derivatives. Our immediate interest lies in the photo-

chemical, thermal and stereochemical properties of the monomers and resultant polymers.

Ultra-high modulus polyethylene by high temperature drawing

In this note we wish to report some remarkable new results obtained recently during an investigation now in progress on the high temperature drawing of linear polyethylene (LPE). This study forms a natural extension of our previous work on the preparation and properties of ultra-high modulus oriented polymers^{1–5}. It also attempts to re-examine, in the light of results for different drawing conditions, the conclusions of recent investigations^{1–4,6} on the inter-relationship between molecular parameters and processing conditions for LPE drawn at 75°C. In particular, our proposal^{2,6} that the drawing behaviour of a semi-crystalline polymer may be interpreted in terms of a network structure having crystalline domains and molecular entanglements as junction points – hence the vital role played by the non-crystalline material – can receive further support or be disproved by the temperature dependence of the drawing process.

We report here results for two grades of LPE: H020-54P (BP Chemicals International, $\bar{M}_w = 312\,000$, $\bar{M}_n = 33\,000$) and Hostalen GUR (Farbwerke Hoechst AG, $\bar{M}_w \sim 3\,500\,000$). Isotropic samples were produced by compression moulding at 160°C and either slow cooling to 110°C and quenching into water at room tem-

perature (160/110/W) or quenching directly into water (160/W), as described previously^{1,2}. Dumb-bell specimens of 2 cm gauge length were then drawn in air at different temperatures in an Instron Tensile Testing Machine using a crosshead speed of 10 cm/min.

The results of these drawing experiments were remarkable in two respects. First, it was found that effective drawing (drawing which produces ultra-high modulus material) can be achieved at temperatures very close or apparently even above the crystalline melting point of the polymer, provided that appropriately high molecular weight polymer is used. Secondly, the ultra-high modulus materials produced at high drawing temperatures can exhibit properties and structural features which are significantly different from those found in products from drawing at 75°C.

In Figure 1 the variation of the draw ratio λ in the plastically deformed region with draw time (t_d) is shown for samples drawn at 115° and 75°C, the results for 75°C being obtained in a previous investigation⁶. Despite some scatter in the present results, there does not appear from these data to be any difference in kind between drawing at 115°C and drawing at 75°C. The increased draw temperature does

Figure 1 Local draw ratio (λ) as a function of time of draw (t_d) for sample H020-54P. $T_d = 115^\circ\text{C}$: \circ , 160/W; \bullet , 160/110/W. $T_d = 75^\circ\text{C}$: —, 160/W; —, 160/110/W

however result in an extension of the curve obtained for 75°C, allowing the production of much higher draw ratios before failure occurs.

When the properties of the drawn materials are examined, the results are more unusual. The 10 sec isochronal stress–strain curve (see Figure 2) for a sample of draw ratio 34 confirms that very high Young's moduli are still obtained from high temperature drawing. Although the value of 47.5 GN/m² at a strain of 10^{–3} is marginally lower than that for low molecular weight LPE drawn at 75°C, these high molecular weight drawn materials show much superior long term creep pro-

First, it was found that effective drawing (drawing which produces ultra-high modulus material) can be achieved at temperatures very close or apparently even above the crystalline melting point of the polymer, provided that appropriately high molecular weight polymer is used. Secondly, the ultra-high modulus materials produced at high drawing temperatures can exhibit properties and structural features which are significantly different from those found in products from drawing at 75°C.

In Figure 1 the variation of the draw ratio λ in the plastically deformed region with draw time (t_d) is shown for samples drawn at 115° and 75°C, the results for 75°C being obtained in a previous investigation⁶. Despite some scatter in the present results, there does not appear from these data to be any difference in kind between drawing at 115°C and drawing at 75°C. The increased draw temperature does

Figure 1 Local draw ratio (λ) as a function of time of draw (t_d) for sample H020-54P. $T_d = 115^\circ\text{C}$: \circ , 160/W; \bullet , 160/110/W. $T_d = 75^\circ\text{C}$: —, 160/W; —, 160/110/W

however result in an extension of the curve obtained for 75°C, allowing the production of much higher draw ratios before failure occurs.

When the properties of the drawn materials are examined, the results are more unusual. The 10 sec isochronal stress–strain curve (see Figure 2) for a sample of draw ratio 34 confirms that very high Young's moduli are still obtained from high temperature drawing. Although the value of 47.5 GN/m² at a strain of 10^{–3} is marginally lower than that for low molecular weight LPE drawn at 75°C, these high molecular weight drawn materials show much superior long term creep pro-

Figure 2 Room temperature 10 sec isochronal stress-strain curves for highly drawn samples of (A) H020-54P, $\lambda = 34$, $T_d = 115^\circ\text{C}$; (B) Hostalen GUR, $\lambda = 17$, $T_d = 135^\circ\text{C}$

erties⁷. These materials are more elastic in their behaviour, and this more than outweighs the slightly lower level of initial modulus.

The ultra-high molecular weight Hostalen GUR could not be drawn to high λ at 115°C . In order to achieve high draw ratios and explore fully the temperature boundaries for effective drawing, the deformation was therefore performed at an air temperature of 135°C i.e. above the melting point of isotropic material. Under these conditions the samples could be drawn to $\lambda = 17$ and the drawn materials exhibited interesting and novel properties. Previously, the draw ratios of this polymer appeared to be limited to about 4 with little or no increase in stiffness over isotropic material. Figure 2 shows that a value of 7 GN/m^2 is obtained for the Young's modulus, and that the stress-strain curve is remarkably linear.

The melting behaviour of these samples reveals very interesting structural differences with the lower molecular weight materials drawn at lower temperatures. The d.s.c. traces for both samples are shown in Figure 3. An unprecedentedly high melting temperature for drawn LPE of 141.5°C is recorded for the H020-54P grade, indicating the extremely high degree of order and continuity of the crystalline phase. On the other hand, the drawn Hostalen GUR shows a double peak with the higher T_m at 139.5°C . Wide-angle X-ray diffraction patterns

for these samples throw light on these differences. That for a drawn samples of the H020-54P grade, shown in Figure 4a, indicates a sharpness for the reflections similar to that obtained previously for ultra-high modulus materials drawn at $T_d = 75^\circ\text{C}$. The photograph for the Hostalen GUR samples is, however, remarkable in showing indications of poorly oriented material in addition to the sharp reflections which can be attributed to highly oriented crystalline material (Figure 4b). A possible explanation of the d.s.c. and X-ray diffraction data is that the high temperature peak and the sharp X-ray reflections arise from material crystallized under stress while the low temperature peak (Hostalen GUR) corresponds to poorly oriented material which crystallizes on cooling down to room temperature.

These results show that the preparation of ultra-high modulus LPE can be successfully extended to higher molecular weight polymers provided that drawing is carried out at high temperatures. For high molecular weight polymers the initial thermal treatment does not appear to influence the drawing process (Figure 1). We have suggested^{2,5} that this is because the high molecular weight material now plays a decisive role in the network structure which undergoes deformation in the drawing process. This idea receives con-

Figure 3 D.s.c. melting curves for highly drawn samples of (a) H020-54P, $T_d = 115^\circ\text{C}$; $\lambda = 25$; (b) Hostalen GUR, $T_d = 135^\circ\text{C}$; $\lambda = 17$.

Figure 4 Wide-angle X-ray diffraction patterns for a sample of (a) H020-54P drawn to $\lambda = 25$ and (b) a sample of Hostalen GUR drawn to $\lambda = 17$

firmation from the present results. It is clear that drawing can be carried out even at temperatures close to or apparently above the crystalline melting point, provided that the molecular entanglements of high molecular weight material are available to guarantee continuity for the network structure.

On the field dependent photoconduction in poly(*N*-vinylcarbazole)

The photogeneration of carriers and their transport in poly(*N*-vinylcarbazole) (PNVC) has been the subject of many investigations¹⁻⁶. The photoconduction in PNVC is the result of a field enhanced carrier generation, explained on the basis of 'geminate recombination'³ of the electron-hole pairs produced and a field assisted drift mobility arising from the hopping mechanism² of the photogenerated holes. In the case of positive electrode illumination with strongly absorbed light (350 nm), the $I - V$ characteristics of PNVC (in a sandwich-cell configuration) is found to be linear for low values of V , but becomes superlinear (with a slope 2 in the double log plot) at higher values⁵ (~ 15 kV/cm). The origin of the superlinearity has been attributed to the following reason.

During their transit across the film towards the negative electrode, the photogenerated holes undergo repeated trapping and release from shallow and intermediate traps, whereas those trapped in deep levels remain bound to the trapping site. Since the trapping probability is proportional to the product of the number of unoccupied trapping sites and the number of free holes available, the field assisted carrier generation results in increased trapping at higher fields. As more and more traps become occupied, the trapping probability decreases, thereby increasing the number of holes available for conduction. The 'knee-point' in the $I - V$ plots should therefore correspond to the onset of trap-filling. Since only intermediate and deep traps are responsible for the above phenomenon (shallow traps being in thermal equilibrium with the valence band), the argument appears to be feasible in the case of PNVC, where the density of deep traps have been estimated to be very small⁶ ($\sim 10^{12}/\text{cm}^3$).

The purpose of the present note is to examine the validity of the above argument, which suggests that the photoelectret charge (Q), obtained by the time integration of the dark depolarization current⁷ (i_{dd}), should increase initially and approach a saturation value near the voltage corresponding to the knee-point in the $I - V$ plot.

The photoconduction and photoelectret measurements were carried out at room temperature (30°C) in a sandwich structure (Al-PNVC-NESA), fabricated by vacuum depositing Al

onto a PNVC layer (100 μm) cast on the NESA glass substrate. The sample was illuminated from the NESA side using a 125 W u.v. lamp, by keeping the NESA electrode positive. The values of photocurrents observed at different times after the commencement of the photopolarization are given in Figure 1 along with the level of dark currents observed at the end of 5 min dark polarization. It is seen that the onset of non-linearity (knee-

point) shifts towards lower voltage as the polarizing time increases. Figure 2 shows the i_{dd} values observed at different times and the photoelectret charge Q ($Q = \int_0^\infty i_{dd} dt$) for the different polarizing voltages. The values of i_{dd} and Q are found to exhibit a maximum for $V = 800$ V, which roughly corresponds to the knee-point in the $I - V$ plot. The broken lines in Figure 2 show that an expression $i_{dd}(t) \propto t^{-1}$ is valid for the i_{dd} decay

Figure 1 The photocurrents (i) in PNVC observed at an interval of A, 5 sec; B, 40 sec; C, 5 min after the application of polarizing voltage (V). ----, denotes the level of 5 min dark currents

Figure 2 Dark depolarization currents (i_{dd}) observed after an interval of A, 5 sec; B, 45 sec; C, 3 min for different polarizing voltage (V) and the PE charge (Q) obtained by $Q = \int_0^{\infty} i_{dd} dt$. 1, 2 and 3 represent typical decay curves for the i_{dd} , for $V = 400$ V, 800 V and 1500 V respectively

with time on both sides of the maximum.

The photoelectret charge observed in the case of organic and inorganic semiconductors usually shows an initial increase with voltage, followed by a saturation⁸ though in the case of anthracene, the $Q - V$ plots (corresponding to the $i_{dd} - V$ plots) exhibited a maximum⁹. The observation of this maximum in the case of anthracene has been explained on the basis of homocharge formation at higher fields due to air breakdown in the sample-electrode interface, since the occurrence of a maximum was absent when an insulating spacer was introduced in this interface⁹. This possibility has to be ruled out in the present case, as there is no gap between the sample and the NESA or Al electrodes.

However, an explanation based on a field assisted detrapping seems to be plausible because of the correspondence between the knee-point in the

$I - V$ plot and the maximum in the $Q - V$ plot. In materials such as PNVC, characterized by a charge transport limited by the release from localized (trapping) states, where this release also is highly field dependent, it is possible that a charge could be trapped at a given state, when the next state is inaccessible at a particular field. However, for a higher applied field, the same state may not act as a trap due to a field enhanced release probability. This has been proved by 'thermally stimulated current' (TSC) experiments in PNVC², which has shown that the TSC peak shift towards lower temperature as the polarizing field is increased, indicating the decreased contribution to the total charge from the deeper traps at elevated fields.

Since trapping centres at considerable depth are either very few or absent in the case of PNVC, as concluded from the 'time of flight'⁶ and photoel-

ectret¹⁰ experiments, it can be assumed that a field as low as 10 kV/cm is able to influence even the deepest trapping sites with a meaningful abundance. It should be noted that such a case cannot arise in materials with an appreciable density of deep-lying traps, as the applied fields cannot influence such deeper levels, thereby explaining the absence of a maximum in the $Q - V$ plots of ordinary photoelectret materials.

From the present results on the photoconductivity in PNVC, it can therefore be concluded that the superlinearity in the $I - V$ plots is not only a consequence of a field enhanced carrier generation and a field assisted hopping transport, but also is due to a significant contribution from the field assisted release from the trapping centres. Further work on the spectral, temperature and illumination intensity dependence of the $Q - V$ characteristics is in progress.

Book Reviews

Block and Graft Copolymerization Volume 2

Edited by R. J. Ceresa

Wiley, London, 1976, 402pp £16.50

Over seventy per cent of the text of this book is devoted to the synthesis, properties and applications of block copolymer polycol surfactants by L. G. Lundsted and I. R. Schmolka. These block copolymers based on poly(ethylene oxide) were first produced in 1950 and have been marketed since then by the Wyandotte Chemical Corporation under the trade names of Pluronic and Tetronics. From the references to patents and publications, both authors have been actively involved in the development of polyol surfactants at Wyandotte. Lundsted was one of the authors of the paper on the synthesis of ABA poly(ethylene oxide-*b*-propylene oxide) in 1951.

Chapter one on preparation and properties covers similar ground to a review by Schmolka published in 1967 on the nonionic surfactant properties of poly(alkylene oxide) block copolymers. More details on block copolymer synthesis have been included in the present book. Chapter two describes the applications of block copolymer surfactants under twenty seven headings. The applications are very wide-ranging. The uses of these surfactants appear to be continually expanding; over a quarter of the references are to papers and patents published from 1970 onwards. Polymer chemists will be particularly interested in the sections on emulsion polymerization, paint, plastics and polymers, polyurethanes, rubber and textiles. These two chapters illustrate that block and graft copolymers often have valuable interfacial properties, the study of which has received less attention than the use of these copolymers as thermoplastic elastomers and impact modifiers.

The remainder of the book is concerned with poly(vinyl chloride). In chapter three the editor reviews the synthesis of block and graft copolymers. In his preface he apologizes for any major omissions in this chapter which is concerned mainly with chemical

and irradiation grafting procedures, either by a monomer to a poly(vinyl chloride) backbone or by vinyl chloride to another polymeric backbone. Thus the work of J. P. Kennedy on cationic grafting is only briefly mentioned and references to his work published during the last three years are not included. The text is less than forty pages long and almost ninety per cent of the literature cited was published before 1970.

In chapter four on the properties and applications of graft copolymers of poly(vinyl chloride) by D. Hardt, less than six per cent of the references were published from 1970 onwards. Consequently, the recent developments in microphase separation in block and graft copolymers and their importance in poly(vinyl chloride) systems are not discussed in detail.

In summary, the first two chapters give a very comprehensive and authoritative review of poly(alkylene oxide) block and graft copolymers. The book should be bought by libraries serving polymer chemists and those interested in polymers at interfaces in colloidal systems. Workers concerned only with poly(vinyl chloride) obtain poor value, because of the high price, £16.50 for 130 pages, and because recent developments are not reviewed owing to the delay in publication. A list of 60 references published from 1971 onwards is included in an addendum.

Photodegradation, Photo-oxidation and Photostabilization of Polymers

B. Ranby and J. F. Rabek

Wiley, London, 1975, 573 pp. £16.50

Polymer chemists and technologists have for long been preoccupied by the deteriorative effects of light on their products. This interest has diversified in various directions over the years to include mechanisms of photolysis and photo-oxidation, photosensitization and photostabilization. In the meantime, rapid advances have been made in understanding the fundamental principles of photochemical and photophysical processes in materials generally.

This book, which is intended for experimental investigators in polymer chemistry, begins by explaining clearly and concisely the general fundamental principles of photochemistry and of the mechanism and kinetics of photodegradation and photooxidation. There follows a long chapter (134 pages) in which the specific reactions of a large variety of polymers are described in detail. A good deal of space is also devoted to photosensitized reactions of polymers, the stabilization of polymers to ultra-violet light and practical methods in the photochemistry of polymers. Interspersed with these longer chapters the overall picture is completed by shorter treatments of such diverse topics as singlet oxygen mechanism of polymer photo-oxidation, energy transfer in polymers, photochemistry of polymers in reactive gases (ozone, sulphur dioxide, nitrogen dioxide and chlorine), the role of photodegradable polymers in the packaging industry and finally weatherability of plastics materials.

The reviewer would confirm the authors' belief that this is the first monograph in which the fundamental photochemical reactions involved in the photodegradation of polymers has been thoroughly discussed. They have admirably succeeded in producing a comprehensive and critical yet easily readable account of the subject and the textual material is supported by a very complete bibliography of 2334 references for those who may require further information on a specific topic.

Scientists with any interest in photoreactions of polymers will wish to and will also find this volume very easy to read from cover to cover. Those more intimately concerned with research and development will find it a valuable source of information and a useful catalyst for the development of new approaches to their subject.

Conference Announcement

The Science and Technology of Water Soluble Polymers

UWIST, Cardiff, 21–23 September 1976

A group representing various societies are holding a symposium on *The Science and Technology of Water Soluble Polymers* at UWIST Cardiff on the 21, 22 and 23 September 1976. The symposium is intended as an international meeting point for academic and industrial scientists interested in water soluble polymers. Some 20 papers will be presented which will include communications from Czechoslovakia, Switzerland, Norway, USA, Hungary, Belgium, France, Britain and Ireland. The topics covered include fundamental science and applications in the food, cosmetics, polymers, textiles, medical, pharmaceutical and photographic fields. Full programmes and application forms are available from The Short Courses Secretary, Planning Section, UWIST, King Edward VII Avenue, Cardiff CF1 3NU, UK.

Electro-optic Kerr birefringence of polystyrenes in dilute solutions

J. V. Champion, G. H. Meeten and G. W. Southwell

Department of Physics, Sir John Cass School of Science and Technology, City of London Polytechnic, London EC3N 2EY, UK

(Received 13 February 1976; revised 19 March 1976)

The electro-optic Kerr effect has been measured for styrene and several high molecular weight polystyrenes in dilute solution in carbon tetrachloride. The results for styrene clearly show free rotation of the phenyl group. The results for polystyrene are in accord with the predictions of the Stuart and Peterlin independently orientating segment theory, and also in agreement with the results to be expected from currently available estimates of the segmental anisotropy provided that the segmental dipole is orthogonal to the segmental end-to-end distance.

INTRODUCTION

Two models have been used to describe the electro-optic Kerr effect in flexible polymer chains. One of these describes the chain as a sequence of dipolar and anisotropically polarizable chemical bonds and enables calculation of the appropriate averages of optical polarizability anisotropy from the conformation and orientation of the chain in an applied strong field. The other describes the chain as a sequence of freely jointed segments having segmental dipolarity and polarizability anisotropy. These segments behave as independently orientating units in the applied strong field. The former model is exemplified by the calculations of Kluk¹, Volkenstein², Dows³, and Nagai⁴ who express the Kerr constant in terms of clearly defined bond parameters, i.e. the number of bonds and their polarizability tensors, dipole moments, bond angles and energies of rotational isomerism. They assume the validity of the bond polarizability tensor additivity scheme and the vectorial addition of bond dipole moments. Both assumptions may be questioned even as first order approximations but the model is applicable to chains of any length.

The segmental model of Stuart and Peterlin⁵ does not express the Kerr constant in terms of clearly defined bond parameters but employs segmental polarizability anisotropies and dipole moments, these being a conformational average of bond anisotropies and moments over a small number of bonds in a sequence. The model is only capable of describing chains having a sufficiently large number of monomer units to analyse statistically, but is not dependent on the assumptions of additivity of bond polarizability tensors and bond dipole moments. Segmental anisotropies are also derivable from flow birefringence, strain-optical birefringence and depolarized Rayleigh light scattering experiments. They provide useful knowledge about the conformational flexibility of the chain in a given solvent. Segmental dipole moments are of similar use. It will be shown that the Kerr constant of a dipolar polymer interpreted with the Stuart-Peterlin theory relates the segmental dipole vector to the axes of the segmental polarizability tensor.

Le Fevre *et al.*⁶ have made Kerr effect measurements of styrene and polystyrene in carbon tetrachloride solution. They found the specific Kerr constant to show a considerable molecular weight dependence in the molecular weight

range 900 to 250 000, and interpreted their data in terms of the re-orientation of the whole polymer chain behaving as a rigid unit under the influence of the applied electric field. This interpretation has subsequently been criticized by Dows³ who showed theoretically that the specific Kerr constant is related to the properties of a segment rather than the whole chain.

Since the molecular weight dependence of specific Kerr constants as found by Le Fevre indicates that the polymer chains are too short to be considered as being composed of a large number of segments, the aim of this work was to repeat the Le Fevre measurements using higher molecular weight polystyrenes, where an interpretation of results in terms of segmental properties should be valid.

EXPERIMENTAL

Material

Samples of polystyrene were used with weight-average molecular weights $M_w = 1, 2.1, 2.8, 8.8$ and 35×10^5 . The first three were obtained from Monsanto, Shell and BDH Ltd, the last two were made by the slow room temperature polymerization of styrene using benzoyl peroxide as a catalyst. The samples were all polydisperse with $M_w/M_n \approx 2$, as shown by g.p.c. measurements. M_w was determined by the techniques of light scattering and dilution viscometry. The solvent used for all samples was Analar grade carbon tetrachloride (Hopkin and Williams). The styrene was supplied by Hopkin and Williams as styrene monomer stabilized by about 0.001% *p*-*t*-butyl catechol. This was regarded as a negligible impurity as contributing to the measured Kerr effect.

Procedure

The apparatus and procedure have been described previously^{7,8}. Measurements were made at $\sim 25^\circ\text{C}$. All solutions were filtered before use with Millipore glass fibre pre-filters. For all solutions the birefringence Δn was proportional to the square of the applied field E , a least squares fit of Δn to E^2 giving the solution Kerr constant $B = \Delta n/\lambda E^2$, λ being 546 nm for the light used in all measurements. B was measured for several concentrations of polystyrene less than 100 kg/m^3 , the excess Kerr constant over the solvent, $B - B_1$, being proportional to the polystyrene

Figure 1 Variation of Kerr constant B with solution concentration c_2 of polystyrene, $M_w = 1 \times 10^5$

concentration c_2 within experimental error. A least squares fit of $B - B_1$ to c_2 then gave the specific incremental Kerr constant dB/dc_2 . Figure 1 shows a typical plot of B versus c_2 . Measurements of the specific incremental relative permittivity $d\epsilon/dc_2$ at low concentrations were made using a Wayne-Kerr B221A bridge and a temperature controlled capacitor. Specific refractive index increments dn/dc_2 were measured using a precision Abbé refractometer.

Results

Table 1 shows values of dB/dc_2 with weight-average molecular weight. Values of $d\epsilon/dc_2$ and dn/dc_2 of $0.4 \times 10^{-3} \text{ m}^3/\text{kg}$ and $0.15 \times 10^{-3} \text{ m}^3/\text{kg}$ were found for all polystyrene solutions, $d\epsilon/dc_2$ being calculated from dn/dc_2 as described previously⁷. For styrene, values of $d\epsilon/dc_2 = 0.235 \times 10^{-3} \text{ m}^3/\text{kg}$ and $dn/dc_2 = 0.118 \text{ m}^3/\text{kg}$ were obtained.

Systematic errors in dB/dc_2 arising from errors in the applied strong field (up to 10^7 V/m) and Kerr cell geometry amounted to about $\pm 2\%$. Random errors in dB/dc_2 measurements were about 10%, including errors in the concentration, the optical compensation and in observation.

THEORY AND DISCUSSION

Theory

The Kerr constant of the solute is defined as $B_2^* = \Delta n_2 / \lambda E^2$ where Δn_2 is that part of the electrically induced solution birefringence arising from the solute when a field of E is applied to the solution. The specific Kerr constant is then given in SI units by⁹:

$$\frac{B_2^*}{c_2} = \frac{750N_A}{n\epsilon_0\lambda M_2} \left(\frac{\epsilon + 2}{3} \right) \left(\frac{n^2 + 2}{3} \right)^2 (\theta_\alpha + \theta_\mu) \quad (1)$$

where

$$45kT\theta_\alpha = (\alpha_{xx} - \alpha_{yy})^2 + (\alpha_{yy} - \alpha_{zz})^2 + (\alpha_{zz} - \alpha_{xx})^2 + 6\alpha_{xy}^2 + 6\alpha_{yz}^2 + 6\alpha_{zx}^2$$

and

$$45k^2T^2\theta_\mu = (\mu_x^2 - \mu_y^2)(\alpha_{xx} - \alpha_{yy}) + (\mu_y^2 - \mu_z^2)(\alpha_{yy} - \alpha_{zz}) + (\mu_z^2 - \mu_x^2)(\alpha_{zz} - \alpha_{xx}) + 6\alpha_{xy}\mu_x\mu_y + 6\alpha_{yz}\mu_y\mu_z + 6\alpha_{zx}\mu_z\mu_x$$

In equation (1), M_2 is the molecular weight of the solute, θ_α is the term describing molecular re-orientation due to the interaction between the molecular polarizability tensor components α_{ij} and the applied field. θ_μ is the dipole term describing molecular re-orientation due to the interaction between the molecular dipole components μ_i and the applied field. In correspondence with recent work, (Vuks¹⁰, Zamkov¹¹, Kuball *et al.*¹²⁻¹⁴, Göb *et al.*¹⁵, and Proutiere *et al.*¹⁶) the factor $[(\epsilon + 2)/3]$ is of the first power rather than the second as was originally used for solutions and liquids by many workers. This change results from distinguishing between the internal polarizing field and the field responsible for the orientational couple acting on a molecule. When the solvent specific Kerr constant cannot be neglected with respect to the solute and it may be assumed that solute-solute interactions are absent at low concentrations, then the solution birefringence is the sum of the component birefringences weighted according to their respective number densities. It follows that:

$$\frac{B_2^*}{c_2} = \frac{dB}{dc_2} - \frac{3B_1}{(\epsilon_1 + 2)} \times \frac{d\epsilon}{dc_2} - \frac{B_1}{n_1} \left(\frac{3n_1^2 - 2}{n_1^2 + 2} \right) \times \frac{dn}{dc_2} + B_1 \bar{v}_2 \quad (2)$$

where the differentials are all limiting values as $c_2 \rightarrow 0$. \bar{v}_2 is the solute partial specific volume given by $1/c_1 [1 - (dc/dc_2)]$. Values of B_2^*/c_2 are shown in Table 1.

Styrene

For styrene, the experimental results will be used to determine the mutual orientation of the C=C bond and the phenyl ring. This mutual orientation is described by the orthogonal torsional angle ϕ between the normal N to the ring and the plane containing the C=C bond and the ring axis of rotation, as described by Figure 2. The axis of rotation of the ring makes an angle $\phi (< 90^\circ)$ to the x axis. The bond polarizability tensor additivity scheme gives the molecular tensor components α_{ij} in terms of the tensor components of the constituent bonds or groups. The anisotropy $\Delta\alpha^{JK}$ of a JK bond is the difference between the tensor components parallel and perpendicular to the length of the bond. All bonds have diagonal polarizability tensors for axes parallel and perpendicular to the bond length. Polar-

Table 1 Experimental values of dB/dc_2 and B_2^*/c_2

Solute	M_w	$(dB/dc_2) \times 10^{18}$ ($\text{V}^{-2} \text{ m}^4 \text{ kg}^{-1}$)	$(B_2^*/c_2) \times 10^{18}$ ($\text{V}^{-2} \text{ m}^4 \text{ kg}^{-1}$)

Polystyrene	2.1×10^5	9.3	10.0
Polystyrene	2.8×10^5	7.1	7.7
Polystyrene	8.8×10^5	8.8	9.5
Polystyrene	35×10^5	7.9	8.6

Figure 2 Styrene: the x axis lies parallel to the $C=C$ bond and the z axis normal to the xy plane containing the $C=C$ bond, the ring rotation axis and the CH bonds. The ring orientation is described by the torsional angle ϕ between the ring normal N and the xy plane

izability symmetry around the bond length axis is assumed for all bonds and for the phenyl ring, where N is the symmetry axis polarizability and $\Delta\alpha^b$ is the ring anisotropy. These assumptions give:

$$\alpha_{xx} - \alpha_{yy} = X - Y + [(N - M) \cos^2 \phi - (N - L)] \cos 2\theta$$

$$\alpha_{yy} - \alpha_{zz} = Y - Z + (N - L) \cos^2 \theta + (M - N) \times (1 + \cos^2 \theta) \cos^2 \phi + (L - M)$$

$$\alpha_{zz} - \alpha_{xx} = Z - X - (M - N) (2 - \cos^2 \theta) \cos^2 \phi + (N - L) \cos^2 \theta + (M - N)$$

$$\alpha_{xy} = (N - L) \sin \theta \cos \theta + (M - N) \sin \theta \cos \theta \cos^2 \phi$$

$$\alpha_{yz} = (N - M) \cos \theta \cos \phi \sin \phi$$

$$\alpha_{zx} = (N - M) \sin \theta \cos \phi \sin \phi$$

where

$$X - Y = \Delta\alpha^{C=C} - 4\Delta\alpha^{CH}(1 - 2 \cos^2 \theta)$$

$$Y - Z = 4\Delta\alpha^{CH} \sin^2 \theta$$

$$Z - X = -\Delta\alpha^{C=C} - 4\Delta\alpha^{CH} \cos^2 \theta$$

$$L - M = \Delta\alpha^{CC} - 2\Delta\alpha^{CH}$$

$$M - N = -\Delta\alpha^b$$

$$N - L = \Delta\alpha^b - \Delta\alpha^{CC} + \Delta\alpha^{CH} \quad (3)$$

The dipole moment μ is assumed to lie parallel to the axis of rotation of the phenyl ring so that:

$$\mu_x = \mu \cos \theta, \mu_y = -\mu \sin \theta, \mu_z = 0 \quad (4)$$

The functions θ_α and θ_μ in equation (1) are then given by:

$$45kT\theta_\alpha = (L - M + Y - Z)^2 + (M - N + Z - X)^2 + (N - L + X - Y)^2 - 6(M - N)(X - Y) \cos^2 \theta \cos^2 \theta - 6(M - N)(Z - X) \cos^2 \phi - 6(N - L)(X - Y) \cos^2 \theta$$

and

$$45k^2T^2\theta_\mu = \mu^2[(X - Y)(3 \cos^2 \theta - 1) + (Y - Z) + (L - M) + (L - N)] \quad (5)$$

Values of $\Delta\alpha^b = -6.67$, $\Delta\alpha^{CH} = 0.33$, $\Delta\alpha^{CC} = 1.58$, $\Delta\alpha^{C=C} = 3.34 \times 10^{-40} \text{ C}^2\text{m}^2/\text{J}$ for $\lambda = 0.546 \text{ nm}$ have been obtained from depolarized light scattering measurements on liquids and solutions¹⁷. Values $\mu = 1.17$ and $1.24 \times 10^{-30} \text{ C m}$ have been given^{6,18} for styrene dissolved in carbon tetrachloride. Graphs of B_2^*/c_2 versus the phenyl ring rotation angle ϕ are shown in Figure 3 for various values of μ and the $=C$ semi-dihedral angle θ , calculated from equations (1), (3) and (4). The experimental value for styrene of $B_2^*/c_2 = 14.2 \times 10^{-18} \text{ V}^{-2} \text{ m}^3 \text{ kg}^{-1}$ indicates $\phi \approx 45^\circ$. A probable explanation of this result is that $\cos^2 \phi = 0.5$ which indicates free rotation of the phenyl ring relative to the rest of the styrene molecule.

Polystyrene

Figure 4 shows B_2^*/c_2 plotted with M_w^{-1} . The near-independence of B_2^*/c_2 with molecular weight shows that the segmental values of θ_α and θ_μ are also molecular weight independent. This is a justification of the basic assumption in the Stuart and Peterlin theory of a large number of orientationally independent segments per polymer chain. Small tacticity deviations from atactic could explain the slight molecular weight dependence of B_2^*/c_2 , as iso- and syndiotactic chains possess markedly different optical anisotropies¹⁹.

The expression given by Stuart and Peterlin⁵ in their theory of the Kerr effect for flexible polymers may be derived from equation (1) where θ_α and θ_μ refer to segmental properties. They assumed the segment to be a polarizability ellipsoid of revolution about its end-to-end distance

Figure 3 Solute specific Kerr constant versus torsional angle ϕ of phenyl ring in styrene. Units of μ are 10^{-30} C m . A, $\theta = 54^\circ$, $\mu = 1.24$; B, $\theta = 54^\circ$, $\mu = 1.17$; C, $\theta = 57^\circ$, $\mu = 1.17$. ----, measured value of B_2^*/c_2

Figure 4 $(B_2^*/c_2) \times 10^{18}$ versus $(M_w \times 10^{-5})^{-1}$ for polystyrene

and to have a permanent dipole moment parallel to this distance. In polystyrene a dipole moment perpendicular to the segment end-to-end distance is expected from the direction of the moments associated with the phenyl groups. Both cases are covered by writing equation (1) in the form:

$$\frac{B_2^*}{c_2} = \frac{750N_A}{n\epsilon_0\lambda M_0} \left(\frac{\epsilon + 2}{3}\right) \left(\frac{n^2 + 2}{3}\right)^2 \times \left[\frac{2(\alpha_l - \alpha_r)^2}{45kTS} \pm \frac{\mu_s^2(\alpha_l - \alpha_r)}{45k^2T^2S} \right] \quad (6)$$

where α_l and α_r are the polarizabilities parallel and perpendicular to the segment end-to-end distance and μ_s is the segmental dipole moment. M_0 is the monomer unit molecular weight and S the number of monomer units per segment which is a parameter describing chain flexibility. The magnitude of μ_s^2 may be derived from available dielectric data since for the whole polymer chain the dipole moment $\langle \mu^2 \rangle = \Phi N_0 \mu_0^2$, where the angular brackets denote a statistical mechanical average of the chain dipole moment over all possible conformations of the polymer chain. Φ is a conformationally dependent parameter which is characteristic of a particular polymer-solvent pair²⁰ and μ_0 is the monomer unit dipole moment. N_0 and N_s are the number of monomer units and segments respectively per polymer chain. Since $S = N_s/N_0$, μ_s^2 may be written as $S\Phi\mu_0^2$ in equation (6), Φ and μ_0 being 0.65 and 1.17×10^{-30} C m respectively for polystyrene in carbon tetrachloride²⁰.

Flow birefringence measurements²¹ show that $(\alpha_l - \alpha_r)$ is negative. Thus the \pm sign in equation (6) is decided according to whether μ_s is perpendicular (+) or parallel (-) to the segment length. Figure 5 shows B_2^*/c_2 calculated from equation (6) plotted with $(\alpha_l - \alpha_r)$ for several values of S , with μ_s parallel or perpendicular to the segment length.

Values of $(\alpha_l - \alpha_r)$ for atactic polystyrene derived from flow birefringence^{21,22} and depolarized light scattering measurements^{22,24,25} demonstrate a solvent dependence as shown in Table 2. This dependence may have a conformational origin since different solvent-solute interactions

will generally produce different segmental lengths. It may also originate optically since the segmental anisotropy is influenced by angular correlation between monomer units and solvent molecules²⁶. The data in Table 2 represents the possible spread in value of $(\alpha_l - \alpha_r)$. Since $S \approx 8^{22,23}$ Figure 5 shows that there is good agreement between experimental and theoretical values of B_2^*/c_2 when the segmental dipole moment is orthogonal to the segment length. For the segmental dipole moment to be parallel to the segment length then $S \leq 5$ which is well outside the range of acceptability²².

CONCLUSION

The experimental values for the specific Kerr constants of various molecular weight polystyrenes in solution with carbon tetrachloride has been compared with the theoretical result as given by the Stuart and Peterlin theory. Using literature values of segmental parameters such as optical anisotropy, number of monomer units per segment and segmental dipole moment, the experimental and theoretical values of specific Kerr constant agree provided that

Figure 5 Theoretical specific Kerr constant versus segmental anisotropy for polystyrene with values of S : A, A', 6; B, B', 8; C, C', 10; calculated from equation (6). — — —, μ_s parallel to segment; — — —, μ_s perpendicular to segment; · · · · · measured value. The horizontal arrow denotes the spread of experimental $(\alpha_l - \alpha_r)$ values

Table 2 Experimental values of segmental anisotropy at 546 nm

Solvent	$(\alpha_l - \alpha_r) \times 10^{40}$ (C ² m ² /J)	Technique
Bromoform	-16.1	Flow birefringence ^{21,23}
Benzene	-15.0	Flow birefringence ²²
Benzene	-15.0	Light scattering ²²
Methylal	-18.9	Light scattering ²²
Cyclohexane	-17.2	Light scattering ²²
Bromoform	-15.0	Light scattering ²²
Chlorobenzene	-13.3	Light scattering ²⁴
—	-18.9	Strain birefringence ²⁶

the direction of the segmental dipole moment is assumed to be orthogonal to the segment length. We regard this agreement, together with the near-independence of specific Kerr constant upon molecular weight, as indicating the validity of the Stuart and Peterlin segmental model in the molecular weight range examined.

Bond polarizability based rotational isomeric state calculations have been made¹⁹ for polystyrene of the optical anisotropy γ^2 which is equal to $\frac{1}{2}\theta_\alpha$ if dispersion of the bond polarizability parameters is neglected. No similar calculations exist for θ_μ and hence B_μ^*/c_2 and therefore no comparison is yet possible between our experimental results and non-segmental theories of the Kerr effect.

^{13}C n.m.r. spectra of some poly(*N*-acyliminoalkenes)

K. J. Ivin, L. C. Kuan-Essig, E. D. Lillie and P. Watt

Department of Chemistry, The Queen's University of Belfast, Belfast BT9 5AG, UK

(Received 3 March 1976)

^{13}C n.m.r. spectra are reported for six poly(*N*-acyliminoalkenes), $-\{N(\text{COR})(\text{CH}_2)_n\}-$ ($n = 2, \text{R} = \text{H}, \text{CH}_3, \text{C}_6\text{H}_5; n = 3, \text{R} = \text{H}, \text{C}_6\text{H}_5$), and $-\{N(\text{COC}_6\text{H}_5)\text{CH}(\text{CH}_3)\text{CH}_2\}-$ (isotactic and atactic), and compared with that for poly(*N*-formyliminopropylene). These linear polymers were made by the isomerization polymerization of the appropriate oxazoline or oxazine derivatives. For the polymers with *N*-formyl or *N*-acetyl side groups the spectra of the main chain carbons show fine structure resulting from restricted rotation about the two nearest N-COR bonds. This fine structure shows a small temperature dependence and in some cases there are indications of the influence of a third N-COR group at the lower temperatures. For the polymers with *N*-benzoyl side groups the rotation of these groups is less restricted than for *N*-formyl and *N*-acetyl and at 120°C no fine structure is observed except that resulting from tacticity in atactic poly(*N*-benzoyliminopropylene), where the carbonyl and main-chain carbons exhibit partly resolved triad structure. At lower temperatures some of the lines broaden because of restricted rotation. In the model compound *N*-ethyl-*N*-methylbenzamide all eight types of carbon atom give two lines at -30°C (in CDCl_3), the two conformers being present in the approximate ratio 58:42. The pairs of lines coalesce in turn as the temperature is raised to 50°C . Spin-lattice relaxation times were measured for the carbon nuclei in poly(*N*-formyliminoethylene), in *N*-ethyl-*N*-methylformamide and in *N*-isopropyl-*N*-*n*-propylformamide. T_1 values increase by two orders of magnitude in going from the polymer to dimethylformamide. ^{13}C chemical shifts are recorded for seven oxazoline and two oxazine derivatives as well as for six model compounds of the polymers.

INTRODUCTION

It has recently been shown¹ that the $^{13}\text{C}\{^1\text{H}\}$ n.m.r. spectrum of isotactic* poly(*N*-formyliminopropylene)² (I), [poly(*N*-formylpropylenimine)] exhibits fine structure which may be interpreted in terms of restricted rotation about the N-CHO bonds. Each main-chain carbon gives four chemical shifts, according to whether the two nearest formyl groups take up *syn* or *anti*-conformations. However the spectrum of this polymer is complicated by two factors: first, there is overlap between the fine structure for the CH and CH_2 carbons; second, the methyl side group causes unequal populations of *syn* and *anti* conformers.

We now report the spectra of poly(*N*-formyliminoethylene) (II), poly(*N*-formyliminotrimethylene) (III) and poly(*N*-acetyliminoethylene) (IV), where these complications are not present; also the spectra of the *N*-benzoyl analogues of I, II and III namely V, VI and VII respectively, and of some model compounds of the *N*-benzoyl analogues.

EXPERIMENTAL

Polymers II to VII were prepared by the isomerization polymerization of the corresponding oxazoline or 1,3-oxazine derivatives II' to VII', using the cationic initiator and conditions listed in Table 1. ^{13}C shifts for these monomers are recorded in Appendix I. The molecular weights

of these polymers, where estimated from viscosity measurements, were found to be low (1000–10 000), as reported in the literature^{3–7}, but in no case were they so low as to reveal end effects in the ^{13}C n.m.r. spectra.

The sources of the monomers were as follows. II' and III' were prepared by Saegusa's method³ in which the appropriate amino-alcohol is reacted with *t*-butyl isonitrile, in the presence of silver cyanide. IV' was a commercial sample (Aldrich).

* In this paper the term 'tacticity' relates to the sequence of configurations about the asymmetric carbon atoms.

Table 1 Polymerization conditions

Compound number	Monomer	Conditions				Reference
		Initiator ^a	Temperature (°C)	Time (h)	Yield (%)	
II'	Oxazoline	3% A	70	4	65	4
III'	5,6-Dihydro-4H-1,3-oxazine	3% A	120	2	32	5
IV'	2-Methyloxazoline	0.7% A	80	50	~60	6
V'	L-2-Phenyl-4-methyloxazoline	0.6% B	100	18	70	this work
V''	2-Phenyl-5-methyloxazoline	1% C	135	160	30	this work
VI'	2-Phenyloxazoline	5% A	120	3	100	6
VII'	2-Phenyl-5,6-dihydro-4H-1,3-oxazine	4% A	150	3	97	7

^aInitiators: A, dimethyl sulphate; B, perchlorate of monomer; C, *p*-toluenesulphonic acid. (mol %)

V' and V'' were prepared by the following series of reactions:

The final stage in each case was carried out by adding a 50% excess of P₂O₅ to molten XI or XIII, the cooled mass then being treated with 10% sodium hydroxide solution. The product separated as an oil, which was extracted with ether, dried over magnesium sulphate and distilled under reduced pressure. For V' the yield was 25%; b.p. 86°C at 3 mmHg; $[\alpha]_{589}^{21.4} = 60.4^\circ$ (neat); -84.3° (10.8 g/100 cm³ in CHCl₃). ¹H n.m.r. (CDCl₃): δ 1.35 (*d*, 3, CH₃), 3.9–4.7 (*m*, 3, CH₂ and CH), 7.45 (*m*, 3, *m*- and *p*- aromatic H), 7.5 (*m*, 2, *o*-aromatic H). In the presence of 25 mol % of the shift reagent Eu(fod)₃ the two CH₂ and the CH signals were separated: δ 2.25 (*d*, 3, CH₃), 4.7 (*t* or *q*, 1, CH₂), 5.19 (*t* or *q*, 1, CH₂), 5.85 (*m*, 1, CH), 7.47 (*m*, 3, *m*- and *p*- aromatic H), 8.8 (*m*, 2, *o*- aromatic H). The geminal splitting constant was 9 Hz and the two vicinal constants 7.5 and 8.0 Hz. Infra-red absorption bands: 1650 cm⁻¹ (>C=N-) and 1260 cm⁻¹ (-C-O-C). This compound appears not to have been prepared before.

For V'' the yield was 61%, b.p. 95°C at 0.5 mmHg; picrate, yellow needles m.p. 166°–167°C. ¹H n.m.r. (CDCl₃): δ 1.4 (*d*, 3, CH₃), 3.85 (*m*, 2, CH₂), 4.77 (*m*, 1, CH), 7.43 (*m*, 3, *m*- and *p*- aromatic H), 7.95 (*m*, 2, *o*- aromatic H). In the presence of 79 mol % of the chiral shift reagent Eu(tfc)₃ only the methyl signal was split as the result of the presence of the two enantiomers. Downfield shifts were observed as follows: CH₂ (3.0), CH (2.1) and *o*- aromatic H (1.9), CH₃ (1.0), *m*- and *p*-H (0.07 ppm).

VI' was prepared as described by Matsuda and Kagiya⁸. VII' was prepared by cyclodehydration of *N*-(3-hydroxypropyl) benzamide using phosphorus pentoxide, as for the preparation of V' and V''. The benzamide derivative was prepared by reaction of benzoyl chloride with propanolamine.

The yield of VII was 25% based on propanolamine; b.p. 72°C at 0.05 mmHg.

N-methylbenzamide and *N,N*-dimethylbenzamide were commercial samples. *N*-ethyl-*N*-methylbenzamide was prepared by Fones' method¹⁰, starting from *N*-methylbenzamide and reacting it first with sodium hydride and then with ethyl iodide; m.p. 25°C.

¹³C n.m.r. spectra were obtained with a WH90 Bruker spectrometer operating at 22.63 MHz in the pulsed Fourier transform mode, with decoupling from protons by broadband irradiation. The free induction decay was recorded at 8K points, transforming to a spectrum with 4K (4096) points. For aqueous (D₂O) solutions dioxane was added as a reference signal, its chemical shift being taken as 69.15 ppm relative to TMS; this value is somewhat arbitrary, being slightly dependent (± 1 ppm) on the medium. For solutions in DMSO-*d*₆, the chemical shift of the centre line of the solvent was taken as 39.67 ppm relative to TMS. For solutions in CDCl₃, chemical shifts were measured directly relative to TMS. Other details are given with each spectrum. Differences in chemical shifts have a precision of ± 0.02 ppm when determined using a sweep width of 2000 Hz.

*T*₁ measurements were carried out using the 180°- τ -90° pulse method and a built-in computer programme giving a least-squares fit to the equation $\ln(1 - A/A_\infty) = \tau/T_1 + \ln 2$. *A*_∞ was determined using a delay time of at least 5*T*₁. Values of *T*₁ were calculated from both areas and intensities and an average value taken.

RESULTS AND DISCUSSION

Poly(*N*-formyliminoethylene) II

The spectrum shown in Figure 1 is for a solution in D₂O at 35°C. The carbonyl carbon gives a single peak at 168.3 ppm. The main-chain carbons give two pairs of peaks, at 47.90 and 47.06, and at 42.77 and 41.86 ppm, which may be assigned to the four possible situations depicted in the following chain (see Figure 1).

The symbols α_s , α_a denote whether the carbon atom is *syn* (*s*) or *anti* (*a*) to the oxygen atom of the formyl group attached to the α -nitrogen atom; similarly for β_s , β_a . The chemical shift differences, $\alpha_a - \alpha_s$, etc. are as expected from small molecules¹ (see Table 4). The total probability of finding a carbon in the $\alpha_o \beta_s$ or $\alpha_a \beta_a$ situation is equal to

Figure 1 ¹³C{¹H} n.m.r. spectrum of $\text{-(N(CHO)CH}_2\text{CH}_2\text{)-}$. 20% solution in D₂O at 35°C. 16320 scans, sweep width 6024 Hz, acquisition time 0.679 sec, pulse width 6 μsec

that of finding it in the $\alpha_s\beta_s$ or $\alpha_s\beta_a$ situation, but the individual probabilities can only be equal either if the formyl groups are randomly oriented or if they take up certain non-random sequences of orientations. An attempt was made to determine the individual probabilities as follows. The spin-lattice relaxation times were first determined using a set of ten τ values between 0.05 and 10.0 sec, with the following results: CHO 0.4 ± 0.2 sec; CH₂ $\alpha_a\beta_a$ 0.3 ± 0.1 sec, $\alpha_a\beta_s$ 0.2 ± 0.1 sec, $\alpha_s\beta_a$ 0.15 ± 0.05 sec, $\alpha_s\beta_s$ 0.25 ± 0.1 sec. The limits of error cover the values of T_1 determined separately from both areas and peak heights. No significant difference between the T_1 values for the main-chain carbons was detected. With gated decoupling and a delay time of 30 sec between pulses the intensity pattern was not greatly changed although one would have expected a symmetrical intensity pattern to emerge ($\alpha_a\beta_s = \alpha_s\beta_a$; $\alpha_a\beta_a = \alpha_s\beta_s$) as a result of elimination of nuclear Overhauser and T_1 effects. The spectrum obtained without decoupling and with a time delay of 4 sec showed too much overlap of the fine structure ($J_{\text{CH}} = 140$ Hz, $J_{\text{CHO}} = 202$ Hz) for a clearcut answer to be obtained but was not inconsistent with equal populations of $\alpha_a\beta_a$, $\alpha_a\beta_s$, $\alpha_s\beta_a$ and $\alpha_s\beta_s$ structures.

Raising the temperature to 80°C caused a downfield shift for the main-chain carbons, the downfield pair moving by about 0.2 ppm and the upfield pair by about 0.4 ppm, i.e. a net decrease in $\alpha_a - \alpha_s$; at the same time the peaks sharpened a little. The converse effect was found on cooling to 5°C, and between 15° and 5°C the fine structure due to the β -splitting disappeared. This effect is presumably connected with an increasing ease of rotation about the main-chain bonds as the temperature is raised.

Poly(N-formyliminotrimethylene) III

The spectrum shown in Figure 2 is for a solution in D₂O at 80°C. The carbonyl carbon gives a single peak at 167.7 ppm. Main-chain carbons adjacent to nitrogen show two pairs of peaks as for II, but the secondary splitting is now smaller since it arises from the conformation of the formyl group attached to the γ -nitrogen. If $\gamma_a - \gamma_s$ is negative, as in *N*-isopropyl-*N*-*n*-propylformamide¹, the line order is (downfield to upfield) $\alpha_a\gamma_s$, $\alpha_a\gamma_a$, $\alpha_s\gamma_s$, $\alpha_s\gamma_a$. The

chemical shift differences $\alpha_a - \alpha_s$ etc. are as expected from small molecules (see Table 4).

The central methylene carbons give the expected 1:2:1 pattern with the assignments indicated on Figure 2 and the formula below.

The $\beta_a - \beta_s$ values are of the magnitude expected¹ (see Table 4).

On reducing the temperature all the peaks move slightly upfield (relative to dioxane), but while the upfield pair of α_s peaks remain well resolved, even at 3°C, the downfield pair of α_a peaks at first show signs of further fine structure, imperfectly resolved at 30°C, which then merges into a single broad peak at 3°C. This suggests that at low temperature the main-chain takes up a conformation which brings a third nitrogen close enough to the α_a carbon so that the conformation of the formyl group about this nitrogen can influence the chemical shift by a through-space effect. The sort of structure which might be involved is indicated below, the relevant carbon atom being underlined. Why this effect should not operate for both α -carbons is not clear, though possibly highly significant.

The intensity distribution in the fine structure is consistent with a random orientation of the formyl groups (compare with polymer II).

Figure 2 ¹³C{¹H} n.m.r. spectrum of $\text{-(N(CHO)CH}_2\text{CH}_2\text{CH}_2\text{)-}$. 10% solution in D₂O at 80°C. 29530 scans; other conditions as in Figure 1

Poly(N-acetyliminoethylene) IV

The spectrum shown in Figure 3 is for a solution in D₂O at 35°C. The carbonyl carbons give a single peak at 176.6 ppm; the methyl carbons also give a single peak, at 22.75 ppm. The methylene carbons give four peaks, with the upfield pair sharper and better resolved than the downfield pair. The assignments are as for II, with methyl replacing hydrogen. There is good reason^{11,12} to believe that the upfield pair corresponds to methylene *syn* to carbonyl, as in II. The differences $\alpha_a - \alpha_s$ are smaller than in the corresponding formamide, again as expected from small molecules¹¹; (see Table 4). It is notable that the average chemical shift for CH₂ in the acetyl compound IV is 3 ppm downfield compared with the formyl compound II and this again parallels the behaviour of model compounds¹³. Any additional steric effect caused by the introduction of the methyl group (which might have caused an upfield shift) is evidently outweighed by an electronic effect.

On raising the temperature to 80°C all the methylene peaks move about 0.3 ppm downfield relative to dioxane but the methyl peak is unaffected. In contrast to II the resolution of the downfield pair of methylene peaks did not improve.

Miron and Morawetz¹⁴ observed that in the ¹H n.m.r. spectrum of IV the methylene protons showed no splitting but the acetyl protons were split into two lines separated by 7 Hz, coalescing at 79°C. A higher temperature would be needed to cause coalescence of the β -splitting (18–26 Hz) in the CH₂ spectrum or of the α -splitting (62–70 Hz).

Poly(N-benzoyliminoethylene) VI

In DMSO-*d*₆ at 120°C single sharp lines were obtained for each carbon: CO, 170.43; C₁ (aromatic) 135.79; C₄, 128.71; C_{2,3}, 127.73, 125.78; CH₂ 44.41 ppm. The absence of fine structure indicates that at 120°C rotation about the N–CO bond is fast on the n.m.r. time scale (>100 Hz) and faster for N–COPh than for N–CHO. This accords with the observed behaviour of small molecules containing these groupings¹⁵; the conjugated PhCO system evidently reduces

Figure 3 ¹³C{¹H} n.m.r. spectrum of $[-N(COCH_3)CH_2CH_2-]$. 30% solution in D₂O at 35°C. 2500 scans; other conditions as in Figure 1

the double-bond character of the N–CO bond. In CDCl₃ at 55°C the peaks remain sharp except for the main-chain carbon which splits into two broad peaks separated by about 3 ppm. At 5°C the aromatic peaks have broadened to the extent that the middle two have merged. This behaviour indicates that for the individual conformations about the N–CO bond the largest chemical shift difference occurs for the main-chain carbons, as expected.

Poly(N-benzoyliminotrimethylene) VII

In DMSO-*d*₆ at 120°C single sharp lines were obtained for each carbon, in the following positions: CO, 170.11; C₁, 136.70; C₄, 128.32, C_{2,3}, 127.67, 125.65; α CH₂, 43.76; β CH₂, 26.35 ppm. Again the rotation about the N–CO bond is fast on the n.m.r. time scale. In CDCl₃ at 32°C the α CH₂ signal is split into two broad peaks separated by about 4.5 ppm, the upfield peak showing secondary splitting of about 0.7 ppm. The β CH₂ signal is broadened into an incipient triplet but the aromatic and carbonyl peaks remain sharp. The behaviour is thus akin to that of poly(N-formyliminotrimethylene) (Figure 2) but with much lower coalescence temperatures.

*Poly(N-benzoyliminopropylene) V and V**

The spectrum of the isotactic polymer V* in DMSO-*d*₆ at 120°C is shown in Figure 4a. Single lines are observed for each carbon, with slight broadening of the main-chain carbon peaks. At room temperature all the lines are broadened, the main-chain carbons being barely distinguishable above the base line. The effect of temperature is similar to that for VI and VII. The spectrum for the atactic polymer in DMSO-*d*₆ at 120°C is shown in Figure 4b. Fine struc-

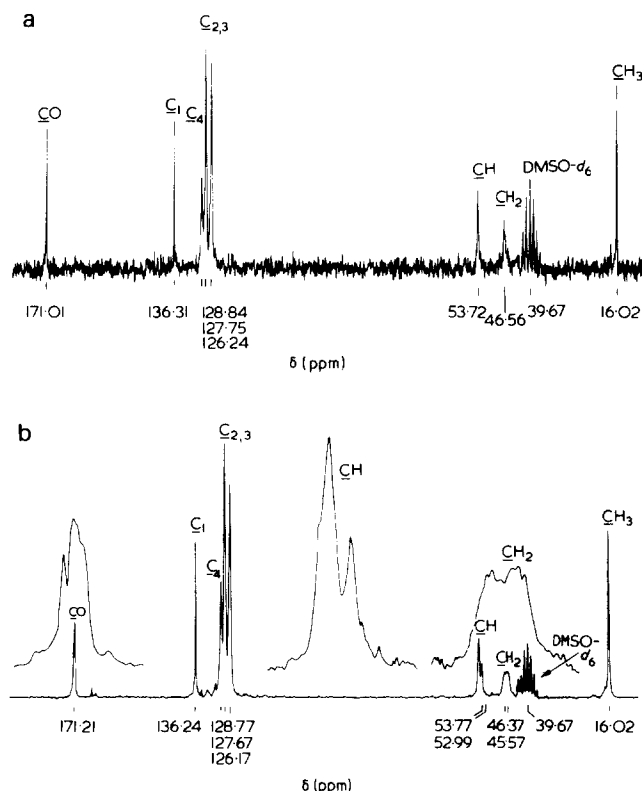

Figure 4 ¹³C{¹H} n.m.r. spectrum of $[-N(COC_6H_5)CH(CH_3)CH_2-]$ (a) Isotactic polymer, 20% in DMSO-*d*₆ at 120°C. 4000 scans; other conditions as in Figure 1. (b) Atactic polymer, 40% in DMSO-*d*₆ at 120°C. 82826 scans; other conditions as in Figure 1. The CO, CH and CH₂ regions are also shown in expanded form

ture may be seen for the CO, CH and CH₂ resonances and this must arise from tacticity effects with respect to the main-chain carbons (CH). The relative intensities may be interpreted in terms of a completely atactic structure with the groupings of lines and tentative assignments to dyad structures shown in Table 2. The *mm* (isotactic) assignments may be made with reasonable certainty, since there is agreement of the aromatic peak positions in Figures 4a and 4b within one channel (0.06 ppm). The rest are made by assuming a gradation of chemical shifts from *mm* to *rr* as normally found in polymers. The direct detection of triad structure in this polymer is made possible by the rapid rotation of the benzoyl groups at 120°C. This is in contrast to poly(*N*-formyliminopropylene) where it was necessary first to remove the formyl groups by hydrolysis before tacticity could be determined^{1,9}. An attempt was made to hydrolyse V for the same purpose but this did not prove successful.

Benzamide derivatives as model compounds of V, VI and VII

The spectra of *N*-methylbenzamide (XIV), *N,N*-dimethylbenzamide (XV), and *N*-ethyl-*N*-methylbenzamide (XVI), were examined. In CDCl₃ or DMSO-*d*₆ XIV showed a single set of sharp lines at all temperatures from -40° to 100°C, probably indicating the presence of a single conformer with CO-NH in the *anti* (*trans*) conformation¹⁵. For XV in DMSO-*d*₆ or CDCl₃ two broadened methyl peaks are observed at 33°C, separated by 91 Hz, which collapse into one sharp peak at 100°C. A coalescence temperature of about 36°C may be predicted from the ¹H n.m.r. spectrum¹⁶.

The spectrum of XVI in CDCl₃ at -30°C is shown in Figure 5. Every carbon atom gives two peaks of unequal intensity. The line positions, separations and approximate coalescence temperatures are shown in Table 3. Assignments to NCH₂ and NCH₃ were made by an off-resonance experiment. The relative intensities were derived from the print-out of areas. A plot of log Δδ against the reciprocal of the coalescence temperature gives a line whose slope corresponds to an activation energy of about 48 kJ/mol (11.5 kcal/mol), somewhat lower than the barrier reported¹⁶ for *N,N*-dimethylbenzamide (14.0 ± 0.25 kcal/mol). The variation in the relative intensities of the pairs of peaks from carbon to carbon is caused by differential nuclear Overhauser effects and differential spin-lattice relaxation times. The average intensity ratio for the eight pairs is 58:42 which is probably close to the actual relative populations of the two conformers. In order to make the assignment to the individual conformers we must make the same assumption as that for IV, namely that the upfield NCH₃ and NCH₂ peaks correspond to a *syn* conformation with

Figure 5 ¹³C{¹H} n.m.r. spectrum of C₂H₅N(COC₆H₅)CH₃. 50% solution in CDCl₃ at -30°C. 512 scans, acquisition time 0.679 sec, post-delay 2 sec, pulse width 11 μsec. In original spectrum each carbon shows 2 distinct lines

respect to the carbonyl oxygen¹ i.e.

The $\alpha_a - \alpha_s$ values are then as shown in Table 4.

Summary of ¹³C chemical shift differences for *syn* and *anti* conformations

The various values which we have determined are brought together in Table 4. It should be noted that $\alpha_a - \alpha_s$ for NCH₃ in *N*-ethyl-*N*-methylformamide was originally assigned a negative value¹. A further experiment using gated decoupling, with a delay time of 75 sec between pulses, has shown that this assignment was incorrect and that $\alpha_a - \alpha_s$ for NCH₃ has in fact a positive value. The spin-lattice relaxation times of the *syn* and *anti* carbons are substantially different and of such a magnitude (see below) that if the spectrum is taken with a short delay time between pulses the relative intensity of the two lines is reversed. The proportions of the two conformers determined from the gated decoupling experiment were 62% and 38%, good agreement being found for the four pairs of lines.

¹³C spin-lattice relaxation times in *N*-isopropyl-*N*-*n*-propylformamide and *N*-ethyl-*N*-methylformamide

For the former these were determined using a 50% solution in D₂O at 35°C. Fourteen sets of data were accumulated, with delay times τ ranging from 0.1 to 6.0 sec. For the latter, 7 sets of data were accumulated with delay times ranging from 1 to 75 sec for a 50% solution in CDCl₃ at 35°C. The results are shown below and compared with published results on dimethylformamide and di-*n*-butylformamide¹³, as well as with those reported above for poly(*N*-formyliminoethylene).

The assignment of the γ -carbons in *N,N*-di-*n*-butylformamide is the reverse of that given in the original paper in order to make $\gamma_a - \gamma_s$ negative as seems more likely - see earlier discussion. It is interesting to note that in *N*-isopropyl-*N*-*n*-propylformamide the relaxation times in the less abundant conformer are mostly longer than those in

the more abundant conformer, suggesting that the less abundant form can take up a more spherical and faster-rotating shape. There is the usual decrease in T_1 as one proceeds from the end to the centre of a short-chain molecule, and also as one goes from small to large molecules. The low T_1 values for the carbon nuclei in the polymer indicate a chain length high enough for the values of T_1 to be determined by the rate of rotation of segments of the chain.

CONCLUSIONS

The ¹³C n.m.r. spectra of all the polymers are as expected from the spectra of simple N-substituted formamides, acetamides and benzamides. Fine structure arises in two ways: first, because of restricted rotation about N-COR bonds; and second, when asymmetric carbons are present, from tacticity effects. The former is always present when R = H or CH₃ (up to 80°C) but can be eliminated when R = C₆H₅ by the use of a sufficiently high temperature (120°C). The

effect of restricted rotation about the N-COR bond is largest for the α-carbon, less for the β-carbon but still significant for the γ-carbon. In the polymers the chemical shifts for the main-chain carbons were governed by the conformation about the two nearest N-COR bonds, with a slight influence of a third, more remote, NCOR group in some cases. For poly(N-benzoyliminopropylene) the tacticity effect can be studied by itself by working at 120°C, but for poly(N-formyliminopropylene) this is not possible and the polymer must first be hydrolysed⁹.

ACKNOWLEDGEMENTS

We thank the Science Research Council for a postdoctoral fellowship (LCK), and Dr L. C. Waring (Belfast) and Dr I. A. Stenhouse (PCMU Harwell) for the ¹³C n.m.r. spectra.

Note added in proof

With improved resolution the spectrum of II (Figure 1) shows fine structure of the carbonyl peak (two lines of equal intensity) and splitting of each of the α_sβ_a and α_sβ_s lines into two equal components (cf. behaviour of α_aβ_a, α_aβ_s peaks of III). In the ¹H 220 MHz spectrum of II in D₂O at 22°C the formyl proton also shows fine structure (three lines, just resolved, spanning 0.03 ppm); the methylene protons give a single peak.

APPENDIX I

Table A1 ¹³C n.m.r. shifts for some oxazolines and 5,6-dihydro-4H-1,3-oxazines, ppm relative to TMS. Solvent CDCl₃, 35°C

^aValues in D₂O taking dioxane as 69.15 ppm

Note 1

Monomer XVII' was prepared by Saegusa's method³ from 2-amino-2-methylpropan-1-ol. Its polymerization was attempted but the product appeared to be oligomeric as judged from its n.m.r. spectrum. The monomer has previously been prepared by another method¹⁷.

Note 2

Three features of the spectra of the aromatic derivatives V', V'' and VI' are of particular interest. The first is the coincidence of the chemical shifts for C_{1'} and C_{4'} in all three cases. Second is the coincidence or near-coincidence of the chemical shifts for C_{2'} and C_{3'} in all three cases. Third is the second order splitting effect observed in off-resonance experiments for C₄ and C₅ in both V' and VI'; also for C_{1'} in all three compounds.

Note 3

The usual rules concerning the effects of substituents on the shifts are obeyed, as exemplified below:

Table A2

		α shift		β shift	
II'	→	I'	C ₄ 7.0	C ₅	6.4
VI'	→	V'	C ₄ 7.1	C ₅	6.6
VI'	→	V''	C ₅ 8.7	C ₄	6.6
I'	→	XVII'	C ₄ 5.7	C ₅	5.1
				C ₆	7.0

APPENDIX II

Summary of ¹³C n.m.r. shifts for poly(N-acyliminoalkenes) and model compounds

For ease of reference these shifts are summarized here, giving only *average* values for those cases where there is fine structure resulting from restricted rotation or tacticity.

Shifts are in ppm relative to TMS, using the following sub-standards where necessary: dioxane (in D₂O), 69.15; DMSO-*d*₆ 39.67; TSP (in D₂O), 0.

Table

Compound number	Polymer formula	Chemical shift	Solvent	Compound number	Model formula	Chemical shift	Solvent
II		a 44.9 b 168.3	D ₂ O/30°C	XVIII		a 33.7 b 162.4	CDCl ₃ /30°C
I		a 19.0 b 49.1 c 56.2 d 168.4	D ₂ O/33°C	XIX		a 11.4 b 21.6 c 23.1 d 43.8 e 48.4 f 162.4	CDCl ₃ /40°C
III		a 28.1 b 45.2 c 167.7	D ₂ O/80°C	XX		a 13.3 b 32.2 c 42.5 d 163.2	CDCl ₃ /35°C
IV		a 22.8 b 47.7 c 176.6	D ₂ O/35°C	XXI		a 21.5 b 36.4 c 170.2	CDCl ₃ /40°C
VI		a 44.4 b 125.8 c 127.7 d 128.7 e 135.8 f 170.4	DMSO/120°C	XV		a 37.3 b 127.0 c 128.2 d 129.4 e 136.4 f 171.4	CDCl ₃ /32°C
V		a 16.0 b 46.0 c 53.6 d 126.2 e 127.7 f 128.8 g 136.1 h 171.2	DMSO/120°C	XVI		a 12.9 b 34.1 c 44.2 d 126.4 e 128.3 f 129.3 g 136.3 h 171.2	CDCl ₃ /-30°C
VII		a 26.4 b 43.8 c 125.7 d 127.7 e 128.3 f 136.7 g 170.1	DMSO/120°C				

The usual rules concerning the effect of substituents are again obeyed, as exemplified below:

II	-	I	CH α shift	= 11.3
			CH ₂ (β + γ) shift	= 4.2
II	→	IV	CO α shift	= 8.3
XVIII	→	XXI	CO α shift	= 7.8
VI	→	V	CH α shift	= 9.2
			CH ₂ (β + γ) shift	= 1.6
XVIII	→	XX	CH ₂ α shift	= 8.8
			CH ₃ γ shift	= -1.5

It is also a general rule that the chemical shifts are higher for the aliphatic carbons in the polymers than in the corresponding model compounds. This may be regarded as a consequence of progressive substitution to form the long chains.

Comparison of the dielectric and viscoelastic properties of two poly (propylene glycol) liquids

Turhan Alper, A. John Barlow and R. Walter Gray

Department of Electronics and Electrical Engineering, University of Glasgow, Glasgow G12 8QQ, UK
(Received 22 January 1976; revised 15 March 1976)

The complex relative permittivities of two poly(propylene glycol) liquids, of molecular weights 380 and 3030, have been determined. Measurements were made in the frequency range 60 Hz to 200 MHz and at temperatures from -64° to $+25^{\circ}$ C. The lower molecular weight liquid showed only one relaxation region, which could be described by the Williams–Watts function with $\beta = 0.51$. The higher molecular weight liquid exhibited a similar main relaxation region and a secondary relaxation, of smaller amplitude, at lower frequencies. The relaxation times and their temperature dependencies are compared with previously determined viscoelastic relaxation and retardation times for the same liquids, and with the results from earlier dielectric studies by Baur and Stockmayer, and by Williams. The differences between the dielectric and mechanical times are discussed.

INTRODUCTION

A previous article¹ described the viscoelastic behaviour of two poly(propylene glycol) liquids, designated P400 and P4000. In general, the complex compliance, $J^*(j\omega)$, of a liquid may be described by:

$$J^*(j\omega) = J'(\omega) - jJ''(\omega) = J_{\infty} + 1/j\omega\eta + J_r^*(j\omega)$$

where J_{∞} ($= 1/G_{\infty}$) is the limiting high frequency compliance, ω the angular frequency of the applied shearing stress, η the steady flow viscosity and $J_r^*(j\omega)$ the complex retardational compliance. The product $J_{\infty}\eta$ is commonly termed the Maxwell relaxation time τ_M . For both poly(propylene glycol) liquids, J_r^* could be described by equation:

$$J_r^*(j\omega) = J_1(\omega) - jJ_2(\omega) = J_r/(1 + j\omega\tau_r)^{\beta}$$

which is analogous to the equation:

$$\epsilon_r^*(j\omega) = (\epsilon_0 - \epsilon_{\infty})/(1 + j\omega\tau_D)^{\beta D}$$

used by Davidson and Cole² in their studies of dielectric relaxation. For P400, the lower molecular weight liquid, ($M_n \sim 380$), the retardational compliance $J_r = 17.4 J_{\infty}$, the parameter $\beta = 0.45$ and the characteristic retardation time τ_r increased with decreasing temperature, reaching a limit of $170 \tau_M$ near 0° C. The viscoelastic behaviour of P400 is similar to that of many non-polymeric organic liquids. For the higher molecular weight liquid, P4000 ($M_n \sim 3030$), the viscoelastic properties were described by the same equation but with $J_r = 85 J_{\infty}$, $\beta = 0.76$ and $\tau_r = 15.4 \tau_M$, remaining constant at least over the temperature range from $+79.5^{\circ}$ to 0° C.

The dielectric behaviour of poly(propylene glycol) liquids has been investigated by several authors. In particular, Baur and Stockmayer³ investigated four liquids of nominal (number-average) molecular weights from 1025 to about 3700, and Williams⁴ has studied an amorphous sample of high molecular weight, $M_n > 10^5$. Other prop-

erties of high molecular weight material have also been determined and have been summarized by McCrum, Read and Williams⁵.

The present work supplements previous studies of dielectric properties by extension of the measurement range to lower molecular weights and to higher frequencies. In addition, since the samples P400 and P4000 used are the same as employed before¹, a quantitative comparison of the viscoelastic retardation and dielectric behaviour is possible.

EXPERIMENTAL

Details of the P400 and P4000 liquids used have been given previously¹. Measurements of the complex relative permittivity, $\epsilon^* = \epsilon' - j\epsilon''$, were made in two frequency ranges, 60 Hz to 200 kHz and 3 to 200 MHz, using conventional bridge techniques. In the lower frequency range a transformer ratio arm capacitance bridge was used, (General Radio, Model 1615A), with a matching generator and detector, together with a two terminal cell. Measurements were made with the cell immersed in a constant temperature bath. The estimated errors in the measurements made using this system are $\pm 1\%$ in ϵ' and $\pm 2\%$ in ϵ'' up to 10 kHz, above this frequency the accuracy decreases slightly. In the higher frequency range an R–X meter was used, (Hewlett Packard Type 250B) with a coaxial cell of capacitance (when empty) of 1.1 pF. The calibration of this cell was checked using liquids of known permittivities. The experimental errors in measurements made up to 100 MHz are estimated to be $\pm 1\%$ in capacitance and $\pm 3\%$ in conductance. Above 100 MHz the accuracy achieved was less because of the distributed impedance of the strips connecting the cell to the meter. The readings were corrected assuming a simple lumped circuit model for the connections. For this cell temperature stabilization was ensured by circulating a liquid at the desired temperature through a jacket around the cell. Temperatures were determined using platinum resistance thermometers and are estimated to be accurate to within $\pm 0.05^{\circ}$ C. Measurements in the high frequency range were made of P400 at temperatures from $+20^{\circ}$ to -22.8° C, and of P4000 from $+16.3^{\circ}$ to -64° C.

A few measurements were also made of a third poly(propylene glycol) liquid, P2000, which was obtained from the same source and processed in the same manner as the other two liquids¹. This liquid has a nominal (number-average) molecular weight of 2000. The dielectric behaviour of this liquid was found to be intermediate between that of P400 and P4000, and showed evidence of two relaxation processes which, however, were not sufficiently separated to allow useful analysis. Accordingly, measurements were limited to the low frequency region and to the temperature range +9.9° to -56°C.

RESULTS AND ANALYSIS

The data were sufficient to define the low frequency limit ϵ_0 for P400 over the range +20° to -61°C, and ϵ_0 for P4000 from +20° to -20°C. The results are shown in Figure 1, together with the variation of ϵ_0 found for other poly(propylene glycol) materials by Baur and Stockmayer³ and by Williams⁴. The high frequency limit ϵ_∞ for P400 was also defined in the range -22° to -61°C, the variation was linear and values at higher temperatures have been obtained by extrapolation.

Considering first P400, at each temperature the component ϵ'' was normalized with respect to its maximum value ϵ''_{\max} , and plotted as a function of $\omega\tau_\alpha$, where τ_α is the reciprocal of the angular frequency at the peak of the ϵ'' curve. The data reduced to a single curve as shown in Figure 2. Similarly, the ϵ' data were plotted as $(\epsilon' - \epsilon_\infty)/(\epsilon_0 - \epsilon_\infty)$ and combined to a single curve by shifting. Figure 3 shows the result plotted in terms of $\omega\tau_\alpha$. The temperature dependence of τ_α is given in Figure 4. For comparison with the viscoelastic retardation behaviour, the time τ_f , defined as the reciprocal of the angular frequency at the peak of the $J_2(\omega)$ curve, is also given in this Figure. A plot of $\epsilon''/(\epsilon_0 - \epsilon_\infty)$ against $(\epsilon' - \epsilon_\infty)/(\epsilon_0 - \epsilon_\infty)$, combining results obtained at three temperatures, is shown in Figure 5.

For P4000, the results showed the presence of two relaxation processes, as found by Baur and Stockmayer³ for a similar liquid. The minor secondary or β -peak of ϵ'' , occurring at lower frequencies than the α -peak, was suffi-

ciently small and separated from the main α -peak to allow comparison of the α -peak with the single process found for P400. Figure 6 shows $\epsilon''/\epsilon''_{\max}$ for P4000 as a function of $\omega\tau_\alpha$. At the lowest frequencies the data for ϵ'' showed a frequency dependent loss attributable to d.c. conductivity and the results given in Figure 6 have been corrected for this effect; the corrections were significant only in the region $\log_{10} \omega\tau_\alpha < -3.5$. The data defining the main peak reduce to the same curve as found for P400. Accordingly,

the ratio of ϵ''_{\max} for the α -relaxation to the permittivity ϵ_α contributed by this process to ϵ_0 has been assumed to be the same, 0.283, as $\epsilon''_{\max}/(\epsilon_0 - \epsilon_\infty)$ for P400. ϵ_α can then be determined and deducted from ϵ_0 to give the sum of ϵ_∞ and ϵ_β , the permittivity for the secondary relaxation.

The ϵ'' curves for the secondary process are not well defined experimentally, they are similar to those obtained by Baur and Stockmayer³. They imply a distributed, but narrow, relaxation spectrum. The best estimate of the maximum value of ϵ'' for the β -process to ϵ_β is 0.4. If this ratio is assumed constant, then ϵ_β may be determined and hence ϵ_∞ . Figure 7 shows the temperature dependence of ϵ_0 , ϵ_α , ϵ_β and ϵ_∞ for P4000, the variation of ϵ_∞ deduced in this manner is linear and the extrapolated value at -64°C is in good agreement with the only measured value for this liquid. The ratio $\epsilon_\alpha/\epsilon_\beta$ is approximately 8, the corresponding value for P2000 is about 18.

The time τ_α and τ_β defined by the main and secondary peaks of the ϵ'' curves for P4000 have also been determined and are included in Figure 4.

Figure 6 Values of $\epsilon''/\epsilon''_{\max}$ plotted against $\log_{10} \omega\tau_\alpha$ for P4000: \circ , -51.5°C ; X , -45.7°C ; \square , -42.2°C ; $+$, -37.0°C ; Δ , -33.0°C ; ∇ , -31.0°C ; \blacksquare , -10.0°C . $---$, the corresponding variation for P400

DISCUSSION

The results (Figure 1) for P400 and P4000 confirm the previous findings of a decrease of ϵ_0 , and its temperature dependence, with increasing molecular weight. Stockmayer and Burke⁶ note that for both linear and branched poly(propylene oxide) ϵ_0 is an almost linear function of hydroxyl content. This is substantiated by the present results, a plot of ϵ_0 against $1/M_n$ is fitted by a straight line within the experimental error limits of molecular weight determination, e.g. at -20°C , $\epsilon_0 = 5.35 + 2220/M_n$. Plots of ϵ_0 against molecular weight or its inverse therefore provide a means of checking relative molecular weights. For P4000, M_n is clearly less than that of the *HMW* sample of Baur and Stockmayer³, for which $M_n \approx 3700$, and the measured value of $M_n \approx 3030$ is compatible with previous results to within about 10%.

Figures 2 and 3 show that the normalized dielectric relaxation curves for $\epsilon''/\epsilon''_{\text{max}}$ and $(\epsilon' - \epsilon_\infty)/(\epsilon_0 - \epsilon_\infty)$ are similar to those found by Williams⁴ for a very high molecular weight polymer. Although Baur and Stockmayer³ comment that the relaxation region broadens with increasing molecular weight there is no difference, within the limits of experimental accuracy, between their results and the present ones for P400 (and for P4000), and only a small increase in the width of the relaxation region as M_n increases to more than 10^5 . The plot of Figure 5 shows a skewed curve, which is not fitted by a Davidson–Cole² distribution of relaxation times – the best fit varying from $\beta = 0.39$ at high frequencies to 0.35 or less at low frequencies. However, the results can be described by the Williams–Watts function⁷, which is defined by the dielectric decay function $\gamma(t) = \exp(-t/\tau_0)^\beta$, where $0 < \beta \leq 1$ and τ_0 is a relaxation time. For P400, the data are fitted within the limits of experimental error by the corresponding frequency – dependent complex permittivity with the parameter $\beta = 0.51$. Williams, Watts, Dev and North⁸ have previously noted that this function describes the dielectric relaxation of a very high molecular weight poly(propylene oxide)⁴, and of the principal relaxation region of several other polymers. The main (α) relaxation process for P4000 (Figure 6) is the same as for P400, and is independent of molecular weight. Figure 4 and Table 1 show that at a given temperature the relaxation times, τ_α , for P4000 and P400 are the same; the value differs only slightly from that found by Williams⁴ for the polymer of $M_n > 10^5$. This similarity of the values of τ_α is accompanied by a comparable lack of dependence of the glass transition temperature T_g on molecular weight in the range 400 to $>10^5$, the values of T_g being within a few degrees of -75°C . The same physical process is clearly involved in the different

polymers, and local segmental motion of the polymer chain has been suggested³. Since τ_α for P400, with only 5 repeat units, is the same as for longer chain polymers, then any particular segmental motion must involve very few bonds, otherwise end effects would have a significant influence. Rather than making any such specific ascription, it is more realistic to regard the form of the α -relaxation as a general characteristic of the co-operative nature of local rearrangements⁹, and due to intermolecular rather than intramolecular movements.

For P400, the proportion of the relaxing permittivity due to end-groups is relatively large, yet their contribution to the relaxation process is in no way different from that of main chain elements. Johari and Goldstein¹⁰ and others¹¹, have pointed out the general similarity of the α -relaxation in amorphous polymers and in supercooled, small molecule liquids. The present results for P400 provide direct confirmation, within the same molecular species, of a common process being responsible; P400 may be regarded either as a very short chain polymer or more realistically, as a supercooled liquid with dielectric and viscoelastic properties similar to those of a non-polymeric liquid¹¹. In this context, it may be noted that the value $\beta = 0.51$, in the Williams–Watts function describing the α -relaxation, defines a stress relaxation curve which is very similar to that predicted theoretically from a relaxation model based upon a defect-diffusion mechanism^{12,13}.

The secondary dielectric dispersion in poly(propylene oxide) has been attributed by Baur, Burke and Stockmayer^{3,6} to the cumulative effect along the chain of the dipole moment (0.18 *D*) of each repeat unit. Since polymerization occurs by head-to-tail additions to the chain, more or less symmetrically about an initiator site, the resultant polarization has a (+ ··· · – ··· · +) form. The measured dielectric relaxation time of the secondary dispersion, its temperature variation and dependence on molecular weight were found to be similar to the corresponding properties of the second normal mechanical relaxation mode of the chain, calculated using the assumption of free-draining conditions as proposed by Rouse¹⁴. However, the apparently satisfactory numerical agreement with the Rouse theory is subject to some reservations. Firstly, the secondary dielectric dispersion is distributed and the longest relaxation time, τ_d , in such a spectrum is, in general, longer than that defined by the peak of the ϵ'' curve, τ_β . For P4000, τ_d may be up to 1.5 τ_β . Secondly, Stockmayer and coworkers compare the dielectric relaxation time and the viscoelastic relaxation time, instead of with the formally analogous retardation time. A spectrum of discrete relaxation times, as postulated in the Rouse theory, implies a spectrum of discrete retardation times, on a time scale these are interleaved between the relaxation times. The first retardational mode τ_a occurs at about 0.45 of τ_1 , the first relaxation mode, and the second retardational mode τ_b lies at about 0.6 of τ_2 , the second relaxational mode. The measured time for the secondary dielectric dispersion may therefore be up to 2.5 times the predicted viscoelastic retardation time. If the non-free-draining approach of Zimm¹⁵ is assumed, then the ratio is greater since this theory gives shorter predicted times¹⁶. In the present work a similar discrepancy is found, $\tau_\beta/\tau_b \approx 6$, (Table 1). Therefore, whilst the accepted explanation of the secondary dielectric dispersion may be correct in general, there are obvious short-comings in the detailed predictions of the theory. If instead of using the macroscopic dielectric times in these comparisons, a microscopic time is calculated using, for example, the factor proposed by Powles¹⁷, then

the discrepancies between mechanical and dielectric times are greater. Connor, Blears and Allen¹⁸ suggest that hydrogen bonding between end-groups increases the effective chain length, and this may account for τ_β being greater than τ_b . It may also be partly responsible for the absence of a secondary dielectric dispersion in very high molecular weight poly(propylene oxide), although random reversals of polarization along the chain and entanglements¹⁹ have also been suggested as possible explanations. An attempt has been made, by extending the range of previous viscoelastic measurements of P4000 to lower frequencies, to see if a mechanical retardation process occurs corresponding to the secondary dielectric dispersion. No separate process was found*.

Williams^{4,5} has shown that the mechanical loss peak of the dynamic shear modulus at the glass-rubber transition which was observed by Saba, Sauer and Woodward²⁰ at 0.37 Hz and -62°C , corresponds to the main (α) dielectric relaxation process in an amorphous high molecular weight poly(propylene glycol). At such a low temperature ($10^3/T \sim 4.7$) both mechanical and dielectric times are greatly affected by small variations in temperature, and any difference between them may be masked. The present results in Table 1 show that there is an appreciable difference between τ_α and the analogous mechanical retardation time τ_J . For P400, $\tau_J \approx 10 \tau_\alpha$ and for P4000, $\tau_J \approx 20 \tau_\alpha$. (For comparison, the time τ_G defined by the peak in the loss component G'' of the shear modulus is also given in the Table.) Whilst it remains possible that the relevant mechanical and dielectric losses have their origins in a common physical mechanism it is clear that there is no close numerical equivalence between τ_J and τ_α .

* However, subject to the uncertainty due to increasing experimental errors at lower frequencies, there is an indication of a gradual increase of the ratio J_p/J_∞ at temperatures above 0°C .

Dimensions of poly(trimethylene oxide) chains in a theta-solvent

D. S. Chiu, Y. Takahashi* and J. E. Mark

Department of Chemistry and the Macromolecular Research Center, University of Michigan, Ann Arbor, Michigan, 48109, USA

(Received 26 February 1976)

Fractions of poly(trimethylene oxide) $\text{--}[(\text{CH}_2)_3\text{--O}]_x\text{--}$ of relatively high degree of polymerization x were studied in liquid-liquid phase equilibria in the poor solvent cyclohexane. The results thus obtained indicate that the ideal or theta-temperature for this system is $27.0 \pm 0.5^\circ\text{C}$. Intrinsic viscosities measured under these conditions were used to obtain a value for the characteristic ratio $\langle r^2 \rangle_0/nl^2$ of the unperturbed dimensions of these chains relative to the number of skeletal bonds and the average square of their length. The resulting value, 3.86 ± 0.08 , is unusually low, a fact which may be attributed to the high degree of conformational randomness in this chain molecule. Consideration of poly(trimethylene oxide) to be an alternating copolymer of ethylene and oxymethylene provides some additional information of interest. It clearly demonstrates that a chemical copolymer can have configuration-dependent properties which are vastly different from those of its parent homopolymers.

INTRODUCTION

Poly(trimethylene oxide) $\text{--}(\text{CH}_2\text{--CH}_2\text{--CH}_2\text{--O})_x\text{--}$ is one of the most interesting chain molecules which may be studied with regard to its spatial configurations in the random-coil state. The polymer may be prepared to relatively high degrees of polymerization x^1 , and has a rather low melting point (35°C)²; its characterization from the experimental point of view should therefore be straightforward. In addition, its investigation³⁻⁵ in terms of the rotational isomeric state theory⁴ of chain configurations is facilitated by two important features of this polyoxide chain. Its repeat unit has a very simple structure and most of the intramolecular interactions occurring in this molecule also occur in other members of the $\text{--}[(\text{CH}_2)_y\text{--O}]_x\text{--}$ series, several of which have now been extensively studied with regard to their configuration-dependent properties⁴⁻⁶. Finally, preliminary evidence¹ indicates that poly(trimethylene oxide) in the random-coil state is an unusually compact chain molecule, judging from approximate values of its unperturbed dimensions as estimated from viscosity measurements in a thermodynamically good solvent.

For the above reasons, the present study was undertaken to determine a reliable experimental value of the characteristic ratio $\langle r^2 \rangle_0/nl^2$ of poly(trimethylene oxide), where $\langle r^2 \rangle_0$ is the chain dimension as unperturbed by excluded volume effects^{1,7}, n is the number of skeletal bonds, and l^2 is the average square of their length. The approach taken, the study of the molecules in a theta (θ) solvent, where excluded volume interactions are known to be nullified⁷, is probably the most reliable method presently available for this purpose. The temperature at which a suitably poor solvent acts as a θ -solvent for poly(trimethylene oxide) will be located by measurements of the critical solution temperatures for liquid-liquid phase equilibria of solutions of the polymer, obtained as a function of its degree of polymerization⁷. Intrinsic viscosities measured in this solvent at the θ -temperature thus established then

directly yield values of the unperturbed dimensions and the characteristic ratio, without the need for approximate corrections for chain expansion due to excluded volume interactions.

Since there has been a considerable amount of interest in the configuration-dependent properties of chemical copolymers⁸⁻¹², it should be noted that poly(trimethylene oxide) may be thought of as an alternating copolymer of ethylene and oxymethylene. It is therefore obviously of considerable interest to compare its statistical properties with those of polyethylene⁴ and polyoxymethylene^{4,13,14}

EXPERIMENTAL

The five fractions of poly(trimethylene oxide) employed in the present study were among those studied previously in a thermodynamically good solvent, and their preparation is thus described elsewhere¹. Their number-average molecular weights M_n , which had been determined by osmometry in benzene at 30°C ¹, are listed in Table I.

A preliminary survey of solvents indicated that cyclohexane should serve as a θ -solvent⁷ for poly(trimethylene oxide) in the vicinity of room temperature. Precipitation temperatures, T_p , for liquid-liquid separations in the reagent-grade solvent were therefore determined for the five fractions listed in Table I, augmented by two others (F1 and F7¹, having values of $M_n \times 10^{-3}$, 53.5 and 153.0, res-

Figure 1 Some typical binodials characterizing liquid-liquid separations in the poly(trimethylene oxide)-cyclohexane system. The fractions represented are described in Table 1, and in a previous study¹: \circ , F10; \triangle , F7; \bullet , F4; \square , F2

pectively). Values of T_p were determined as a function of composition, for all seven fractions, using simple visual inspection, in the usual manner¹⁵. The volume fraction v_2 of polymer in each solution at 23°C was obtained from the weights of polymer and solvent, and the specific volumes at this temperature. Values of v_2 thus obtained were in good agreement with direct pycnometric measurements on the solutions themselves.

Viscosities of the poly(trimethylene oxide) fractions in the cyclohexane were determined in a Cannon-Ubbelohde viscometer. Each fraction was studied at a minimum of four concentrations, in the range 0.03 to 2.17 g/dl, and values of the relative viscosity ranged from 1.02 to 2.03.

RESULTS AND DISCUSSION

The binodials for the liquid-liquid phase separations were obtained by plotting values of the precipitation temperature against composition. Typical results are shown in Figure 1. The maximum of each binodal is the critical solution temperature T_c at that particular degree of polymerization x . Although some of the data scatter somewhat, presumably because of the relatively low molecular weights of some of the fractions, the values of T_c obtained are probably accurate to $\pm 0.2^\circ\text{C}$. Their reciprocals were plotted against the molecular size function indicated by theory, in the usual manner⁷. The results are presented in Figure 2, where the line shown was located by least-squares analysis. The intercept gives the value of T_c in the limit of infinite chain length, which is the θ -temperature of the system. We thus obtain $\theta = 27.0^\circ\text{C}$, with an uncertainty estimated to be $\sim \pm 0.5^\circ\text{C}$. The entropy of dilution parameter ψ_1 ⁷, obtained from the slope of this curve, was found to have the relatively large value 1.0.

Values of the intrinsic viscosity $[\eta]$ of the poly(trimethylene oxide) fractions in cyclohexane at 27.0°C were obtained from the solution viscosities in the usual manner⁷;

the results are given in Table 1. They are plotted logarithmically against the number-average molecular weight in Figure 3, and were found by least-squares analysis to be represented by the relationship:

$$[\eta] = 8.89 \times 10^{-4} M_n^{0.519} \quad (1)$$

The fact that the exponent on the molecular weight is one-half⁷ within experimental error confirms cyclohexane to be a θ -solvent for poly(trimethylene oxide) at 27.0°C . Values of the unperturbed dimensions $\langle r^2 \rangle_0$ are therefore directly calculable from the equation:

$$[\eta] = \Phi (\langle r^2 \rangle_0 / M_n)^{3/2} M_n^{1/2} \quad (2)$$

which is applicable to any random-coil polymer in a θ -solvent⁷; under these conditions, the constant Φ has the value 2.5×10^{21} dl/mol cm^3 ^{7,16}. The unperturbed dimensions thus obtained were expressed relative to nl^2 , with $n = 4(M_n/M_0)$, where $M_0 = 58.08$ is the molecular weight of the repeat unit, and $l^2 = 2.19 \text{ \AA}^2$ ¹. The resulting values of the characteristic ratio are given in Table 1 and are seen to be independent of molecular weight, as expected^{4,7}.

The average value $\langle r^2 \rangle_0 / nl^2 = 3.86 \pm 0.08$ is in excellent agreement with the value 3.94 ± 0.17 obtained from viscometric and osmometric measurements in a thermodynamically good solvent, benzene at 30°C ¹. The agreement may be somewhat fortuitous, however, in that it is frequently

^aThe pertinent experimental studies are cited in ref 4. ^bThe actual experimental result is 6.7 at 140°C; it was corrected to the vicinity of 25°C by means of the coefficient $d(\ln \langle r^2 \rangle_0)/dT$. ^cApproximate value estimated from intrinsic viscosities¹³ obtained in a thermodynamically good solvent at 25°C, using a value of 2.1×10^{21} for the hydrodynamic constant $\Phi^{1,16}$. ^dVery approximate value estimated from intrinsic viscosities obtained in two thermodynamically good solvents at 25° and 90°C, respectively^{13,14}. ^ePresent study. ^fRef 1

very difficult to correct satisfactorily for the excluded volume effects present in thermodynamically good solvents^{17,18}. In any case, the characteristic ratio found for poly(trimethylene oxide) is unusually small, and is probably the smallest of those^{2,4} which are reliably known, to a high degree of accuracy†. This compactness of the poly(trimethylene oxide) chain is due to its high conformational randomness; two of the skeletal bonds of the repeat unit have a preference for *gauche* rotational states, whereas the other two have a preference for the alternative *trans* states^{1,3,5}.

In addition, it is of instructional value to note that poly(trimethylene oxide) may be considered an alternating copolymer of ethylene and oxymethylene units, and it is thus of interest to compare its configuration-dependent properties with those of its parent homopolymers polyethylene $(\text{—CH}_2\text{—CH}_2\text{—})_x$ and polyoxymethylene $(\text{—CH}_2\text{—O—})_x$. Pertinent results are given in Table 2. Polyethylene is seen to have a relatively high value, 7.6¹⁴, for the characteristic ratio in the vicinity of 25°C; polyoxymethylene, at the same temperature, has one of the highest values^{1,13}, 12‡, reported to date. This is due to the fact that these two homopolymeric chains exhibit a preference for conformations of high spatial extension; in polyethylene the preference is for *trans* or planar zig-zag conformations⁴, and in polyoxymethylene it is for *gauche* states giving rise to helical sequences⁴. High spatial extension is *not* preserved, however, upon mixing the two types of units, in alternating sequence, to give poly(trimethylene oxide). The characteristic ratio of poly(trimethylene oxide) is in fact very much smaller than the corresponding value for either homopolymer, since *gauche* states cause disruption of the planar *trans* sequences, while *trans* states likewise disrupt the helical *gauche* sequences. Similarly, the large negative values reported for the temperature coefficient $d(\ln \langle r^2 \rangle_0)/dT$ of the unperturbed dimensions of polyethylene and polyoxymethylene are of course a direct result of the fact that the spatially extended conformations in these chains are of relatively low energy⁴. Again, destruction of the conformational regularity in polyethylene and in polyoxymethylene by the intermixing of these two repeat units in poly(trimethylene oxide) has the marked effect of reducing its value of $d(\ln \langle r^2 \rangle_0)/dT$ essentially to zero¹. These compari-

† It is of course important to use the same conventions in calculating values of the characteristic ratio in comparisons of this type. In polypeptides, for example, 'virtual bonds' of length 3.80 Å are frequently used to replace three consecutive skeletal bonds, of lengths 1.53, 1.32, and 1.47 Å, respectively^{4,8}. For uniformity, therefore, characteristic ratios thus calculated would have to be multiplied by the factor $[3.80^2/(1.53^2 + 1.32^2 + 1.47^2)] = 2.31$.

‡ Stockmayer and Chan¹³ calculate the somewhat lower value 10.5 ± 1.5 , using $\Phi = 2.5 \times 10^{21}$ rather than the value 2.1×10^{21} we used to obtain $\langle r^2 \rangle_0/nl^2 \cong 12^1$. We consider the uncertainty associated with this assignment to be minor compared with other uncertainties^{19,20} inherent in the use of such extrapolation methods²¹ in the interpretation of viscometric data.

sons strikingly illustrate the very large error which may be introduced by use of the assumption⁹ that a chemical copolymer should have statistical properties intermediate to those of its parent homopolymers.

Mechanism of polysilazane thin film formation during glow discharge polymerization of hexamethylcyclotrisilazane

A. M. Wróbel, M. Kryszewski and M. Gazicki

Centre of Molecular and Macromolecular Studies, Polish Academy of Sciences, Łódź, Boczna 5, Poland

(Received 13 February 1976; revised 31 March 1976)

Preparation of thin polymer films by the glow discharge polymerization of hexamethylcyclotrisilazane has been studied. The effect of basic parameters of the process, such as time, pressure and current density on the polymer deposition kinetics has been established. It has been found that the curves of polymer deposition rate *versus* monomer vapour pressure have the same shape as the adsorption isotherms. The experimental relationships $R = f(p)$ have been analysed by means of the adsorption equations BET and HJ. A good agreement between the experimental results and adsorption equations suggests an adsorption mechanism of the polysilazane film formation. The effect of polymerization conditions on the properties and morphology of thin polysilazane films has been also investigated.

INTRODUCTION

In recent years there has been an increasing interest in the formation of thin polymer films by the polymerization of monomer vapours initiated by a glow discharge. The polymer films obtained by this technique on suitable substrates may find wide and various applications in modern technology¹⁻⁶ because of their interesting mechanical, thermal and electrical properties. Much attention has been given to the preparation of thin films from organosilicon monomers. The polymer films from these monomers have a high electric resistance, high dielectric strength and high thermal stability⁷⁻⁹.

The present paper reports the results of a study of the effect of some of the parameters of the glow discharge polymerization of hexamethylcyclotrisilazane, such as time, pressure and current density on the polymer film deposition rate. The results show a close relationship between the polymerization conditions and properties and morphology of thin films giving at the same time a partial explanation of the physical mechanism of film deposition. Using hexamethylcyclotrisilazane as monomer with Si-N bonds, we wished to verify the possibility of using the glow discharge process for preparation of thin polymer films of extremely high thermal stability as indicated in our previous paper¹⁰.

EXPERIMENTAL

The glow discharge polymerization was carried out in an electrode static system. A schematic diagram of the apparatus used in this study is shown in *Figure 1*. The discharge chamber consisted of a 20 dcm³ glass bell jar with two parallel electrodes, made of stainless steel, fixed inside. Freshly rectified hexamethylcyclotrisilazane placed in a feeder was thoroughly degassed by freezing-thawing evacuation cycles until the pressure was less than 10⁻⁵ Torr. Before starting the polymerization the chamber was evacuated to 5 × 10⁻⁶ Torr and then monomer vapour from the feeder

was admitted until the pressure inside the chamber reached a fixed value. The pressure inside the chamber was measured by means of a differential micromanometer filled with silicon oil DC-704. An electric field was then applied to the electrodes whereupon a glow discharge took place and as a result a polymer thin film was deposited on the electrodes. The polymerizations were carried out at an electrode temperature of 20°C for 30 sec, the monomer vapour pressure being varied over the range 0.05–0.5 Torr. Discharge current densities were 0.2–7.1 mA/cm² at a

Figure 2 Weight of deposited polymer as a function of deposition time. Current density, 2 mA/cm²; pressure, 0.4 Torr

fixed frequency of 20 kHz and a fixed electrode separation of 3 cm.

The polymer film deposition rates were calculated from the amount of polymer deposited on the electrodes measured gravimetrically. A series of at least five experiments was made in order to calculate an average value of the deposition rate (R), and to find a point for the kinetic relationship curves.

Hexamethylcyclotrisilazane was purified by rectification using a Perkin-Elmer column, Model 151, with teflon spinning band and then the purity tested by gas chromatographic analysis.

RESULTS AND DISCUSSION

Effect of deposition time

The relationship between weight of polymer deposited on the electrode and duration of discharge was found for constant monomer vapour pressure 0.4 Torr and constant current density 2 mA/cm². As can be seen from Figure 2 the amount of polymer deposited increases linearly with the discharge time. This would suggest that the deposition rate is constant over the time range under investigation. The deposition rate calculated from the gradient is $R = 14.6 \mu\text{g}/\text{cm}^2 \text{ sec}$. The straight line extrapolated to zero time does not go through the origin, but intersects the polymer weight axis. This is probably connected with the change in conditions of the monomer adsorption resulting from the alteration of substrate by the polymerization process. As soon as the first layer of monomer molecules adsorbed on the metal surface of electrode is polymerized, adsorption of new monomer molecules takes place on a polymer layer already formed. Hence, the conditions of adsorption for the first layer are different from those for the next layers.

A similar phenomenon was observed in the polymerization of toluene by Tuzov *et al.*¹¹ who suggested a catalytic influence of the substrate.

Effect of monomer vapour pressure

Dependence of deposition rate on the monomer vapour pressure for polysilazane film was determined for various current densities: 0.6, 1.1 and 2.3 mA/cm². The curves obtained are shown in Figure 3. They are completely different from curves of an analogous relationship reported by other authors¹²⁻¹⁷. The different shapes of curves may result from the relatively low saturated vapour pressure of hexamethylcyclotrisilazane ($p_0 = 0.7$ Torr at 20°C) in comparison with considerably higher p_0 values for other monomers used in kinetic studies of glow discharge polymerization (for example, p_0 for styrene 4.8 Torr). It is interesting to note, that the curves of polysilazane deposition rate vs. vapour pressure have similar shapes to the adsorption isotherms of II type according to Brunauer^{18,19}. It can be seen in Figure 3 that within the range 0.05–0.3 Torr the deposition rate increases with pressure, reaching a saturation state over a certain pressure value. The course of the curves within this pressure range is explained by the fact that the number of monomer molecules adsorbed on the electrodes increases with increase in pressure. Over certain pressure values, for a given current density when all the active electrons present in the discharge zone take part in the initiation of polymerization, the film deposition rate reaches a constant value independent of pressure and limited only by the current density. This explains the appearance of distinct plateau in the curves (Figure 3) at current densities 0.6 and 1.1 mA/cm². The increase in deposition rate observed over the range 0.3–0.4 Torr may be due to a rapid increase in monomer adsorption since the range of these pressures is close to saturated vapour pressure p_0 of hexamethylcyclotrisilazane, and under these conditions a partial vapour con-

Figure 3 Polymer deposition rate at various current density as a function of monomer vapour pressure; deposition time 30 sec. Δ , 2.3; \bullet , 1.1; \circ , 0.6 mA/cm²

Figure 4 Polymer deposition rate at various pressure as a function of current density; deposition time 30 sec. Δ , 0.4; \blacksquare , 0.3; \bullet , 0.2, \circ , 0.1 Torr

condensation is likely to occur. In accordance with adsorption isotherms^{18,19}, the volume of molecules adsorbed increases asymptotically to infinity if $p \rightarrow p_0$, hence for p close to p_0 a multimolecular quasi-liquid layer of the adsorbate may be produced on the substrate. Therefore, the glow discharge polymerization of hexamethylcyclotrisilazane at pressure $p > 0.3$ Torr may be initiated in the quasi-liquid phase. This would cause the process yield to increase considerably and would explain the increase in the film deposition rate within this pressure range. The results show that adsorption of monomer plays a significant part in the mechanism of polysilazane film formation as initiated by the glow discharge.

Effect of discharge current density

The dependence of polysilazane film deposition rate on current density (j) (Figure 4) was determined at various monomer vapour pressures: 0.1, 0.2, 0.3 and 0.4 Torr. The relationships obtained at pressures 0.1, 0.2 and 0.3 Torr are consistent with data from the literature^{14,17,20,21} describing analogous relations for other monomers. It can be seen in Figure 4 that the deposition rate increases with the discharge current density and reaches a constant value over a current density defined for the given pressure. Some decrease in the deposition rate observed at 0.1 Torr and over 1.7 mA/cm^2 may be due to partial degradation of the polymers formed. The films obtained under these conditions, were cracked and badly adhered to the substrate. The relationship $R = f(j)$ for a pressure 0.4 Torr is completely different, and as is seen in Figure 4, the increase in the deposition rate is observed over the whole range of current densities used. The relationship is linear over the range $0.6\text{--}3.4 \text{ mA/cm}^2$, and when extrapolated to zero

current density, intersects the R axis. This different course of the relationship at 0.4 Torr pressure is probably due to the initiation of polymerization in a multimolecular quasi-liquid layer of monomer which at this pressure may be produced on the substrate as a result of partial vapour condensation. This fact explains the rapid rise in the deposition rate observed within the whole range of current densities used and the distinct curve shift from the origin of coordinates. The results are in agreement with the curves $R = f(p)$ for $p > 0.3$ Torr and confirm the correctness of our assumption on the initiation of polymerization in a quasi-liquid phase.

Properties and morphology of polysilazane thin films

It was found that the appearance of films and their properties depend to a great extent on the polymerization parameters. As the pressure increased at a constant current density the film became softer and much more adhesive to the substrate but when the current density increased at a constant monomer vapour pressure the film properties changed in the reverse direction. Solubility measurements showed that polysilazane films contained a small fraction soluble in non-polar solvents such as benzene or carbon tetrachloride but they were completely insoluble in acetone. The films prepared at constant pressure and low current densities ($\approx 1 \text{ mA/cm}^2$) contained about 16% by wt soluble fraction. The soluble fraction content decreased with increasing current density and the films obtained over 4 mA/cm^2 were completely insoluble. Insolubility of the films is a result of crosslinking taking place in the glow discharge polymerization. The degree of crosslinking increases with the current density as indicated by the loss of the soluble fraction in films obtained at higher current densities.

It was observed that under certain conditions homogeneity of the films was affected by powder products. Over 2 mA/cm^2 the powders were observed almost over the whole range of pressure used. At $1\text{--}2 \text{ mA/cm}^2$ the powder appeared at higher pressures while below 1 mA/cm^2 the films were transparent. It was also found that at constant current density and pressure the powder regions grew with the discharge duration. Figures 5 and 6 show electron micrographs of surfaces both of homogeneous film and powder region, respectively. In the powder region (Figure 6) one can easily observe distinct spheres on the film surface. The powder formation, also reported by other authors²¹⁻²⁸, is a typical feature of the glow discharge polymerization and according to a generally accepted opinion it is due to initiation of the process in the gas phase.

Mechanism of film formation

The results presented suggest that adsorption is a determining factor in the mechanism of polysilazane film formation. Nevertheless it should be noted, that the mechanism of film formation is not as simple as that of the adsorption process. During the film formation a continuous renewing of the substrate surface takes place resulting from growing film thickness. While in classic adsorption at a constant temperature and pressure a dynamic equilibrium state exists characterized by a constant volume of adsorbed molecules, here the equilibrium state can be determined by the volume adsorbed within the time unit because of the continuous renewal of substrate surface. It is clear that this volume depends not only on temperature and pressure but also on the film deposition rate, and thus on the current density.

Figure 5 Electron micrograph of homogeneous polysilazane film formed at 1 mA/cm², 0.3 Torr

Figure 6 Electron micrograph of powder region in polysilazane film formed at 3 mA/cm², 0.3 Torr

Accepting such an assumption, one can verify whether the experimental relationship between polymer deposition rate and pressure is consistent with the Brunauer, Emmett and Teller (BET) multi-layer adsorption equation²⁹:

$$\frac{p}{\nu(p_0 - p)} = \frac{1}{c\nu_m} + \frac{1 - c}{c\nu_m} \frac{p}{p_0} \quad (1)$$

where ν is the volume of adsorbed gas, ν_m is the volume of monolayer, p is the pressure in the system, p_0 is the saturated vapour pressure of the adsorbate and c is a constant. The equation is a linear function of relative pressure p/p_0 . If one assumes that the polymer deposition rate is proportional to the volume of adsorbed monomer ($R \propto V$), the experimental relationships $R = f(p)$ (Figure 3) can be expressed in the form $p/R(p_0 - p) = f(p/p_0)$ according to the BET equation. These relationships as determined by equation (1) are shown in Figure 7. The curves obtained have similar shapes to those of typical BET isotherms^{18,19}. One can say that to an approximation the relationships for current densities 1.1 and 2.3 mA/cm² are linear only for $p/p_0 \leq 0.2$. This narrow linear range is a characteristic feature of BET isotherms as the multilayer adsorption equation is not free from some imperfections. The dependence of polysilazane film deposition rate on pressure, $R = f(p)$,

can be also described by the Harkins–Jura³⁰ (HJ) equation:

$$\ln \frac{p}{p_0} = B - \frac{A}{\nu^2} \quad (2)$$

which expresses the linear relationship $\ln(p/p_0) = f(1/\nu^2)$. Using previous assumptions, experimental relationships $R = f(p)$ were verified in the system $\ln(p/p_0) = f(1/R^2)$ according to equation (2). The linear relationships observed almost over the whole pressure range (Figure 8) show that the HJ equation describes the experimental results well.

A good agreement of the experimental relationships $R = f(p)$ with the adsorption equations would confirm the accuracy of our hypothesis on the adsorption nature of polysilazane film formation mechanism. It should be noted, however, that in the case of glow discharge polymerization, the adsorption phenomenon is a very complex one. In comparison to the classic adsorption dealing with a homogeneous gas, here we have a gas mixture, produced by monomer fragmentation, which consists of components of various adsorption constants. Therefore, the use of classic adsorption equations to describe the formation mechanism of polymer film is a certain simplification of this complex process.

An attempt was also made to verify the quantitative model of mechanism for glow discharge polymerization postulated by Denaro *et al.*¹³. Their theory put forward a radical mechanism of polymerization and linear relationship $1/R = f(1/p)$. The non-linear nature of this relation found by us in the case of polymerization of hexamethyl-

Structure of glow discharge polysilazane thin films

A. M. Wróbel, M. Kryszewski and M. Gazicki

Centre of Molecular and Macromolecular Studies, Polish Academy of Sciences, Łódź, Boczna 5, Poland

(Received 13 February 1976)

Thin polysilazane films have been prepared by glow discharge polymerization of hexamethylcyclotrisilazane in an electrode static system. An increase in pressure in the reaction system observed during polymerization indicated that the monomer underwent fragmentation in the glow discharge. The structures of thin polysilazane films prepared at various current densities have been determined by elementary analysis, infra-red spectroscopy and gas chromatography. It has been found that fragmentation of hexamethylcyclotrisilazane takes place mainly through the cleavage of Si—C bonds and that methyl group content in the polymer film structure decreases with increasing current density. The mechanisms of reactions leading to polysilazane film formation have been discussed.

INTRODUCTION

Attention has been given to the use of the glow discharge technique for polymerization of organosilicon compounds in order to prepare thin polymer films with good dielectric properties and high thermal stability. Many investigations reported in the literature were carried out to study the properties and structure of polysilazane films¹⁻⁵. Among the great number of organosilicon compounds organosilazanes deserved particular attention. Polymers prepared from these compounds by a conventional polymerization have much higher thermal stability than polysiloxanes⁶. Using organosilazane monomers in the glow discharge process one can produce polymer films with good electrical properties⁷ and very high thermal stability⁸.

The aim of the present paper was to study the chemical structure of thin polysilazane films prepared by the glow discharge polymerization of hexamethylcyclotrisilazane and to establish a relation between polymerization conditions and polymer structure. However, one should be aware of the fact that examination of chemical structure of thin polymer films prepared by glow discharge in monomer vapour is difficult because of the complex mechanism of polymerization. Monomer molecules in the glow discharge undergo fragmentation by collisions with accelerated electrons or ions. In the gas phase several segments of molecules are formed which have definite probabilities of polymer film formation. Various molecule segments have different polymerization rate constants and different adsorption constants. Their contribution to the polymerization mechanism is difficult to establish, as the quantity of them in the total number of reactive molecules is not always known. Thus, the glow discharge polymerization can be considered as a copolymerization of numerous segments with different functions giving a polymer with a highly crosslinked structure. It is clear, that the chemical structure and properties of the polymer film will be closely related to the parameters of glow discharge.

EXPERIMENTAL

Glow discharge polymerizations of hexamethylcyclotrisilazane were carried out by means of the electrode static

system. Details of the apparatus used for this study have been reported previously⁹. Polysilazane samples were prepared in a glow discharge operating at 20 kHz. Polymer was formed as a thin film on the surfaces of two parallel stainless steel electrodes with the electrode separation fixed at 3 cm. Polymerization was carried out at an electrode temperature of 20°C and a constant discharge time of 30 sec with a fixed monomer vapour pressure of 0.3 Torr. Current density applied was within the range 0.2–6.4 mA/cm².

Infra-red spectra of the polymers were obtained by removing the polymers from the metal surface and dispersing in KBr discs. The spectra were run on a Unicam Model SP 1200 spectrophotometer.

Pyrolysis of the polymers was carried out in a Jeol pyrolyzer unit, Model PL 723. A polymer sample of 0.2 mg placed in the pyrolyzer was heated at 750°C for 15 sec. The volatile components of the pyrolysis products were directed immediately to the injection part of a Jeol, Model JGC 1100, gas chromatograph, equipped with a flame ionization detector. The stainless steel separation column 1 m × 3 mm i.d. was filled with a 5A 60/80 mesh molecular sieve. The column was heated at a constant rate of 10°C/min starting from the initial temperature of 40°C. Nitrogen was used as a carrier gas and the flow rate was 60 cm³/min.

Hexamethylcyclotrisilazane was purified as described previously⁹.

RESULTS AND DISCUSSION

Effect of glow discharge on pressure variation

It was observed that during glow discharge polymerization of hexamethylcyclotrisilazane a considerable increase in pressure took place in the reaction system. In order to obtain a quantitative picture of this phenomenon, measurements of pressure increase were made at various current densities. Increases in pressure, Δp , were measured after 30 sec of discharge and were calculated in relation to the initial monomer vapour pressure, p_M . To avoid an error caused by a pressure increase due to desorption of gases adsorbed on walls of the bell jar, a series of discharges were carried out in nitrogen under the same conditions. In this

Figure 1 Effect of discharge current density on the relative pressure increase in the reaction system. Monomer vapour pressure $p_M = 0.1$ (A) and 0.3 Torr (B), discharge time 30 sec, frequency 20 kHz

way the relative pressure increase calculated from measurements was below 1%.

Relationships between the relative pressure increase, $\Delta p/p_M$, and current density, found for two various monomer vapour pressures 0.1 and 0.3 Torr are shown in Figure 1. It can be seen, that the pressure increase in the reaction system rises with increasing current density.

The phenomenon of pressure increase in the reaction system results from the monomer molecule fragmentation taking place during the glow discharge. Due to high energies of glow discharge reaching several electron volts, and even more, the initiation of polymerization proceeds spontaneously. This can lead to bond cleavages in the monomer molecule resulting in the formation of several segments in the gas phase and followed by pressure increase in the system. Higher pressure increases observed at lower monomer vapour pressure ($p_M = 0.1$ Torr) are connected with the fact that the kinetic energy of plasma particles increases with decreasing pressure as a result of increased mean free path. Hence, at lower pressures, as a result of collisions of monomer molecules with plasma particles of considerably higher energy, fragmentation of the monomer proceeds to a greater extent than at higher pressures. This explains the steeper shape of the curve for $p_M = 0.1$ torr (Figure 1). In accordance with the curves in Figure 1 one can draw a conclusion that the degree of fragmentation of hexamethylcyclotrisilazane depends strictly on the discharge conditions and increases with current density.

Interesting data on the pressure variation during glow discharge polymerization are reported by Yasuda *et al.*¹⁰⁻¹². These authors in their studies on polymerization of numerous aliphatic and aromatic compounds have found that fragmentation of monomer manifested by the pressure increase depends only on the structural features of the monomer¹². Pressure increase was observed during polymerization of almost all the saturated hydrocarbons used. High

hydrogen content in the gas phase indicated that most fragmentations of these compounds proceeded with C-H bonds cleavage.

Analysing the bond energy in a hexamethylcyclotrisilazane molecule (I) one can state that the Si-C bond has the lowest energy equal to 3.3 eV¹³ as compared with 3.6 eV for a Si-N bond¹⁴.

This would suggest that fragmentation of the compound in glow discharge proceeds most easily through Si-C bonds cleavage with the methyl groups splitting off. One may assume, that the fragmentation of monomer, resulting in a significant change of the gas phase composition, affects the chemical structure of the polymer films. The observed relationship between pressure increase and current density (Figure 1), being in close relation to fragmentation of hexamethylcyclotrisilazane, shows that the chemical structure of polysilazane films should depend to a great extent on the discharge parameters.

Composition of thin films

In order to examine the effect of polymerization conditions on the composition of glow discharge polysilazanes, elementary analysis of polymer films prepared at various current densities was carried out. Silicon, carbon, hydrogen and nitrogen contents were determined with oxygen content being calculated by difference. The results are given in Table 1. It can be seen, that the polymer contains less carbon, hydrogen and nitrogen than the monomer. The results of chemical analysis in terms of molar contents of particular elements in relation to silicon versus current density are illustrated in Figure 2. It can be seen, that molar contents of carbon and hydrogen in polysilazane decrease linearly with increasing current density.

The straight lines of C/Si and H/Si extrapolated to zero value of current density pass through the points representing contents of these elements in the monomer (C/Si = 2 and H/Si = 7). The decrease of carbon and hydrogen contents in the polymer observed with increasing current density proves, that hexamethylcyclotrisilazane is subject to strong fragmentation which results in cleavage of Si-C

Table 1 Composition of glow discharge polysilazane thin films formed with different current densities and at 20 kHz, 0.3 Torr, 30 sec

bonds and the methyl groups splitting off. Consequently, the number of the fragmentation products in the gas phase increases with current density causing a pressure increase in the system, which is consistent with the results shown in Figure 1.

A slight decrease of nitrogen content in the polymer (Figure 2) may be a result of the partial hydrolysis of Si-N bonds devoid of sufficient steric hindrance because of the methyl groups splitting off and therefore more susceptible to the action of hydrolytic agents. However, one can not exclude fragmentation of silazane ring leading to Si-N bonds cleavage.

From the elementary analysis it can be seen that glow discharge polysilazanes contain a certain amount of oxygen. As is seen in Figure 2, the oxygen content increases with current density. The presence of oxygen in glow discharge polymers has been reported by numerous authors¹⁵⁻¹⁹ and ascribed to the reaction of free radicals trapped in films with air oxygen. The polymer films prepared by these authors¹⁵⁻¹⁹ contained a certain amount of unsaturated bonds and as a result of this they showed high reactivity with oxygen or water vapour after exposure to the atmosphere. It should be noted that the monomers normally used to prepare thin polymer films contained unsaturated groups and hence one can understand the presence of a great number of unsaturated products in the polymer structure. The presence of oxygen in glow discharge polysilazane structure is a more complex problem because of the rather different chemical structure of monomer (absence of unsaturated bonds). As was already noted the presence of oxygen may be a result of the partial hydrolysis of Si-N bonds leading to the formation of Si-OH or Si-O-Si groups. On the other hand however, polysilazane films, similar to other glow discharge polymer films, may contain free radicals generated during glow discharge, which readily react with air oxygen. The presence of oxygen in the structure of glow discharge polysilazane seems likely to be due to both the processes mentioned. In order to obtain general information on the fragmentation products in the gas phase the change of H/C ratio in the polymer composition was analysed. Figure 3 shows the change of H/C ratio in glow discharge polysilazane as a function of current density. As can be seen the H/C ratio in the polymer grows linearly with current density and the value

of H/C found by extrapolation to zero current density is in a good agreement with the respective ratio for monomer, where H/C = 3.5.

The change in H/C ratio observed proves, that as the current density increases the carbon content in polysilazane decreases to a greater extent than the hydrogen content. This means that the gas phase is expected to contain fragmentation products in the form of unsaturated hydrocarbons such as ethylene or acetylene. The amount of these components in the gas mixture should increase with current density according to the plot in Figure 3. It might be interesting to quote results obtained by Kabayashi, Bell and Shen^{19,20} who investigated the composition of glow discharge polymers prepared from saturated and unsaturated hydrocarbons. They found that each of the polymers studied was hydrogen deficient in comparison to its respective monomers. This suggested that the polymers were highly crosslinked and contained significant amounts of unsaturation. The observed carbon deficiency in the case of glow discharge polysilazane would lead to the conclusion that the polymer can be expected to possess a highly saturated structure.

Chemical structure of thin films

In order to examine the effect of polymerization conditions on the polymer structure infra-red analysis was performed using polysilazane prepared at various current densities within the range 0.2–6.4 mA/cm² with the remaining parameters being constant. It followed from qualitative estimation that the i.r. spectra of glow discharge polysilazane are similar within the whole range of current densities used. A comparison of the i.r. spectra of glow discharge and conventional polysilazanes revealed the existence of analogous absorption bands²¹. A typical spectrum of glow discharge polysilazane and a spectrum of hexamethylcyclotrisilazane are shown in Figure 4. Both in the monomer spectrum and in that of the polymer there is a strong absorption of Si-NH-Si group revealed in the bands at 3400, 1170 and 930 cm⁻¹.

The bands correspond to $\nu(\text{NH})$, $\delta(\text{NH})$ and $\nu_{\text{as}}(\text{SiNSi})$ vibrations respectively. The presence of Si(CH₃)₂ groups in the polymer is characterized by the strong, sharp band at 1250 cm⁻¹ corresponding to $\delta_{\text{s}}(\text{CH}_3)$ vibration. The appearance of intense absorption bands in the polymer spectra at 2140 and 1030 cm⁻¹ which are absent in the monomer spectrum is interesting. The first of them at 2140 cm⁻¹ corresponds to $\nu(\text{SiH})$ vibrations. This group may be form-

Figure 3 Hydrogen-carbon ratio in polysilazane film as a function of current density

Figure 4 Infra-red spectra of hexamethylcyclotrisilazane (A) and polysilazane formed at 2 mA/cm², 20 kHz, 0.3 Torr, 30 sec (B)

ed as a result of monomer fragmentation connected with cleavage of Si–C and C–H bonds. The second absorption band at 1030 cm⁻¹ is a typical one for methylene groups between two silicon atoms and corresponds to $\omega(\text{CH}_2)$ vibration. The presence of Si–(CH₂)₁ or ₂–Si bonds was confirmed also in the structure of glow discharge polysiloxanes prepared from octamethylcyclotetrasiloxane²² by mass spectrometry. The absorption within the range 1100–1000 cm⁻¹ is also characteristic for $\nu_{\text{as}}(\text{SiOSi})$ vibration. This bond, as noted previously, may be formed as a result of hydrolysis of Si–N–Si bond. The appearance of a wide and non-symmetrical absorption band in this range in the polysilazane spectra is because of the overlap of signals from Si–CH₂–Si and Si–O–Si bonds present in the polymer structure. A very weak absorption band at 840 cm⁻¹ in the polymer spectrum is due to the presence of Si(CH₃)₃ groups in the polymer structure and corresponds to $\nu(\text{SiC})$ and $\rho(\text{CH}_3)$ vibrations. These groups confirm the fragmentation of silazane ring caused by the cleavage of Si–N bonds.

The results presented only give a qualitative picture of the chemical structure of thin polysilazane films. Much more information has been provided by quantitative interpretation of the i.r. spectra of polymers prepared at various current densities. Using this method, a change in relative intensity of absorption bands at 2140 and 1250 cm⁻¹, corresponding to SiH and SiCH₃ groups respectively, has been observed. It may be assumed that the absorption peak area at 2140 cm⁻¹, A_{SiH} , corresponds to the number of Si–H bonds in the polymer structure which enables the loss of methyl groups at the silicon atoms to be determined, while the absorption peak area at 1250 cm⁻¹, A_{SiCH_3} , corresponds to the total number of the methyl groups linked to silicon atoms. Hence the ratio $A_{\text{SiH}}/A_{\text{SiCH}_3}$ is a factor which characterizes, to some extent, the loss of methyl groups due to the monomer fragmentation. The plot of $A_{\text{SiH}}/A_{\text{SiCH}_3}$ ratio versus current density is shown in Figure 5. It can be seen that the deficiency of methyl groups in the polysilazane structure increases linearly with the current density. It should also be noted that the straight line (Figure 5) when extrapolated to zero current density passes through the origin of the coordinate system, which is consistent with the fact that an absorption band corresponding to the Si–H bond does not exist in the monomer spectrum. The above relationship has a similar course to that shown in Figure 3 and confirms the results of elementary analysis. Making a similar assumption, a change in relative intensity of absorption bands at 1170 and 930 cm⁻¹, corresponding to N–H and Si–N bonds respectively, has been analysed. If A_{NH} and A_{SiN} represent the areas determined from the absorption peaks in these bands, thus ratio $A_{\text{NH}}/$

A_{SiN} is a factor which characterizes the –NH– group content in the polymer structure. A plot of this ratio as a function of current density is shown in Figure 5. The value of $A_{\text{NH}}/A_{\text{SiN}}$ at zero current density was calculated from the monomer spectrum. As can be seen from Figure 5 the ratio $A_{\text{NH}}/A_{\text{SiN}}$ decreases with increasing current density, which means that there is a loss of –NH– groups in the polysilazane structure. This process may be due only to a transition of secondary nitrogen into tertiary through elimination of hydrogen from –NH– groups and formation of (>Si)₃N groups. Such groups have been identified by Krüger²¹ and Andrianov²³ in the structure of conventional polysilazane prepared from hexamethylcyclotrisilazane. The presence of Si–CH₂–Si and (>Si)₃N groups proved by i.r. analysis suggests that the structure of glow discharge polysilazane thin films is highly crosslinked which would explain the insolubility of the films observed previously⁹.

Interesting information about the structure of glow discharge polymers can be gained by examination of its pyrolysis products with the aid of gas chromatography. Samples of polysilazane prepared at different current densities were pyrolyzed at 750°C in nitrogen, with the gas products passing through a chromatographic column. The identification of peaks in the chromatograms pointed out that methane was a main component of the pyrolysis products. Ethylene was also found as well as small amounts of ethane, propane, acetylene and propylene. A typical chromatogram of the pyrolysis products is shown in Figure 6. Relative contents of the pyrolysis products expressed by a ratio of the peak area of particular components to methane, for polysilazane prepared at 1 mA/cm², are listed in Table 2. The data in Table 2 suggest, that besides methane the remaining components may be formed as a result of secondary reactions. The appearance of methane in the pyrolysis products is a result of the homolytic decomposition of Si–CH₃ groups. The methyl radicals formed in this way recombine with hydrogen radicals detached from the polymer structure, thus giving methane. This high methane content in the pyrolysis products confirms the results of elementary analysis which pointed out a high H/C ratio in glow discharge polysilazane.

Mechanism of polymerization

The results presented show that the chemical structure of polysilazane film is a very complex one and is formed

Figure 5 Relative i.r. absorption intensities: ○, $A_{\text{SiH}}/A_{\text{SiCH}_3}$; △, $A_{\text{NH}}/A_{\text{SiN}}$, as a function of current density

Figure 6 Chromatographic pyrolysis pattern of glow discharge polysilazane formed at 1 mA/cm², 20 kHz, 0.3 Torr, 30 sec. Pyrolysis conditions: temperature 750°C, heating time 15 sec, sample size 0.2 mg. A, methane; B, ethane; C, propane; D, ethylene; E, acetylene; F, propylene

as a result of the large number of various reactions initiated in the glow discharge. Detailed mechanism of glow discharge polymerization is difficult to elucidate, and opinions on this subject found in the literature are often inconsistent. According to the theory of Denaro *et al.*¹⁷, concerning the polymerization of styrene and its derivatives, the process is initiated mainly by free radicals generated by collisions of free electrons present in the plasma with monomer molecules. Yasuda¹² and Kabayashi^{19,20}, who have examined the polymerization of various hydrocarbons, have also concluded that the process proceeds according to a free-radical mechanism. A completely different conclusion has been drawn from the studies of Thompson and Mayhan²⁴ on styrene polymerization. Their results have shown that positive ions play a significant part in the initiation process. In spite of these different opinions on the nature of glow discharge polymerization it is most likely that two initiation mechanisms may occur simultaneously: a radical and an ionic. Such a hypothesis is supported by the fact that electrons present in plasma have some energy distribution and consequently by collision with monomer molecules may produce both radical and ionic species capable of initiating the polymerization. It is still a problem to establish the contribution of particular species in the whole initiation process. This contribution seems to be dependent not only on the electron energy distribution but also on the structural features of monomer.

Accepting such a consideration it is possible to describe the mechanism of some reactions leading to form identified structure fragments of glow discharge polysilazane. As a result of collision with accelerated electrons or ions of plasma, monomer molecules can be converted to an excited state. These excited molecules may then fragment into radical or ionic active species capable of propagating polymerization. According to the radical mechanism the fragmentation of hexamethylcyclotrisilazane molecule may proceed as follows:

Methyl and hydrogen radicals formed in the above reactions may produce methane and ethane by a suitable recombination in the gas phase. These compounds may then be converted by plasma to various gas products such as ethylene, acetylene as well as hydrogen, methyl, ethyl and vinyl radicals^{19,20}. The radicals (II) formed in reaction (1) by recombination with atomic hydrogen (reaction 3) may produce Si-H bonds identified in the polymer structure,

Monomer molecules by collision with accelerated electrons of plasma may also fragment according to ionic mechanism (4),

Table 2 Volatile pyrolysis products of glow discharge polysilazane formed at 1 mA/cm², 20 kHz, 0.3 Torr, 30 sec, determined by gas chromatography. Pyrolysis temperature 750°C

Component	Relative content (%)
Methane	100.0
Ethane	1.8
Propane	0.1
Ethylene	15.8
Acetylene	1.0
Propylene	1.5

Reaction (4) is a typical fragmentation which takes place in a mass spectrometer^{25,26}. The peak corresponding to cation (IV) has been found²⁶ to be present in mass spectra of hexamethylcyclotrisilazane, independent of the electron beam energy used, within the range 10–70 eV. Taking into consideration that plasma electrons have similar energies as those in the mass spectrometer²⁴ it is very probable that the ionization of hexamethylcyclotrisilazane molecules in the glow discharge may occur according to reaction (4)

Cations (IV) produced by the ionization of monomer may initiate the polymerization as follows:

Dimer (V) may be ionized further and produce trimer through reaction with the next monomer molecule, and so on. Further growth of the macromolecule may take place also by a reaction of dimer (V) with cations (IV) present in the gas phase. The polymerization proceeding according to the mechanism presented is accompanied by transition of secondary nitrogen into tertiary and formation of (\geq Si)₃N groups in the polymer structure. This is confirmed by a decrease in the number of –NH– groups in the polymer as illustrated in Figure 5. The mechanism is also supported by the fact that a peak corresponding to dimer of structure (V) was found in mass spectra of the soluble fraction of glow discharge polysilazane²⁶. It is worth noticing that a similar mechanism was first proposed by Andrianov²³ for conventional polymerization of hexamethylcyclotrisilazane. It should be noted that polymerization according to reaction (5) may lead to the formation of branched and highly crosslinked polymer.

Crosslinking may also take place through the recombination of macroradicals type (I) and (III) to produce Si–(CH₂)₁ or 2–Si groups identified in the polymer structure.

The process may proceed as follows:

The reaction mechanism presented here may be considered only as a part of such a complex process as the glow discharge polymerization. We hope that the studies started by us on polymer structure and gas phase composition by means of gas chromatography and mass spectrometry will allow better elucidation of the mechanism of glow discharge polysilazane formation.

CONCLUSIONS

(1) The fragmentation of hexamethylcyclotrisilazane in glow discharge predominantly occurs through Si–C bond cleavages with the methyl groups splitting off.

(2) A decrease in methyl group content in glow discharge polysilazanes with increasing current density proves that polymers contain a significant amount of inorganic structure.

(3) Carbon deficiency in glow discharge polysilazanes by comparison with monomer points out that polymers are highly saturated.

(4) A decrease in NH group content in glow discharge polysilazane with increasing current density, suggests that the polymerization of hexamethylcyclotrisilazane may proceed through Si–N linking with cleavage of N–H and Si–C bonds. This process leads a highly crosslinked polymer being formed.

ACKNOWLEDGEMENTS

Upper and lower critical solution temperatures in poly (ethylene glycol) solutions

Susumu Saeki, Nobuhiro Kuwahara, Mitsuo Nakata, and Motozo Kaneko

Department of Polymer Science, Hokkaido University, Sapporo, Japan

(Received 7 January 1976; revised 19 March 1976)

Upper and lower critical solution temperatures have been determined for solutions of poly(ethylene glycol) in t-butyl acetate and water over the molecular weight range of $M_n = 2.18 \times 10^3$ to $\sim 1020 \times 10^3$. The phase diagram for solutions of poly(ethylene glycol) ($M_n = 719 \times 10^3$) in t-butyl acetate was expressed as the 'hour glass' type, while the phase diagram for solution of poly(ethylene glycol) ($M_n = 2.18 \times 10^3$ to $\sim 2.29 \times 10^3$) in water was expressed as the 'closed loop' type. The value of the pressure dependence of the lower critical solution temperature $(dT/dP)_c$ in the poly(ethylene glycol) ($M_n = 1020 \times 10^3$)/water system over the pressure range of 0 to ~ 50 atm was negligibly small and positive.

INTRODUCTION

Investigation of the phase separation behaviour of polymer solutions over a wide range of molecular weights gives useful information on the dependence of the reduced residual chemical potential or the χ parameter on temperature, pressure, and concentration. The expression of χ_1 as a function of temperature derived by Patterson *et al.*¹⁻⁶ and Flory *et al.*⁷⁻¹⁰ has predicted the occurrence of phase separations at the lower critical solution temperature (*LCST*) and the upper critical solution temperature (*UCST*) in non-polar polymer solutions¹¹⁻²⁰ and the continuous change from the endothermic behaviour near the *UCST* to the exothermic near the *LCST* passing through the athermal condition in the intermediate temperature region between the *UCST* and the *LCST*¹⁴. The χ_1 parameter represented by a parabolic-like function of temperature with a minimum has been correlated with the polymer chain dimension in the dilute polymer solution with a maximum in the intermediate temperature region between θ_u and θ_l ²⁰⁻²², in which θ_u and θ_l are respectively the Flory temperatures for the *UCST* and *LCST*. The phase diagram of the 'closed loop' type with both the *UCST* and *LCST* in aqueous solutions e.g. nicotine-water²³, butyl glycol-water²⁴, poly(ethylene glycol)-water²⁵, and poly(riboadenylic acid)-water²⁶ has been distinguished from that in non-polar polymer solutions, e.g. polystyrene solutions^{13,16,17} and polyethylene solutions¹⁸. The behaviour of phase separation for the aqueous solutions has been explained by the existence of a special interaction, e.g. the hydrogen bond, which is beyond the scope of usual solution thermodynamics. A theoretical prediction for the phase diagram of the 'closed loop' type has been suggested by Barker and Fock²⁷ with the introduction of the molecular interaction depending on the relative orientation and by Scatchard and Wilson^{28,29} with the expression for the excess free energy of mixing. The temperature dependence of the second virial coefficient A_2 of a poly(riboadenylic acid) solution at neutral pH in 1 to ~ 1.33 mol sodium chloride²⁶ is represented by a parabolic-like curve with a minimum at 40°C in harmony with the parabolic-like temperature dependence of the mean square radius of gyration $\langle s^2 \rangle$ with a minimum

at 40°C . The behaviour of A_2 or $(1/2 - \chi_1)$ and $\langle s^2 \rangle$ over the temperature range of θ_u to $\sim \theta_l$ in the poly(riboadenylic acid) solutions is in extreme contrast to the temperature dependence of χ_1 and $\langle s^2 \rangle$ in the non-polar polymer solutions¹⁹⁻²¹. The phase separation behaviour of the *LCST* and the temperature dependence of A_2 for solutions of cellulose-, amylose-, and polyvinyl-carbanilate in polar solvents reported by Burchard³⁰ are also remarkably different from those for the non-polar polymer solutions and also for the aqueous solutions.

The *LCST* for solutions of poly(ethylene glycol) in methyl, ethyl, n-propyl, and iso-butyl acetate, acetone, and methyl ethyl ketone were observed in our preliminary experiments. However, we are interested in the appearance of both *UCST* and *LCST* in poly(ethylene glycol) solutions, which is a very general phenomenon in polymer solutions. In this paper the typical phase diagrams of the 'hour glass' type and of the 'closed loop' type with solutions of poly(ethylene glycol) in t-butyl acetate and water, are presented. We have also examined the pressure dependence of the *LCST* for solutions of poly(ethylene glycol) in water.

EXPERIMENTAL

Poly(ethylene glycol) [Union Carbide, Chemical Division Product Polyox WSR 301: $M = 4000 \times 10^3$; Wako Pure Chemical Industries, Product poly(ethylene glycol) 4000: $M = 3000$ and Nakarai Chemicals, Product poly(ethylene glycol) 20 000: $M = 15 \times 10^3$ to $\sim 25 \times 10^3$] were fractionated into seven fractions for the Polyox WSR 301, seven fractions for the poly(ethylene glycol) 4000, and thirteen fractions for the poly(ethylene glycol) 20 000. Fractionation was carried out by the solution fractionation technique called the coacervation method. After adding n-heptane to the poly(ethylene glycol)/benzene solution (concentration < 0.10 g/dl) the solution was kept for a day at 40°C in a water bath controlled to $\pm 0.01^\circ\text{C}$. After complete attainment of the liquid/liquid phase equilibrium for solutions of the Polyox WSR 301 and the poly(ethylene glycol) 20 000 or liquid/solid equilibrium for solutions of the poly(ethylene glycol) 4000, the dilute solution, in which

Figure 1 Temperature/weight fraction phase diagram for the poly(ethylene glycol) samples in t-butyl acetate: ∇ , $M_n = 719 \times 10^3$; \circ , $M_n = 21.2 \times 10^3$; \triangle , $M_n = 14.4 \times 10^3$; ∇ , $M_n = 8.0 \times 10^3$

lower molecular weight poly(ethylene glycol) is richer, was carefully separated from the concentrated solution phase. A fractionated poly(ethylene glycol) was obtained from the dilute phase and the concentrated phase was redissolved in a mixture of benzene and n-heptane for further fractionation. The fractionated samples were dried for more than two weeks at 40°C under vacuum. Reagent grade t-butyl acetate (500 g) was refluxed for 2 h over ~ 15 g of acetic anhydride and dried over anhydrous potassium carbonate. The dried solvent was fractionally distilled using a column 100 cm in length and 10 mm in diameter packed with stainless steel helices. Fractionally distilled water was obtained using a specially designed distillation apparatus, which was repeatedly washed by steam for seven years.

Several solutions of each polymer sample were prepared in t-butyl acetate and water for cloud point curve determinations, in the concentration range 0.3 to ~ 43 wt% and flame sealed under dry nitrogen gas in 7 mm i.d. cylindrical cells. Cloud point temperatures for the UCST and LCST were optically¹⁷ determined with an accuracy of $\pm 0.1^\circ\text{C}$ in a silicon oil bath over the temperature range 40° to $\sim 240^\circ\text{C}$. After measuring the precipitation temperatures for the LCST, the thermal degradation of poly(ethylene glycol) was examined by the reproducibility of the precipitation temperature for the UCST. Errors caused by thermal degradation are estimated to be 1.5° to $\sim 2.0^\circ\text{C}$ for the poly(ethylene glycol)/t-butyl acetate system, while no thermal

degradation was observed for solutions of poly(ethylene glycol) ($M_n = 2.18 \times 10^3 \sim 2.29 \times 10^3$) in water. Cloud point temperatures under pressure have been measured over 0 to ~ 50 atm using the pressure apparatus described in detail elsewhere³¹. Solutions for the cloud point temperature measurements under pressure were stirred with a magnetic stirrer for at least 24 h and then sealed using pure mercury inside the solution cells.

The molecular weights of the poly(ethylene glycol) samples were determined from the values of the limiting viscosity number $[\eta]$ for solutions of poly(ethylene glycol) in benzene at 20° and 25°C , according to the equation^{32,33}:

$$[\eta] = 4.8 \times 10^{-4} M^{0.68}$$

at 20°C ³² for $0.1 < M \times 10^{-3} < 20$

and $[\eta] = 3.97 \times 10^{-4} M^{0.686}$

at 25°C ³³ for $80 < M \times 10^{-3} < 5200$

Viscosity measurements were carried out with negligible kinetic energy corrections with an Ubbelohde-type viscometer with the aid of a water bath controlled to within $\pm 0.02^\circ\text{C}$. The concentration of solutions was determined by evaporating a known volume to dryness and weighing the residue. Viscosity data were treated by double extrapolation of η_{sp}/C and $\ln \eta_r/C$ against C to determine the limiting viscosity number, where η_{sp} and η_r are respectively the specific and the relative viscosity and C is the concentration (g/dl).

RESULTS

Phase diagrams of solutions of poly(ethylene glycol) in t-butyl acetate and water are shown in Figures 1 and 2, where w_2 is the weight fraction of the polymer. Complete miscibility of the poly(ethylene glycol) ($M_n = 719 \times 10^3$)/t-butyl acetate system occurs at concentrations < 4 wt% and > 29 wt% of the polymer. Although the maximum and minimum points of the cloud point curves for the low molecular weight poly(ethylene glycol) in t-butyl acetate and poly(ethylene glycol) in water systems deviate slightly from the critical points depending on the polydispersity of the samples, the deviation from the critical points should be quite small as the polymer samples were obtained by the solution fractionation technique^{34,35}. Since we are mainly interested in semi-quantitative features of miscibility, the maximum and minimum temperatures in the phase diagrams are taken as the critical solution temperatures for UCST and LCST, respectively. Values of UCST and LCST under saturated vapour pressure for the systems are compiled in Table 1. Coalescence of the UCST and LCST in the t-butyl acetate system would occur at $\sim M_n = 41 \times 10^3$, while both the UCST and LCST in the water system would disappear at $\sim M_n = 2.14 \times 10^3$ giving complete miscibility over the whole concentration range.

The pressure dependence of the cloud point temperatures at four concentrations in the vicinity of the critical concentration for the LCST in the poly(ethylene glycol) ($M_n = 1020 \times 10^3$)/water system is shown in Figure 3, where the value of $(dT/dP)_c$ for the LCST is pointed out to be negligibly small and positive ($0.004^\circ\text{C}/\text{atm}$). The cloud point curves of the poly(ethylene glycol)/water system were obtained under a solution vapour pressure of 20 to ~ 30 atm for the UCST and 1 to ~ 10 atm for the

Figure 2 Temperature/weight fraction phase diagram for the poly(ethylene glycol) samples in water: X, $M_n = 1020 \times 10^3$; O, $M_n = 21.2 \times 10^3$; A, $M_n = 14.4 \times 10^3$; V, $M_n = 8.0 \times 10^3$; B, $M_n = 2.29 \times 10^3$; D, $M_n = 2.27 \times 10^3$; +, $M_n = 2.18 \times 10^3$

LCST, depending on the molecular weight of the samples. Corrections of the LCST to the zero pressure condition for aqueous solutions would be small, while the corrected values of the LCST for the t-butyl acetate solutions would be lower than the observed ones by $0.4 \sim 0.6^\circ\text{C}/\text{atm}$ depending on the solution vapour pressures³⁶⁻⁴⁰.

DISCUSSION

According to the Patterson-Delmas theory of corresponding states the polymer-solvent interaction parameter of χ_1 is expressed by¹⁻⁶:

$$\chi_1 = -(U_1/RT)v^2 + (C_{p,1}/2R)\tau^2 \quad (1)$$

where U_1 and $C_{p,1}$ are the configurational energy and configurational heat capacity of the solvent respectively, R is the gas constant, and both the v^2 parameter and the τ parameter are the temperature independent molecular parameters. The v^2 parameter is related to the cohesive energy and segment size of the solution components, while the τ parameter is determined from the characteristic temperature reduction parameters (T^*) of the solvent (1) and polymer (2). It is convenient to rewrite equation (1) when applying it to polymer solutions using thermodynamic relations such as the thermodynamic equation of state and the difference relation between the heat capacities at constant pressure (C_p) and at constant volume (C_v)⁴:

$$-U_1 = \gamma_{v,1}V_1T \quad (2)$$

and

$$C_{p,1} = \gamma_{v,1}V_1T\alpha_1 \quad (3)$$

where $\gamma_{v,1}$ is the thermal pressure coefficient, α_1 is the thermal expansion coefficient, and V_1 is the molar volume of the solvent. The χ_1 expression coupled with equations (2) and (3) is independent of the model used for the configurational energy of the liquid. The calculated curve for χ_1 against temperature for the poly(ethylene glycol)/t-butyl acetate system using equation (1) coupled with the equation of state of the van der Waals model⁷, the experimental values of α_1 for t-butyl acetate over the temperature range of 20° to 95°C ²⁰ and extrapolated values of α_1 over 95° to 160°C is shown in Figure 4, where the values of the configurational energy (v^2 term), the configurational heat capacity (τ^2 term) in equation (1), and values of the χ_1 (crit) are also included. Values of the v^2 , τ^2 , and c_1 parameters, and the characteristic reduction parameters such as P^* , T^* , and V^* for the poly(ethylene glycol)/t-butyl acetate system are listed in Table 2. The values of the χ_1 (crit) are determined by neglecting $\chi_2\phi_2$ and higher terms in the χ parameter¹⁰ and are given by:

$$\chi_1(\text{crit}) = (1/2)(1 + r^{-1/2})^2 \quad (4)$$

where r is the ratio of the characteristic molar volume reduction parameter (V^*) of the polymer and solvent. The parabolic-like temperature dependence of χ_1 with a mini-

imum in the t-butyl acetate system is brought about by both an increasing contribution of the τ^2 term and decreasing contribution of the ν^2 term with increase in temperature.

The direct prediction of the temperature dependence of χ_1 in the poly(ethylene glycol)/water system by equation (4) is represented by the parabolic-like temperature dependence with a maximum. The temperature dependence of $\gamma_{v,1}$ for water^{41,42} is expressed by the parabolic-like temperature dependence with a maximum at ~150°C. This is contrary to the theoretical prediction from the reduced equation of state of the van der Waals model, which predicts a monotonous decrease of γ_v with an increase in temperature. The experimental values of γ_v for many liquids such as methane, n-heptane, benzene⁴², etc., monotonously decrease with increasing temperature. The increase of $\gamma_v = (\partial S / \partial V)_T$ with an increase in temperature observed in

water reflects the fact that the ratio of entropy change to enlargement of volume increases as the temperature increases. This behaviour is consistent with a contribution to the entropy originating from the break down of the structure of the water caused by an increase in temperature. In the light of these facts it is suggested that the phenomenon of the UCST and LCST in the poly(ethylene glycol)/water system is brought about by essentially different interactions from that of non-polar polymer solutions.

The value of $(dT/dP)_c$ for the LCST in the poly(ethylene glycol)/water system is related by^{43,44}:

$$\left(\frac{dT}{dP}\right)_c = \lim_{\substack{T \rightarrow T_c \\ \phi_2 \rightarrow \phi_c}} \frac{T(\partial^2 V / \partial \phi_2^2)_{T,P}}{(\partial^2 H / \partial \phi_2^2)_{T,P}} \quad (5)$$

where H and V are the enthalpy and the volume per mole mixture and ϕ_2 is the concentration of the polymer. The negligibly small and positive value of $(dT/dP)_c$ for the LCST in the aqueous solution corresponds to the negligibly small and positive value of $(\partial^2 V / \partial \phi_2^2)$ or the small negative excess volume of mixing because of the positive value of $(\partial^2 H / \partial \phi_2^2)$ in the vicinity of the LCST. The present value of $(dT/dP)_c$ for the LCST of the aqueous solution is consistent with the negative excess volume of mixing observed in the poly(ethylene glycol) ($M_n = 5 \times 10^3$)/water system at 65°C over the wide concentration range²⁵. The value of $(dT/dP)_c$ for the LCST in the poly(ethylene glycol)/water system (0.004°C/atm) is extremely small compared to the values of $(dT/dP)_c$ for the LCST in non-polar polymer solutions³⁶⁻⁴⁰, e.g. polystyrene/methyl acetate (0.45°C/atm)³⁷ and polystyrene/t-butyl acetate (0.65 ~ 0.70°C/atm)⁴⁰.

In this work it is emphasized that the phenomenon of the UCST and LCST and the pressure dependence of the LCST in the poly(ethylene glycol)/water system are caused by a special interaction between the poly(ethylene glycol) and water beyond the scope of van der Waals interactions, while the appearance of the UCST and LCST in the t-butyl acetate system can be explained by the recent theories of polymer solution thermodynamics by Patterson and Flory. It is also suggested from the temperature dependence of χ_1 estimated by equation (4) that the sign of the excess partial molar heat capacity⁴⁵ is negative for the t-butyl acetate system and positive for the water system.

Anomalous diffusion of water in glassy polymers

G. A. Pogany

Koninklijke/Shell Laboratorium, Amsterdam (Shell Research b.v.) The Netherlands
(Received 12 November 1975; revised 7 April 1976)

Anomalous diffusion of water has been observed in polystyrene and in epoxy resin. Sudden changes in the boundary conditions can cause the absorbed water to agglomerate and form a second phase within these polymers. The agglomerated water can force the polymer segments apart and create permanent crazes. The diffusion of water in crazed polymers is non-Fickian. The solubility becomes a function of the total pressure and the amount of water taken up from liquid water is much more than that absorbed in saturated water vapour.

INTRODUCTION

Many diffusion processes can be adequately described by Fick's first and second laws¹. However, deviations from Fickian diffusion in polymers have been observed². In these cases the diffusion coefficient becomes dependent not only on temperature, but also on time and concentration. Non-Fickian diffusion is usually explained by some kind of interaction between polymer and penetrant³⁻¹¹.

In the past special attention was paid to the anomalous diffusion of water in glassy polymers^{12,13}. More recently, this behaviour has been attributed to the presence of voids in the polymer¹⁴⁻¹⁸.

This paper presents the results of some experiments concerning the absorption of water by polystyrene and by epoxy resin. A qualitative explanation is given of the observed anomalies.

EXPERIMENTAL

Materials

The following materials were used: a pure, commercial, high molecular weight polystyrene homopolymer ('Carinex' HR), and a somewhat lower molecular weight polystyrene containing about 0.1 wt% of a finely dispersed (~1 μm), non-compatible, polymeric additive. Both samples were compression moulded into sheets of 1 and 3 mm thickness and cut into squares of approximately 10 × 10 cm.

In addition, samples of epoxy phenolic lacquers cast on tin plates were examined.

Technique

The dried and weighed polystyrene samples were immersed in water baths kept at 20°, 50°, 80° and 100°C, with an accuracy of ±1°C. At different intervals a sample was removed, plunged into ice-cold water, removed, dried of surface water with blotting paper, weighed on an analytical balance and returned to the bath. The whole procedure took about 30 sec. The purpose of using ice-cold water was to quench the sample and lower the diffusion constant so as to reduce the loss of absorbed water during weighing.

This process has been described by Braden¹⁹, except for the use of ice-cold water. Static electric charges sometimes developed during the surface drying of the samples, causing erratic weighing results. This problem was overcome by

ionizing the air with a spark from a Tesla coil inside the balance chamber²⁰.

The maximum solubility was found from a plot of the weight increase versus the logarithm of time. The diffusion constant can be calculated from such a curve using the relationship:

$$D = \frac{0.049L^2}{t_{1/2}}$$

where, D = diffusion constant in cm²/sec; L = thickness of the specimen in cm; $t_{1/2}$ = half-time of saturation in sec.

In addition to measuring the diffusion and solubility constants, we made use of an optical and an electron microscope.

RESULTS

Compression moulded sheets of pure, high molecular weight polystyrene immersed in water at temperatures up to 80°C (their approximate glass-transition temperature, T_g) absorbed water according to the sigmoid curves shown in Figure 1. These results proved reproducible after a number of absorption-desorption cycles. Sometimes, however, it was impossible to obtain a well-defined plateau of maximum absorption within the experimental time.

Figure 2 shows that the low molecular weight polystyrene, with a small amount of non-compatible polymeric additive dispersed in it, kept on increasing in weight at the same temperatures. Figure 3 shows that the pure, high molecular weight polystyrene behaved similarly at 100°C.

Figure 1 Absorption of water by pure polystyrene, $L \approx 3$ mm. A, 22°C; B, 50°C; C, 80°C

Figure 2 Absorption of water by polystyrene with additive, $L = \sim 3$ mm. A, 22°C; B, 50°C; C, 80°C

Figure 3 Absorption of water by polystyrene at 100°C, $L = \sim 1$ mm. ●, With additive; ○, pure

(Note the increased scales on both axes and the reduction in sample thickness from 3 to 1 mm.) Even more significant is the 100°C absorption curve of the lower molecular weight polystyrene, also depicted in Figure 3.

Solubility values and diffusion constants calculated from Figures 1 and 2 are presented in Table 1. The values for the non-pure polymer are based on the assumption that equilibrium has been reached in 10 000 min.

On the basis of the results given in Figures 1 and 2 one might expect a higher maximum weight to be reached at 100°C, since the saturated vapour pressure of water (driving force) increases with temperature faster than the solubility decreases. Moreover, the diffusion constant increases with temperature, so that the new maximum should be attained quicker. However, the uptake of water by the samples in Figure 3 shows no sign of reaching a maximum, in spite of the very long times involved.

In the 100°C experiment we observed that as long as the pure polystyrene samples were immersed in the hot water, they were transparent. On removal and cooling they turned opaque. On being returned to the hot water, they again became transparent. Opacity first developed on the outer faces of the test plate and moved inwards with time. We further observed that the opacity did not disappear with the complete removal of the absorbed water at room temperature, but faded away quickly when the dried sample was heated above its glass-transition temperature. The heated sample then became transparent again and remained so at all temperatures.

We induced opacity in a pure polystyrene sample by keeping it in a water bath at 100°C for 168 h. After removal of all the absorbed water *in vacuo* at room temperature, we repeated the 80°C absorption experiment. The still opaque sample proved to absorb much more water than the original, transparent one, as shown in Figure 4, which should be compared with Figure 1, curve C.

The additive-containing polystyrene sample was already opaque to start with. Whereas the pure polystyrene gave reproducible results at temperatures up to and including 80°C, this polymer took up increasingly large quantities of water on repeated absorption at 80°C (not shown). This material, too, was kept in a 100°C water bath for 168 h, along with the pure polymer. After drying at room temperature now it took up as much water at 80°C as the pure polystyrene (see Figure 4).

A transparent sample of pure polystyrene and two samples of the same material made opaque by prolonged immersion in hot water were allowed to absorb water at 80°C. They were then subjected to a series of experiments involving the consecutive use of vacuum, water, air saturated with water vapour, and saturated water vapour only (no air) at 50°C. Each condition was maintained for at least 48 h (2880 min), which – according to Figure 1 – is sufficiently long for equilibrium to be reached. Figure 5 shows the equilibrium values obtained, connected by straight lines, which serve as visual aids only.

Table 1 Solubility values and diffusion constants for pure polystyrene and polystyrene with additive

Unit	Temperature (°C)	Pure polystyrene	Polystyrene with additive
Solubility (cm ³ /cm ³ /cmHg)	22	0.385	0.533
	50	0.141	0.205
	80	0.053	0.073
Diffusion constant (cm ² /sec × 10 ⁷)	22	1.7	0.9
	50	5.6	3.1
	80	16.0	9.6

Figure 4 Reabsorption of water by polystyrene at 80°C after 168 h in 100°C water (to induce crazing) and desorption, $L = \sim 1$ mm. ■, Pure; △, with additive

Figure 5 Water absorption and desorption experiments with compression moulded polystyrene (HR) plates. Each step measured after 48 h. ○, opaque; ●, opaque; ■, transparent

Figure 6 Desorption of water at 50°C from polystyrene sheets after immersion in water at 80°C for 50 h. X, Opaque; □, slightly opaque; ●, transparent

There seemed to be a difference between the equilibrium conditions of the transparent and the opaque samples. For the latter, a further difference was observed between samples submerged in the liquid water and those exposed to saturated water vapour only. The total amount of water retained in the opaque samples was no longer proportional to the partial pressure of water vapour, but proved to be a function of the total absolute pressure.

Three samples of pure polystyrene, one transparent, one slightly opaque and one opaque, were immersed in water at 80°C for two days and then transferred to a 50°C bath. The resultant weight loss as a function of time is shown in Figure 6. Interestingly, although the starting points were widely different, the three samples lost about equal amounts of water and reached a new equilibrium in about equal times.

Another glassy polymer, epoxy phenolic lacquer, is regularly subjected to hot water in practice. As coating material in tin cans it has to withstand sterilization. In certain cases (e.g. inadequate cure) white spots appear on the lacquer, a phenomenon known to the industry as 'blushing'. It is known that the part submerged in the water (100°C or higher but still below its T_g of about 140°C) exhibits more blushing than the part just above the water level, which is still in contact with the saturated vapour (see Figure 7).

Using an optical and an electron microscope we found that blushing is a result of the development of a large number of small voids (see Figure 8). These voids are not inherently present in the polymer but develop on sterilization. We have further established that just as with the polystyrene samples, as reported above, these voids appear on cooling the sample after its removal from the hot water. The voids remain after drying but heal if the sample is heated above its T_g .

DISCUSSION

It is evident from these experiments, that under certain conditions the diffusion of water in glassy polymers, such as polystyrene, can become non-Fickian. That is to say that the absorption curve is no longer sigmoid in shape, and an apparent diffusion constant, which could be calculated, would depend on the amount of water already absorbed (see Figure 4). This kind of behaviour has been recognized as such in the literature and many an explanation has already been offered. In the most general cases some kind of polymer/penetrant interaction²⁻⁶ or even swelling⁷⁻¹⁰ is postulated, whereas in others the general term 'active sites' is used¹¹. However, none of these theories can be applied to the polystyrene/water system.

It is more likely that in our systems the active site is nothing but a void^{14,17,18}. The existence of a submicroscopic network and free volume in glassy polymers is well established²¹⁻²³. There is further evidence to suggest the presence of local order and disorder²⁴⁻²⁶. To accommodate a water molecule, this hole must have a diameter of at least 3 Å. Since we observed no opacity in the pure polystyrene up to 80°C the diameter of the voids must be below 300 Å. Sarbolouki²⁷ measured the diffusion of water through cellulose acetate membranes of different porosities. He concluded that for 'true' diffusion the pore size should be 3-5 Å, and that above this value the diffusion constant should increase abruptly. However, using pore sizes up to 74 Å, he did not find any evidence of non-Fickian behaviour.

In our experiments the anomalous diffusion coincided with sample opacity, which we think points to the presence of discontinuities having a size of at least 300 Å. Anomalous diffusion and opacity have been linked before by others¹². Opacity or crazing in glassy polymers can be induced by mechanical stress²⁸⁻³⁰ or by a solvent^{8,9,31-33}. Drioli *et al.*¹⁵ induced crazing during diffusion measurements by applying pressure and measured its effect. If crazing is induced e.g. by creep even permanent gases behave anomalously in subsequent diffusion experiments¹⁶. Barrer and Barrie reported¹³ that crazing can result from clustering of water molecules during the experiment.

The term crazing is usually used to describe cavitation in the material due to local weakness as a result of tensile stress. It has been demonstrated that in glassy polymers these crazes contain, besides voids, continuous (oriented) polymeric material. The presence of such oriented matter in our samples has not been established, thus the use of the term craze in this context may be incorrect. Since the term 'solvent crazing' is so widely used, however, we felt justified in using the same term here.

In a non-homogeneous system permeability should be proportional to the concentration and the permeability of the individual components. This was confirmed for some systems³⁴ but not for others^{35,36}. Presumably, the adhesion and continuity at the interface play an important role. For the polystyrene with the polymeric additive we found that while the diffusion constant decreased the solubility had increased to values far above the level expected from its composition. We conclude that the dispersed particles had increased the voids content of the sample.

Figure 7 Optical micrograph of the border line in blushing lacquer. The darker part was submerged in liquid water, the lighter part was in contact with the saturated vapour only

Figure 8 Electron micrographs of an undercured epoxy phenolic lacquer before and after sterilization in hot water. (a) Before sterilization, magnification 1000X; (b) after sterilization not submerged in water, magnification 1000X; (c) after sterilization submerged in water, magnification 1000X; (d) as for (c), magnification 10 000X

We further confirmed Barrer and Barrie's finding that crazing is caused by clustering of water in the pure polystyrene and epoxy resin samples. Our observations suggest the following mechanism: first the hot, absorbed water is dispersed in the polymer in units smaller than 300 \AA , then on rapid cooling the vapour pressure drops and the polymer attempts to eject the excess amount of water it holds. However, desorption is slow and in the meantime the surplus

water forms a second phase within the polymer. It agglomerates in places of least resistance and in near spherical shape to minimize its surface area. The holes created by the clusters remain as long as the polymer is in the glassy state.

It is known that mechanically crazed samples of polymers 'heal' when heated above their glass-transition temperature³⁷. We found the same to be true for 'absorption-

crazed' polymers. Above their glass transition temperature the mobility of polymer segments is restored and if the obstruction (i.e. absorbed water) has been removed the holes created by the forced deformation close permanently. If water is still present, it re-disperses and the sample becomes temporarily transparent again.

If the cycle of immersion in hot water and cooling is repeated some permanent damage is bound to occur, resulting in the creation of new holes and an increased water uptake in subsequent measurements. Thus *Figure 3* probably represents a polymer with a continuously increasing degree of crazing and solubility. As evidence in support of this hypothesis, we can report that some of the samples eventually developed visible cracks and broke up during an extended test.

It is difficult to be certain about where the non-Fickian process begins. In the pure polystyrene we first observed the development of a cobweb-like network of crazes. We believe this to represent the grain boundaries of individual polymer particles (extruded nibs) which were subsequently compression moulded. Evidently, the compression moulding process did not fully destroy the protection given by the oriented surface of the extruded particles.

The diffusion of water from the voids into the polymer remains Fickian, but the continuously increasing solubility suggests the overall process to be non-Fickian. The water in the crazes, whatever its quantity, is in thermodynamic equilibrium with its surroundings. The flow in and out of them is controlled by hydrostatic pressure differences and not by differences in partial pressure alone. This model may be used to explain the results of other workers^{38,39} who reported differences between diffusion of liquids and their vapours.

Polyethylene and polytetrafluoroethylene crystals: chain folding, entropy of fusion and lamellar thickness

Alan E. Tonelli

Bell Laboratories, Murray Hill, New Jersey 07974, USA

(Received 14 January 1976; revised 17 February 1976)

Chain folding in polyethylene (PE) and in polytetrafluoroethylene (PTFE) crystallites is simulated on the computer in an attempt to determine if the large disparity in their lamellar thicknesses has its origin in any differences between their inherent abilities to fold. PE and PTFE chains of 6 to 15 carbon atoms are permitted to adopt each of their many rotational isomeric state (RIS) conformations, and each is checked for the presence of a chain fold. The conformational energetics of both polymers are used to calculate the probabilities of generating both randomly and adjacently re-entering chain folds. Depending on the RIS model adopted for PTFE, calculated probabilities for generating randomly re-entering folds are found to be comparable in PE and PTFE. Adjacently re-entering folds, however, are much more easily formed in PE than in PTFE. Despite the greater ease of folding PE chains, the relative energies required to create a unit area of chain fold are estimated to be nearly the same for both polymers in agreement with results obtained from the kinetic theory of chain folding. Consequently, in agreement with the recent proposal of Bassett and Davitt, it is concluded that the greater lamellar thickness of PTFE crystals is attributable exclusively to their lower entropy of fusion. An analysis of the possible reasons for the low entropy of fusion of PTFE is also presented.

INTRODUCTION

Melt crystallized polytetrafluoroethylene (PTFE) is unusual among crystalline polymers¹ with regard to its thick lamellae. Lamellar thicknesses of 1000–2500 Å are typically observed for PTFE, while by comparison polyethylene (PE) crystallized from the melt normally consists of lamellae 300–400 Å in thickness.

The disparity in lamellar thicknesses observed between melt crystallized PTFE and PE and its origin were recently the subjects of a study reported by Bassett and Davitt². They concluded that both polymers obey the kinetic theory of chain folding³, and PTFE derives its unusually thick lamellae from its low entropy of fusion.

The motivation for the present study of the inherent ability to fold PTFE and PE chains stems from the work of Bassett and Davitt². By comparing the probabilities of generating folds in PTFE and PE it is hoped that the underlying basis for the low entropy of fusion of PTFE, which results in a high melting temperature as well as thick lamellae, could be determined.

CALCULATION OF FOLD PROBABILITIES

Identical C–C bond lengths (1.53 Å) and C–C–C valence angles of 112° for PE and 116° for PTFE are adopted⁴ for PTFE and PE chains containing from 6 to 15 carbon atoms. The usual rotational isomeric state (RIS) model for PE is employed⁵. Each of the three staggered rotamers about each bond is permitted, with the two *gauche* rotational states ($g^\pm = \pm 120^\circ$) assigned an energy of $E_g^\pm = 500$ cal/mol higher than the *trans* state ($t = 0^\circ$). Neighbouring *gauche* states of opposite sign ($g^\pm g^\mp$) are allowed, but at a cost of $E_{gg}^\pm = 2.0$ kcal/mol.

Two different RIS models developed by Bates and Stockmayer^{6–8} for PTFE are adopted. The three-state model is identical to that described for PE except that $E_g^\pm = 700$ –1400 cal/mol and $E_{gg}^\pm > 4.0$ –5.0 kcal/mol. In the four-state model the *trans* rotational state is replaced by two states t^\pm symmetrically displaced by $\pm 15^\circ$ from the planar zig-zag. The $t^\pm g^\mp$, $g^\pm t^\mp$, and $g^\pm g^\mp$ states for neighbouring bonds are disallowed, and the $t^\pm g^\pm$, $g^\pm g^\pm$, and $t^\pm t^\mp$ states are assigned energies of 950, 950 and 1750 cal/mol, respectively, relative to the $t^\pm t^\pm$ and $g^\pm t^\pm$ states.

The RIS model of PE has been successful in predicting the dimensions and their temperature dependence⁵ and the constant volume entropy of fusion for PE⁹, the depolarized light scattering of n-alkanes¹⁰, and the dipole moments of the terminally substituted dibromo-n-alkanes¹¹ $\text{Br}-(\text{CH}_2)_n\text{Br}$. Because of the insolubility of PTFE experimental determination of the conformational characteristics of isolated PTFE chains is difficult. Instead, Bates and Stockmayer⁷ have measured the dipole moments of α,ω -dihydroperfluoroalkanes, $\text{H}-(\text{CF}_2)_n\text{H}$, with $n = 4, 6, 7, 8$ and 10. Their three- and four-state RIS models of PTFE, which were described above, successfully reproduce the experimental dipole moments of these α,ω -dihydroperfluoroalkanes.

A right-handed Cartesian coordinate system is defined with origin at the first carbon atom of the chain and the X-direction (same as C-axis in crystal) taken perpendicular to the H–C₁–H or F–C₁–F planes in the PE and PTFE chains, respectively. The positions of carbon atoms C₃ through C₁₅ in this reference frame are calculated for each of the RIS conformations generated. If the component of the C₆–C₁₅ position vectors along the X-axis is smaller than 0.3 to 0.5 Å, then a randomly re-entering fold is

assumed to have been formed provided the X -coordinates of the intervening atoms C_3-C_{14} are at least 1.0–1.3 Å above C_1 . This ensures that none of the atoms C_2-C_{n-1} in a C_1-C_n fold penetrate, or approach too closely, the crystal surface.

Each randomly re-entering fold generated above is tested further to determine whether or not it also belongs to the subgroup of adjacently re-entering folds. If the sum of the Y^2 and Z^2 components of the C_6-C_{15} position vectors is $\geq [ID - (0.3 \text{ to } 0.5 \text{ Å})]^2$ or $\leq [ID + (0.3 \text{ to } 0.5 \text{ Å})]^2$, where ID is the interchain separation in the crystal ($ID = 5.0 \text{ Å}$ for PE and 5.6 Å for PTFE)¹², then the fold formed is termed adjacently re-entering.

The 0.3 to 0.5 Å tolerances permitted in generating folds presumably corrects, at least partly, the artificial built in rigidity of the PE and PTFE chain models employed, i.e. the rigid valence angles and the perfect staggering of the rotational states.

A probability is calculated for each of the randomly and adjacently re-entering folds so generated. This is achieved by multiplying the pairwise dependent rotational state statistical weights $\mu_{\alpha\beta}$, where for bond i in state β and bond $i - 1$ in state α , $\mu_{\alpha\beta} = \mu_{i-1=\alpha, i=\beta} = \exp(-E_{\alpha\beta}/RT)$, for each of the $n - 2$ bond rotations in the n carbon atom

folds. This product of statistical weights is then divided by the sum of the products of statistical weights for every conformation (fold plus non-fold) possible for an n carbon atom chain, which is the configurational partition function. The resulting number is the fractional probability of forming a particular fold of n carbon atoms in length. The melting temperatures of PE and PTFE (140° and 330°C , respectively) are used in the calculation of the fold probabilities.

RESULTS AND DISCUSSION

Tables 1 and 2 contain the calculated fractional probabilities for forming folds of from 6 to 15 carbon atoms in PE and PTFE chains which re-enter the crystal surface in either a random or adjacent manner, respectively. The relative probabilities of forming randomly re-entering folds in PE and PTFE chains depend markedly on the RIS model adopted for PTFE. When the three-state RIS model is assumed for PTFE, the resulting fold probabilities are comparable to those calculated for randomly re-entering PE. On the other hand, the four-state model of PTFE leads to randomly re-entering fold probabilities much reduced from those calculated for PE.

Table 3 Comparison of the entropies of fusion* of PE and PTFE

Polymer	ΔS_f	$(\Delta S_f)_v$	ΔS_v	ΔS_{conf}
PE	2.34	1.82	0.52	1.76
PTFE	1.14	0.77	0.37	1.60

* All entropies are given in eu/mol of repeat units (CH_2 or CF_2)

In contrast to the behaviour of the randomly re-entering folds, the probabilities of forming adjacently re-entering PE folds are considerably greater than the probabilities calculated for adjacently re-entering PTFE folds. This disparity in adjacently re-entering fold probabilities is independent of the *RIS* model adopted for PTFE.

Since it is becoming increasingly evident^{3,12-15} that the primary mode of folding in polymer chain crystals is the adjacent re-entry of portions of the same polymer chain, we restrict our attention to the probabilities calculated for adjacently re-entering folds. If the disparity in the fold probabilities calculated for PE and PTFE chains is interpreted in terms of differences in fold energy, q , in kcal/mol of folds, then it is possible to conclude from the probabilities presented in Table 2 that $q(\text{PTFE}) \geq 1.5q(\text{PE})$. This conclusion is based on the assumption that the fold probability is proportional to the Boltzmann factor of q at the melting temperature.

The fold energy, or work required to form a fold, q constitutes an important ingredient in the kinetic theory of chain folding³. Of direct concern here is the relation between the lamellar thickness l and the fold energy q . In the kinetic theory of chain folding³:

$$l = \frac{2\sigma_{\text{eff}}}{\Delta S_f \Delta T} + \delta l \quad (1)$$

and

$$\sigma_{\text{eff}} = \sigma + \frac{q}{2A_0} \quad (2)$$

where ΔS_f is the entropy of fusion per unit volume of the crystal, ΔT is the undercooling, σ is to a good approximation the lateral surface free energy of the polymer crystal, δl is nearly constant at 10–40 Å, and A_0 is the cross-sectional area of a chain in the crystal. Since for most polymer crystals³ $\sigma \ll q/2A_0$:

$$l \approx \left(\frac{q}{A_0 \Delta S_f \Delta T} \right) \quad (3)$$

From an analysis of lamellar thickness *versus* undercooling data, fold energies of 5 and 7.5 kcal/mol of fold have been obtained for PE and PTFE³, respectively. In other words it was found that $q(\text{PTFE}) = 1.5q(\text{PE})$ in kcal/mol of fold which is not inconsistent with the difference in fold energies derived here from the calculated fold probabilities.

Division of q by the cross-sectional area of a chain in the crystal A_0 leads to nearly identical ratios q/A_0 for PE and PTFE. As stressed by Bassett and Davitt² this means (see equation 3) that at a given undercooling the difference in the lamellar thicknesses observed for PE and PTFE crys-

tals grown in the bulk is directly attributable to the difference in their per unit volume entropies of fusion i.e. $\Delta S_f(\text{PE}) \approx 3.0 \Delta S_f(\text{PTFE})$. Thus, even though the inherent abilities of PE and PTFE to fold in adjacently re-entering fashion differ greatly, when they are translated into fold energies q and divided by fold area $2A_0$ the closely similar values of $(q/2A_0)$ obtained for both polymers eliminates them as the principal source of the disparity in lamellar thicknesses.

Turning finally to the difference in the entropies of fusion of PE and PTFE, which Bassett and Davitt² and we believe to be the sole source of the disparity in their lamellar thicknesses, it may be worthwhile to devote a few comments to the most likely sources of this entropy difference. When the entropies of fusion¹⁶ for PE and PTFE expressed per mole of repeat units, i.e. 2.34 and 1.14, respectively, are converted to a per unit of crystalline volume basis, the two-fold disparity is further magnified to over a three-fold difference, i.e. 0.167 eu/cm³ (PE) and 0.0502 eu/cm³ (PTFE). Even if the molar entropies of fusion were identical for PE and PTFE, the smaller molar density of the PTFE crystal would still result in a smaller volume entropy of fusion for PTFE and larger lamellae according to equation (3).

The entropy of fusion ΔS_f may be divided into two separate contributions¹⁷, the constant volume $(\Delta S_f)_v$ and the volume expansion ΔS_v entropies of fusion. Each of these contributions for PE and PTFE is listed in Table 3. Furthermore it has been demonstrated^{9,18} for a wide variety of polymers that the constant volume contribution $(\Delta S_f)_v$ is closely approximated by the gain in intramolecular (intra-chain) conformational entropy ΔS_{conf} experienced by each polymer chain upon melting. ΔS_{conf} can be calculated^{9,18} from the *RIS* model of a polymer chain, such as the three- and four-state models used to calculate the fold probabilities of PE and PTFE, by assuming that each polymer chain in the crystal is restricted to a single conformation. When applied to PE and PTFE the conformational entropies obtained are those shown in the final column of Table 3.

For PE $(\Delta S_f)_v \approx \Delta S_{\text{conf}}$, while for PTFE $(\Delta S_f)_v \approx \frac{1}{2}(\Delta S_{\text{conf}})$. Upon melting, half of the conformational entropy gain expected for the PTFE chains is not realized resulting in a total entropy of fusion significantly lower than that of PE and a larger lamellar thickness as well. Either the PTFE chains in the melt are partly ordered, preventing the complete achievement of the *RIS* entropy, or some conformational disorder exists in the crystal resulting in a non-zero conformational entropy for the crystalline PTFE chains. Based on statistical thermodynamic arguments¹⁹ and recently reported suggestions²⁰ of conformational isomorphism in PTFE crystals, we believe that conformational disordering* of the crystalline PTFE chains to be the most probable cause of the observed loss in conformational entropy upon melting.

In combination, the lower molar density of and probable conformational disorder in PTFE crystals are sufficient to cause the necessary reduction in the per unit volume entropy of fusion which leads to their increased lamellar thickness.

* Conformational disordering of the PTFE chains in the crystal is to be distinguished from the rotation and/or translation of rigid chains known²¹⁻²⁴ to occur in PTFE crystals below the melting point which serve to reduce the volume expansion entropy of fusion ΔS_v , but not the constant volume contribution $(\Delta S_f)_v$.

ACKNOWLEDGEMENT

Thanks are due to H. Schonhorn for bringing the subject of this paper to the author's attention.

Determination by ATR infra-red spectroscopy of the chemical composition of the surfaces of rubber/resin adhesive films is described. An excess concentration of resin at the surfaces compared with the bulk is found, this being shown to be dependent on the solvent, the overall bulk concentration of resin, the thickness of the film and time of equilibration. A proposed qualitative mechanism explains the appearance of the concentration profile in terms of the solubility characteristics of the system and the evaporation rate of the solvent.

INTRODUCTION

Modern adhesive systems of the pressure sensitive type are based on mixtures of several components, the exact formulations generally being based on empirical knowledge. The compatibility of the components is largely unknown and the phase structure of such systems has received comparatively little study¹⁻⁵. In addition, many of these adhesives are solvent based, i.e. the adhesive components are dissolved in a solvent which is used as a carrier to assist in the application of a thin film of the adhesive to the substrate. The solvent subsequently evaporates leaving the adhesive film on the substrate. Although the system may be a homogeneous solution at the normal solvent concentrations, during the evaporation stage any incompatibility within the mixture will become evident, and the nature of the solvent and the evaporation conditions might be expected to influence the final structure of the adhesive film. Incompatibility between the components in the adhesive might be expected to lead to a surface composition which is not identical with that of the bulk. Recent evidence⁶ has shown that solvent evaporation from thin films can give fractionation of incompatible components. A knowledge of the surface composition of adhesive films seems fundamental to an understanding of the mechanism of adhesive bond formation and failure, since it is the surface properties of the films which are of critical importance in this context.

A two component adhesive system was chosen, closely approximating to current industrial practice, consisting of natural rubber and a commercially available tackifying resin (glycerol ester of partly hydrogenated wood rosin). The function of the resin is to plasticize the rubber, and enable the adhesive to adhere easily to a wide variety of substrates. The maximum ability to adhere as measured by the tack energy⁷ may be developed in this type of adhesive with high loadings of the resin (up to 80% by volume). The pure resin is a brittle, glassy solid. The rubber and resin mixtures were dissolved in a variety of solvents, films were cast and the solvent allowed to evaporate; the chemical

composition of the film at the air/adhesive and adhesive/substrate interfaces was examined by internal reflection infra-red spectroscopy (ATR).

ATR has been used extensively to study qualitatively the chemical composition of surfaces of polymeric materials such as paint films^{8,9} and the chemical reactions occurring at the surfaces of such films under the influence of various environments¹⁰⁻¹². One of the problems inherent with quantitative analysis by ATR is obtaining consistent contact efficiency between the surface of the film and the internal reflection crystal. To overcome this, an internal standard was used, thus calibration curves were prepared by relating the intensity of a concentration dependent absorption to the intensity of an absorption which was not sensitive to changes in composition.

An examination of the fundamentals of the theory of ATR¹³ shows that the totally reflected beam from the crystal/adhesive interface penetrates the adhesive film, and the depth of penetration (dp), perpendicular to the interface, of the evanescent wave is given by Harrick¹³ as:

$$dp = \frac{\lambda}{2\pi n_1} (\sin^2\theta - n_{21}^2)^{-1/2} \quad (1)$$

where λ is the wavelength of the radiation in air, θ is the angle of incidence and n_{21} is the ratio of the refractive indices of the crystal (n_1) and the sample (n_2). The evanescent wave is selectively attenuated according to the infra-red activity of the sample in the region from the surface to a depth dp . Thus by varying θ or λ different depths of penetration into the sample may be achieved, and hence the variation of chemical composition of surface layers of varying thickness may be examined.

EXPERIMENTAL

Materials

Natural rubber. $\bar{M}_n = 736\,800$ g/mol; $\bar{M}_w = 927\,600$ g/mol; relative density = 0.900 at 293K.

Purification technique. The rubber was dissolved in

Figure 1 Ratio R_1 of absorption intensities at $5.78 \mu\text{m}$ (A) and $8.13 \mu\text{m}$ (B) to the internal standard absorption at $6.90 \mu\text{m}$ plotted against volume fraction of resin on the crystal surface

toluene (1–2 mass percent concentration), filtered through a No. 4 glass sinter to remove insoluble impurities. The natural rubber was then precipitated by adding excess acetone, filtered and dried to constant mass in a vacuum desiccator at 5 Torr and $293 \pm 2\text{K}$.

Resin. Staybelite Ester 10 (Hercules Powder Co.) glycerol ester of partly hydrogenated wood rosin which consisted of approximately 84% diester and 16% triester. $\bar{M}_n = 993 \text{ g/mol}$; relative density 1.066 at 293K ; softening point (Ring and Ball¹⁴) 358.5K .

Solvents. Analar grade reagents used without further purification.

ATR INFRA-RED SPECTRA

Spectra of the adhesive surfaces were obtained by use of a Perkin–Elmer model 457 grating infra-red spectrophotometer fitted with a Wilks model 9 multiple internal reflectance attachment. A KRS-5 crystal (eutectic mixture of thallos bromide and iodide) of width 20 mm and length 50 mm was used, having a 45° entrance and exit face, giving up to 25 reflections. This system gave a maximum transmission through the internal reflectance attachment corresponding to 35–45% of the intensity of the unattenuated reference beam. All spectra were obtained using a medium scan rate, which required approximately 15 min to scan from 4000 cm^{-1} ($2.5 \mu\text{m}$) to 250 cm^{-1} ($40 \mu\text{m}$).

The method was calibrated by casting separate films of pure rubber and pure resin in toluene onto adjacent areas of the same crystal. The solvent was allowed to evaporate completely under ambient temperature conditions ($293 \pm 2\text{K}$). By varying the length of the rubber and resin films (constant film width of 20 mm) various area ratios could be obtained. Thus spectra corresponding to the whole composition range were recorded. Two concentration-dependent absorptions were selected, at 1730 cm^{-1} ($5.78 \mu\text{m}$) and 1230 cm^{-1} ($8.13 \mu\text{m}$), both associated with the ester linkage of the resin. An absorption at 1450 cm^{-1} ($6.90 \mu\text{m}$) was selected as the internal standard, since the intensity of this absorption (due to the methyl, methylene and methyne bending vibrations, present in both resin and rubber) was not significantly concentration-dependent. The ratios R ,

of the absorption intensities at 1730 cm^{-1} and 1230 cm^{-1} to the internal standard absorption intensity at 1450 cm^{-1} are plotted against the percentage by area of resin on the crystal surface in Figure 1. The standard deviations in R , are within $\pm 0.2\%$.

The compositions of the adhesive films at the adhesive/substrate interface were examined by casting mixtures of rubber and resin dissolved in solvent (2.3% by mass) directly onto the KRS-5 crystal and allowing the product to evaporate completely under ambient conditions ($293 \pm 2\text{K}$). By controlling the concentration and volume of the solutions used for a given area of crystal, a constant dry film thickness of $5.20 \mu\text{m}$ was produced, and used for all measurements except where otherwise stated. The spectrum of the adhesive film was scanned as soon as all the solvent had evaporated from the film, usually within 20 min (the retained solvent concentration was less than $10^{-3}\%$). The ratios of the absorption intensities at 1730 cm^{-1} and 1230 cm^{-1} to the absorption intensity at 1450 cm^{-1} were calculated and hence the volume fraction of resin in the surface layer was found by reference to the calibration curves (Figure 1).

The compositions of the adhesive films at the adhesive/air interface were examined by casting the adhesive solutions onto an inert support film and laminating the dry film to the KRS-5 crystal. The intensity of the spectrum obtained in this manner was significantly affected by the modulus of the film and the lamination pressure, but the use of an internal standard removed the problems normally associated with variable contact efficiency.

Measurements were made using an internal reflection angle of 45° . The refractive indices of rubber and resin were measured by the usual methods in the visible region of the electromagnetic spectrum and equation (1) used to calculate the depth of penetration, dp . The depths of penetration dp corresponding to the concentration-dependent absorption at wavelengths, λ , of $5.78 \mu\text{m}$ (1730 cm^{-1}) and $8.13 \mu\text{m}$ (1230 cm^{-1}), were calculated to be $1.33 \mu\text{m}$ and $1.87 \mu\text{m}$ respectively.

Since the refractive indices of the rubber and resin may vary with the wavelength of the radiation, the depth of penetration was confirmed experimentally. Films of rubber of known thickness were cast onto a poly(ethylene terephthalate) support film and laminated onto the crystal face. The spectrum of the backing film was visible at $5.78 \mu\text{m}$ (ester absorption) when viewed through a $1.30 \mu\text{m}$ thick rubber film, but was not visible through a $1.35 \mu\text{m}$ thick film. This indicated that the depth of penetration at a wavelength of $5.78 \mu\text{m}$ was between $1.30 \mu\text{m}$ and $1.35 \mu\text{m}$; which is in good agreement with the theoretical value of $1.33 \mu\text{m}$.

All experimental data represent the mean of twelve spectra recorded for each composition. This procedure was used to compensate for random variations in the spectrum due to fluctuations in environmental conditions.

RESULTS AND DISCUSSION

The system was dissolved in toluene and investigated most thoroughly since this is a solvent often used in industrial practice. In all cases, adhesive films prepared from toluene solutions gave spectra which indicated a higher concentration of resin at the surface than the overall resin concentration for the whole film, based on the known masses of rubber and resin in the initial solution. The results are most

Figure 2 Fractional surface excess of resin for 5.2 μm films cast from toluene solutions for two depths of penetration: 1.33 μm (○); 1.87 μm (●)

easily displayed by defining a fractional surface excess i.e.

fractional surface excess =

$$\frac{\text{observed surface layer volume fraction of resin}}{\text{overall bulk volume fraction of resin}} \quad (2)$$

Figure 2 shows the variation in fractional surface excess with bulk volume fraction of resin for films cast from toluene solutions, using two depths of penetration of the radiation. Representative mean deviations are shown. The results were identical, within experimental uncertainties, for both the adhesive/substrate and the air/adhesive interfaces. It can be seen (a) that the fractional surface excess decreases as the bulk volume fraction of resin increases; (b) that the fractional surface excess decreases as the depth of penetration of the radiation increases.

These observations are consistent with the view that at the surface itself, there is an excess of resin for all compositions. It must be appreciated that the ATR technique is giving concentration data characteristic of surface layers of thicknesses which are not negligible compared with the total thickness of the adhesive film (5.20 μm). The results presented in Figure 2 suggest that in the dry adhesive film there exists a concentration gradient of resin varying from a maximum at each interface to a minimum at the centre of the film.

Figures 3 and 4 show the results obtained for the fractional surface excess of resin as a function of the bulk volume fraction of resin for films of increased thickness (11.40 μm), compared to the previous data of Figure 2. As the film thickness is increased, so the surface excess concentration of resin decreases.

The possibility that interactions between the rubber and resin cause changes in absorption intensities or the ratio of absorption intensities was investigated. Films of known thickness of pure resin and pure rubber were cast from

toluene solution onto each face of a rock salt plate. The transmission spectrum of this combination was recorded and compared with the transmission spectrum of a mixture of rubber and resin cast from solutions onto a single face of the rock salt plate. Both spectra thus measured the absorptions of identical amounts of rubber and resin, in one case without any possible interactions and in the other case with interactions possible. The spectra were identical within experimental uncertainties, showing that interactions between rubber and resin in the dry film do not cause spurious effects which might have suggested an excess of resin at the interface.

In order to assess the influence of the chemical and physical properties of the solvents on the composition of the surface layer of adhesive films, the volume fraction in the surface layers was measured for a wide range of solvents for five overall bulk resin compositions at two depths of penetration (Table 1) for 5.20 μm thick films. In all cases the data refer to both adhesive/substrate and air/adhesive interfaces, with no significant differences in composition being

	1.87	0.078	0.272	0.458	0.643	0.862

shown between the two interfaces. The general pattern of the results followed those shown in *Figure 1* for toluene. At least for the lower depth of penetration, all systems show an excess of resin in the interfacial layer, with the fractional surface excess of resin decreasing with increasing overall volume fractions of resin in the mixture. The absolute values of the fractional surface excesses of resin and their dependence on the overall concentration of the mixture are seen to be dependent on the solvent used in the film forming operation.

Since it has been shown that the fractional surface excess of resin is identical at either interface, and that it decreases with increasing depth of the surface layer, the volume fraction of resin, y , may be assumed to follow a simple parabolic relationship as a function of film thickness, x , having a minimum at $x = 0$, the centre of the film, and maxima at the film interfaces $-x_{\text{min}}$ and $+x_{\text{max}}$ (*Figure 5*). It may be seen from *Figure 4* that the experimentally observed volume fractions y_1, y_2, y_1^1 and y_2^1 represent the mean volume fractions with layers of thickness $(x_{\text{max}} - x_1), (x_{\text{max}} - x_2)$ etc. The mean bulk concentration for the film is y_{av} . The simplest equation for this parabolic relationship is:

$$y = ax^2 + b \quad (3)$$

where a and b are constants. Integration with respect to x gives:

$$\int y dx = \int (ax^2 + b) dx \quad (4)$$

Now

$$\int_{x_1} y dx = y_1(x_{\text{max}} - x_1) \quad (5)$$

Hence:

$$\int_{y_1}^{x_1} (x_{\text{max}} - x_1) = \left[\frac{ax^3}{3} + bx \right]_{x_1}^{x_{\text{max}}} \quad (6)$$

A further two equations may be obtained by considering the integrals between x_{max} and x_2 , and x_{max} and x_1 . Insertion of the known values of y_{av}, x_1, x_2 and x_{max} and the experimentally determined values of y and y_2 yield three equations and two unknowns a and b . Optimum values of a and b are thus calculated, from which may be calculated the volume fraction of resin at the interfaces y_{max} , and at

Figure 5 Variation of volume fraction of resin, y , as a function of the distance, x , from the central plane of the film

the centre of the film y_{\min} .

The maximum and minimum resin concentrations for 5.20 μm films, calculated in the manner described above, are presented in Table 2, in which the vapour pressure and cohesive energy densities of the solvents are also tabulated. Within the limits of the assumption of a parabolic dependence of y on x , the y_{\min} and y_{\max} values are estimated to be accurate to within $\pm 2\%$ of y . The calculated resin concentration at the interface often exceeds a volume fraction of unity for an average resin concentration of 0.884. This suggests that the surface of the film consists entirely of resin to some depth.

The results in Table 2 confirm that there are considerable differences in the composition of the interfaces of an adhesive film compared with the composition of the central plane of the film when first produced. However, when the films were allowed to equilibrate for approximately 500 days, the surface compositions of the film became identical to the overall bulk compositions. This indicates that the heterogeneity of such adhesive films is a consequence of the solvent evaporation stage, and that subsequent diffusion within the film will equalize the composition throughout the film. It can therefore be appreciated that adhesive properties of such films are likely to be appreciably time-dependent if equilibration has not been attained subsequent to film formation. Under the normal industrial conditions in which such adhesives are used, it is unlikely that they will be left for such a period before being used for bonding purposes. It is therefore necessary to propose a mechanism of film formation by solvent evaporation which would account for the concentration profile. The initial solution, containing solvent, rubber and resin may be assumed to be homogeneous. As the solvent is lost, the concentration of rubber and resin increases. As the resin has a higher cohesive energy density ($4.16 \times 10^8 \text{ J/m}^3$ compared with $2.94 \times 10^8 \text{ J/m}^3$) it is likely that the rubber and resin are incompatible to some extent. Hence the resin will act as a non-solvent for the rubber. Under these conditions, the rubber-rich phase is

likely to precipitate out of solution first, as a consequence of the lower contribution to the free energy of mixing with the solvent for a given volume of high molar mass rubber compared with an equal volume of low molar mass resin. Since the density of the natural rubber is less than that of the resin any tendency to settling out will favour movement of the resin plus solvent phase downwards towards the substrate interface, leading to an excess of resin at this interface. However, the movement of the rubber-rich phase is likely to be restricted in view of the high viscosity of this phase. The solvent evaporation process involves transport of solvent from the bulk of the drying film to the air/adhesive interface by spontaneous convection currents¹⁵⁻¹⁷ and subsequent loss of solvent to the atmosphere. Since the solvent is resin rich, this process will transport the mobile resin molecules to the air/adhesive interface, where solvent molecules are lost leaving an excess concentration of resin at the adhesive/air interface. Loss of solvent from the evaporating film is fast enough to prevent the resin diffusing back into the bulk of the film; essentially freezing the concentration profile for the film with surface excess of resin at both interfaces. The lower fractional surface excess of resin observed for the 11.4 μm thick films is consistent with the longer drying time required for a thicker film, leading to more diffusion of resin back into the bulk of the film. The concentration dependence of the fractional surface excess of resin may be caused by the variation in resin mobility with volume fraction of resin within the film. At low volume fractions of resin, the resin will exhibit maximum mobility, since the solubility limit of resin in solvent will not be reached until the final stages of the drying process. At high volume fractions of resin, the resin will exhibit minimum mobility, since the solubility limit of resin in solvent will be reached at an earlier stage of the drying process. Thus the fractional surface excess of resin should decrease with increasing overall volume fraction of resin in the mixture. The qualitative mechanism outlined, suggests that the surface excess of resin depends on the solubility characteristics of the ternary rubber/resin/solvent system and the

Figure 6 The degree of film heterogeneity measured by $\gamma_{\max} - \gamma_{\min}$ plotted against cohesive energy density of solvent, at an overall bulk volume fraction of resin of 0.086, for a variety of solvents. Dry film thickness $5.2 \mu\text{m}$

film drying time. The latter variable may also affect the temperature of the drying film and hence the solubility characteristics. The cohesive energy densities of the three components may be compared as a guide to the likely solubility characteristics for the system and the vapour pressures of the solvents may be compared as an indication of the rate of film formation. It is clear from a consideration of the data in Table 2 that no single overall correlation exists between the surface concentrations of resin and the cohesive energy densities and vapour pressures of the solvents over the whole concentration range of adhesive formulations. In general, however, the highest surface concentrations of resin tend to be shown by solvent systems having cohesive energy densities which are furthest removed from that of the rubber, and having high vapour pressures. These are the systems which would show minimum mobility for the rubber, due to fast drying times. A general trend can be discerned. If the heterogeneity of the films measured as $\gamma_{\max} - \gamma_{\min}$ (at 0.086 overall volume fraction of resin, where the resin excess is most pronounced) are plotted against cohesive energy density of the solvent, the heterogeneity increases as the cohesive energy density of the solvent increases from a value corresponding to that of the natural rubber up to a value corresponding to that of the resin (Figure 6). This is consistent with the idea that maximum mobility of the resin plus solvent phase and minimum mobility of the rubber-rich phase leads to highest values for the resin concentration at the interfaces of the adhesive film.

The heterogeneous nature of the rubber plus resin adhesive films, when cast from solvents, and the dependence of the degree of heterogeneity on the solvent, thickness of film and time for equilibration have demonstrated that the study

of adhesive properties of such films must take those parameters into account, since the surface properties of such adhesives are usually thought to be of vital importance in the adhesive bonding process.

CONCLUSIONS

Adhesive films consisting of natural rubber and a resin (glycerol ester of partly hydrogenated wood rosin), when cast from solvent, contain a concentration variation throughout the film, with maximum resin concentrations at the air/adhesive and adhesive/substrate interfaces. The magnitude of the fractional surface excess depends on the solvent, the overall bulk resin concentration, the thickness of the film and the time for equilibration after the film has dried. The concentration variation may be represented by a parabolic function, and hence the concentration of resin at the interfaces may be estimated. The resin excess appears to be related to the mechanism of the film forming process in which the solubility characteristics and rate of evaporation of the solvent are important parameters.

ACKNOWLEDGEMENTS

The authors would like to thank Evode Holdings Ltd, for sponsoring this research programme and allowing the publication of the data obtained. They would also like to thank the Wolverhampton Polytechnic for the use of their spectroscopic facilities.

Modification of the fastness properties of dyed wool through grafting*

N. S. Batty, A. J. Gradwell and J. T. Guthrie

Department of Colour Chemistry and Dyeing, University of Leeds, Leeds LS2 9JT, UK
(Received 22 December 1975; revised 26 March 1976)

Methods are described whereby the light fastness and wash fastness properties of dyed wool can be improved through grafting small quantities of acrylonitrile onto the wool. Four dye classes are covered together with six techniques of copolymerization. Preliminary data from studies of the fading of dyes in solution with and without acrylonitrile are presented. These show that acrylonitrile reduces the rate of fading of most of the dyes investigated, irrespective of the chromophore structure. Radiation induced processes are more successful than those based on chemical initiation whilst post-irradiation induced grafting of acrylonitrile onto wool, followed by conventional dyeing offers particular promise for effectiveness and industrial exploitation.

INTRODUCTION

Recent work in this department has dealt with intrinsically coloured polymers¹⁻³. One of the many systems investigated involved the 'copolymerization' of acrylonitrile with vinylsulphonyl dyestuffs by high energy γ -radiation induced processes¹⁻². In this work it was noticed that solutions of dye containing acrylonitrile were markedly more stable to radiation than were those exposed without acrylonitrile. The more academic aspects of this observation are still under investigation. Here we are concerned with the applied aspects, more specifically with possible improvements to the light fastness (*LF*) and wash fastness (*WF*), acquired through the application of acrylonitrile, of wool treated with dyes from various classes. Also of interest are the effects of acrylonitrile on the fading characteristics of these dyes in aqueous solution.

Much work has been devoted to improving the physical properties of wool by grafting with acrylic monomers. The complex nature of the substrate makes any truly quantitative approach difficult, if not impossible. Thus, although many of the improvements have been substantiated, the mechanism of action is usually far from well understood. The characteristics of fading and the wash fastness of dyes on wool have also been extensively covered but many points require consideration. In fading, these include concepts such as energy transfer within the substrate which could lead to chromophore stability, the role of oxygen in the fading process, protection against damage by the use of additives, relationships between chromophore constitution and resistance to fading and the dye-concentration dependence of fading. Equally, the fundamental aspects of fastness to washing are noteworthy. These include the physical state of the dye during removal from the fabric, the mechanism of removal, the possible simultaneous removal of low molecular weight species from the matrix and so on. Ideally, any attempt at improving a particular aspect of wool's performance must not reduce its other qualities, though this is often difficult to achieve.

There have been several reports concerned with the radiation induced modification of wool⁴⁻⁶. It is opportune to consider whether or not the expertise gained might be extended. This point is of importance to the present survey of possible improvements to the light fastness and wash fastness of dyed wool, though other facets such as crease resistance, drape, shrinkage resistance and so on can be dealt with in this context.

We have investigated three dye classes namely basic dyes, acid dyes and reactive dyes, in terms of their fading and wash fastness on wool. Basic dyes are not used with wool because of their very poor light fastness properties although examples showing moderate wash fastness do exist. However, basic dyes are known to exhibit satisfactory light fastness on substrates based on polyacrylonitrile^{7,8}. Thus, a combination of wool and polyacrylonitrile should exhibit improved light fastness relative to wool alone, though other properties might be adversely affected. The position regarding other dye types was less certain. Two types of acid dye were considered, acid levelling dyes and acid milling dyes. The former show intermediate light fastness but poor wash fastness. Acid milling dyes have both good light and wash fastness so one might anticipate little improvement through grafting. The Remazol dyes, based on the vinylsulphonyl system show good wash fastness but variable light fastness. Previous experience with these dyes suggested that polyacrylonitrile would enhance their light fastness though the position regarding the wash fastness was uncertain.

The general approach to this work is one of simplicity in operation, geared to existing techniques with slight modifications. Little emphasis is placed on the deposition of acrylic monomers on wool using chemical initiators, other than azobisisobutyronitrile, although a variety of such systems does exist. These have been adequately dealt with elsewhere⁸ and need not be considered further here.

EXPERIMENTAL

Reagents

Acrylonitrile was supplied by BDH Ltd, UK. The inhibitor was removed and the monomer purified by standard

methods. With the exception of the Remazol dyestuffs (Hoechst-Cassella Dyestuffs Ltd, Manchester, UK) all the dyes were used as supplied by the manufacturer. Remazol dyestuffs were converted to the free vinyl form, as described in an earlier publication¹, before use. Azobisisobutyronitrile (AIBN) was used as supplied, though *N,N*-dimethylformamide (DMF) was distilled before use. Commercially available carbonized wool flannel was used as the substrate, after soxhlet extraction with ethanol and ether and prolonged washing with distilled water. Before exposure to either dye or dye/monomer solutions, the wool was soaked in boiling water for 15 min, allowed to cool, and always maintained in a moist condition.

It is fully appreciated that the previous history of the wool and its origin are important factors in any subsequent modifications. This point provides an extension to the present work and will be covered in a later publication.

Dye solutions

The dye solutions were formulated to satisfy the wt % dye on wool stated in Table 1. The wool substrates were

dyed from a 50/1 liquor/wool ratio and invariably exhaustion of the dye bath was observed. Basic dyes were applied from baths containing 0.5% acetic acid (based on the weight of wool), acid levelling and acid milling dyes from baths containing 2-3% sulphuric acid (based on the weight of wool) whilst the reactive dyes were applied from neutral aqueous solution.

Monomer solutions

Throughout this work the concentration of acrylonitrile in aqueous solution was maintained at 3% v/v which gave a weight of acrylonitrile in solution approximately equal to the weight of wool. For irradiations carried out in the presence of dye/acrylonitrile mixtures, the monomer solution constituted the liquor for the dye.

Procedures

In order to investigate various aspects of the influence of polyacrylonitrile on the physical properties of wool, several methods of grafting were applied. These are coded in

Table 1 and in the Results. Both chemical and physical methods of initiation were used. The details are as follows:—

(A) Information relating to the wash fastness and light fastness of the dyestuffs on wool, as supplied by the manufacturer of the dyes.

(B) Information acquired from our application of the dyes to carbonized wool flannel using conditions specified by the dye manufacturer. This treatment varies slightly depending on the dyestuff.

(C) Wool, dye and acrylonitrile used simultaneously in water with AIBN (applied as 0.1 g in 5 cm³ of methanol) as initiator and heated to 90°C on a rotary dyer for 1 h.

(D) Wool was treated with acrylonitrile from aqueous solution and water/DMF mixtures with AIBN (applied as 0.1 g in 5 cm³ of methanol), at 90°C for 1 h before dyeing.

(E) The wool was dyed, then grafted using AIBN (0.1 g in 5 cm³ of methanol), aqueous solutions of acrylonitrile, and at temperature of 90°C for 1 h.

(F) Wool, after exposure to high energy γ -radiation (16 h at a dose rate of 1.65×10^{-2} Mrad/h), was treated with aqueous solutions of acrylonitrile at 60°C in a rotary dyer. The modified samples were then dyed.

(G) Simultaneous irradiation of wool in aqueous solutions of acrylonitrile using the conditions outlined in procedure (F), before dyeing.

(H) Simultaneous irradiation of wool in aqueous solutions containing acrylonitrile and the dyestuff under conditions given in procedure (F). Irradiation was followed by heating at 90°C in a rotary dyer for 1 h.

(I) As conditions used in procedures (C) to (H), without the acrylonitrile. These systems act as standards so that the effects of the initiation processes alone on the light fastness of the dyed wool could be assessed.

Dyeing procedure

Samples of acrylonitrile grafted wool, standard wool and wool grafted with acrylonitrile in the presence of the dye, were all treated at 90°C \pm 2°C for 1 h on a rotary dyer to ensure efficient, level dyeing.

Pre-polymerization procedure

Simultaneous. Chemical initiation: the monomer solution (with or without dye) was made up as specified and 0.1 g of AIBN in 5 cm³ of methanol added. Tared, water equilibrated wool was added and the mixture shaken thoroughly before heating on a rotary dyer at 90°C, for 1 h.

Physical initiation: the monomer solution (with or without dye) containing tared, pre-swollen wool was irradiated at ambient temperatures (19° \pm 2°C) using the 10 000 Ci ⁶⁰Co radiation facility, located in the Department of Physical Chemistry at the University of Leeds, Leeds, UK

Post-irradiation

The time elapsing between cessation of irradiation and subsequent processing was approximately 10 min.

In post-irradiation processes samples of pre-swollen wool were irradiated in sealed tubes. These were then exposed to the dilute aqueous monomer solution for 30 min before dyeing.

All polymerizations were carried out in air using conventional dyeing tubes equipped with efficient screw sealing caps. Identical treatments were applied to the standards (Condition I) but in the absence of acrylonitrile.

Post-polymerization procedure

Copolymerization under conditions (C)–(H) gives rise to attendant homopolymerization of acrylonitrile. Polyacrylonitrile, being insoluble in the monomer solution, precipitates from solution. Attempts to remove homopolymer and unreacted monomer involved washing with water/DMF (5/95) mixtures. Whilst this treatment removes the monomer and loosely attached homopolymer, truly grafted polymer will be unaffected. Problems with homopolymer should not arise in method (F), though the same procedure was applied in order to remove any unreacted monomer. Water assists the swelling of the wool substrate and thus facilitates removal of any occluded homopolymer. However, as aqueous/DMF mixtures are prone to aggregation effects the use of these as washing media should be closely defined. The above ratio of water/DMF (5/95) was reached after previous experimentation.

Light fastness

A standard¹⁰ method for assessing the light fastness of wool was applied. A fading lamp, Microscal Ltd, based on a mercury–tungsten fluorescent bulb was used throughout the samples exposed until the contrast between the exposed and covered portions of the wool sample was equal to Grade 3 on the grey scale¹¹. Light fastness standards, 1–8, were exposed under identical conditions to the wool specimens and assessment of fastness made.

Wash fastness

Samples were assessed for wash fastness using the ISO 2¹² procedure with two modifications. (a) Staining was not assessed hence the dyed sample was free in the test solution. (b) Restrictions on sample size limited the specimen available for assessment. Consequently each dyed piece (5 cm \times 4 cm) was treated alongside undyed wool flannel of identical dimensions.

Fading of dyes in solution

Solutions of each of the dyes in water and water/acrylonitrile (95/5) were used. The dye concentration was arranged to give an optical density between 1.4 and 1.9 for the unexposed solution. Sealed tubes containing the dye solution were exposed using the Microscal light source. Fading was assessed over twenty days at regular intervals. Measurements were made on a Unicam SP800A spectrophotometer.

RESULTS AND DISCUSSION

The results in terms of changes in the light fastness and wash fastness of dyed wool specimens arising from treatment given are listed in Table 1 together with general observations. Preliminary investigations involved extensive grafting (up to 25% based on the original weight of wool). This level of grafting gave poor wash fastness results. Hence for this work the level of grafting was considerably reduced by using solutions of lower monomer concentration.

Studies of the level of grafting, obtained using the wool/acrylonitrile system with 3% v/v aqueous monomer solutions, indicated the difficulties associated with quantitative assessments of the extent of grafting using gravimetric techniques. These arise mainly from differences in equilibrium moisture content, removal of soluble fractions from the wool and the presence of occluded homopolymer, where relevant.

Attempts to reduce errors included the use of blanks, treated similarly but in the absence of acrylonitrile, condi-

tioning of the wool before and after treatment, careful handling during experimentation to avoid losses and attempted extraction of homopolymer and unreacted monomer. The levels of grafting recorded (as seen through weight changes in the wool after suitable correction), using the conditions (C)–(H), were always in the range of 1–2% based on the original weight of wool. These values must be treated with caution since no information is available relating to the uniformity of grafting. However the weight of acrylonitrile involved, grafted onto the wool, is similar to the weight of dye deposited on the fibre. Each experimental procedure was repeated four times in this preliminary investigation.

Initiation of polymerization under simultaneous conditions using dye/acrylonitrile mixtures produced coloured homopolymers. With the exception of the Remazol dye-stuffs, the colour strength of the homopolymeric species was weak, hence the homopolymer did not compete with the wool for the dye in solution. Remazol dyestuffs gave highly coloured homopolymer and so competition between the wool and homopolymer for the dye in solution resulted in weaker dyeings on wool. Generally the depth of shade was lower than was observed with untreated wool and acrylonitrile-grafted wool.

From *Table 1* the following observations can be made:

(i) Use of acrylonitrile grafted wool with basic dyes leads to slight improvements in the wash fastness but significant improvements in light fastness. Particular benefits appear from radiation induced processes – especially post-irradiation grafting of acrylonitrile, followed by dyeing (F). The basic dye standards (methylene blue, Rhodamine B, Magenta P and Methyl Violet), although showing less improvement in light fastness than the Astrazone Basic Dye-stuffs, are worthy of further consideration, because of their superior wash fastness.

(ii) Marked improvements to the light fastness of acid levelling dyes were noted though the wash fastness was unchanged. Radiation induced processes show particular promise in this series.

(iii) Acid milling dyes on wool show good wash fastness and reasonable light fastness without any modification. Use of acrylonitrile modified wool yields a product with very slightly improved wash fastness (except H) though moderate improvements to the light fastness are apparent.

(iv) Remazol reactive dyes show good wash fastness on wool which is maintained with the modified varieties [except for (E)]. Moderate improvements to the light fastness are apparent throughout.

(v) Results relating to conditions (C)–(H), in the absence of acrylonitrile were monitored with regard to light fastness and wash fastness (Code I). These results were then compared with those shown in *Table 1*.

The following points are relevant: (a) No changes in any of the wash fastness characteristics of the dyed wool samples were observed. In instances involving chemical initiation non-reproducibility of colour, shade and depth was observed. No changes in dyeing characteristics were observed for samples subjected to high energy radiation.

(b) Improvements to light fastness were marginal in most instances though in no case was the light fastness reduced as a consequence of exposure to the processes outlined. However with certain systems, using high energy irradiation, a noticeable improvement in the light fastness was observed. Whilst these improvements did not match those observed using polyacrylonitrile grafts, any improvement is significant. Post-irradiation was more effective in this respect.

Those dye-wool composites showing improvement are Rhodamine BN, Methyl Violet, Astra Diamond Green, Naphthalene Red JS and Coomassie Blue.

Fading of dyes in solution

The fading of aqueous dye solutions in the presence of acrylonitrile, compared with those irradiated in the absence of acrylonitrile, has been observed. With three exceptions (including Astrazone Yellow 7GLL) acrylonitrile reduced the rate of fading. Protection by the acrylonitrile was shown to be a property of the solution and not the result of a filtering action, since irradiation of dye solutions in tubes contained in slightly larger tubes with acrylonitrile – to provide a film of acrylonitrile around the inner tube – showed no reduction in the rates of fading. Two dyes (Astrazone Blue BG and Remazol Golden Yellow) showed no change in their rate of fading when mixed in solution with acrylonitrile. With these exceptions, all dyes were given appreciable protection. It is worth noting that apart from the Remazol dyes, all dyes monitored for fading in solution were used as supplied by their manufacturer, without further purification. This makes any interpretation of the fading characteristics difficult because of the complexity of the dye system. However the improvements imparted by acrylonitrile have been demonstrated in a realistic manner.

GENERAL DISCUSSION

The concept of radiation induced modification of textiles has been the subject of much interest though recently attention has been placed on the industrial use of accumulated expertise. This technique is at a more advanced stage in the packaging industry and in modification of cellulose^{13–15}. Improvements to physical properties of textiles by chemically initiated processes, involving the initiator, the monomer and the substrate simultaneously, are used to some extent but give rise to problems. These include secondary reactions arising from initiator fragments, initiator decomposition products, and direct interaction with the substrate. With many dyestuffs these side reactions are serious since they result in the decomposition of the dye. This leads to non-reproducible results in terms of shade and levelness of dyeing.

With few exceptions the use of acrylonitrile, irrespective of the treatment given (C–H), improves the light fastness and/or the wash fastness of the dyed wool specimens. However, great benefits are gained from the use of radiation induced processes (F–H) and especially treatment (F). In process (F) we are concerned with the irradiation of moist wool, exposure of the irradiated wool to the aqueous/monomer solution and then transfer of the grafted wool to the dyebath, whence the wool is dyed as usual. No problems with homopolymerization arise and there is no reduction in the dye uptake.

In those treatments involving copolymerization of wool with acrylonitrile before dyeing, very bright shades are obtained. This phenomenon is probably associated with a reduction in the yellowing tendency of the wool, though Rattee and Singh⁸ have noted that acrylic monomers enhanced the yellowing of wool when transition metal ion catalysts are used with peroxydisulphates as the initiating system. It was found that the addition of formaldehyde to the reaction mixture considerably reduced the tendency to yellowing. Such yellowing leads to dullness of shade on dyeing.

The noted improvements in the wool's fastness properties are surprising. Earlier work, using higher levels of grafting (up to 25% by wt of wool) gave wash fastness results which were disappointing. Reduction of the level of grafting to approximately 1–2% gave improved wash fastness though it is appreciated that the grafting is unlikely to be homogeneous. Further work is needed before a satisfactory explanation of such improvements can be offered.

As expected, the presence of polyacrylonitrile in wool dyed with basic dyes improved the light fastness though to varying extents, depending on the dye. Less anticipated was the superior light fastness, obtained with the acid leveling dyes, especially for samples containing no residual initiator or initiator fragments (processes F–H). Marginal improvements with the acid milling dyes and the reactive dyes suggest that polyacrylonitrile has potential as an anti-fading agent even for dyes with nominally good light fastness.

The complex nature of the systems and of the light fastness properties of dyes on wool is shown by these observations of improved light fastness even in the absence of the acrylonitrile, and has been noted by operators in related work¹⁶. This opens up an area of research into the effects of radiation on wool in relation to the light fastness of subsequently dyed samples and may be indicative of the destruction of centres which might otherwise take part in fading processes. Whilst the marginal nature of these improvements makes any conclusions highly speculative, it does suggest that further work could be pursued along similar lines.

Work is now in progress to find out if the improvements noted with grafted samples are particular to the polyacrylonitrile modified system and are a feature of the grafted polymer, or whether such improvements are obtained using other grafted polymer–wool composites, suggesting that the improved fastness properties arise from reaction with those sites in wool which would otherwise become involved in secondary reactions resulting in poor light fastness by some type of complex mechanism. One possibility involves the reaction between the acrylic monomer and reactive groups such as the amino-acid end-groups in the wool. This would reduce any electron transfer between the wool and the dye which would otherwise lead to eventual breakdown of the chromophore. If this mechanism is valid then protection of the chromophore should be possible using a variety of acrylic monomers. Hence, we are not limited to acrylonitrile. This proposed mechanism is supported by the data given in *Table 1* since improvements observed with

samples which were dyed before deposition of polymer occurred (condition E) were negligible compared with those obtained by simultaneous dyeing and deposition or by deposition of monomer followed by dyeing. However much remains to be done before proven satisfactory explanations can be offered.

The application of high energy, radiation induced processes on an industrial basis would be much simpler than those dependent on chemical initiation. Such a process could operate on lines similar to those proposed for the treatment of cellulose, about which much more has been written. This approach would require considerable changes in outlook when compared with conventional wool pre-treatment. The problems are far from insurmountable though they do exist. The low levels of grafting required to achieve significant improvements suggest that vapour-phase grafting processes offer potential though such modifications would present technological problems.

Palladium / π - complexes as catalysts for olefin polymerization

Fereidun Hojabri, Mir-Mohammad Mohaddes and Afiat Talab

Department of Chemistry, Arya Mehr University of Technology, Tehran, Iran
(Received 18 September 1975)

Polymerization of different types of olefins was investigated with a palladium/ π -allylic complex as catalyst. Polymerization was possible only with those olefins which have a bicyclo structure. Compounds with two double bonds reacted as easily as mono-olefins. The effect of temperature on reaction rate was studied and an activation energy of 21.3 kcal/mol calculated for the polymerization reaction of bicyclohepta-2,5-diene.

INTRODUCTION

Palladium chloride has been used before for the polymerization of cyclo-olefins^{1,2}. Since palladium in the form of PdCl₂ is not very active, we applied a π -allylic complex of palladium to the polymerization. The π -allylic complex was prepared from β -pinene and Pd(C₆H₅CN)₂Cl₂³. We tried to polymerize different types of olefins to find out if the higher activity of palladium in this catalyst system would allow the polymerization of simpler olefins. Ethylene and propylene are not polymerized with palladium chloride under normal conditions^{4,5}.

EXPERIMENTAL

Palladium complex was dissolved in 200 ml of an aromatic solvent such as benzene or toluene. 100 ml of olefin were added and the mixture heated in a one litre autoclave equipped with stirrer and temperature control. In experiments with propylene the autoclave and solvent were first cooled to -40°C and the propylene in liquid form was added. Samples were taken from the reaction mixture at different stages of polymerization and the content of olefin was determined by gas chromatographic analysis. The polymer was precipitated by addition of polar solvents to the viscous liquid product. Molecular weights for the polymers were determined with a vapour pressure osmometer.

RESULTS AND DISCUSSION

In a series of experiments bicyclohepta-2,5-diene (I), norbornene (II), cyclohexene (III) and 1-hexene were used in polymerization with palladium- π -allylic complex.

The results of polymerization of these compounds are summarized in Table I. Polymerization of bicyclohepta-2,5-diene (I) and norbornene (II) was fast between 140° and 200°C. Cyclohexene which has only one ring showed only a very small amount of polymerization after long reaction times. 1-Hexene which is an open-chain olefin showed under the same reaction conditions no polymerization at all with palladium/ π -complex.

Bicyclohepta-2,5-diene polymer was decomposed to monomeric diene and gave, by hydrogenation, a compound with the same structure as the polymer obtained from norbornene. Figure 1 shows the n.m.r. spectra of bicyclohepta-2,5-diene polymer (A), hydrogenated polymer (B) and norbornene polymer (C). The last two compounds are saturated and have no double bond in their polymer chain. The strong band at 3060 cm⁻¹ in the infra-red spectrum of the polymer, indicating the presence of a carbon-carbon double bond, also disappeared in the hydrogenated polymer (Figure 2). Hydrogenation was only possible at higher temperatures and pressures (70°C, 20 atm), using Pd/C as catalyst. At normal pressure and temperature and with Raney nickel no hydrogenation took place. These results indicate that bicyclohepta-2,5-diene and

Figure 2 Infra-red spectra of: A, bicyclohepta-2,5-diene polymer; B, hydrogenated polymer

Figure 3 Polymerization pattern of bicyclohepta-2,5-diene and norbornene

norbornene display the same polymerization pattern (Figure 3).

The fact that norbornene was polymerized easily, but cyclohexene only to a very small extent, suggests that a rigid structure is necessary for an olefin to polymerize with palladium complexes. Apparently, this is an important feature for the formation of π -complexes as intermediate between the double bond and palladium. Because of the lack of a rigid structure, formation of these intermediates needs higher activation energy with cyclohexene than with norbornene. Rotation of the chain hinders the formation of these intermediates in the case of 1-hexene and therefore no polymerization can occur.

Propylene, like 1-hexene, did not show any tendency to polymerize with palladium/ π -allylic complexes. Only small amounts of dimers and trimers of propylene were obtained at 60 atm and up to 130°C. Addition of HCl (1 cm³, 1 M) to the catalyst system did not change its activity and only promoted the formation of chloropropane.

Figure 6 Plot of log k' versus $1/T$

KINETICS OF POLYMERIZATION

Polymerization of bicyclohepta-2,5-diene (BCHD) was carried out at 110°, 140°, 175° and 200°C with different amounts of catalyst. Tables 2–5 show the results of these experiments. The rate of polymerization increased with increasing temperature and concentrations (Figures 4 and 5). The linearity of variation of $1/[BCHD]$ with time at constant temperature and constant catalyst concentration shows that the polymerization reaction is second-order for bicyclohepta-2,5-diene. The reaction rate follows equation (1):

$$r = -\frac{d[BCHD]}{dt} = k'[BCHD] \quad (1)$$

$$k' = k [\text{catalyst}]^m$$

Calculated k' for different temperatures are shown in Table 6. The plot of log k' versus $1/T$ is represented in Figure 6. From this plot an activation energy of 21.3 kcal/mol was calculated for the polymerization reaction.

Distribution of abnormal groups in natural rubber

D. R. Burfield, L. C. Chew and S. N. Gan

Department of Chemistry, University of Malaya, Kuala Lumpur 22-11, Malaysia
(Received 18 February 1976)

Fresh samples of natural rubber were fractionated and the distribution of epoxy and amine groups over the molecular weight range was investigated. The origin of these abnormal groups is suggested. A scheme is proposed to explain the formation of lactone groups from the reaction products of the rubber epoxide and simple amino-acids. The presence of other functional groups is discussed.

INTRODUCTION

Natural rubber, although predominantly hydrocarbon, is known to contain definite proportions of oxygen and nitrogen as integral parts of the macromolecule. The oxygen content has variously been interpreted as owing to the presence of hydroxyl^{1,2}, carboxyl², aldehyde³⁻⁶, lactone⁷, and epoxide^{8,9} groups, whilst the nitrogen content is generally assumed to be owing to proteinous material either tenaciously held or chemically bonded to the rubber. These abnormal groupings are not uniformly distributed over the whole molecular weight range but appear to be concentrated in the very low and high (or gel) molecular weight fractions. The intermediate fractions are relatively pure hydrocarbon.

Comparison of the results of different workers is hampered by the fact that the nature, number and distribution of such groups may be affected by several factors including: (a) clonal source of rubber; (b) use of fresh or stored rubbers; (c) storage conditions, i.e. whether stored as dry rubber or ammonia preserved latex; (d) conditions of isolation. In addition natural rubber is very prone to oxidation which can readily affect the molecular weight distribution and simultaneously introduce oxygen groups into the macromolecule. It is tempting to assume that the oxygen content arises as a result of oxidation of rubber subsequent to its isolation from the tree, but work with fresh rubber latex, taking stringent precautions to preclude oxidation, show this is not the case².

Recently it has been fairly conclusively shown that rubber contains epoxide groups⁹. It was speculated that the epoxide content was predominantly located in the lower molecular weight fractions because of discrepancy in the number of such groups as determined by a direct titration technique⁹ and a degradation method⁸.

This paper describes the fractionation of a fresh rubber sample and the subsequent determination of the variation of epoxide group content with molecular weight.

EXPERIMENTAL

Isolation of rubber

The natural rubber used in these experiments was isolated from freshly tapped rubber latex, clone RRIM 600, and used immediately. The rubber was precipitated by diluting the latex with an equal quantity of water and slowly adding the diluted latex, with stirring, to excess methanol. The precipitated rubber was extensively washed

with water, pressed into thin sheets and dried under vacuum at 50°C.

Fractionation

Fractionation was performed on a 1% w/v solution of rubber in toluene, stabilized with 1% w/v 2,6-di-(*t*-butyl)-*p*-cresol. The fractionation apparatus consisted of a 2 litre pear-shaped flask, equipped with stirrer, nitrogen inlet and exit, and dropping funnel for the methanol precipitant. The whole assembly was mounted in a thermostat bath at 30.00° ± 0.02°C and was continuously purged with a slow stream of oxygen-free nitrogen.

Methanol, as non-solvent, was added dropwise to the vigorously stirred solution, until a definite turbidity was observable. The temperature of the solution was first increased by 4°–5°C so as to redissolve the precipitate and subsequently returned to the original temperature overnight. The resultant precipitate was then run out of the fractionation apparatus (via a stopcock mounted at the bottom of the flask) and centrifuged for 10 min. The supernatant was tipped back into the flask, while the precipitate was added to excess methanol. The rubber was then filtered off and dried under vacuum.

The fractionation was repeated so as to obtain all together 5 molecular weight fractions, designated F₁ to F₅. The intrinsic viscosity of each fraction together with that of the unfractionated rubber was determined by viscosity measurements on dilute solutions of rubber in benzene at 30°C.

Determination of epoxide and amine group content

The number of epoxide and amine groups in each fraction was determined by a direct titration technique previously described⁹.

RESULTS AND DISCUSSION

The rubber isolated from freshly tapped latex dissolved readily in toluene, on gentle stirring overnight. There was no observable gel fraction. This is in contrast to the partial solubilities and high gel contents generally observed with samples from ammonia preserved latices and crepe rubbers¹⁰. The gel content thus presumably arises through crosslinking reactions in rubber which occur on storage either in latex, or dry rubber⁹. The intrinsic viscosity of the initial unfractionated rubber (6.66 cm³/g) is close to the value of 6.95 cm³/g determined recently for this clonal rubber by other workers⁶.

Table 1 Fractionation data

Fraction	Weight fraction, W_i	$[\eta]$	Amine concentration		Epoxide concentration		Amine/Epoxide
			mol/10 ⁶ g rubber	mol % ^a	mol/10 ⁶ g rubber	mol % ^a

^a mol % \equiv mol of functional group per 68g of rubber \times 100;
 $\sum W_i = 1.009$

The results (Table 1) clearly show that the epoxide content of natural rubber is predominantly, although not exclusively, associated with the higher molecular weight fraction of natural rubber and is not the same as the low molecular weight 'oxide' fraction previously reported^{2,11}. In addition the amine content appears to be related to the epoxide content, being on average over the fractions approximately half its value, although lower molecular fractions show a tendency towards a smaller proportion of amine groups (see Table 1). The presence of both epoxide and amine groups and their inter-relationship can be rationalized in the following way.

Epoxidation of the macromolecule may occur within the tree at the same time as the biosynthesis, or, alternatively the two reactions may not be related. It seems likely that the epoxidation occurs enzymatically since enzyme catalysed epoxidation reactions are well known¹², and rubber latex is an ideal medium for such enzyme activity. The reaction may be represented as:

If the higher molecular weight fractions represent 'older' rubber molecules this would then explain the predominance of epoxide groups in these fractions since the epoxide content would presumably increase with reaction time. Alternatively the epoxide content might be connected with the actual biosynthesis.

Subsequent reactions of proteins or free amino-acids with some of the epoxide groups would lead to the incorporation of detectable amine groups, e.g.

This would explain the parallel relationship between the epoxide and amine content, and the tendency for the ratio amine/epoxide to increase with the higher molecular weight fraction.

That reaction (2) is feasible has been demonstrated by the reaction of amylene oxide with glycine, in aqueous media, which is shown to proceed to completion within about 36 h at room temperature¹³. Further supporting evidence that this reaction can occur in latex is provided by the addition of ³H labelled glycine to rubber latex. The labelled glycine is found to be incorporated into the rubber, to a level which approaches the concentration of epoxide groups (Table 2). Further details of these experiments are to be reported. Fractionation of rubber treated with labelled glycine shows that the incorporation is predominantly in the high molecular weight fraction (Table 3), which is again consistent with the above proposals. It should be pointed out that this latter fractionation is not directly comparable with the results presented in Table 1 since, although rubber from the same clonal source was used, amino-acids have been shown to cause crosslinking of the rubber¹⁴, and this may well affect the molecular weight distribution.

It seems likely that the high molecular weight fraction in which these abnormal groups are concentrated is equivalent to the insoluble (gel) fraction in which lactone groups were observed⁷. These apparently unrelated observations may be brought together since Gregg⁷ has presented evidence that base hydrolysis of the gel fraction (i.e. the high molecular weight fraction containing the major portion of structure III) shows the presence of the salt of a carboxylic

Table 2 Incorporation of ³H labelled glycine into rubber

Clonal source	Epoxide concentration (mol/10 ⁶ g rubber)	Amount of glycine incorporated (mol/10 ⁶ g rubber)
RRIM 600	93	89
PR 107	69	60
PB 49	46	20

Reaction conditions: $T = 30^\circ\text{C}$; $t = 4$ days; [glycine ³H] = 0.016 mol/dm³; [rubber] = 30 g/dm³; pH of latex = 8.1 ± 0.2

Table 3 Fractionation of ³H-glycine treated rubber

Fraction	$[\eta]$	Amount of glycine incorporated (mol/10 ⁶ g rubber)
F ₁	9.82	34
F ₂	6.11	6
F ₃	4.44	4
F ₄	2.38	4
F ₅	0.72	5

Clonal rubber = RRIM 600; conditions for glycine incorporation same as Table 2

markedly reduce the solubility of the rubber in non-polar solvents is shown by Gregg⁷, who found that rubber, resulting from base hydrolysis of the gel fraction, and thus presumably containing carboxylic salt residues only gelled in benzene. However, acidification of the solution with acetic acid allowed ready dissolution of the rubber.

If the above reasoning is correct the pH at which the rubber is isolated could have a profound influence on the subsequent fractionation behaviour of the rubber, since the presence of free acid or salt would markedly affect the solubility of the different rubber fractions. Thus low molecular weight fractions containing appreciable quantities of acid groupings could be readily relegated to the insoluble gel fractions.

Recently, in a comprehensive g.p.c. study of the effect of clonal variations on molecular weight distribution Subramaniam⁶ has shown that clonal rubbers exhibit distinctly bimodal distributions. In particular, 'soft' rubbers of low average molecular weight show the presence of a sizeable low molecular weight fraction. The presence of such a low molecular weight fraction was noted earlier by Westall¹⁶, who speculated that this fraction might be a basic building block for higher molecular weight macromolecules. What makes these observations of particular interest is that it is the same 'soft' rubbers which provide significant amounts of both this low molecular weight fraction and the low molecular weight oxide fraction observed by Bloomfield². Thus if there is any substance to Westall's hypothesis it is quite possible that the building-up process involves the abnormal oxygen groups discovered by Roberts¹ and Bloomfield². The nature of these groups thus definitely merit further investigation.

The presence of carbonyl or more specifically aldehyde groups in natural rubber has yet to be unambiguously established. The presence of such groups has been inferred by the inhibiting effect of amines and dimedone on cross-linking reactions in natural rubber, which were purportedly caused by these functional groups³⁻⁵. As has been pointed out amines are not specific reagents for carbonyl groups⁸, and the action of dimedone is not unequivocally established since it may well react with other non-rubber substances present in rubber, which catalyse the crosslinking reaction⁶. Recently reported estimations of carbonyl groups in natural rubber by reaction with 2,4-dinitrophenylhydrazine⁶, suffer from the same drawback that this reagent cannot be considered a specific reagent for carbonyls, for example,

reaction products with epoxides have been reported¹⁷. Further work is obviously necessary in this area.

It needs to be emphasized that the oxygenated groups discussed in this paper are restricted to those already present in rubber as it leaves the tree. Without doubt oxidation of rubber subsequent to this event will lead to the incorporation of additional oxygen functional groups including hypoperoxide groups which have not been considered in the above discussion. Analysis of stored rubber samples may thus lead to erroneous conclusions since not only may the functional groups already present in the rubber be modified by chemical reaction, but additional oxygenated groups may also be introduced.

CONCLUSIONS

The epoxide content of natural rubber is concentrated in the higher molecular weight fractions. The presence of lactone groups in the same fraction can be attributed to ring closure of the reaction product between amino-acids and the macromolecular epoxide.

Time-dependent failure of poly(methyl methacrylate)

Robert J. Young* and Peter W. R. Beaumont

Department of Engineering, University of Cambridge, Cambridge CB2 1PZ, UK

(Received 25 February 1976; revised 22 March 1976)

A theory has been developed to explain the time-dependent failure of poly(methyl methacrylate) (PMMA) (and possibly all glassy polymers). The analysis uses the concepts of linear elastic fracture mechanics and it has been shown that by making simple assumptions it is possible to predict the lifetimes of PMMA specimens under static load from the strain-rate dependence of Young's modulus for the material.

INTRODUCTION

Many structural materials, when subjected to a static load, fracture after a period of time which varies inversely with the magnitude of the applied load. This phenomenon is sometimes called 'static fatigue' or 'creep rupture'. The Griffith theory of fracture is based on a classical elastic model which cannot, unless modified, account for the observed behaviour. It predicts that a stress only infinitesimally less than the fracture strength of the material would be sustained for an infinite period of time. The theory may be extended to explain creep rupture in several ways: (a) the size of flaws present in the material may be increased by chemical attack until the crack reaches critical dimensions, and (b) the environment may reduce the fracture-surface energy of the material by adsorption of chemical species at the crack tip.

Many theories based upon the time-dependent fracture of polymers have approached the problem from an entirely different viewpoint (Berry¹, Beuche², Zhurkov³). They have adopted a molecular model and taken the basic premise that the failure process is characterized by an activation energy, where the height of the energy barrier is reduced by some function of the applied stress. Berry¹ has reviewed some of these theories; he criticized them for being too phenomenological in that they produce arbitrary fitting constants that have little physical meaning. It is clear that the rupture of molecular bonds is an important process but like Berry we emphasize the need for a theory of fracture in amorphous glassy polymers which includes both the microscopic and macroscopic aspects of the failure process at the tip of the crack.

In this paper we have developed a theory to explain the time-dependent failure of poly(methyl methacrylate) (PMMA) in terms of the parameters controlling the growth of a crack and that can be readily measured. It is based on a theory by Williams and Marshall^{4,5} and takes a linear elastic fracture mechanics approach to explain slow crack growth in this material. It has been shown by several groups of workers^{5,6} that in PMMA the crack growth rate (da/dt), can be described as a unique function of the stress intensity factor (K) for a given temperature and environment. Williams and Marshall^{4,5} used a constant crack opening displacement (δ) criterion to explain, at least qualitatively,

the variation of crack velocity $V(=da/dt)$ with K , in terms of the strain-rate dependence of the Young's modulus (E). Young and Beaumont⁶ have applied the $V(K)$ relationship to successfully predict the lifetimes of specimens of PMMA held at different stress levels. In this paper we have proposed an extension of these two theories to predict the lifetimes of components made from PMMA (and possibly all glassy polymers) directly from measurements of Young's modulus, E , as a function of strain-rate.

MODELS

Constant δ criterion

The constant δ criterion was first developed by Williams and Marshall⁴ to explain the relationship between V and K for PMMA. It assumes that a craze at the tip of a crack in PMMA is equivalent to a Dugdale line plastic zone⁷. The zone of length R is illustrated schematically in Figure 1 and for a non-work-hardening material is given by⁸:

$$R = \frac{\pi}{8} \left(\frac{K}{\sigma_y} \right)^2 \quad (\sigma < 0.5 \sigma_y) \quad (1)$$

under conditions of plane strain or plane stress. The value of crack opening displacement, δ_t , at the crack tip is assumed to be fixed and is given by Corten⁸ as:

$$\delta_t = \frac{K^2}{\sigma_y E} \times \phi \quad (2)$$

where $\phi = 1$ under plane stress conditions and $\phi = (1 - \nu^2)$ for conditions of plane strain, where ν is Poisson's ratio. For PMMA, ν^2 is of the order of 0.1 and so the difference between the two conditions is only of the order of 10%. Brown and Ward⁹ have shown that the assumption that a craze can be modelled by the Dugdale plastic zone is a reasonable one. For simplicity we have taken ϕ equal to 1 throughout our analysis even though the specimens used are probably too thick for plane stress conditions to prevail.

The Young's modulus, E , for the polymer is a function of the applied strain-rate, $\dot{\epsilon}$. There is evidence to suggest that the yield strain, e_y , is fairly insensitive to both strain-rate and temperature (e.g. Marshall *et al.*⁵) and so:

$$\sigma_y = e_y E(\dot{\epsilon}) \quad (3)$$

* Present address: Department of Materials, Queen Mary College, University of London, London E1 4NS, UK.

Figure 1 Dugdale line plastic zone at the tip of a crack under the action of an applied stress σ (after Williams and Marshall⁴)

Combining equations (2) and (3) gives:

$$K = (\delta_t e_y)^{1/2} \times E(\dot{\epsilon}) \quad (4)$$

In order to relate the crack velocity (V) to K it is necessary to first of all determine the relationship between $\dot{\epsilon}$ and V . If t is the time-scale of the deformation of a volume element adjacent to the crack tip, then:

$$\dot{\epsilon} \sim e_y/t \quad (5)$$

In this time, t , the crack will have moved a distance R at a velocity, V , and so:

$$t \sim R/V \quad (6)$$

Combining equations (1), (2) and (3) gives:

$$R = \frac{\pi}{8} \frac{\delta_t}{e_y} \quad (7)$$

and therefore:

$$t \sim \frac{\pi}{8} \frac{\delta_t}{e_y} \frac{1}{V} \quad (8)$$

Combining equations (5) and (8), then:

$$\dot{\epsilon} \sim \frac{8}{\pi} \frac{e_y^2}{\delta_t} V \quad (9)$$

which shows a direct proportionality between $\dot{\epsilon}$ and V [since $(8/\pi)(e_y^2/\delta_t)$ is a constant]. Equation (9) describes the relationship between $\dot{\epsilon}$ and V that is required to predict the variation of K with $E(\dot{\epsilon})$ and hence to determine the relationship between K and V .

The values of e_y , δ_t and $E(\dot{\epsilon})$ are known or can be readily measured. It should be possible therefore to construct a plot of $V(K)$ with no fitting parameters.

Time-to-failure predictions

Fracture involves two processes both of which may be time-sensitive; (a) crack initiation and (b) crack propagation. The lifetime of a PMMA specimen can be considered to be the sum of the times for the completion of these two processes. This means that:

$$\psi_f = \psi_i + \psi_p$$

where ψ_f is the time-to-failure, ψ_i and ψ_p are the times to initiate and propagate a crack to some critical size respectively, at which point catastrophic failure occurs.

Notched specimens. For notched or precracked specimens the initial crack will be present and so ψ_i will be zero. This means that the time-to-failure of such a specimen will be governed entirely by the time taken to propagate the crack and so:

$$\psi_f = \psi_p$$

The time-to-failure, ψ_f , at constant stress is given in this case therefore by the integral¹⁰:

$$\psi_f = \int_{a_i}^{a_c} \frac{1}{V(K)} da \quad (10)$$

where a_i is the initial (or inherent) crack size and a_c is the crack size at which the crack becomes unstable. The definition of the stress intensity factor, K_I is given by:

$$K_I = \sigma_a Y(a)^{1/2} \quad (11)$$

where Y is a geometrical factor (equal to $(\pi)^{1/2}$ for infinitely wide specimens) and σ_a is the applied stress. The subscript I refers to the crack opening mode of failure. Combining equations (10) and (11) gives:

$$\psi_f = \frac{2}{\sigma_a^2 Y^2} \int_{K_{Ii}}^{K_{Ic}} \frac{K_I}{V(K_I)} dK_I \quad (12)$$

where K_{Ii} is the initial value of K_I and K_{Ic} is the value of K_I at which the crack becomes unstable. In polymers K_{Ic} may be the value of K_I at which there is an adiabatic-iso-thermal transition⁴. K_{Ic} is normally called the 'plane strain fracture toughness' of the material.

All the parameters in equation (12) can be determined experimentally and the integration can be performed either analytically or numerically depending upon the complexity of the relationship between V and K_I .

Unnotched specimens. Calculation of the time-to-failure in this case is more complicated since ψ_i must also be taken into account. It is possible to obtain a conservative prediction of ψ_f by assuming ψ_i is negligible. However, this may lead to a gross underestimation of specimen lifetimes.

EXPERIMENTAL

Materials

The material used throughout this investigation was commercial Perspex (manufactured by ICI Ltd) acrylic

Figure 2 Schematic representation of the Double-Torsion specimen. The shaded area represents the fracture surface

sheet. 6.4 mm thick sheet was used for the Young's modulus determinations, 5.0 mm thick sheet was used for the slow crack growth measurements, and 3.2 mm thick sheet was used for the time-to-failure measurements.

Young's modulus determinations

The Young's modulus, E , of PMMA was determined as a function of strain-rate using a 3-point bend test performed on an Instron mechanical testing machine. The relationship between the applied load, P , and the displacement of the centre of the specimen, y , is given by:

$$P = \frac{4Ebh^3}{L^3} \times y \quad (13)$$

for specimens of rectangular cross-section, (thickness h and breadth b). L is the distance between the supports. The Young's modulus, E , was determined from the slope of a plot of P against y and the specimen dimensions. The plot was linear over the range of strain investigated (up to 0.005).

$V(K)$ determination

Measurements of crack velocity, V , as a function of stress intensity factor, K_I , were made at $20 \pm 2^\circ\text{C}$ using the Double-Torsion (DT) test, (Figure 2). This test and its applicability to PMMA have been described in detail elsewhere⁶. It can be shown¹¹ that the stress intensity factor, K_I , is independent of crack length, a , and for an elastic material is given by:

$$K_I = PW_m \left[\frac{3(1 + \nu)}{Wt^3t_n} \right]^{1/2} \quad (14)$$

where P is the applied load, W_m is the moment arm, ν is Poisson's ratio (~ 0.33 for PMMA), W is the bar width, t is the bar thickness and t_n is the plate thickness in the plane of the crack.

Measurements of crack velocity may be made quite simply by following a growing crack with a travelling microscope. However other, more convenient methods may also be employed which have the advantage of removing the necessity of directly observing the crack. Marshall *et al.*⁵ have favoured a constant displacement-rate method. Under conditions of constant displacement rate, the crack propagates at a constant load, P , and it can be shown that¹¹:

$$\left(\frac{dy}{dt} \right) = BPV = \text{constant} \quad (15)$$

where B is a constant related to the slope of a compliance calibration curve for the material.

The approach that has been used primarily in this paper is the constant displacement method. With the specimen held at constant displacement, the load falls off gradually as the crack extends in a controlled manner. The crack growth rate is given by¹⁰:

$$\left(\frac{da}{dt} \right) = V = \frac{-P_{i,f}}{P^2} \left(a_{i,f} + \frac{C}{B} \right) \left(\frac{dP}{dt} \right)_y \quad (16)$$

where $P_{i,f}$ is the initial (or final) load, P is the instantaneous load, $a_{i,f}$ is the initial (or final) crack length, and B and C are constants relating to the slope and intercept of a compliance analysis calibration curve for the DT specimen, $(y/P)f(a)$, respectively. The values of B and C were 7×10^{-5} and 8×10^{-4} mm/N respectively for 5 mm thick Perspex sheet.

The crack velocity can be found therefore directly from the rate of load relaxation $(dP/dt)_y$, providing the material does not suffer from mechanical relaxation as a result of, for example, molecular rearrangements in the arms of the DT specimen. This source of error may be reduced by pre-loading the sample to a value of load where the crack growth rate is very low ($V < 10^{-10}$ m/sec).

Observations of the crack front profile show that the crack extends further along the lower face of the specimen than the upper one⁶. The crack velocity is therefore smaller than that given by equation (16) by a factor which is dependent on the crack front profile¹⁰ and is of the order of 0.4 for 5 mm thick sheet.

Time-to-failure measurements

Time-to-failure measurements were made upon single edge-cracked tensile specimens 25 mm wide and loaded to a value of σ_a of 2.7 ± 0.1 MN/m². Cracks were introduced into the specimens by sawing a notch into one edge of the specimen and forcing a razor blade into the root of the notch. The cracks formed were between 9 mm and 13 mm long giving a range of values of stress intensity factor (K_{Ii}). For this particular range of crack lengths the geometrical factor Y , in equation (11) was of the order of 4.

RESULTS AND DISCUSSION

Young's modulus measurements

The measured variation of Young's modulus, E , with crosshead speed is given in Figure 3 in the form of a log-log plot. The crosshead speed has also been converted to an 'average' strain-rate corresponding to the rate of strain in the specimen half way between the neutral axis and the specimen surface. It can be seen that although the data is presented in the form of a log-log plot, the slope of the curve, n , is continually changing indicating that at this temperature (20°C) the material is near to a relaxation peak. This may correspond to the β -transition⁶.

$V(K)$ measurements

The data points in Figure 4 are measured values of V as a function of K_I for PMMA in air at $20 \pm 2^\circ\text{C}$. The different symbols refer to points obtained from various relaxation experiments on the same and different specimens. The solid curve in Figure 4 is a $V(K)$ curve derived from the $E(\dot{\epsilon})$ curve in Figure 3 using the analysis described

Figure 3 The Young's modulus of PMMA at $20 \pm 2^\circ\text{C}$ as a function of crosshead speed and strain-rate

Figure 4 $V(K)$ diagram for PMMA at $20 \pm 2^\circ\text{C}$. —, theoretical line derived from the $E(\dot{\epsilon})$ data in Figure 3 using the values of the constants: $\delta_f = 1.73 \times 10^{-6}$ m; $e_y = 0.038$

earlier. The Young's modulus E has been converted to K_I using equation (4). The crack opening displacement (δ_f) for PMMA has been determined by Brown and Ward⁹ to be 1.73×10^{-6} m. The yield strain e_y , has been chosen so that the theoretical curve follows the measured data. This gives a value for e_y of 0.038. A compressive stress-strain

curve for PMMA is given in ref 12. The point of maximum stress, which is conventionally taken to be the yield point, occurs at a strain of the order of 0.08. The curve deviates from linearity well below this strain and plastic deformation takes place at values of stress below the maximum¹². A value of yield strain of the order of 0.04 is therefore not unreasonable. The strain-rate, $\dot{\epsilon}$, has been converted into a crack velocity V through equation (9) using the same values of e_y and δ_f as before.

It can be seen that the fit of the theoretical line to the measured data is very good. However, the range of crack velocities over which the curves and the data overlap is small. This is because the crack velocities corresponding to strain-rates that can easily be measured using an Instron are rather low ($<10^{-6}$ m/sec). Williams¹³ and Marshall *et al.*⁵ have shown qualitatively that the slopes of the predicted and measured $V(K)$ curves would be of the same order. Now by evaluating the $V(K)$ relationship at very low crack velocities we have shown that good quantitative agreement between the data and the theory can be obtained.

Time-to-failure measurements

Pre-cracked specimens. As well as using the constant δ criterion to explain slow crack growth in PMMA it can be used for the prediction of times-to-failure of pre-cracked PMMA specimens held under conditions of constant stress. In this case it was shown earlier that ψ_f is controlled by the time for crack propagation ψ_p . Figure 5 gives the measured times-to-failure of pre-cracked tensile specimens of PMMA as a function of initial stress intensity factor. The solid line in Figure 5 is the time-to-failure curve predicted from the $V(K)$ relationship (Figure 4) which in turn had been obtained from the $E(\dot{\epsilon})$ measurements (Figure 3). The $V(K)$ relationship was used in equation (12) with a value of K_{Ic} of $1.6 \text{ MN/m}^{3/2}$ (Young and Beaumont⁶). The broken line in Figure 5 is the predicted time-to-failure curve obtained in a similar way but using the experimentally obtained $V(K)$ data presented in Figure 4. It can be seen that all the measured points lie on or above the theoretical predictions. This shows that it is possible to integrate the $V(K)$ function [obtained from the $E(\dot{\epsilon})$ relationship] and obtain a conservative estimate of the times-to-failure.

Some of the scatter may be due to the variation in crack front profile following cracking or bifurcating of the craze

Figure 5 Time-to-failure data for pre-cracked PMMA specimens at $20 \pm 2^\circ\text{C}$. - - - -, predicted ψ_f derived from the data points in Figure 4; —, prediction from the $E(\dot{\epsilon})$ in Figure 3

Figure 6 Time-to-failure data for PMMA as a function of applied stress σ . The data was obtained by Regel¹⁴ at 25°C, Zhurkov³ at 18°C and that given by Ogorkiewicz¹⁶ was measured at 20°C. The heavy line is the predicted time-to-failure curve for 20°C derived from the $E(\dot{\epsilon})$ data in Figure 3 and using an inherent flaw size for PMMA of 0.075 ± 0.005 mm (Berry¹⁵)

at the crack tip. The predictions presented here are for a crack with a single craze at the crack tip and any imperfections at the crack tip will lead to failure at times longer than those predicted by the analysis.

Unnotched specimens. Some experimental time-to-failure curves for unnotched specimens of PMMA are given in Figure 6. The curve of Zhurkov was used in a previous publication where it was shown that for ψ_f in the range 10^{-3} to 10^3 sec agreement could be obtained between the measured ψ_f values and ψ_f predicted solely from crack propagation using the measured $V(K)$ relationship. The analysis predicted a value of the inherent flaw size, a_0 , of 0.073 ± 0.005 mm, which is close to the value obtained by Berry¹⁵ for PMMA at 20°C. The ψ_f curve obtained by ICI Ltd for Perspex and presented by Ogorkiewicz¹⁶ is given in Figure 6. It does not agree particularly well with the experimentally determined curves of Zhurkov³ or Regel¹⁴, which are also presented in Figure 6. For a given level of applied stress the values of ψ_f given by Ogorkiewicz are approximately two orders of magnitude longer. This may be due to differences in the grade of PMMA used. Indeed, Berry¹ has shown that large differences in flaw size and fracture surface energy may be found between different grades of nominally the same material. This implies that comparisons between measured and predicted values of ψ_f should only be made for the same material. This means that in this present investigation direct comparisons should only be made for data on Perspex.

The heavy line in Figure 6 is the calculated ψ_f curve for specimens of Perspex containing inherent flaws of 0.075 ± 0.005 mm (Berry¹⁵) and using the $V(K)$ relationship (Figure 4) derived from the $E(\dot{\epsilon})$ curve in Figure 3. The time to initiate these inherent flaws, ψ_i , has been assumed to be zero and ψ_f has been calculated solely from ψ_p . The calculated line has a shallower slope and falls to the left of the measured curve for Perspex. This implies that the assumption that ψ_i is zero is incorrect and means that there must be an incubation period during which the inherent flaws are formed. It is thought (Andrews¹⁷) that the inherent flaws are crazes which have grown to a critical length

at which point they begin to break down and act as cracks of a length equivalent to the inherent flaw size. It is known that an incubation period is needed for crazes to nucleate and grow (A. Argon; personal communication). Oxborough and Bowden¹⁸ have shown that the formation of crazes in polystyrene is stress and time-dependent. It is clear therefore that the formation of the inherent flaws will be time-dependent. The results of Regel¹⁴ would appear to confirm this since he found that well before the PMMA specimens finally fractured, cracks or crazes appeared on their surfaces after an initial incubation period.

Limitations of the theory

It is clear that this theory can only be applied to polymers in which crack propagation takes place by the extension of a single craze which may be modelled as a Dugdale plastic zone. It will not be directly applicable to polymers such as polystyrene where the crack and crazes at the crack tip may be branched¹⁹.

The assumption that the crack opening displacement, δ_f , and the yield strain, e_y , are insensitive to both strain-rate and temperature will only be an approximation. The variation of these two parameters could be incorporated into the theory but the extra complication involved would probably not be worthwhile.

The time-to-failure for unnotched samples requires careful consideration. It is clear that even the experimental data is not in very good agreement. Even so it is essential that in order to accurately predict the time-to-failure of unnotched PMMA specimens we must have a complete knowledge of both the craze and crack growth kinetics.

CONCLUSIONS AND IMPLICATIONS

It has been shown that the relationship between the crack velocity, V , and the stress intensity factor, K_I , for PMMA can be explained quantitatively in terms of a critical crack opening displacement criterion. It has been possible, using simple assumptions, to construct a $V(K)$ diagram for PMMA from measurements of the Young's modulus as a function of strain-rate. Good agreement is found between the derived $V(K)$ curve and the measured data.

The analysis has been extended to predict the lifetimes of PMMA specimens held under constant stress. For specimens containing sharp cracks, it has been possible to make a conservative prediction of their times-to-failure. For unnotched samples the agreement is not so good and it appears that an incubation period is required during which time the inherent flaws must grow. A complete analysis for this case would have to include knowledge of both the craze and crack growth kinetics.

It has been shown that knowing the yield strain, crack opening displacement and initial crack length it is possible, with certain precautions, to predict the lifetime of PMMA components under stress by measuring the strain-rate dependence of the Young's modulus. This could eliminate the necessity of measuring crack velocities and may be a valuable method of predicting the time-dependent strength of other glassy polymers.

A thermoanalytical comparison between ram and screw extruded polypropylene

F. W. Hampson and T. R. Manley

Department of Materials Science, Newcastle upon Tyne Polytechnic, Newcastle upon Tyne NE1 8ST, UK

(Received 20 October 1975; revised 12 March 1976)

Thermoanalytical methods are useful in comparing the effects of extrusion on talc filled polypropylene. Differential thermal analysis, either by the conventional technique, or in an atmosphere initially of nitrogen to which oxygen is introduced, is the most convenient way of studying the extruded polymers. The polymer is more degraded by screw extrusion than by ram extrusion. Critical oxygen index measurements confirm the d.t.a. results.

INTRODUCTION

Extrusion is the most widely used technique for processing polymers¹. A screw feed is usually employed but recently there has been considerable interest in ram extruders. Work on ram extruded polyethylene has already been reported in this series². Thermoanalytical techniques are well established for the characterization of polymers³ and the critical oxygen index flammability test has been found to be of value in quality control studies⁴. It was decided, therefore, to compare these with the conventional quality control tests to monitor differences in the properties of polypropylene that had been extruded by ram and screw techniques.

EXPERIMENTAL

For differential thermal analysis a Dupont 900 apparatus in the so called DSC mode was used. Samples of approximately 15 mg were heated to 400°C at 8°C/min in still air, with an empty aluminium cup as the reference cell. In the second series of experiments, the polypropylene was initially heated under static nitrogen and oxygen was instantaneously introduced at a flow rate of 8 ml/sec near 200°C as indicated in *Figure 3*.

The critical oxygen index (COI) was measured on a Stanton Redcroft FTA. The results are the mean of ten samples. Each sample was a semi-circular rod 75 mm long and 6.35 mm radius. A gas flow of 4 cm/sec was used with butane ignition (30 sec, 15 mm flame). This is substantially the method of ASTM D 20863-70.

The polypropylene was a powder HS6 10E (ICI Ltd) containing a tertiary butyl type as an anti-oxidant and was used as supplied, 35% by wt of talc was added to the polypropylene in a tumbler dry powder mixer before extrusion, in order to provide economical reinforcement. It can be seen that the mechanical shearing action of the screw raises the temperature of the screw extruded polymer by 22°C, in spite of the fact that the polymer stays for a much shorter period in the heated zones than the ram extruded polymer does.

A prepactor (ram controlled compactor unit) assisted the feeding of the powder to the screw extruder to ensure that the product was homogeneous.

Operating conditions were as follows:

	Single ram extruder	Single start screw extruder
Ratio length to diameter of barrel	96:1	20:1
Diameter of die orifice	0.375 in (9.53 mm)	0.375 in (9.53 mm)
Temperature of orifice (°C)	230	230
Temperature of barrel (°C) ±2°C	Zone 1 137 Zone 4 230	Zone 1 190 Zone 4 215
Temperature of polymer (°C) (a) at orifice (b) after cooling	230 ± 2 15	252 ± 3 15
Take-off speed for polymer (m/min) (extrudate cooled with water)	0.456	4.56

Tensile strength and extension under load were determined at 20°C on an Instron Model TT-DM. In both cases the extension rate was 100 mm/min. Specimens were rods 75 mm long and 9.5 mm in diameter.

In the COI studies of talc filled polypropylene samples a hard crust may form on the test sample surface during the initial ignition period (before the onset of uniform cone burning surface). If this char is removed from the softened surface of the sample and the test recommenced on the softened cone surface produced, a steady flame and reproducible results are obtained.

RESULTS

Differential thermal analysis

The d.t.a. curves for the polypropylene powder before and after ram extrusion are shown in *Figure 1*. *Figure 2* shows the d.t.a. of the screw extruded material and in *Figure 3* the d.t.a. curves are seen of the polypropylene powder, before and after extrusion by both methods examined by heating in an atmosphere of static nitrogen with the admission of oxygen around 200°C. The unextruded powder in *Figure 1*, curve A and the talc filled powder, *Figure 1*, curve B, both show evidence of premelting which is usually attributed to the presence of material of less

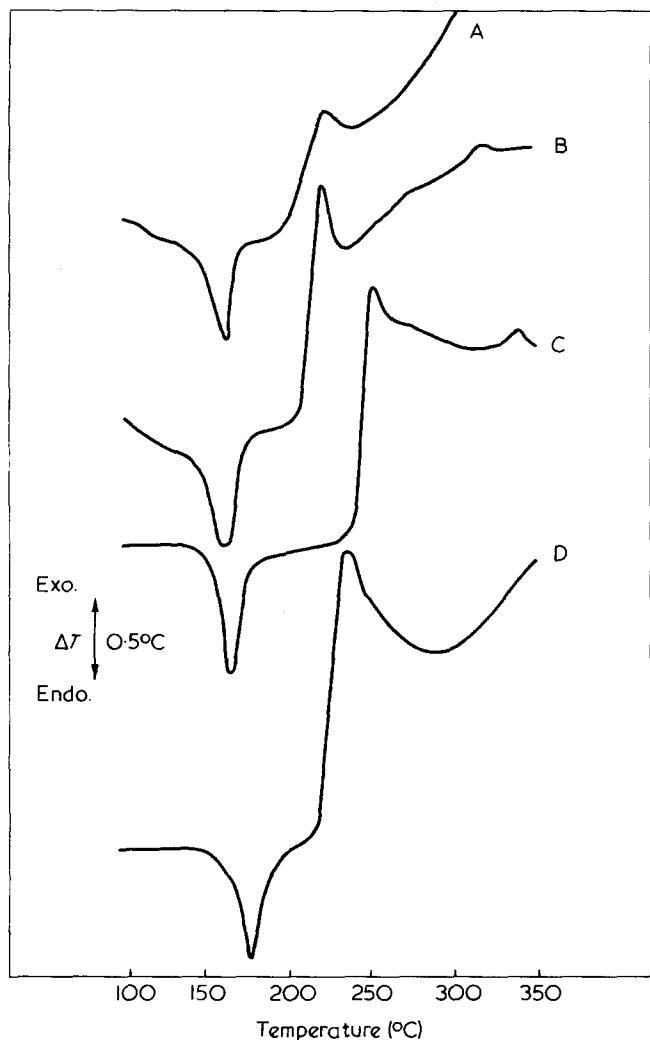

Figure 1 D.t.a. of powder and ram extruded polypropylene + talc. A, Powdered polypropylene, not extruded; B, powdered polypropylene + talc, not extruded; C, ram extruded polypropylene, aged 12 days at 155°C; D, ram extruded polypropylene, aged 21 days at 155°C

ordered structure than the normal crystalline polymer. The samples after extrusion, Figure 1, curves C and D and Figure 2 having had heat treatment do not show this initial premelting. In the unextruded talc filled powder, the oxidation begins to occur around 200°C. It is noticeable that the onset of oxidation is later in the extruded samples and this is attributed to the better mixing of the inhibitor in the extruded material. The d.t.a. curves both in still and flowing atmospheres were closely reproducible except above 450°C by which time most of the polymer had been consumed.

We now come to a significant difference between the two techniques. The sample in Figure 1, curve C was ram extruded and then aged in still air for 12 days at 155°C; the curve obtained is similar to that for shorter ageing periods of eight and five days respectively which are therefore not shown. The corresponding curves, Figure 2, curve C, for screw extruded material held for 12 days for 155°C shows that the ram extruded material is significantly more stable after this ageing period, as seen in Table 1. After the ram extruded material has been aged for 21 days, Figure 1, curve D, it can be seen that the inhibitor is beginning to be used up and ageing is occurring around 200°C. This curve is very similar to that of Figure 2, curve B of a screw extruded material after 8 days. After 21 days ageing, oxidation is occurring almost immediately after the melting

endotherm and it is obvious that the useful life of the screw extruded material has already been completed. In Figure 3 we present the results for the differential thermal analysis of the original polypropylene, the powder plus the talc filler, and for samples that were extruded on the ram and screw machines and subsequently aged for 21 days at 155°C. These samples were initially heated in static nitrogen and then oxygen was introduced at the point indicated on the graph to obtain the exotherm. The technique has been widely used to study the effect of inhibitors on the oxidation of polyolefins⁵. The change in scale of the ΔT after the introduction of the oxygen should be noted. In addition after such a vigorous reaction the base-line will not be that of the original polypropylene. It is clearly seen that the sample in Figure 3, curve C that had been ram extruded still retains much material for oxidation whilst for the screw extruded material, Figure 3, curve D, the reaction is almost complete before the oxygen is introduced. This difference is also seen between Figure 1, curve D and Figure 2, curve D but is greatly enhanced by the introduction of oxygen. This technique of introducing oxygen into d.t.a. conducted under nitrogen is a very sensitive and rapid method for determining the amount of oxidation that a sample has undergone and this could well be the preferred way of quality control testing by d.t.a. of extruded materials.

CRITICAL OXYGEN INDEX

Samples were examined after various periods of ageing in air on a metal free surface at 155°C. In addition, a further sample was aged for 21 days at 155°C in contact with copper, in order to get a figure for the COI of the fully oxidized material.

The results of the critical oxygen index are shown in Table 2. The improvement in oxidation stability of the ram extruded material over the screw extruded material is clearly seen. A COI of 21.27 for material oxidized in the presence of copper, is the maximum COI value. It can be seen from Table 2 that the critical oxygen index is not sufficiently sensitive to distinguish between extruded material that had been aged for 21, 12, 8 or 5 days. On the other hand, it clearly shows the difference between the ram and screw extruded material. The screw extruded polypropylene is nearing the end of its useful mechanical efficiency as shown by a COI of 20.73% close to the maximum value. In an industrial process involving repetitive heating to 155°C and cooling to ambient temperatures over periods of 2 h the screw extruded material withstands only 2 or 3 2 h cycles before mechanical failure occurs. The ram extruded material shows no oxidative degradation (COI 17.82%) and remains mechanically serviceable for

50 to 60 2 h cycles. It is interesting to note that the critical oxygen index indicates the onset of degradation before any physical discolouration of samples is seen.

TENSILE STRENGTH AND DENSITY

The ram extruded material had a density of 1.15 compared to 1.08 in the screw extruded material. For 100% sample compactness using polypropylene of SG 0.892 and talc of SG 2.65, a density of 1.176 would be anticipated. The maximum possible consolidation has thus not been achieved by either process, and small voids were seen in the screw extruded material, but were not visible at 20x magnification in the ram extruded polypropylene.

The tensile strengths of the two materials after ageing are shown in Table 3. The ram extruded material retains its tensile strength longer, as would be expected since the d.t.a. indicates that it has degraded less. The latter technique is much simpler than tensile testing and is therefore preferable for quality control work.

The screw extruded material exhibits drawing effects by necking under excess loads prior to fracture. The ram ex-

truded material remains as a fused structure which shows a brittle fracture with no necking under breaking load conditions.

CONCLUSIONS

Thermoanalytical methods give information on flammability, dispersion, degradation and thermal history. It is possible with controlled ageing, to obtain results indicative of the component life of an extrudate before the onset of visible degradation. This is particularly valuable when pigmented materials are in use and coloured oxidation product formation is masked.

Differential thermal analysis is a useful means of detecting and following the onset of oxidative degradation and exhaustion of antioxidant, without the need for testing large samples of material with heavy test machinery and is thus a convenient quality control test for prognostication of the life of extruded materials. D.t.a., with controlled admission of oxygen into an initially inert atmosphere is the better quality control technique.

Critical oxygen index results show insufficient ageing differential to be of value for process control purposes.

The screw extruder appears to cause greater degradation than the ram extruder. This indicates that the mechanical shearing action of the screw is much more destructive than the longer time spent at high temperatures and pressure within the ram extruder. The effect of the extrusion

process on antioxidant effectiveness is demonstrated; d.t.a. is a useful analytical tool to study these effects.

If a ram extrusion process with less degradative action from processing could be developed to achieve the same speed throughout as is obtainable by screw extrusion methods, valuable savings in material usage could be obtained as less scrap was lost by degradation during processing and recycling. Continuous ram extrusion is now being extensively investigated⁶.

Failure criterion for the fracture of structural adhesive joints

R. A. Gledhill and A. J. Kinloch

Ministry of Defence, Explosives Research and Development Establishment, Waltham Abbey, Essex
EN9 1BP, UK

(Received 19 February 1976; revised 26 March 1976)

The long-term strength of stressed, structural adhesive joints, consisting of aluminium alloy substrates bonded with an epoxide adhesive, has been investigated. The applied adhesive fracture energy, G_{Ic} , is shown to be linearly dependent upon the logarithmic time-to-failure; the failure time decreases as the value of G_{Ic} is increased. The fracture of these joints over eight decades of time is uniquely described by the hypothesis that there is a critical plastic-zone size developed at the crack tip at failure.

INTRODUCTION

Structural adhesives are relatively brittle, high modulus, thermosetting materials, usually based upon epoxide resins, and are being increasingly used in many diverse engineering applications. This has generated a need for the mechanical properties of bonded structures to be ascertained and for pertinent failure criteria to be established. The efficient design of bonded structures, and the accurate prediction of safe-working life, are dependent upon such data being available.

Structural joints fail by progressive crack growth and thus no failure criterion based on average stress or modulus (reflecting, for example, gross yielding or buckling) is appropriate, and the failure criterion must be founded upon the initiation and propagation of flaws inherent in the joint. Since the basic tenet of continuum fracture mechanics theory¹ is that the strength of most real solids is governed by the presence of flaws, and since the theory enables the manner in which they propagate under stress to be analysed mathematically, the application of fracture mechanics to adhesive joint failure has recently received considerable attention.

It has been shown^{2,3} that the concepts of continuum fracture mechanics are applicable to the failure of structural adhesives joints but the measured adhesive fracture energies, G_{Ic} , are orders of magnitude greater than expected from theoretical considerations of solely brittle fracture⁴. This is in accord with fracture studies on other glassy polymers¹ and arises from the energy that must be dissipated in producing local plastic deformation at the tip of the crack, in addition, to that required for the rupture of molecular bonds. It has subsequently been shown that the value of G_{Ic} is not a 'joint constant' but is a function of test temperature⁵, crack velocity⁶⁻⁸ and test environment^{8,9}. However, all this work has been concerned with relatively short-term tests; the present investigation examines the long-term stability of structural joints under imposed stresses. A main aim is to develop a failure criterion, for such joint fracture, by employing a continuum fracture mechanics analysis.

EXPERIMENTAL

Determination of G_{Ic}

The specimen geometry employed in this investigation was a tapered double cantilever beam joint and is shown

schematically in *Figure 1*. The substrate material was aluminium alloy, to specification British Standard 1474 NE4, which was machined into cantilever beams, 152 mm long, 6.4 mm thick and with a height, h , varying between 16.0 and 31.5 mm. The surfaces to be bonded were first subjected to a liquid- and vapour-degreasing bath of trichloroethane, then grit-blasting with 180–220 mesh alumina, then degreasing again and finally were allowed to air-dry. The epoxide adhesive employed was a diglycidyl ether of bisphenol A crosslinked with 9.4 mass per cent of a tertiary amine curing agent [tri-2-ethyl hexanoate of 2,4,6-tris(dimethylamino-methyl)phenol]. Immediately prior to joint preparation the aluminium alloy substrates were treated as described above, adhesive spread on the treated faces and the two beams pressed lightly together; small pieces of plastic sheet, previously inserted in the adhesive at the far ends of the joint, were employed to control the thickness of the epoxide resin layer to 0.50 ± 0.06 mm. Further, a piece of Teflon tape, about 30 mm long, 6.4 mm wide and 0.08 mm thick, was previously placed, approximately in the centre of the adhesive layer and at the narrow end of the joint, to assist in propagating a 'starter' crack later. Excess adhesive on the beam sides was wiped off and to effect cure of the adhesive the joint was held at 23°C for 96 h, followed by 1½ h at 100°C and finally 2½ h at 180°C, and then allowed to cool slowly. The specimens were then conditioned at 23°C and 56% r.h. for a few days prior to testing.

To obtain a natural, sharp, starter crack for subsequent experiments the arms of the specimen were separated at a constant rate of 8.5×10^{-3} mm/sec using an Instron tensile

Figure 1 Sketch of tapered double cantilever beam specimen

Figure 2 Typical schematic load-displacement record for stick-slip crack growth

testing machine. Now, for this particular adhesive and joint geometry, crack propagation occurs intermittently⁶, in a stick-slip manner, as is shown schematically in Figure 2. The fundamental reasons why unstable, stick-slip crack growth, rather than continuous, stable crack growth, is observed in this material/geometry combination is not fully understood. Similar differences in fracture behaviour have previously been ascribed to geometry effects¹⁰, β -relaxation transitions occurring in the polymer¹¹, a change from isothermal to adiabatic crack propagation (e.g. ref 12), environmental effects^{8,10} and the morphology of the material¹. Further, our current work¹³ suggests that the shape and sharpness of the crack tip, and the strain distribution in the immediate vicinity of the crack tip, prior to crack propagation may be of some importance.

After several crack initiation/arrest cycles, when the crack length was between 50 and 90 mm, the specimen was removed from the tensile testing machine and the sharpness of the crack tip examined using transmission optical microscopy. Initial observations indicated, however, that it was not possible to insert reproducibly sharp cracks; similar difficulties have been experienced by other workers¹⁴⁻¹⁶. Indeed, using the technique described above crack tip radii ranged between 1 and 200 μm and improvement in the reproducibility was not obtained by employing other techniques such as cooling the specimen in liquid nitrogen prior to crack insertion, propagating a longer crack, using a razor blade instead of the Teflon tape to initiate the blunt starter crack, etc. To ensure minimum, reproducible values of the adhesive fracture energy the technique as described was employed but only the sharp cracks, having tip radii of $1.5 \pm 0.5 \mu\text{m}$, were selected for subsequent testing. Initial work showed that the value of G_{Ic} was not significantly dependent upon the crack tip radius within these limits.

The tapered double cantilever beam joint was then placed in a creep machine (a 'Unisteel Stress Corrosion' apparatus, manufactured by W. H. Mayes and Son Ltd.) and the required load gently applied via a double lever system giving a 30:1 loading ratio. The test temperature and humidity were maintained at 23°C and 56% r.h. The crack tip was frequently observed using a travelling microscope, fitted with an eyepiece graticule unit which permitted a minimum crack growth increment of 0.01 mm to be detected. The failure time was taken as the time between the application

of the total load and the time when the crack had propagated completely through the specimen.

The adhesive fracture energy, G_{Ic} , was ascertained from the relationship¹⁷:

$$G_{Ic} = \frac{4P_c^2 m}{E_s b^2} \quad (1)$$

where P_c is the applied load, E_s is the modulus of the substrate (68.9 GPa), b is the specimen thickness and m is a geometry factor given by¹⁸:

$$m = \frac{3c^2}{h^3} + \frac{1}{h} \quad (2)$$

where c is the crack length corresponding to a height of substrate beam, h . Values of m are shown as a function of crack length in Figure 3 and are in good agreement with values ascertained from experimental calibrations^{18,19}.

Determination of the creep modulus

The method of determining the creep modulus, $E(t)$, as a function of time has been described in detail elsewhere^{20,21} and it is sufficient to note that values of $E(t)$ for samples of the epoxide resin, cured as detailed above, were ascertained at stress-levels of 18.5, 36.1, 48.0 and 53.4 MPa.

Uniaxial stress-strain measurements

Dumb-bells of the epoxide resin were cast in silicone-rubber moulds and cured as described previously. The

Figure 3 The geometry factor, m , as a function of crack length, c , for the tapered double cantilever beam specimen

Figure 4 The relationship between the applied adhesive fracture energy, G_{1c} , and joint failure time

dumb-bells had a gauge-length of 30 mm and a cross-sectional area of about 10 mm^2 . Uniaxial stress-strain curves were obtained at 23°C and at strain-rates from $7.1 \times 10^{-3} \text{ sec}^{-1}$ to $2.8 \times 10^{-5} \text{ sec}^{-1}$, using an Instron tensile testing machine and a strain-gauge extensometer.

RESULTS

Determination of G_{1c}

The relationship between the applied adhesive fracture energy, G_{1c} , and the resulting failure time is shown in Figure 4; a linear relation exists between G_{1c} and logarithmic failure time with the failure time decreasing as the value of G_{1c} is increased. Several other interesting observations were recorded during the course of these determinations. First, the locus of joint failure was cohesive in the epoxide adhesive, with the crack propagating along the centre of this layer. Second, the failure time represented an incubation period; the original starter crack was never observed to propagate until the very end of the experiment, at the instant of fracture, when it propagated extremely rapidly. The part of the total failure time during which the crack was actually growing was confined, therefore, approximately to milliseconds. This is in accord with previous work⁶ where the short-term, initiation, adhesive fracture energy was studied as a function of initial crack velocity. For this particular geometry and adhesive it was found that the velocity of crack growth was always greater than about 20 m/sec; crack velocities slower than this were never observed. In the present experiments, however, even though unstable crack growth occurred, no crack arrest was observed. This was probably due to (a) the relatively high crack velocities and short specimen length; (b) the fact that a constant load, rather than a constant displacement, was applied to the specimen during crack growth and thus no decay in the applied load occurred as the crack length increased during crack propagation, obviously a fall in the applied load would assist crack arrest; (c) the tapered-double-cantilever-beam specimen has a poor geometrical stability factor which hinders the attainment of stable crack growth¹⁰, especially when a relatively large crack-length to specimen-length ratio is employed²², as in the present experiments. Third, within the time-scale of the current experiments, there was no discernible minimum value of G_{1c} , below which joint failure did not occur.

Determination of the creep modulus

The creep modulus, $E(t)$, of the epoxide adhesive is

shown as a function of time in Figure 5 and these results clearly demonstrate that $E(t)$ is also a function of the applied stress level, i.e. the epoxide material exhibits non-linear viscoelastic behaviour. An empirical, curve-fitting exercise revealed that the value of $E(t)$ in GPa could be represented by:

$$E(t) = 2.27361 + 0.33261 \ln t - 0.02076 (\ln t)^2 + 0.02192 \sigma - 0.01175 \sigma \ln t + 0.00052 \sigma (\ln t)^2 \quad (3)$$

where σ is the applied stress level (MPa) and t the time (sec). The average difference between the experimental values of $E(t)$ shown in Figure 5 and values calculated from equation (3) is 7.0%.

DISCUSSION

A failure criterion

It had been hoped that the adhesive fracture energy would prove to be a working criterion for the long-term stability of these structural adhesive joints upon being stressed. However, while it had been expected that the value of G_{1c} might well have been dependent upon such variables as test temperature and crack velocity, its dependence on a parameter such as an incubation time cast grave doubts as to its usefulness as a failure criterion.

Nevertheless, a unique failure criterion may be derived by considering the fracture behaviour from the viewpoint of the crack opening displacement model of an elastic-plastic material²³⁻²⁵ the deformation of which is elastic up to the yield stress, σ_y , and then becomes fully plastic. The plastic zone at a crack tip, according to this model, is shown schematically in Figure 6, where δ is the crack opening displacement and r_y is the radius of the plastic zone at the crack tip.

Now, in plane-strain, the plastic zone size, r_{1y} , is given by²³:

$$r_{1y} = \frac{K_I^2}{6\pi\sigma_y^2} \quad (4)$$

Figure 5 The creep modulus, $E(t)$, of the epoxide adhesive as a function of time: A, 18.5; B, 36.1; C, 48.0; D, 53.4 MPa

Figure 6 Schematic drawing of the crack opening displacement model of an elastic-plastic material

where K_I is the stress-intensity factor, related to G_I by^{19,23,24}:

$$K_I^2 = \frac{EG_I}{(1-\nu^2)} \quad (5)$$

where E is the modulus of the adhesive and ν its Poisson's ratio. By combining equations (4) and (5) to eliminate K_I :

$$r_{Iy} = \frac{G_I E}{6\pi(1-\nu^2)\sigma_y^2} \quad (6)$$

Now for many polymers^{26,27}, including epoxide resins²⁸, it has been shown that the yield strain, ϵ_y , is largely insensitive to both strain rate and temperature and thus equation (6) may be simplified if ϵ_y is taken as constant and

$$\sigma_y = E\epsilon_y \quad (7)$$

Substituting equation (7) into (6):

$$r_{Iy} = \frac{G_I}{6\pi(1-\nu^2)\epsilon_y^2 E} \quad (8)$$

At fracture, $r_{Iy} = r_{Iyc}$ and $G_I = G_{Ic}$. Now it has been shown that both G_{Ic} and E are time-dependent. Therefore:

$$r_{Iyc} = \frac{1}{6\pi(1-\nu^2)\epsilon_y^2} \cdot \frac{G_{Ic}}{E(t)} \quad (9)$$

Thus, if the value of $G_{Ic}/E(t)$ is a constant over the time-scale of the experiments, a constant value of r_{Iyc} might be deduced which would provide a unique failure criterion for the fracture of these structural adhesive joints. Indeed Williams and coworkers^{12,27} have recently shown that a constant r_{yc} criterion, derived from a Dugdale line-plastic-zone model, is valid for poly(methyl methacrylate) and polycarbonate over a wide range of test temperatures and rates.

Calculations of r_{Iyc}

To calculate a value of r_{Iyc} values of $E(t)$, G_{Ic} , ϵ_y and ν are required.

Now, since the epoxide adhesive exhibits non-linear viscoelastic behaviour, derivation of pertinent values of $E(t)$, from either Figure 5 or from equation (3), requires that an appropriate value for the applied stress level, σ , be selected. A typical uniaxial stress-strain curve for the epoxide resin is shown in Figure 7 and, since the material is relatively brittle, with no evidence of bulk yielding, no yield-load drop is recorded. A 'yield point' was therefore

defined as the point of intersection of two tangent lines on the stress-strain curve²⁹ and this value, σ_c , taken as the appropriate value of σ to use for deducing $E(t)$. The value of σ_c from Figure 7 is 42 MPa and was not significantly dependent upon the strain-rate employed.

Experimentally obtained values of G_{Ic} were taken from Figure 4 and values of $E(t)$, at a stress-level of 42 MPa and at a corresponding time, t , ascertained either by interpolation of Figure 5 or from equation (3). Values of G_{Ic} and $E(t)$ so determined are plotted in Figure 8 and both

Figure 7 Typical uniaxial stress-strain curve of the epoxide material

Figure 8 The adhesive fracture energy, G_{Ic} , as a function of the corresponding value of the creep modulus, $E(t)$, of the adhesive. O, for values of $E(t)$ interpolated from Figure 5. X, for values of $E(t)$ calculated from equation (3)

Table 1 Yield-strain, ϵ_y , as a function of strain-rate

Log_{10} (strain-rate) (sec^{-1})	Yield strain, ϵ_y
-2.15	0.016
-2.55	0.013
-2.85	0.015
-3.15	0.015
-4.15	0.018
-4.55	0.014

methods of deducing $E(t)$ yield a linear proportionality between G_{Ic} and $E(t)$ (having a combined correlation coefficient of 0.984). $G_{Ic}/E(t)$ is therefore constant and has a value of $0.059 \pm 0.006 \mu\text{m}$. This means that the value of r_{Iyc} is a constant over the entire time-scale of eight decades, over which the fracture experiments were conducted, and thus provides a unique failure criterion.

Values of 'yield strain' were determined from the uniaxial stress-strain curves as exemplified in Figure 7, and are shown in Table 1. The yield strain, ϵ_y is not significantly dependent upon the strain-rate employed and its mean value is 0.015.

Thus, taking the value of ν of the epoxide adhesive as 0.35, the value of r_{Iyc} from equation (9) is $16 \mu\text{m}$. If, in ascertaining the values of $E(t)$, a stress-level, σ_c , of, say, 36 or 48 MPa had been chosen, (instead of the 42 MPa value used above) a constant value of r_{Iyc} would still have been obtained, but its value would have been $13 \mu\text{m}$ or $19 \mu\text{m}$ respectively. Thus, the hypothesis that a constant value of r_{Iyc} provides a unique failure criterion, is not dependent upon the value of σ_c chosen for deducing values of $E(t)$.

Furthermore, a constant r_{Iyc} criterion implies that there is also a critical crack opening displacement, δ_c , for fracture which may be deduced from¹²:

$$\delta_c = \frac{G_{Ic}}{E(t)\epsilon_y(1-\nu^2)} \quad (10)$$

The value of δ_c so determined is $4.5 \mu\text{m}$.

Finally, the wider implications of the proposed constant r_{Iyc} criterion may be considered. This is a criterion for the onset of crack propagation but the total time-to-failure, t_f , of a pre-cracked structural adhesive joint is given by:

$$t_f = t_i + t_p \quad (11)$$

where t_i is the incubation time and t_p the time the crack takes to propagate through the specimen. In the present experiments $t_i \gg t_p$, and hence $t_i \approx t_f$, and thus the attainment of the critical value of r_{Iy} not only provides a criterion for the onset of crack propagation but also provides one for total fracture of the structure. However, for other adhesive/geometry combinations, t_p may well not be negligible and, in such cases, G_{Ic} as a function of t_i , rather than t_f , must be used to deduce the value of r_{Iyc} .

CONCLUSIONS

The long-term strength of stressed, structural adhesive joints has been investigated and the following main conclusions reached:

(a) A linear relationship exists between the applied adhesive fracture energy, G_{Ic} , and the logarithmic failure time; the failure time decreases as the value of G_{Ic} is increased.

(b) Within the time-scale of the present experiments no discernible minimum value of G_{Ic} , below which joint failure did not occur, was recorded.

(c) From a fracture mechanics analysis it has been demonstrated that there is a critical value of the plastic zone size, r_{Iyc} , at the crack tip at which fracture occurs. This gives a unique failure criterion for the fracture of these joints over eight decades of failure time. A value for r_{Iyc} of $16 \mu\text{m}$ is indicated.

Photoelastic non-equilibrium behaviour of natural rubber networks

F. de Candia, A. Tagliatela and V. Vittoria

Laboratorio di Ricerche su Tecnologia dei Polimeri e Reologia, CNR, 80072 Arco Felice (Napoli), Italy

(Received 9 December 1975; revised 22 March 1976)

INTRODUCTION

In previous papers¹⁻⁴ we have reported results from studying the elastic and thermoelastic behaviour of rubber-like networks obtained by vulcanizing elastomers such as natural rubber and *cis*-polybutadiene in the presence of a solvent, and analysing the mechanical behaviour in the bulk dry state. A feature of such materials is that they follow the Gaussian equation for the rubber elasticity^{5,6} very closely.

This feature is related to the particular vulcanization technique and thus to the topology of the network. The conformational state of the network chains which in the preswollen rubbers are in a supercoiled state^{1,2}, is particularly relevant. Taking into account this property, a working hypothesis has been given, which suggests that in the monodirectional elongation the chain supercoiling is a direct cause of a smaller degree of orientation in the strain direction, when compared to a conventional vulcanizate at the same strain value. Therefore, the tendency for chain-chain interactions or chain-chain aggregations induced by the strain to arise is smaller in a preswollen network than in a conventional vulcanizate. Moreover, the supercoiling, and the consequent high concentration of crosslinking points may be, in the same way, a direct cause of a smaller degree of order in the rubber-like network, such as an order resembling chain bundles.

This hypothesis is related to the main hypothesis that deviations from the rubber elasticity theory can be related to the presence in the amorphous material of some degree of order present before or induced by the strain^{7,8}.

In other papers^{9,10} our aim was to give experimental support to the suggested effects of the supercoiling on the mechanical behaviour. Results ob-

tained by analysing the viscoelastic behaviour of an ethylene-propylene copolymer⁹, and the crystallization kinetics under stress of natural rubber¹⁰ seem to give support to our hypothesis.

In the present paper we have studied the photoelastic behaviour in strain cycles where the maximum strain is increased step by step. The materials used were natural rubber vulcanized both in bulk and in the swollen state. The results are discussed in the light of these two different vulcanization techniques and give more direct evidence to our model.

EXPERIMENTAL AND RESULTS

The networks analysed were prepared in the usual way¹⁻⁴. The preswollen network, denoted as Gaussian-NR, was vulcanized in a chlorobenzene solution with the following composition: 0.3 rubber, 0.7 solvent.

The initiator was dicumylperoxide (3% of the polymer weight), and vulcanization was carried out at 120°C for 2 h. The conventional network, denoted as normal-NR, was vulcanized at 145°C for 45 min using 0.3% of dicumylperoxide as initiator. The stress-strain plots for these two samples reported in terms of the Mooney-Rivlin equation⁵, and corrected for the effect of the solvent during vulcanization¹, give values of the same order for the molecular weight of the network chains, M_c . In particular M_c is 10 800 and 8100 for the normal-NR and Gaussian-NR, respectively.

The photoelastic measurements were carried out using a system that gives the force and the birefringence values. The force was measured with a force transducer, and the birefringence was detected following the Senarmont method¹¹. The hysteresis photoelastic loops were obtained by stretching and relaxing the sample step by step with

5 min intervals between two successive points. For each sample four hysteresis loops were obtained with a gradually increased maximum strain value. In the first loop α_{\max} was 2, 3 in the second, and so on up to 5, where α_{\max} is the maximum strain ratio in a given hysteresis loop.

In *Figure 1* results obtained with the normal-NR are shown. The birefringence Δn is plotted vs. the true stress $\tau\alpha$. The arrows indicate the increasing and decreasing strain. In *Figure 2*, results obtained with the Gaussian-NR are reported. In *Table 1* we report the quantitative data for the photoelastic hysteresis loops in terms of the functions ϕ and ϕ_{rel} . ϕ is the hysteresis area, while ϕ_{rel} is the relative amount of ϕ with respect to the total integral of the function Δn vs. $\tau\alpha$.

DISCUSSION

The photoelastic measurements, as carried out in this paper, can give evidence of irreversibility phenomena in the time scale of the experiment. In fact, the birefringence is a physical quantity which is a direct measure of the optical anisotropy of the sample, where the optical anisotropy is the effect of the chain orientation in the strain direction. As is well known in the literature⁵, and as explained in a previous paper¹², if the chain orientation is partly irreversible in the time scale of the experiment, we observe an hysteresis loop in the photoelastic plots. The irreversibility of the chain orientation is related to a reduced conformational freedom, which can be an effect of chain interaction or aggregation induced by the deformation, or, in more drastic situations, due to chain crystallization.

Considering the present work, the photoelastic hysteresis loops can promise a direct support to our picture regarding the topology of the preswollen networks and the relation between the particular topology and the Gaussian mechanical behaviour observed for these materials. In the light of these few considerations we can analyse the

Figure 1 Photoelastic hysteresis loops obtained with the normal-NR. The maximum value of the strain is increased from 2 to 5 going from left to right. The birefringence $\Delta n \times 10^4$ is reported versus the true stress $\tau\alpha$ in kg/cm^2 . The arrows indicate the increasing and decreasing strain

Figure 2 Photoelastic hysteresis loops obtained with the Gaussian-NR. Maximum strain values as in Figure 1 from 2 to 5 going from left to right

Table 1 Numerical values relative to the photoelastic hysteresis loops

Sample	α_{\max}	$\phi \times 10^4$ (kg/cm ²)	ϕ_{rel}
Normal-NR	2	6.77	0.10
	3	167.60	0.18
	4	223.54	0.22
	5	1914.88	0.28
Gaussian-NR	2	0	0
	3	0	0
	4	54.92	0.13
	5	203.80	0.24

results obtained in the summarized form of *Table 1*. The term ϕ in *Table 1* is a quantitative measure of the degree of irreversibility of the deformation process.

As shown in *Table 1* the experimental data indicate a drastic difference between the normal-NR and the Gaussian-NR. For the latter, in fact, at α_{\max} 2 and 3, a completely reversible behaviour is observed, while at α_{\max} 4 and 5, even if ϕ indicates the presence of a deformation mechanism irreversible in the time scale of the experiment, the numerical values for ϕ are clearly smaller than the corresponding values detected for the normal-NR sample. The effect is not so drastic, but equally evident, on ϕ_{rel} , for which the difference seems to decrease on increasing the strain.

This is in good agreement with the crystallization data previously pub-

lished¹⁰. In other words the samples of normal-NR and Gaussian-NR give evidence of a very different degree of irreversibility of the photoelastic behaviour in the time scale of the experiment. In the light of this evidence it seems possible to state that the ideal mechanical behaviour of the preswollen samples is related to higher degree of reversibility of the deformation mechanism.

Considering the particular topology of the preswollen samples, and the significance of the photoelastic data, these results support our model, suggesting the ideal behaviour to be a consequence of the smaller tendency of these materials to give rise to chain-chain aggregations, or, in general, to interaction before or induced by the strain. In fact, even if other mechanisms of relaxation can give effects of irreversibility, the photoelastic measurements indicate that an important role is played on relaxation by a residual orientation of the chains with a smaller conformational mobility, related to chain-chain effects induced on stretching.

Finally, we wish to pay some attention to another feature of the preswollen networks, i.e. the number of physical entanglements. In fact, this particular vulcanization technique is the cause of a reduced concentration of entanglements in the volume unit^{1,13}. We believe that this property plays a role at

the level of the mechanical behaviour¹³, but, at the same time, the interaction effects are believed to have greater relevance.

Results of this and of a previous paper¹⁰ seem to give firm support to the last hypothesis.

Filler enhancement of rubber modulus

David W. Southwart

Dunlop Ltd, Precision Rubbers Division, Shephed, Loughborough, Leicestershire LE12 9EQ, UK

(Received 28 February 1976; revised 2 April 1976)

Many attempts have been made to relate the modulus of filled vulcanizates, showing the phenomenon termed reinforcement, to the modulus of the unfilled vulcanizate and the filler concentration.

Several modifications of the Einstein viscosity equation have been developed and applied, including the introduction of a shape factor to allow for the asymmetric nature of carbon black aggregates¹.

Many workers have chosen to express data in the form of 'modulus enhancement', equal to E/E_0 where E and E_0 are the modulus of filled and unfilled vulcanizates respectively. Not

only is modulus dependent on such factors as type of filler, strain, deformation history, test method etc., but so also is the modulus enhancement. Mullins and Tobin's² static Young's modulus data obtained at small extensions, on initial extension of natural rubber vulcanizates filled with HAF black, fit the equation:

$$E/E_0 = 1 + 0.67fc + 1.62f^2c^2 \quad (1)$$

where c is the volume fraction of filler, when f the shape factor is given a value of 6.5 (*Table 1*).

Payne's³ data from his study of the dynamic properties of rubbers in shear

show that the enhancement of in-phase modulus is reduced markedly as strain amplitude is increased; they further show how heat treatment of the mix reduces the enhancement. His data for butyl rubber filled with HAF black are given in *Table 2*, in comparison with theoretical values now calculated from equation (1) after putting $f = 6.5$. With normally compounded vulcanizates it is clearly the enhancement at high strain which approximates to the theoretical relationship. Heat treatment enormously reduces the effect of strain except at very high filler concentration.

Sircar and Lamond⁴ have obtained data on a wide range of elastomers filled with a high-structure HAF black. Their dynamic shear moduli values differed slightly from those of Payne, in showing a slight increase to a maximum modulus with very small increases

Table 1 Numerical values relative to the photoelastic hysteresis loops

Filler enhancement of rubber modulus

David W. Southwart

Dunlop Ltd, Precision Rubbers Division, Shephed, Loughborough, Leicestershire LE12 9EQ, UK

(Received 28 February 1976; revised 2 April 1976)

Many attempts have been made to relate the modulus of filled vulcanizates, showing the phenomenon termed reinforcement, to the modulus of the unfilled vulcanizate and the filler concentration.

Several modifications of the Einstein viscosity equation have been developed and applied, including the introduction of a shape factor to allow for the asymmetric nature of carbon black aggregates¹.

Many workers have chosen to express data in the form of 'modulus enhancement', equal to E/E_0 where E and E_0 are the modulus of filled and unfilled vulcanizates respectively. Not

only is modulus dependent on such factors as type of filler, strain, deformation history, test method etc., but so also is the modulus enhancement. Mullins and Tobin's² static Young's modulus data obtained at small extensions, on initial extension of natural rubber vulcanizates filled with HAF black, fit the equation:

$$E/E_0 = 1 + 0.67fc + 1.62f^2c^2 \quad (1)$$

where c is the volume fraction of filler, when f the shape factor is given a value of 6.5 (*Table 1*).

Payne's³ data from his study of the dynamic properties of rubbers in shear

show that the enhancement of in-phase modulus is reduced markedly as strain amplitude is increased; they further show how heat treatment of the mix reduces the enhancement. His data for butyl rubber filled with HAF black are given in *Table 2*, in comparison with theoretical values now calculated from equation (1) after putting $f = 6.5$. With normally compounded vulcanizates it is clearly the enhancement at high strain which approximates to the theoretical relationship. Heat treatment enormously reduces the effect of strain except at very high filler concentration.

Sircar and Lamond⁴ have obtained data on a wide range of elastomers filled with a high-structure HAF black. Their dynamic shear moduli values differed slightly from those of Payne, in showing a slight increase to a maximum modulus with very small increases

Table 1 Young's modulus enhancement for natural rubber vulcanizates filled with HAF black

0.0383	1.30	1.27
0.0611	1.49	1.52
0.0954	2.01	2.04
0.144	3.12	3.05
0.233	8.77	5.73

Data from ref 2

in dynamic strain amplitude. The data in *Table 3* show that modulus enhancement is dependent on both the strain and the polymer type. Values calculated from equation (1), with $f = 6.5$, depend on the polymer density but range from 5.6 to 8.0, and fall between those quoted for enhancement at the two strains (*Table 3*).

Other data confirm the dependence involved on strain and polymer type but indicate that the modulus variation from polymer to polymer for a given filler and concentration, may be less than the variation of the modulus enhancement value (*Table 4*). This is particularly noticeable with a filler such as Aerosil 300 which gives values far in excess of those predicted by equation (1) with $f = 6.5$.

Previous workers^{5,6} have had some success in fitting a modified Einstein equation to their data by making some allowance for bound rubber determined on the unvulcanized polymer/filler mixture. The bound rubber, with a particular filler, depends on the polymer and may at least qualitatively explain the differences in modulus enhancement; but neither the decrease in dynamic modulus with increase of strain amplitude, nor the decrease due to heat treatment (*Table 2*), can be attributed to a decrease in bound rubber.

Unvulcanized silicone rubber/silica mixes, at low strains, are sufficiently elastic to allow Young's modulus values to be determined⁷. Some such mixes on remilling show a decrease of Young's modulus with no significant change in bound rubber; other mixes on remilling and subsequent storage show an increase of Young's modulus accompanied by an increase in bound rubber.

These several effects and anomalies can, however, be explained in terms of three types of structure which are assumed to be present: adsorbed rubber, interparticular rubber and filler-filler structure^{8,9}.

Generally, straining temporarily

Table 2 Dynamic modulus enhancement for butyl rubber vulcanizates filled with HAF black

Polymer type	Modulus enhancement							
	Young's modulus (MPa)			From equation (1)				
	No filler	SAF black	Aerosil 300	Actual	SAF black	Aerosil 300	SAF black	Aerosil 300
Natural rubber	0.9	2.3	22.5	2.6	25	4.7	3.8	
Nitrile rubber	1.2	4.9	22.8	4.1	19	5.1	4.1	
Silicone rubber	0.5	5.0	~27*	10	~54	5.1	4.1	

Data from ref 8; *value obtained by extrapolation of data for 0 to 40 phr of Aerosil 300

disturbs any three-dimensional filler-filler structure present and, in a vulcanizate, reversibly reduces the contribution of this structure to the modulus without any change in the other two structures. This may be the explanation of the quoted dynamic results, and of the comparable effects in a silicone rubber/silica vulcanizate⁸.

More severe straining, while decreasing the number of contacts, or near contacts, between filler particles, may expose hitherto unreacted sites on the filler surface to active sites on the

polymer. This can lead to an increase of adsorbed rubber and/or interparticular rubber, and consequently to an increase in modulus and bound rubber; it occurs in the case of the remilling of the second class of silicone rubber/silica mixes mentioned above.

Improvement of filler dispersion e.g. by hot milling of butyl rubber/HAF black mixes, reduces the extent of filler-filler structure and its contribution to modulus; there may be a concurrent increase in polymer-filler interaction, exhibited as an increase in bound rubber etc.

If filler dispersion is good, and no unreacted filler sites exist, filler–filler structure is at a low level and a high degree of straining will lead to the re-arrangement of the interparticular rubber chains (as postulated by Boonstra¹⁰), or to their scission. The former will allow partial reversibility, the latter irreversibility, of modulus reduction; bound rubber is not significantly changed because any broken chain ends will still be present as adsorbed rubber. This is the situation occurring in many systems and the remilling of the first class (see above) of unvulcanized silicone rubber/silica mixes provides a good example of the phenomenon.

The properties of a vulcanizate depend upon the concentrations of the three structures when crosslinking

takes place, polymer in the form of adsorbed rubber, interparticular rubber and matrix rubber being involved.

Until methods can be found for quantifying the structures, and the various changes, during vulcanization, it appears unlikely that the problem of modulus enhancement will be solved.

A re-examination of the necessity of the mosaic concept in polymer crystals

I. R. Harrison

Department of Materials Science, Pennsylvania State University, Pennsylvania 16802, USA

A. Keller and D. M. Sadler

H. H. Wills Physics Laboratory, University of Bristol, Bristol BS8 1TL, UK

and E. L. Thomas

Department of Engineering and Material Science, University of Minnesota, Minneapolis, Minnesota 55455, USA

(Received 18 February 1976; revised 15 April 1976)

We would like to suggest a reappraisal of the notion of mosaic blocks within polymer crystals in the light of the implications of recent diffraction results. The concept has an importance with regard to the fundamental nature of polymer crystals^{1–3} and in addition has a wider significance, since it has become influential in the interpretation of polymer deformation⁴ and mechanical behaviour⁵.

The X-ray diffraction pattern from polymers, ever since their first observations⁶ were noted for their broad diffraction maxima. In view of considerations of inherent polymer disorder, these peak widths were interpreted quite naturally in terms of small crystallite (or 'micelle') size. Polymer crystals were first directly observed by crystallization from dilute solution and subsequently also in the bulk^{7–9}. The crystal entities have been identified as lamellae, with the polymer chains either parallel or at a particular angle ϕ to the lamellar normals. ϕ can have

a value of up to 45°; in polyethylene single crystals it is usually around 30°.

As is well known, the thickness of these lamellae is in the range of 100–300 Å and corresponds to the fold length. Hence the limited size of the crystals along the chain direction has acquired a very specific molecular interpretation and is satisfactorily accounted for by the chain folding behaviour. However, the solution grown crystals were seen to extend laterally over many microns, even tens of microns. In spite of this the X-ray reflections from planes parallel to the chain directions (i.e. $(hk0)$) of collected assemblies of such crystals were still broadened — even if to a somewhat lesser extent — than in the usual polycrystalline bulk material. This indicates that what are seen as single crystals by microscopy do not yield $hk0$ X-ray reflections as sharp as expected from extended regions of a coherent crystal lattice. Nevertheless, when the crystals are extended in the thickness

direction (the so-called chain extended crystals grown under pressure) the $hk0$ reflections are sharp¹⁰.

Measurement of successive orders of diffraction enabled a separation of the line broadening effect into crystal distortion and crystal size components^{1,2}. Although some contribution from the former was established, an effective mosaic size not much greater than the lamellar thickness was found (e.g. 300 Å mosaic size for 130 Å thick polyethylene single crystals). It has now been suggested that there is an intrinsic structural unit corresponding to a mosaic block within the lamellae^{1–3,10,11}. To reach this conclusion it has been assumed¹² that one of the three principle axes which are necessary to describe a mosaic unit is parallel to the chains (along (001) , i.e. $\phi = 0$).

The effective block size assessed in this way increases in proportion with the lamellar thickness, which has led to the postulate of an equilibrium block shape satisfying a Wulff surface criterion¹¹. The blocks themselves are visualized as having slightly differing c axes orientations; the boundaries separating them would thus be twist boundaries¹.

More recently an electron microscope investigation was undertaken in order to observe the postulated blocks directly. It was believed that owing to the misorientations in question the

If filler dispersion is good, and no unreacted filler sites exist, filler–filler structure is at a low level and a high degree of straining will lead to the re-arrangement of the interparticular rubber chains (as postulated by Boonstra¹⁰), or to their scission. The former will allow partial reversibility, the latter irreversibility, of modulus reduction; bound rubber is not significantly changed because any broken chain ends will still be present as adsorbed rubber. This is the situation occurring in many systems and the remilling of the first class (see above) of unvulcanized silicone rubber/silica mixes provides a good example of the phenomenon.

The properties of a vulcanizate depend upon the concentrations of the three structures when crosslinking

takes place, polymer in the form of adsorbed rubber, interparticular rubber and matrix rubber being involved.

Until methods can be found for quantifying the structures, and the various changes, during vulcanization, it appears unlikely that the problem of modulus enhancement will be solved.

As is well known, the thickness of these lamellae is in the range of 100–300 Å and corresponds to the fold length. Hence the limited size of the crystals along the chain direction has acquired a very specific molecular interpretation and is satisfactorily accounted for by the chain folding behaviour. However, the solution grown crystals were seen to extend laterally over many microns, even tens of microns. In spite of this the X-ray reflections from planes parallel to the chain directions (i.e. $(hk0)$) of collected assemblies of such crystals were still broadened — even if to a somewhat lesser extent — than in the usual polycrystalline bulk material. This indicates that what are seen as single crystals by microscopy do not yield $hk0$ X-ray reflections as sharp as expected from extended regions of a coherent crystal lattice. Nevertheless, when the crystals are extended in the thickness

direction (the so-called chain extended crystals grown under pressure) the $hk0$ reflections are sharp¹⁰.

Measurement of successive orders of diffraction enabled a separation of the line broadening effect into crystal distortion and crystal size components^{1,2}. Although some contribution from the former was established, an effective mosaic size not much greater than the lamellar thickness was found (e.g. 300 Å mosaic size for 130 Å thick polyethylene single crystals). It has now been suggested that there is an intrinsic structural unit corresponding to a mosaic block within the lamellae^{1–3,10,11}. To reach this conclusion it has been assumed¹² that one of the three principle axes which are necessary to describe a mosaic unit is parallel to the chains (along (001) , i.e. $\phi = 0$).

The effective block size assessed in this way increases in proportion with the lamellar thickness, which has led to the postulate of an equilibrium block shape satisfying a Wulff surface criterion¹¹. The blocks themselves are visualized as having slightly differing c axes orientations; the boundaries separating them would thus be twist boundaries¹.

More recently an electron microscope investigation was undertaken in order to observe the postulated blocks directly. It was believed that owing to the misorientations in question the

mosaic blocks should be directly visible by diffraction contrast within the electron microscopic image¹³. However, the crystals proved to be uniform in diffraction contrast. The same investigation also examined the electron diffraction patterns and quantified the observation, (noted ever since the discovery of polymer single crystals) that the reflections appear unusually sharp for a polymer. An effective block size of more than 2000 Å was obtained from the diffraction peak width. Thus not only has the mosaic itself remained unobserved within the crystals, but the actual diffraction effects produced by these crystals denied their existence. Admittedly, different types of radiation, sample mounting and recording geometries were used. Nevertheless it is indisputable that while there can be various extraneous sources which may contribute to broadening, there is nothing but the intrinsic perfection of the crystal which can make reflections sharp. It follows that polymer crystals can be highly perfect in the lateral direction, and it remains to be discovered why they produce line broadening in the usual X-ray diffraction pattern.

Recent X-ray measurements have revealed one extraneous source of broadening¹⁴. It was found that the reflections are broader if the solution grown single crystals are dried into a mat, as usually carried out for X-ray diffraction studies, than if they are in the form of a sludge in mineral oil. The same was observed in subsequent experiments where the crystals were left as a sludge in their original liquor (xylene)¹⁵. Clearly sedimentation and drying introduces a mosaic character of the crystal in addition to any present after growth. Nevertheless, even without drying there is still appreciable line broadening, as compared with electron diffraction. It is then pointed out that this residual broadening would correspond to diffraction from thin crystals with oblique chains in a 'powder diagram', where the effective crystallite size as determined by the Scherrer equation is a measure of the perpendicular distance through the set of crystallographic planes, i.e. $T/\sin \phi$ where T is the length of the crystalline stem within the lattice¹⁴.

It will be clear at this juncture that a fundamental re-examination of the basis of the mosaic concept is needed. This is the principle purpose of the present note. No new discovery is being claimed besides the examination of familiar principles of diffraction in the

context relevant to established structural features of polymer crystals.

The argument as evolved in discussion between the authors of this note is based on the reciprocal lattice construction pertaining to a lamellar crystal of finite thickness but with long range crystalline register laterally. In this case each reciprocal lattice point will be broadened into a spike along the direction of the lamellar normal. This spike will only coincide with c^* , the chain direction, if $\phi = 0$. It should be emphasized that at no time have any polyethylene crystals been verified as having ϕ exactly zero degrees when the crystals are in suspension or in aggregates. Thus the spike should be inclined at a finite angle ϕ to $\langle 001 \rangle$. The rest of the argument relates to the different possible modes of intersection of the spikes and the Ewald sphere.

If only one well defined crystal orientation exists within the sample the intersection can only be a point, whatever the value of ϕ (Figure 1). As discussed below, this situation can only be realized in electron diffraction. The more usual situation, which always pertains for X-ray diffraction, is when more than one crystal orientation is present. Consider first that the crystals are all random such as would give a 'powder' pattern. The observed signal is now the consequence of a superposition of reciprocal lattice points of different crystals, i.e. the spikes superimpose to give a shell of finite thickness in reciprocal space and hence a broadened reflection (Figure 2). Approximating the spike as being length $1/T$, where T is the crystal thickness, the shell width b which will govern the total breadth of the ring in a powder pattern will be

$$b = \frac{\sin \phi}{T} \quad (1)$$

where b is inversely related to the mosaic size (Figure 2). Note first that this line broadening only occurs if $\phi \neq 0$. Secondly, note that full randomization is not necessary to give this line width. Within sedimented aggregates, single crystals acquire a spread of orientation with relation to the plane of sedimentation, and a misorientation of only a very few degrees is sufficient to produce a line width of similar magnitude to that in a powder pattern. This is simplest to show analytically for small curvatures of the Ewald sphere in which case the minimum range 2α (Figure 2b) is approximated by

Figure 1 (a) Schematic section through a polymer crystal, as seen along one set of $h k 0$ planes of spacing d . T is the thickness of the crystal, and ϕ defines chain obliquity. (b) Corresponding reciprocal lattice construction, the lattice points being approximated as spikes. The incident radiation direction is vertical; a section through the Ewald sphere is shown intersecting the spikes in points. (Both spikes can intersect simultaneously in the case of electron diffraction)

$$\tan \alpha = \frac{d \cos \phi}{2T} \quad (2)$$

For a typical strong $h k 0$ reflection and a typical value of ϕ and T ¹⁶ 2α would be about 2° . This description of 'powder' type diffraction is entirely equivalent to the rigorous derivation of the modified Scherrer equation¹⁷ whereby the 'effective mosaic size' for a reflection is given by the interaction length through a crystallite in a direction perpendicular to the reflecting planes in question.

Hence we identify two well defined situations, depending on whether or not the precision of crystal lattice orientation is within the few degrees described by equation (2) or not. The former case can only occur for individual polymer crystals in electron diffraction as selected under the electron microscope, though in practice, the precision of orientation may not be sufficient even here (e.g. if Bragg fringes are visible, a whole range of orientation must be present)*.

The latter case, namely that the precision of crystal orientation is lower than defined by equation (2) will apply to all X-ray work which is always on aggregates.

* Footnote given on p738

Figure 2 (a) As Figure 1a but with a range of orientations. (b) The corresponding reciprocal lattice construction; the intersections now define a line on the Ewald sphere whose length is related to $T/\sin \phi$

On the basis of X-ray evidence alone therefore there are two possible explanations for line broadening even as confined to the 'crystal size' contribution alone (i.e. lattice distortion apart). If one assumes that the lamellar normals are parallel to the chains the extension of the lattice register in the lateral direction will need to be limited to a few 100 Å and from this the mosaic block structural unit would follow. As an alternative, we can account for the same line broadening effect on the basis of the well established structural feature of chain obliquity in the way described above. We consider that the electron microscope results are deci-

* The structure of the crystal as observed in the electron microscope is not always as in suspension owing to changes occurring when the crystals are dried down on to the support film. It is then possible for crystals to collapse by chain slip so that ϕ becomes zero, although the original chain tilt can be demonstrated by special methods¹⁶. Alternatively the crystal may collapse by tilt, such that tent shaped crystals show characteristic pleats. There is evidence from wide-angle X-ray diffraction that in this case the original value of ϕ is retained when macroscopic aggregates are dried¹⁶. In the first case all principal $hk0$ reflections will be visible in the usual setting of the sample where the beam is perpendicular to the support. In the latter case (collapse by tilt) only some particular reflections, if any, are seen unless the sample plane is tilted. Whichever the case, it does not affect the issue that a sharp reflection is obtained as long as the orientation is uniform within the crystal or sufficiently large portions of it.

sively in favour of the latter interpretation. This alternative also explains the decrease in X-ray $hk0$ 'crystal size' broadening with lamella thickness¹⁸ with no need to invoke the equilibrium Wulff shape¹¹ in a system not normally considered as being in equilibrium in any case.

It would follow that sharp reflections might be observable for polymers where there is no such chain obliquity as in polyethylene. This prediction has been strikingly verified by recent observations on polyoxymethylene¹⁴ and isotactic polystyrene¹⁹; here the $hk0$ reflections were very much narrower than in polyethylene. In fact in the better explored polyoxymethylene system close numerical correspondence was found between the peak broadening crystal size and the crystal size determined from the slope of the observed shallow pyramid (2°) ('mosaic size' of 2300 against 2500 Å predicted).

We would in this way question the necessity of the mosaic concept as an intrinsic feature in polymer crystallization. To avoid possible misrepresentations, we are anxious to stress that we do not question the existence of small crystal blocks, which may produce X-ray line broadenings, due to genuine size limitations to the coherently diffracting lattice under appropriate circumstances, such as are likely to be present in the more complex and yet partly unexplored morphologies of the bulk where X-ray reflections are usually broad. Also, they are likely to arise in systems which results from deformation as in drawn fibres etc. What we do question is the necessity for invoking an intrinsic structure unit of a specific size and shape as a necessary attribute of polymer crystallization. Neither do we question the self-consistency of the existing theoretical treatment of line broadening. All we wish to point out is that these treatments have derived analytical results on certain assumptions, which imply a particular model, and that different physical consequences can be deduced on the basis of an alternative model which requires no postulate beyond established structural knowledge. What is more, the interpretation that we advocate does not imply any contradiction between different diffraction techniques in the particular case of single crystals.

To conclude we may sum up the various factors which could contribute to the crystal size component of the X-ray line broadening as we feel this

has not been done before in its entirety:

Broadening with coherent lattice

(1) Thin crystals with oblique chains coupled with at least slight misorientation (the subject of the present note).

(2) Different lattice spacings in different crystal sectors. This item under the term 'subcell distortion' is documented throughout the literature on polymer single crystals²¹ and is attributed to the distorting effect of the folds. It produces multiplicity of spots in electron diffraction patterns in individual crystals (e.g. Figure 21 ref 7). It is clear that in principle it will contribute to the broadening of appropriate lines when the crystals are in the form of aggregates even if no other source of broadening is present. On the basis of existing data²¹ this effect, however, should be small.

Broadening by genuine limitation of lateral crystal size (incoherent lattice)

(1) Induced by the process of sedimentation and drying. This may be a total artefact, but it may well relate to some fine-structural feature we do not yet know about. It has been so far only recorded for X-ray work, but may also occur on individual crystals in the electron microscope.

(2) A genuine limit to lateral chain register. This is clearly the case when the crystals are genuinely small in such a direction. This will be the case for thin bundles in fringed micelles which act as tie points for physical gelation²⁰. The same is expected from thin fibres produced by flow orientation.

When all the foregoing causes of mosaic-type line broadening are absent, sharp reflections are observed. In these circumstances, the evidence may be judged to leave no scope for the mosaic block concept as an intrinsically general feature of polymer crystallization.

The glass transition temperature of poly(*N*-vinyl pyrrolidone) and the effect of water

Y. Y. Tan and G. Challa

Department of Polymer Chemistry, State University of Groningen, Groningen, The Netherlands

(Received 15 January 1976; revised 5 April 1976)

In the literature several conflicting values of a glass transition temperature (T_g) of poly(*N*-vinylpyrrolidone)* (PVP) were found¹⁻⁸, ranging from 54° to 175°C (Table 1). These may be attributed to the large influence of sorbed moisture due to the hygroscopic nature of the material, as will be shown by the present measurements.

PVP samples containing various known amounts of water were scanned in a Perkin-Elmer DSC-1B differential scanning calorimeter. The PVP was a commercial sample, Luviskol K-90 BASF (Germany), having a viscosity-average molecular weight of 750 000. The results are shown in Figure 1.

The onset of the transitions were taken as the T_g values (see inset in Figure 1). If the best fitting curve was drawn through these T_g values, on extrapolation to zero water content a T_g value for PVP of $175 \pm 1^\circ\text{C}$ (448K) was obtained. The effect of diluents and plasticizers on the T_g of a polymer may be expressed by the equation^{9,10}:

$$1/T_g = w_1/T_{g1} + w_2/T_{g2}$$

where the subscripts 1 and 2 pertain to

* Poly[1-(2-oxo-1-pyrrolidiny)ethylene]

Table 1 T_g values of PVP

T_g (°C)	Literature reference
54	1

175	6,8

Details mentioned in ref 2

polymer and diluent or plasticizers, respectively. Applied to the PVP/H₂O system the equation becomes:

$$1/T_g = w_{\text{PVP}}/T_{g\text{PVP}} + w_{\text{H}_2\text{O}}/T_{g\text{H}_2\text{O}}$$

where $T_{g\text{H}_2\text{O}}$ represents the glass transition temperature of water, $w_{\text{H}_2\text{O}}$ the weight fraction of water, and $w_{\text{PVP}} = 1 - w_{\text{H}_2\text{O}}$.

A plot of $1/T_g$ in K⁻¹ versus $w_{\text{H}_2\text{O}}$ appeared to be linear over the whole range (0-16.1% H₂O). As $T_{g\text{PVP}}$ was

found to be 448K it can be derived that $T_{g\text{H}_2\text{O}} = 128\text{K}$ (-145°C), a value which agrees well with 135K¹¹ and 134K^{12,13} found by other means.

This extremely low value provides water with a very effective T_g depressing activity if it is homogeneously absorbed in a polymer.

Hence for hydrophilic polymers such as PVP, careful drying at the highest temperature possible, preferably under a nitrogen blanket, is necessary in order to obtain correct T_g values.

Distribution and desorption of free radicals in the emulsion polymerization of styrene

B. W. Brooks and M. K. Qureshi

Department of Chemical Engineering, Loughborough University of Technology, Loughborough, Leicestershire LE11 3TU, UK
(Received 19 March 1976)

INTRODUCTION

The emulsion polymerization of styrene is often regarded as one of the few emulsion polymerization systems that conforms to 'case 2' of the Smith-Ewart model¹. A number of reasons have been suggested for this conformity; one of these is the apparent absence of radical migration from the polymer particles. Thus, the average number of radicals per particle, \bar{n} , would be ≥ 0.5 for styrene polymerization.

In this paper some experiments are described in which the emulsion polymerization of styrene, which has attained a constant polymerization rate, is subjected to step-changes in the supply rate of free radicals. These experiments provide information on the value of \bar{n} and show that radical desorption from polystyrene particles takes place.

THEORY

Prediction of \bar{n}

The present experiments deal with the region where the conversion of monomer to polymer is a linear function of time. Therefore, it is valid to assume that the distribution of radical populations in the particles has reached a steady state. If radicals are able to desorb from the particles they must be subsequently re-absorbed by the particles (assuming that mutual reaction of radicals in the continuous aqueous phase is negligible). Thus the number of particles which contain n free radicals, N_n , is given by the recursion expression¹:

$$\begin{aligned} &BN_{n-1} + m(n+1)N_{n+1} \\ &+ (n+1)(n+2)N_{n+2} \\ &= N_n[n(n-1) + mn + B] \end{aligned}$$

where

$$B = m\bar{n} + E, \quad E = \nu q_w/k_t N_w$$

$$\text{and } m = k_0 a/k_t$$

In these expressions ν is the volume and a is the area of a polymer particle, k_t is the rate coefficient for radical-radical termination reactions in the particles, k_0 is the rate coefficient for radical desorption from the particles, N_w is the total number of particles per unit volume of emulsion and q_w is the rate of production of new free radicals from the decomposition of initiator.

A general solution to the recursion expression may be obtained if it is first transformed into an ordinary second-order differential equation. This technique was used by Stockmayer² and also Ugelstad *et al.*³ who also allowed for radical re-absorption. For a given value of m , \bar{n} can be obtained as a function of E . This function contains the ratio of two modified Bessel functions the values of which are obtained from series expressions. Thus, this mathematical procedure, although elegant, eventually requires numerical manipulations and the approximation of series. In view of this, an alternative and simpler procedure for solving the recursion equation is now obtained by allowing the maximum value of n to be 4. This transforms the recursion expres-

sion into a set of linear equations which can be solved exactly for given values of E and m . Since the value of \bar{n} in the present work (and in many other cases also) is $\gg 1$, the assumption that $n \leq 4$ is at least as good as the assumptions made in previous treatments.

Examples of the solutions resulting from this simpler procedure are shown in Figure 1. In Figure 1, \bar{n} was obtained from individual values of n_1 , n_2 , n_3 and n_4 by using the relationship $\bar{n} = \sum n N_n / \sum N_n$.

EXPERIMENTAL

Styrene was freed from inhibitor by washing with aqueous sodium hydroxide. The initial composition of all reaction mixtures was as follows (parts by weight): styrene, 100; water, 214; sodium laurylsulphate, 7; ammonium persulphate, 5; sodium hydroxide, 5. Polymerizations were carried out in agitated glass vessels under nitrogen. Conversion to polymer was monitored by periodically extracting samples of the reaction mixture and weighing the recovered polymer. The polymerizations were carried out in three different ways: (a) at 30°C; (b) at 30°C with post-addition of extra initiator; (c) initiated at 60°C and subsequently cooled to 30°C. Cooling of reaction mixtures from 60° to 30°C was achieved by rapid replacement of water in the thermostated bath. In some cases, precalculated amounts of cold oxygen-free water were also added to the reactor. This cold water contained ammonium persulphate and sodium hydroxide in the same concentrations as those initially present in the reactor. No extra surface-active agent was added. A new constant polymerization rate was attained in ~5 min.

Distribution and desorption of free radicals in the emulsion polymerization of styrene

B. W. Brooks and M. K. Qureshi

Department of Chemical Engineering, Loughborough University of Technology, Loughborough, Leicestershire LE11 3TU, UK
(Received 19 March 1976)

INTRODUCTION

The emulsion polymerization of styrene is often regarded as one of the few emulsion polymerization systems that conforms to 'case 2' of the Smith-Ewart model¹. A number of reasons have been suggested for this conformity; one of these is the apparent absence of radical migration from the polymer particles. Thus, the average number of radicals per particle, \bar{n} , would be ≥ 0.5 for styrene polymerization.

In this paper some experiments are described in which the emulsion polymerization of styrene, which has attained a constant polymerization rate, is subjected to step-changes in the supply rate of free radicals. These experiments provide information on the value of \bar{n} and show that radical desorption from polystyrene particles takes place.

THEORY

Prediction of \bar{n}

The present experiments deal with the region where the conversion of monomer to polymer is a linear function of time. Therefore, it is valid to assume that the distribution of radical populations in the particles has reached a steady state. If radicals are able to desorb from the particles they must be subsequently re-absorbed by the particles (assuming that mutual reaction of radicals in the continuous aqueous phase is negligible). Thus the number of particles which contain n free radicals, N_n , is given by the recursion expression¹:

$$\begin{aligned} &BN_{n-1} + m(n+1)N_{n+1} \\ &+ (n+1)(n+2)N_{n+2} \\ &= N_n[n(n-1) + mn + B] \end{aligned}$$

where

$$B = m\bar{n} + E, \quad E = \nu q_w/k_t N_w$$

$$\text{and } m = k_0 a/k_t$$

In these expressions ν is the volume and a is the area of a polymer particle, k_t is the rate coefficient for radical-radical termination reactions in the particles, k_0 is the rate coefficient for radical desorption from the particles, N_w is the total number of particles per unit volume of emulsion and q_w is the rate of production of new free radicals from the decomposition of initiator.

A general solution to the recursion expression may be obtained if it is first transformed into an ordinary second-order differential equation. This technique was used by Stockmayer² and also Ugelstad *et al.*³ who also allowed for radical re-absorption. For a given value of m , \bar{n} can be obtained as a function of E . This function contains the ratio of two modified Bessel functions the values of which are obtained from series expressions. Thus, this mathematical procedure, although elegant, eventually requires numerical manipulations and the approximation of series. In view of this, an alternative and simpler procedure for solving the recursion equation is now obtained by allowing the maximum value of n to be 4. This transforms the recursion expres-

sion into a set of linear equations which can be solved exactly for given values of E and m . Since the value of \bar{n} in the present work (and in many other cases also) is $\gg 1$, the assumption that $n \leq 4$ is at least as good as the assumptions made in previous treatments.

Examples of the solutions resulting from this simpler procedure are shown in *Figure 1*. In *Figure 1*, \bar{n} was obtained from individual values of n_1 , n_2 , n_3 and n_4 by using the relationship $\bar{n} = \sum n N_n / \sum N_n$.

EXPERIMENTAL

Styrene was freed from inhibitor by washing with aqueous sodium hydroxide. The initial composition of all reaction mixtures was as follows (parts by weight): styrene, 100; water, 214; sodium laurylsulphate, 7; ammonium persulphate, 5; sodium hydroxide, 5. Polymerizations were carried out in agitated glass vessels under nitrogen. Conversion to polymer was monitored by periodically extracting samples of the reaction mixture and weighing the recovered polymer. The polymerizations were carried out in three different ways: (a) at 30°C; (b) at 30°C with post-addition of extra initiator; (c) initiated at 60°C and subsequently cooled to 30°C. Cooling of reaction mixtures from 60° to 30°C was achieved by rapid replacement of water in the thermostated bath. In some cases, precalculated amounts of cold oxygen-free water were also added to the reactor. This cold water contained ammonium persulphate and sodium hydroxide in the same concentrations as those initially present in the reactor. No extra surface-active agent was added. A new constant polymerization rate was attained in ~5 min.

RESULTS

In all isothermal experiments the polymerization rate was constant between 0 and 65% conversion. The two methods of cooling from 60° to 30°C produced substantially the same results. It can be seen from *Table 1* that the addition of extra amounts of ammonium persulphate at 30°C does not change the polymerization rate. The data in *Table 1* show that the polymerization rate at 60°C is 6.77 times faster than that at 30°C. Also, polymerizations which are carried out at 30°C throughout are 1.96 times faster than those started at 60°C and subsequently cooled to 30°C. By taking the propagation rate constant for styrene as 332 l/mol sec at 60°C and 52.6 l/mol sec at 30°C⁴ and by assuming the monomer concentration in the particles to be 5.07 mol/l at 60°C and 5.76 mol/l at 30°C⁵ we obtain the following values for the stationary number of growing free radicals: $9.23 \times 10^{17} \text{ l}^{-1}$ for polymerization at 60°C; $7.47 \times 10^{17} \text{ l}^{-1}$ for polymerization at 30°C and $3.82 \times 10^{17} \text{ l}^{-1}$ for polymerization started at 60°C and cooled to 30°C.

DISCUSSION

Since the addition of extra persulphate at 30°C had no effect on the polymerization rate, we may deduce from *Figure 1* that $\bar{n} \approx 0.5$ under these conditions (because \bar{n} is almost independent of E and q_w when $\bar{n} \approx 0.5$). If this was the case, N_w would be $1.49 \times 10^{18} \text{ l}^{-1}$ which leads to a value of E of about 1.6×10^{-2} before the addition of extra persulphate (assuming the rate constant for persulphate decomposition at 30°C = $3.60 \times 10^{-8} \text{ sec}^{-1}$ ⁶ and $k_t = 2.24 \times 10^7 \text{ l/mol sec}^4$). This value is in the region where $\bar{n} \approx 0.5$ providing $m \gg 10^{-2}$ (see *Figure 1*); thus the assumptions are self consistent.

The results of previous workers (who used the same chemicals as are used here) indicate that for any given recipe, the number of particles produced at 60°C is about 3 times greater than the number produced at 30°C^{7,8}. Consequently polymer particles which are produced in isothermal experiments at 30°C will be larger (and less numerous) than the particles produced in the experiments which are started at 60°C and subsequently cooled to 30°C.

Thus, in comparing these two sets of experiments, it can be seen that E is about 9 times smaller in the 'thermally quenched' experiments than in the isothermal experiments (v is inversely proportional to N_w). This lowering of E

Figure 1 Variation of \bar{n} with E for various values of m : A, $m = 0$; B, $m = 10^{-4}$; C, $m = 10^{-3}$; D, $m = 10^{-2}$; E, $m = 10$

Table 1 Effect of step-changes on polymerization rate

Initial temperature (°C)	Change introduced	Conversion at change (%)	Polymerization rate before change (%/min)	Polymerization rate after change (%/min)
30	none	—	0.757	—
30	a	35	0.725	0.725
30	b	38	0.750	0.750
30	b	45	0.725	0.725
30	b	60	0.750	0.750
60	none	—	5.00	—
60	c	52	4.76	0.350
60	c	50	4.80	0.414
60	d	54	5.40	0.370
60	d	33	5.00	0.474
60	d	48	5.10	0.281

a, addition of twice the original initiator; b, addition of 4 times original initiator; c, external cooling to 30°C; d, internal cooling to 30°C

causes the value of \bar{n} to be reduced by a factor of about 6. From *Figure 1* it can be seen immediately that m must be >0 at 30°C. Since a four-fold increase in E produces no change in \bar{n} while a nine-fold decrease in E reduces \bar{n} by about 85% we can see from *Figure 1* that the value of m for styrene polymerization at 30°C is in the region of 10^{-2} . Precise values of m are difficult to obtain because the value of a (and therefore m) is not exactly the same in the two sets of experiments. With reference to *Figure 1* it can be seen that the value of \bar{n} may not change markedly during the period of particle growth because the values of both E and m are increasing during this period. Since \bar{n} at 60°C appears to be less than \bar{n} at 30°C (in the isothermal experiments) and the value of E is probably larger at 60°C, it seems that the value of m increases with temperature.

It may be concluded that the desorption rate of free radicals from polystyrene particles is low (k_0 is about $2 \times 10^{-8} \text{ m/sec}$ at 30°C). However, even this low desorption rate can have an appreciable effect on the value of \bar{n} and the polymerization rate.

Polymerization of *N*-vinylcarbazole in systems containing maleic anhydride and benzoyl peroxide

Polymerization of *N*-vinylcarbazole (NVC) in benzene can be initiated at 60°C by benzoyl peroxide (BPO) or azoisobutyronitrile (AIBN) but the kinetics of the reactions promoted by the two initiators and the characteristics of the resulting polymers are quite different^{1,2}. Mixtures of BPO and AIBN give rise to polymers having bimodal distributions of molecular weight, confirming that the initiators give rise to polymerizations of fundamentally different types. It is believed that BPO is involved in a one-electron transfer with NVC and gives rise to a cationic polymerization. It has been shown³ that, when monomer of very high purity is used with BPO, about 4% of the polymer differs from the remainder, resembling the polymer made using AIBN and having the characteristics expected for the product of a radical polymerization. Confirmation of the nature of the main polymerization promoted by BPO might be obtained by initiating with mixtures of BPO and substances known to form charge-transfer complexes with NVC giving rise to cationic polymerization. It seemed that maleic anhydride (MAH) might be suitable for this purpose but the first experiments revealed anomalies meriting close attention. Polymer precipitated as it was formed when both MAH and BPO were present but initial rates could be measured. *Figure 1* shows that the rate of polymerization for a system containing both initiators considerably exceeds the sum of the rates produced by them separately.

The amounts of MAH incorporated in the polymeric products of low conversion experiments were found using ¹⁴C-MAH. Systems without added initiator gave products completely soluble in chloroform and containing only one MAH unit for approximately 100 NVC units. Systems including BPO gave products only partly soluble in chloroform although completely soluble in pyridine; they contained appreciable quantities of MAH but unexpectedly the proportion decreased con-

Figure 1 Effect of MAH on rate of polymerization at 60°C of NVC at 1 mol/dm³ in benzene. ○, Systems free from added initiator; ●, systems containing BPO at 2.07 × 10⁻³ mol/dm³

tinuously as the mole fraction of MAH in the NVC/MAH mixture was increased from 0.1 to 0.9 (see *Figure 2*). The compositions were unaltered by performing the polymerizations in complete darkness using (MAH + BPO) and NVC solutions previously stored in the dark. The proportion of MAH in the product was increased by the presence during polymerization of a small amount of ammonia but was unaffected by replacing BPO with AIBN.

Polymers produced from mixtures NVC/MAH/BPO in benzene were subjected to prolonged Soxhlet extraction with chloroform. They split into two fractions: the soluble fraction was a homopolymer of NVC containing very little combined MAH, and the other a copolymer of NVC with MAH at a mole fraction of about 0.40 (see *Figure 2*).

These results disagree with a statement⁴ that NVC and MAH with AIBN at 50°C do not undergo copolymerization. It appears that benzene solutions

Figure 2 MAH contents of polymers made at 60°C with NVC at 1 mol/dm³ in benzene. □, Systems free from added initiator; ○, BPO at 2.07 × 10⁻³ mol/dm³; ●, as for (○) but small amount of ammonia present during polymerization; +, as for (○) but reaction performed in darkness; X, BPO replaced by AIBN; △, chloroform-insoluble fractions from products from systems (○)

of NVC with MAH containing either BPO or AIBN give rise to the simultaneous formation of a homopolymer of NVC and a copolymer which may not be far removed from an alternating copolymer of MAH with NVC. The system NVC/MAH resembles those of NVC with fumaronitrile or diethyl fumarate⁵ and vinylidene cyanide with unsaturated ethers⁶, in that homopolymers can be formed spontaneously while copolymers can be

made using additives known to dissociate to radicals. Further studies are in progress.

Book Reviews

Advances in Polymer Friction and Wear
Volumes 5A and 5B
Edited by Lieng-Huang Lee
Plenum, New York, 1975, 840 pp. \$35.50

This two-volume set, the fifth volume of the series of Polymer Science and Technology provides a unique survey of both theoretical and practical aspects of polymer tribology. It reports the First International Symposium on the subject held in Los Angeles, which was sponsored by the Division of Organic Coatings and Plastics Chemistry and co-sponsored by the Division of Cellulose, Wool and Fibre Chemistry and Colloid and Surface Chemistry of the American Chemical Society. The proceedings contains all revised or expanded papers together with discussions, introductory remarks by session chairman, the plenary lectures and the symposium address.

Following the sequence of the sessions the book consists of eight parts:

- (1) Mechanisms of Polymer Friction and Wear
- (2) Polymer Properties and Friction
- (3) Characterisation and Modification of Polymer Surfaces
- (4) Polymer Surface Lubrication and Solid Lubricants
- (5) Polymer Properties and Wear
- (6) Friction and Wear of Polymer Composites
- (7) Polymer Tribology Research in the USSR
- (8) Trends in Polymer Tribology Research

The first three parts are in volume 5A and the remaining five in volume 5B.

For the benefit of polymer chemists, in most parts there is a state-of-the-art review. Most papers present recent research results in science or technology pertaining to the subject matter. A general discussion devoted to the future of polymer tribology research is included. Thus the book covers the past, the present and the future of this important branch of interdisciplinary science.

Part one introduced by L. H. Lee contains the plenary lecture of D. Tabor on 'Friction, adhesion and boundary lubrication of polymers' a survey of the effects of surface energetics on polymer friction and wear and papers on the adhesion mechanism of rubbers, the interaction between PTFE and iron and fracture mechanics aspects of polymer wear.

T. L. Thomson introduces the six papers on the nature of polymer friction in part two which illustrates some of the complexities of the problem of friction. J. J. Bikerman discusses the nature of polymer friction and the other papers cover the effects of deformation on friction in the context of extrusion, studies of solid film lubrication, studies of relating polymeric molecular structure to friction and the effects of velocity and temperature.

Part three introduced by D. V. Keller contains six papers which demonstrate that the surface characterization of polymers is well underway. The plenary lecture by D. T. Clark on 'The application of ESCA to studies of structure and bonding in polymers' reviews most of the current areas of applicability to polymers and the potential of the technique for the investigation of friction and wear phenomena.

The six papers of part four introduced by D. Dowson cover polymer surface lubrication and solid lubricants and indicate that the fundamental and applied problems posed by the newer solid lubricants and composites provide a formidable challenge to physi-

cists, chemists and engineers by the multidisciplinary approach required.

Polymer properties and wear are covered in part five by five papers introduced into the background of the subject by G. J. J. Griffin. The papers deal with the wear topic from a variety of viewpoints and are all concerned with 'ordinary functional' rather than exotic materials. Two of the contributors deal with the problem of polymer wear in the human machine and emphasize the increasing importance of bio-engineering.

D. H. Buckley introduces the six papers of part six concerned with friction and wear of polymeric composites. These cover thermally anisotropic plastics bearing materials, wear of phenolic resin - asbestos friction materials, wear mechanisms of polymers at cryogenic temperatures, wear characteristics of fluoropolymer composites, wear of nylon by paper and wear of dental restoratives.

Part seven introduced by K. C. Ludema contains five papers covering polymer tribology research in the USSR which outline the current state-of-the-art and offer a better understanding of the terminology, apparatus and equipment used in the USSR.

The last part, 'Trends in polymer technology' contains three contributions; the symposium address, 'Probing the effects of entanglements in rubber networks' by J. D. Ferry, 'Chemical and physical effects associated with polymer tribology' by M. O. W. Richardson and an overview of the conference and closing remarks by K. C. Ludema as well as some general discussion.

Short biographical sketches of many of the contributors are given and a complete author and subject index for both volumes is given at the end of each volume.

The books are well produced and attractively bound and should be a valuable reference source for all concerned with polymer science and technology.

As to be expected with this modern method of publication some tables are difficult to read e.g. p 674, 675 and 676 and some electron micrographs have suffered in quality in reproduction.

Degradation and Stabilisation of Polymers
Edited by G. Geuskens
Applied Science, Barking, 1975, £8.00

This book consists of nine papers given at a conference in Brussels under the above title. It is not as the title appears to imply, a systematic review of the field, although there are some valuable review papers dealing with particular aspects of polymer degradation and stability, notably Grassie on present trends in polymer degradation, Braun on PVC degradation and Wright on heat-resistant organic polymers. The latter is a particularly valuable systematic review, not only of recent developments but also of the principles underlying the development of thermally stable polymers.

The remaining papers (Hawkins on polyolefins, Chien on hydroperoxides in polymer degradation, Geuskens and David on polystyrene, Wiles on fibre-forming polymers, Sohma on e.s.r. studies of mechano-chemical degradation and Guillet on polymer photochemistry) are not critical reviews but accounts of research originating in the laboratories of the authors. As such they present

made using additives known to dissociate to radicals. Further studies are in progress.

Degradation and Stabilisation of Polymers
Edited by G. Geuskens
Applied Science, Barking, 1975, £8.00

This book consists of nine papers given at a conference in Brussels under the above title. It is not as the title appears to imply, a systematic review of the field, although there are some valuable review papers dealing with particular aspects of polymer degradation and stability, notably Grassie on present trends in polymer degradation, Braun on PVC degradation and Wright on heat-resistant organic polymers. The latter is a particularly valuable systematic review, not only of recent developments but also of the principles underlying the development of thermally stable polymers.

The remaining papers (Hawkins on polyolefins, Chien on hydroperoxides in polymer degradation, Geuskens and David on polystyrene, Wiles on fibre-forming polymers, Sohma on e.s.r. studies of mechano-chemical degradation and Guillet on polymer photochemistry) are not critical reviews but accounts of research originating in the laboratories of the authors. As such they present

Book Reviews

carefully argued points of view which are not, however, necessarily accepted by other workers in the field.

There are some important omissions from the book which detract from its general value. There is no mention at all of the degradation and stabilization of elastomers or of rubber modified thermoplastics, both of which are of considerable interest to polymer scientists and technologists. Nor is there any discussion of high temperature processing operations and their effect on subsequent service stability of polymers and one is left with the impression that many of the degradation processes discussed are carried out under conditions which bear little relation to those to which polymers are subjected in practice.

In spite of these shortcomings, the book will be of considerable value to the research specialist since it is a major function of a conference of this nature to stimulate the presentation of original work in a rapidly advancing field.

Polymer—Plastics Technology and Engineering Volume 4

Edited by L. Naturman

Marcel Dekker, New York, 1975, 249 pp. \$32.50

The editorial policy in this volume has been to maintain the shift of emphasis from polymer characterization and properties to polymer engineering and processing. To this end a series of review articles have been presented mainly on the state of art in the various branches of polymer technology and engineering.

The articles range from rather specific topics such as epoxy resin casting processes, reduction of creep in high acrylonitrile and other polymers, interpretation of gel permeation chromatography, to urethane elastomers, asbestos in polymers, and then more general papers on elastic fracture mechanics and continuum mechanics of solid polymers. Although all of these topics were meant to be covered by review type articles, there is a wide disparity between the various presentations. Some are so specific as to materials and processing as to be more in the nature of technical reports of limited interest. Others were more what one expects of a review article. In any case a review will always be useful if it contains up to date references to the research literature. Sadly one of the articles 'Asbestos in polymers' contains no references, while others were certainly not up to date. For example the latest reference in 'continuum mechanics' was for a book published in 1971.

As a whole this volume of the series lack coherence in the choice of review papers. The only feature that they loosely have in common is that they deal mainly with polymer processing and engineering, but perhaps this is what the editor had in mind. The price \$32.50 for 249 pages is rather high even in these of high inflation.

Heparin, Structure, Function and Clinical Implications

Edited by Ralph A. Bradshaw and Stanford
Wessler

Plenum Press, New York, 1975, 422 pp. \$39.1

Polysaccharides encompass the plant and animal kingdoms: they exhibit astonishing diversity in nature, intermeshing structurally and interacting on a molecular level with numerous other biological macromolecules. Of those polysaccharides known to be essentially linear in construction the relative complexity (or simplicity) of the repeating chemical sequence lies within reasonable bounds. Thus, for example, the plant celluloses, mannans, xylans and the insect cuticle chitins, just to name a few, are all relatively straightforward homopolymers, whereas the bacterial capsular polysaccharides are more complex, often involving four to six different saccharide units per repeat sequence. The animal connective tissue polysaccharides, with which heparin may be loosely associated, are intermediate in the spectrum of complexity: they are polysaccharides with molecular weights in the range 10^3 to over 10^6 Daltons. Heparin is the most highly charged of this group, drenched with sulphate appendages, and preferring a molecular weight close to the lower end of this scale. It occurs as packets of polymeric material in mast cells and is released as and when required.

The blood anti-coagulant properties associated with heparin and its role as an anti-lipemic (fat-clearing) agent have aroused considerable medical interest and its clinical application has encouraged pharmacological preparation and standardization. Thus scientific interest in heparin and its behaviour embraces medicine, biochemistry, chemistry plus a little physics, and with so many aspects of heparin being investigated simultaneously, often involving specialized techniques, a conference was organized in an attempt to correlate this wealth of information. The book represents the proceedings of the International Symposium on Heparin, held in St. Louis, Missouri in May 1974.

The collected contributions are segregated into three main sections. The first deals with the structural aspects of heparin covering the molecular properties, biosynthesis, biological properties and including analytical and pharmacological considerations. The first part discusses the chemistry of heparin and its molecular architecture. It is near this point that the related macromolecule heparan sulphate (also confusingly referred to as heparitin sulphate) creeps into the text. The nomenclature is somewhat novel, to say the least, since heparan sulphate is 'heparin-like' but contains on average approximately 70% less sulphate groups! This substance has generated considerable interest recently since it appears on cell surfaces and may have a controlling influence on intercellular adhesion. However, returning to heparin, the evidence accumulated relating to the biosynthetic process strongly favours polymerization followed by epimerization of the sugar residue D-glucuronic acid to L-iduronic acid coupled with, or followed by sulphation of the polymer.

This is a further example in the polysaccharide field where post-polymerization modifications are carried out to suit particular biological roles. Synthetic polymer chemists might well be enlightened by examining the inherent shrewdness in the manufacture of some of these natural polymers.

The biological properties of heparin certainly change as a function of the varying chemical structures that occur, especially from different sources, but no clear correlation has yet emerged. The ambiguities in this area certainly create unforgivable headaches for those responsible for standardization of such an important drug.

The second section covers the functional aspects of heparin: parts of the complex 'waterfall' process of blood clotting are examined in detail. My only criticism of the book relates to this section, — nowhere can one find a concise layout of this 'waterfall' or 'cascade' process which involves about eight steps, where A interacts with B and which in turn controls conversion of C to D etc. As Macfarlane pointed out in 1964 the whole blood clotting process may be likened to a multistage amplifier probably with positive and/or negative feedback — after all, when we cut ourselves we do not wish to clot to death! Thus, I judge, many readers will be lured into details about such substances as antithrombin (one of the factors involved in the process) without first having the opportunity of grasping the gist of the blood clotting sequences and the relevance of heparin. One can eventually pull out some of the essentials from the text. During the coagulation of blood thrombin is produced from its precursor, prothrombin, on lipid surfaces and in the presence of calcium ions. Thrombin, which is a proteolytic enzyme, interacts with fibrinogen and initiates the development of the fibrin clot. The outsider in this arena is antithrombin, which as its name implies, neutralizes thrombin thus safeguarding fibrinogen. Heparin accelerates this neutralization between thrombin and antithrombin by a couple of orders in magnitude. As mentioned earlier heparin is also a fat-clearing agent. Intravenous injections of heparin triggers the release of the enzyme lipase into the circulating blood which can then fragment the fatty lipoproteins.

In the final section relating to the clinical aspects of heparin Dr Stanford Wessler points out the frightening fact that about 15% of Americans are hospitalized every year and one sixth of these die from venous thromboembolism! Heparin, when administered in carefully controlled doses, behaves as an effective anticoagulant for the prevention of the possibly fatal formation of blood clots after surgery. Additionally heparin has a potential role in inhibiting the clotting process in the early stages without increasing the danger of excessive bleeding, and may well reduce the risk of clotting in women using oral contraceptives.

This book, consisting of some thirty-three papers on selected aspects of heparin in 422 pages, is an excellent reference text for those wishing to familiarize themselves with the heparin macromolecule. The editors have made an excellent job of juxtapositioning the individual contributions to produce a coherent text. The bright red textured dust cover is almost appropriate.

Book Reviews

Advances in Polymer Friction and Wear

Volumes 5A and 5B

Edited by Lieng-Huang Lee

Plenum, New York, 1975, 840 pp. \$35.50

This two-volume set, the fifth volume of the series of Polymer Science and Technology provides a unique survey of both theoretical and practical aspects of polymer tribology. It reports the First International Symposium on the subject held in Los Angeles, which was sponsored by the Division of Organic Coatings and Plastics Chemistry and co-sponsored by the Division of Cellulose, Wool and Fibre Chemistry and Colloid and Surface Chemistry of the American Chemical Society. The proceedings contains all revised or expanded papers together with discussions, introductory remarks by session chairman, the plenary lectures and the symposium address.

Following the sequence of the sessions the book consists of eight parts:

- (1) Mechanisms of Polymer Friction and Wear
- (2) Polymer Properties and Friction
- (3) Characterisation and Modification of Polymer Surfaces
- (4) Polymer Surface Lubrication and Solid Lubricants
- (5) Polymer Properties and Wear
- (6) Friction and Wear of Polymer Composites
- (7) Polymer Tribology Research in the USSR
- (8) Trends in Polymer Tribology Research

The first three parts are in volume 5A and the remaining five in volume 5B.

For the benefit of polymer chemists, in most parts there is a state-of-the-art review. Most papers present recent research results in science or technology pertaining to the subject matter. A general discussion devoted to the future of polymer tribology research is included. Thus the book covers the past, the present and the future of this important branch of interdisciplinary science.

Part one introduced by L. H. Lee contains the plenary lecture of D. Tabor on 'Friction, adhesion and boundary lubrication of polymers' a survey of the effects of surface energetics on polymer friction and wear and papers on the adhesion mechanism of rubbers, the interaction between PTFE and iron and fracture mechanics aspects of polymer wear.

T. L. Thomson introduces the six papers on the nature of polymer friction in part two which illustrates some of the complexities of the problem of friction. J. J. Bikerman discusses the nature of polymer friction and the other papers cover the effects of deformation on friction in the context of extrusion, studies of solid film lubrication, studies of relating polymeric molecular structure to friction and the effects of velocity and temperature.

Part three introduced by D. V. Keller contains six papers which demonstrate that the surface characterization of polymers is well underway. The plenary lecture by D. T. Clark on 'The application of ESCA to studies of structure and bonding in polymers' reviews most of the current areas of applicability to polymers and the potential of the technique for the investigation of friction and wear phenomena.

The six papers of part four introduced by D. Dowson cover polymer surface lubrication and solid lubricants and indicate that the fundamental and applied problems posed by the newer solid lubricants and composites provide a formidable challenge to physi-

cists, chemists and engineers by the multidisciplinary approach required.

Polymer properties and wear are covered in part five by five papers introduced into the background of the subject by G. J. J. Griffin. The papers deal with the wear topic from a variety of viewpoints and are all concerned with 'ordinary functional' rather than exotic materials. Two of the contributors deal with the problem of polymer wear in the human machine and emphasize the increasing importance of bio-engineering.

D. H. Buckley introduces the six papers of part six concerned with friction and wear of polymeric composites. These cover thermally anisotropic plastics bearing materials, wear of phenolic resin - asbestos friction materials, wear mechanisms of polymers at cryogenic temperatures, wear characteristics of fluoropolymer composites, wear of nylon by paper and wear of dental restoratives.

Part seven introduced by K. C. Ludema contains five papers covering polymer tribology research in the USSR which outline the current state-of-the-art and offer a better understanding of the terminology, apparatus and equipment used in the USSR.

The last part, 'Trends in polymer technology' contains three contributions; the symposium address, 'Probing the effects of entanglements in rubber networks' by J. D. Ferry, 'Chemical and physical effects associated with polymer tribology' by M. O. W. Richardson and an overview of the conference and closing remarks by K. C. Ludema as well as some general discussion.

Short biographical sketches of many of the contributors are given and a complete author and subject index for both volumes is given at the end of each volume.

The books are well produced and attractively bound and should be a valuable reference source for all concerned with polymer science and technology.

As to be expected with this modern method of publication some tables are difficult to read e.g. p 674, 675 and 676 and some electron micrographs have suffered in quality in reproduction.

Degradation and Stabilisation of Polymers

Edited by G. Geuskens

Applied Science, Barking, 1975, £8.00

This book consists of nine papers given at a conference in Brussels under the above title. It is not as the title appears to imply, a systematic review of the field, although there are some valuable review papers dealing with particular aspects of polymer degradation and stability, notably Grassie on present trends in polymer degradation, Braun on PVC degradation and Wright on heat-resistant organic polymers. The latter is a particularly valuable systematic review, not only of recent developments but also of the principles underlying the development of thermally stable polymers.

The remaining papers (Hawkins on polyolefins, Chien on hydroperoxides in polymer degradation, Geuskens and David on polystyrene, Wiles on fibre-forming polymers, Sohma on e.s.r. studies of mechano-chemical degradation and Guillet on polymer photochemistry) are not critical reviews but accounts of research originating in the laboratories of the authors. As such they present

Book Reviews

carefully argued points of view which are not, however, necessarily accepted by other workers in the field.

There are some important omissions from the book which detract from its general value. There is no mention at all of the degradation and stabilization of elastomers or of rubber modified thermoplastics, both of which are of considerable interest to polymer scientists and technologists. Nor is there any discussion of high temperature processing operations and their effect on subsequent service stability of polymers and one is left with the impression that many of the degradation processes discussed are carried out under conditions which bear little relation to those to which polymers are subjected in practice.

In spite of these shortcomings, the book will be of considerable value to the research specialist since it is a major function of a conference of this nature to stimulate the presentation of original work in a rapidly advancing field.

Polymer—Plastics Technology and Engineering Volume 4

Edited by L. Naturman

Marcel Dekker, New York, 1975, 249 pp. \$32.50

The editorial policy in this volume has been to maintain the shift of emphasis from polymer characterization and properties to polymer engineering and processing. To this end a series of review articles have been presented mainly on the state of art in the various branches of polymer technology and engineering.

The articles range from rather specific topics such as epoxy resin casting processes, reduction of creep in high acrylonitrile and other polymers, interpretation of gel permeation chromatography, to urethane elastomers, asbestos in polymers, and then more general papers on elastic fracture mechanics and continuum mechanics of solid polymers. Although all of these topics were meant to be covered by review type articles, there is a wide disparity between the various presentations. Some are so specific as to materials and processing as to be more in the nature of technical reports of limited interest. Others were more what one expects of a review article. In any case a review will always be useful if it contains up to date references to the research literature. Sadly one of the articles 'Asbestos in polymers' contains no references, while others were certainly not up to date. For example the latest reference in 'continuum mechanics' was for a book published in 1971.

As a whole this volume of the series lack coherence in the choice of review papers. The only feature that they loosely have in common is that they deal mainly with polymer processing and engineering, but perhaps this is what the editor had in mind. The price \$32.50 for 249 pages is rather high even in these of high inflation.

Heparin, Structure, Function and Clinical Implications

Edited by Ralph A. Bradshaw and Stanford
Wessler

Plenum Press, New York, 1975, 422 pp. \$39.1

Polysaccharides encompass the plant and animal kingdoms: they exhibit astonishing diversity in nature, intermeshing structurally and interacting on a molecular level with numerous other biological macromolecules. Of those polysaccharides known to be essentially linear in construction the relative complexity (or simplicity) of the repeating chemical sequence lies within reasonable bounds. Thus, for example, the plant celluloses, mannans, xylans and the insect cuticle chitins, just to name a few, are all relatively straightforward homopolymers, whereas the bacterial capsular polysaccharides are more complex, often involving four to six different saccharide units per repeat sequence. The animal connective tissue polysaccharides, with which heparin may be loosely associated, are intermediate in the spectrum of complexity: they are polysaccharides with molecular weights in the range 10^3 to over 10^6 Daltons. Heparin is the most highly charged of this group, drenched with sulphate appendages, and preferring a molecular weight close to the lower end of this scale. It occurs as packets of polymeric material in *mast* cells and is released as and when required.

The blood anti-coagulant properties associated with heparin and its role as an anti-lipemic (fat-clearing) agent have aroused considerable medical interest and its clinical application has encouraged pharmacological preparation and standardization. Thus scientific interest in heparin and its behaviour embraces medicine, biochemistry, chemistry plus a little physics, and with so many aspects of heparin being investigated simultaneously, often involving specialized techniques, a conference was organized in an attempt to correlate this wealth of information. The book represents the proceedings of the International Symposium on Heparin, held in St. Louis, Missouri in May 1974.

The collected contributions are segregated into three main sections. The first deals with the structural aspects of heparin covering the molecular properties, biosynthesis, biological properties and including analytical and pharmacological considerations. The first part discusses the chemistry of heparin and its molecular architecture. It is near this point that the related macromolecule heparan sulphate (also confusingly referred to as heparitin sulphate) creeps into the text. The nomenclature is somewhat novel, to say the least, since heparan sulphate is 'heparin-like' but contains on average approximately 70% less sulphate groups! This substance has generated considerable interest recently since it appears on cell surfaces and may have a controlling influence on intercellular adhesion. However, returning to heparin, the evidence accumulated relating to the biosynthetic process strongly favours polymerization followed by epimerization of the sugar residue D-glucuronic acid to L-iduronic acid coupled with, or followed by sulphation of the polymer.

This is a further example in the polysaccharide field where post-polymerization modifications are carried out to suit particular biological roles. Synthetic polymer chemists might well be enlightened by examining the inherent shrewdness in the manufacture of some of these natural polymers.

The biological properties of heparin certainly change as a function of the varying chemical structures that occur, especially from different sources, but no clear correlation has yet emerged. The ambiguities in this area certainly create unforgivable headaches for those responsible for standardization of such an important drug.

The second section covers the functional aspects of heparin: parts of the complex 'waterfall' process of blood clotting are examined in detail. My only criticism of the book relates to this section, — nowhere can one find a concise layout of this 'waterfall' or 'cascade' process which involves about eight steps, where A interacts with B and which in turn controls conversion of C to D etc. As Macfarlane pointed out in 1964 the whole blood clotting process may be likened to a multistage amplifier probably with positive and/or negative feedback — after all, when we cut ourselves we do not wish to clot to death! Thus, I judge, many readers will be lured into details about such substances as antithrombin (one of the factors involved in the process) without first having the opportunity of grasping the gist of the blood clotting sequences and the relevance of heparin. One can eventually pull out some of the essentials from the text. During the coagulation of blood thrombin is produced from its precursor, prothrombin, on lipid surfaces and in the presence of calcium ions. Thrombin, which is a proteolytic enzyme, interacts with fibrinogen and initiates the development of the fibrin clot. The outsider in this arena is antithrombin, which as its name implies, neutralizes thrombin thus safeguarding fibrinogen. Heparin accelerates this neutralization between thrombin and antithrombin by a couple of orders in magnitude. As mentioned earlier heparin is also a fat-clearing agent. Intravenous injections of heparin triggers the release of the enzyme lipase into the circulating blood which can then fragment the fatty lipoproteins.

In the final section relating to the clinical aspects of heparin Dr Stanford Wessler points out the frightening fact that about 15% of Americans are hospitalized every year and one sixth of these die from venous thromboembolism! Heparin, when administered in carefully controlled doses, behaves as an effective anticoagulant for the prevention of the possibly fatal formation of blood clots after surgery. Additionally heparin has a potential role in inhibiting the clotting process in the early stages without increasing the danger of excessive bleeding, and may well reduce the risk of clotting in women using oral contraceptives.

This book, consisting of some thirty-three papers on selected aspects of heparin in 422 pages, is an excellent reference text for those wishing to familiarize themselves with the heparin macromolecule. The editors have made an excellent job of juxtapositioning the individual contributions to produce a coherent text. The bright red textured dust cover is almost appropriate.

POLYMER in the USA

Many of POLYMER's readers will have noticed various changes in the appearance of the journal over the years. Some of these have been minor and of little importance (such as the recent change to a three column format for the *Notes to the Editor* and *Letters* sections). Others, such as the change in page size in 1972 and the introduction of more modern printing methods in 1975 have made a bigger impact, allowing more material to be published and some reduction in the inflationary spiral of increased production costs. The observant reader of *this issue* will have noticed a change in appearance to the inside front cover of far greater significance than anything previously – the appointment of a group of Editors for the USA.

However, this change is more than just an appearance and should be seen as a fresh and positive approach by the journal. The presence of these Editors will hopefully encourage more authors in North America to submit contributions to POLYMER in the knowledge that each submission will be refereed by their immediate contemporaries to the standard expected of this journal. This will also help to minimize delays in the refereeing procedure so that publication to a worldwide audience can be made quickly and accurately; our previous performance should testify to that. It is understandable that many potential authors in the past have felt reluctant to break with tradition by publishing outside their own country. Now, by placing POLYMER's new facilities and current reputation before the North American polymer community on the same level as our competitors already based there, we ask to be judged not as direct competitors but as complementary publishers whose aim is to continue to serve the international interests of polymer research. By having the services of such eminent scientists to act as US Editors for POLYMER, their range of experience and specialist knowledge will cover most areas of the field. Inevitably new techniques, new technologies, fresh developments as well as different materials will evolve with the need for academic debate in public (the biomaterials and biopolymers field is one area with an exciting potential). Thus an ever-increasing group of specialists will become involved with the refereeing process and this will ensure that POLYMER remains a living organ in dynamic equilibrium with its environment ('constantly changing yet constantly unchanged').

Growth is another aspect of the living process and these changes will represent further growth for POLYMER so that some of the great wealth of polymer research from the USA can be published alongside the present existing material.

Airspeeding service

We are pleased to announce that from the July 1976 issue, all copies of POLYMER destined for North America have been airfreighted to New York and posted from there *at no additional cost to subscribers*. This should mean that readers will receive their copy during the period of the cover date where before it had been taking anything from 2 to 6 months to reach a library in the USA. The publishers would be interested to hear how the system works in practice.

Directional diffusion rates in keratin

Ian C. Watt

*Division of Textile Physics, CSIRO, Ryde, New South Wales 2112, Australia
(Received 8 December 1975; revised 20 April 1976)*

The kinetics of sorption of water vapour have been measured for keratin prepared by slicing horsehairs into discs so that the major part of the external surface of the discs was composed of cross-sections of the original fibres perpendicular to the fibre direction. For diffusion-controlled absorption no significant difference in the diffusion coefficients of the horsehair discs or intact keratin was detected indicating that diffusion in the longitudinal or lateral directions in keratin fibres, occurs at similar rates. However, the initial rate of absorption by the discs was faster by a factor equivalent to the increased surface to volume ratio. The rates of absorption approached similar values for anomalous sorption where stress relaxation in the keratin contributes largely to the water uptake and the rate of stress relaxation is sufficiently fast to occur concurrently with diffusion into the keratin. This occurs at high penetrant concentrations and for large integral absorption steps. The similar rates of absorption, despite the difference in surface areas, is not evidence that diffusion is more rapid in a lateral direction but supports the concept of a coupled diffusion—relaxation sorption mechanism.

INTRODUCTION

Keratin is not isotropic with respect to swelling in water and this had led to speculation that diffusion rates in wool fibres may be dependent upon the direction of travel of the penetrant. However, no conclusive evidence on this question is available. The geometry of wool fibres is such that there is a large surface to volume ratio. The molecular chains are oriented in the direction of the fibre axis and since orientation in the direction of travel is thought to be responsible for decreased rates of absorption in amorphous polymers with continued sorption cycles¹, the ability of water molecules to diffuse longitudinally may be considerably less than their ability to diffuse laterally in the fibres.

Penetration initially occurs perpendicular to the surface and the basic assumption that all diffusion takes place in a direction perpendicular to the surface probably provides a reasonable approximation in calculation of diffusion rates. The present paper reports on experiments designed so that the calculated rates of diffusion of water vapour longitudinally and laterally into horsehair keratin could be compared. Horsehair was sectioned perpendicular to the fibre axis, to form flat discs; the surface area of the discs being composed of new surface created by the sectioning, and the original surface of the horsehair. Thus, diffusion perpendicular to the flat surfaces of the discs would be in the longitudinal direction of the original fibres while diffusion across the curved surface would be perpendicular to the fibre direction.

EXPERIMENTAL

Preparation of materials

The keratins used were horsehair, taken from the tail, and Merino wool fibres cleaned by six washes in cold petroleum ether followed by thorough soaking in distilled water until the pH of the wash water was unchanged by the keratin. Successive sections of average thickness 20 μm were microtomed from a number of horsehairs embedded in parallel array in a paraffin wax, using a Cambridge rotary rocking microtome. Another portion of horsehair, of dry

diameter the same as the average diameter of the microtomed horsehairs, was kept intact.

Apparatus and procedure

Sorption measurements were carried out by a gravimetric technique using quartz spiral spring balances (sensitivity 500 cm/g) mounted in evacuable sorption chambers, the whole apparatus being enclosed in an air thermostat. Two identical chambers were set up side by side and connected to the same reservoir of water vapour and to a wide-bore differential mercury manometer. The temperature was controlled to $\pm 0.01^\circ\text{C}$ and the spring extensions read to 0.01 mm with cathetometers. A length of horsehair weighing 8 mg was suspended from one spring and from the other an equivalent weight of horsehair discs, each 20 μm thick, was suspended by spreading the sections thinly on a non-sorbing plastic sheet attached to the end of the spring.

The dry diameter of the intact horsehair and the average dry diameter of the sliced horsehair discs was 170 μm . Thus, the surface area, A , of an x cm length of this horsehair would be $A = 2\pi 85x \times 10^{-4} \text{ cm}^2$. The additional surface exposed by microtoming an equivalent length of horsehair of this diameter into 20 μm sections would be:

$$2 \frac{x}{20 \times 10^{-4}} \times \pi(85 \times 10^{-4})^2 \text{ cm}^2 = \pi x 85^2 \times 10^{-5} \text{ cm}^2 \\ = 4.25A \text{ cm}^2$$

Thus, the total surface of the microtomed sections was $5.25A \text{ cm}^2$ of which $A \text{ cm}^2$ was the original surface lying parallel to the fibre axis and $4.25A \text{ cm}^2$ was new surface perpendicular to the fibre axis.

RESULTS AND DISCUSSION

Interval sorption

Rates of uptake of water vapour by keratin are dependent on the initial concentration of water and the size of

Figure 1 Uptake of water vapour by keratin at 35°C as a function of $(\text{time})^{1/2}$ following a 0–4.5% r.h. humidity increment. ●, Horsehair snippets; X, intact horsehair; □, Merino wool fibres

the concentration increment². Sorption over a large concentration range has been termed integral sorption and over a small concentration range, interval sorption. For such small concentration increments absorption may occur in two stages; the second stage much slower than the first³. The uptake during the first stage of absorption occurs by a Fickian mechanism with a concentration-dependent diffusion coefficient. Accordingly, in order to determine diffusion coefficients the horsehair samples were equilibrated with water vapour at various concentrations and subjected to small increments of vapour pressure.

Low humidities. Initially the samples were evacuated to attain an equilibrium dry weight and subjected to a 0–4.5% r.h. humidity increment at 35°C. The uptake curve for the intact horsehair and the corresponding uptake for the horsehair snippets are shown in Figure 1 where the water contents of the keratin samples are plotted as a function of $(\text{time})^{1/2}$. The uptake curve for 20 μm diameter Merino wool fibres is included for comparison.

Fickian sorption is characterized by an initially linear plot of absorption or desorption as a function of $(\text{time})^{1/2}$. Crank⁴ has given mathematical solutions for the amount of penetrant entering a cylinder, or a thin film, at any time following an instantaneous change of surface concentration to a constant value and assuming an infinite supply of penetrant. The two cases yield different shaped uptake curves because of the different geometry. When plotted as a function of $(\text{time})^{1/2}$ the linear portion of the uptake curve for the plane film persists to as much as 50% of the equilibrium value, while the uptake for the cylinder becomes concave to the abscissa soon after the commencement of absorption and reaches equilibrium at half the value for the plane for a sample of equivalent surface area. Thus it is essential to consider only initial rates of uptake.

The diffusion coefficient for water vapour into intact horsehair over the range 0–4.5% r.h. was calculated from the data presented in Figure 1 to be $2.7 \times 10^{-10} \text{ cms}^2/\text{sec}$. This is in good agreement with the value of $2.4 \times 10^{-10} \text{ cms}^2/\text{sec}$ obtained for the diffusion of water vapour into Merino wool fibres for the same concentration increment. The greater surface to volume ratio for the snippets compared to the intact horsehair allows the uptake of water vapour to approach equilibrium more quickly in the former case. The coefficient of diffusion into the two parallel surfaces of the discs can be calculated from the appropriate expression for a plane film if the initial uptake is considered uniform over the whole surface, and yields a value of $2.5 \times 10^{-10} \text{ cms}^2/\text{sec}$.

A simpler comparison can be obtained from the initial slopes of the uptake curves for horsehair; these differ by a factor of 5 whereas the ratios of surface area in the two cases is 5.25:1. If the original surface is assumed to absorb at the same rate in both cases, the difference in rate of uptake over the two surfaces is less than 7% and must be considered within the experimental error. Thus, the diffusion of water into keratin at low concentrations is virtually isotropic. Similar results were obtained for desorption when the samples were evacuated to dryness after equilibration at 4.5% r.h.

Intermediate humidities. At intermediate humidities, and for small increments of humidity, absorption into wool fibres occurs in two distinct phases. An increasing proportion of the uptake occurs in the second stage as the initial water content is increased and reaches a maximum for wool conditioned at around 50% r.h.⁵ Similar data were obtained for the horsehair samples equilibrated at 50% r.h. and subjected to a 4% r.h. increment of humidity. The fractional change in water content for the step is plotted in Figure 2 as a function of $(\text{time})^{1/2}$ for the intact horsehair and the snippets. The ratio of the initial rates of uptake is 4.7:1 but the second stage uptake which continued for 5 days occurs at the same rate in the two cases. This supports the contention that the mechanism of absorption in the second stage is not diffusion-controlled and is consistent with the notion that it results from a relaxation mechanism which occurs uniformly throughout the keratin following the entry of water during the first stage of uptake⁵.

High humidities. As the water content of the horsehair samples increased a continued reduction was observed in the difference in the rates of uptake of the snippets and the intact horsehair. For the small increment of 83–86% r.h. the ratio of the initial rates of uptake was reduced to 2.25:1. However, it must be emphasized that the uptake in this region displays anomalous sorption characteristics over the whole range and the comparison of rates is only an estimate in that uptake is not strictly linear as a function of $(\text{time})^{1/2}$ and there is no clear separation into two stages.

Integral sorption

Integral sorption embraces the two mechanisms of sorption mentioned previously, i.e. a diffusion-controlled entry of water vapour and an additional uptake of water as a result of stress relaxation in the keratin. In such a coupled diffusion-relaxation system the relative contribution of each of these mechanisms to the total uptake will vary according to the concentration range of the step. The dependence of uptake on sample thickness is also variable according to the concentration range. A better comparison,

Figure 2 Interval absorption. Fractional water content change as a function of $(\text{time})^{1/2}$ for horsehair subjected to a 50.0–54.0% r.h. humidity increment. A, Horsehair snippets; B, intact horsehair

Figure 3 Integral absorption. Uptake of water vapour by keratin as a function of $(\text{time})^{1/2}$ for the humidity range of 0–80% r.h. at 35°C. A, Intact horsehair; B, horsehair snippets; C, Merino wool fibres

therefore, is obtained by considering the rates of uptake by Merino wool fibres of 20 μm diameter and the horsehair snippets over the same concentration range. If the wool fibres are considered as cylinders and the snippets as infinite plane films, the wool fibres should have double the surface area for the same weight of sample. Because the curved surfaces of the snippets contribute appreciably to their total surface area this ratio is less for the snippets used here; the surface area of the 20 μm diameter wool fibres is 1.67 times the surface area of the horsehair snippets for the same weight of keratin.

For the sorption steps of 0–25% r.h. and 0–50% r.h. the rate of uptake by horsehair snippets was approximately 60% of the initial rate of uptake by Merino wool fibres. Sorption into the intact horsehair was much slower because of the increased diameter of the sample and the consequent reduction in surface to volume ratio. Thus, there is little evidence that absorption in the longitudinal direction occurs at a different rate from absorption perpendicular to the original surface of the fibre.

For integral absorption at humidities approaching saturation the situation changes. The rate differences become progressively less as the humidity range is increased and at high humidities the intact horsehair absorbs water vapour at a rate which approaches the rate of uptake by the snippets despite the difference in surface area. In Figure 3 the uptake curves for the intact horsehair, horsehair snippets and the Merino wool fibres for the humidity step of 0–80% r.h. show the greatly decreased differences in uptake rates compared to the corresponding absorption curves of Figure 1.

Desorption of the samples by evacuation to dryness showed that the discs desorbed rapidly at a rate similar to that for Merino wool fibres while the intact horsehair, after an initial rapid desorption, approached equilibrium slowly such that the time to reach dryness became proportional to $(\text{diameter})^2$.

CONCLUSIONS

The rate of diffusion of water into keratin fibres is similar in the directions parallel to, and perpendicular to the fibre direction. However, the uptake of water is influenced by the ability of the keratin to stress relax after swelling. For small increments of water vapour pressure the diffusion process and the stress relaxation process can be separated; the former leads to rates of uptake proportional to the surface area and the latter to rates of uptake independent of surface area. When stress relaxation occurs concurrently with diffusion the contribution of the stress relaxation mechanism becomes the rate controlling step throughout the sample and the dimensions of the sample become less important in determining the rate of uptake. The apparent slower rate of uptake in the direction parallel to the fibre direction at higher humidities follows from the rapid rate of stress relaxation in this region.

A further deduction which may be made from these results is that because diffusion coefficients for the two samples of horsehair and the wool fibres are similar, it appears to be a reasonable assumption to consider wool fibres as smooth cylinders for purposes of treatment of sorption data, despite the surface irregularities present.

ACKNOWLEDGEMENT

The author wishes to thank Mr R. Morris for the careful preparation of the keratin samples used in this study.

Small-angle neutron scattering studies of molten and crystalline polyethylene

(Received 4 March 1976)

Small-angle neutron scattering studies have been made of molten and crystalline polyethylene using samples containing small amounts of deuterated polyethylene (PED) in a protonated polyethylene (PEH) matrix. Careful studies were made of PED aggregation effects, and by a combination of solution blending techniques and rapid quenching from the melt, it was possible to prepare samples with a statistical distribution of PED molecules in the PEH matrix. Measurements of radius of gyration ($\langle S^2 \rangle_w^{1/2}$ at low κ [$\kappa = (4\pi/\lambda) \sin \theta \leq 2 \times 10^{-2} \text{ \AA}^{-1}$] in the melt and in the solid state gave very similar values which may be summarized as $\langle S^2 \rangle_w^{1/2} = (0.46 \pm 0.05)M_w^{1/2}$ for both phases. This correspondence of values indicates that on a rapid quench, diffusion is sufficiently slow that the molecule crystallizes with a similar spatial distribution of mass elements to that possessed in the melt. Measurements of scattering data over a wide κ range ($6 \times 10^{-3} \leq \kappa \leq 0.12 \text{ \AA}^{-1}$) have also been made from samples showing no aggregation effects. Calculations indicate that it is difficult to fit this data in terms of models which postulate adjacent chain re-entry in one crystallographic plane for this type of sample.

INTRODUCTION

Small-angle neutron scattering (SANS) using the D-H system has proved successful in studying amorphous polymers in the solid state¹ and above T_g^2 , and crystalline polymers above their melting point^{3,4}. When applied to the study of crystalline polymers in the solid state several experimental problems were encountered which were associated with voids of sub-microns dimensions formed between the crystalline and amorphous regions and the segregation into clusters of the tagged molecules during sample preparation³.

The first of these problems is overcome in the case of polyethylene, by using deuterated polyethylene (PED) in a matrix of protonated polyethylene (PEH). Normally void scattering dominates low-angle X-ray scattering from polyethylene, but in the case of neutron scattering from PEH, cancellation between the positive scattering length of C ($b_C = +0.66 \times 10^{-12} \text{ cm}$) and the negative scattering from ¹H ($b_H = -0.37 \times 10^{-12} \text{ cm}$) means that the coherent neutron scattering is almost completely eliminated. In PED on the other hand no such cancellation is possible since the scattering lengths of carbon and deuterium are nearly of the same magnitude and the same sign.

The second problem, the formation of clusters of tagged molecules, can be overcome by a combination of appropriate solution blending techniques and rapid quenching from the melt as described below. The segregation of PED chains within the PEH matrix was first mentioned by Stehling *et al.*⁵, who measured the difference in melting points in two series of deuterated and protonated alkanes. They showed that PED has a melting point $\sim 6^\circ\text{C}$ below that of PEH and discussed how this might arise from differences in the entropy or enthalpy of the two polymers. They pointed out that there was a danger of segregation and that a statistical distribution of tagged molecules could not be assumed.

EXPERIMENTAL

The first samples prepared were solution blended in boiling xylene and precipitated into methanol at room temperature. The resultant powders were washed in methanol and dried in a vacuum oven at 70°C and subsequently compression moulded at 190°C into sheets $\sim 1 \text{ mm}$ thick, suitable for neutron measurements. After compression moulding the samples were removed from the press and quenched into water at room temperature. Further details of sample preparation, the experimental SANS technique, together with the measured SANS data, are given in refs 3 and 6. It was concluded from an analysis of this data that clusters of 15–30 PED molecules had occurred in the solid state, and that the clustering was reduced or eliminated by thermodynamic mixing when performing measurements in the melt over periods of several hours^{3,6}.

In order to reduce or eliminate the clustering problem in the solid state, the method of sample preparation was varied, and it was eventually found that virtually unclustered solid samples could be prepared by substituting *ortho*-dichlorobenzene (*o*-DCB) for xylene in the above procedure, and quenching from the melt after compression moulding. *o*-DCB has a boiling point $\approx 180^\circ\text{C}$ (compared to xylene $\approx 140^\circ\text{C}$), which is well above the melting point of polyethylene ($\approx 135^\circ\text{C}$) and will therefore enhance the probability of complete dissolution of the two polymers. By this method samples coded A3, A6, PE 18, 21, 22, 23, 24 and 25 (*Table 1*) were made. *Table 1* shows the molecular weights of the matrix and deuterated molecules and also the polydispersity and concentration of the tagged PED molecules. The scattering parameters found in *Table 1* are defined and discussed below.

For all these samples the matrix was linear unbranched PEH and the crystallinity indices of this series, as measured by X-ray diffraction and density flotation methods, were typically $65 \pm 2\%$. In order to further characterize the morphology of the rapidly quenched material, typical samples were analysed by small-angle X-ray scattering (SAXS)

methods. The measurements were performed on a SAXS scattering facility which utilized a 5 kW rotating anode, pin-hole collimation and a position sensitive proportional counter⁷. The $\text{CuK}\alpha$ radiation was monochromatized before scattering and very well collimated in both directions. No resolution corrections were therefore necessary and the differential scattering cross-section, $d\Sigma/d\Omega$, was measured in absolute units. A typical scattering pattern is shown in Figure 1 and shows a well resolved first maximum at $\kappa = 4\pi\lambda^{-1} \sin \theta = 0.024 \text{ \AA}^{-1}$. Typical Bragg-law 'spacings' calculated from the position of the first maximum are in the range $254 \pm 10 \text{ \AA}$ for fast quenched samples. The occurrence of well resolved maxima in the SAXS patterns is good evidence for the existence of lamellar structures in the samples.

If samples are slow cooled from the melt it is to be expected that separation could again occur due to the well established separation mechanism by which the higher melting component will crystallize first on slow cooling. It was to avoid this separation mechanism that samples were initially quenched rapidly from the melt. We attempted to check by thermal analysis for possible segregation on slow cooling, the measurements being made in a Perkin-Elmer DSC-2 differential scanning calorimeter. As thermal methods cannot easily detect PED at the normal level of 1–10%, measurements were made on a 50:50 mixture. The mixture (components as PE 25) was solution blended (*o*-DCB) and precipitated into methanol. As prepared, this showed a single melt endotherm on heating to 160°C. Subsequent cooling relatively rapidly from the melt at 5°C/min gave a single crystallization exotherm and the anticipated single melt endotherm on reheating. There is no evidence to suggest that phase separation has occurred. However, cooling from the melt slowly at 0.62°C/min resulted in two clearly resolvable crystallization peaks, (Figure 2a) and a distinct shoulder in the subsequent melt endotherm at a temperature consistent with the melting point

of the deuterated material (Figure 2b). From this data we can conclude that fast quenching from the melt consider-

Figure 1 SAXS pattern from bulk polyethylene, rapidly quenched from the melt

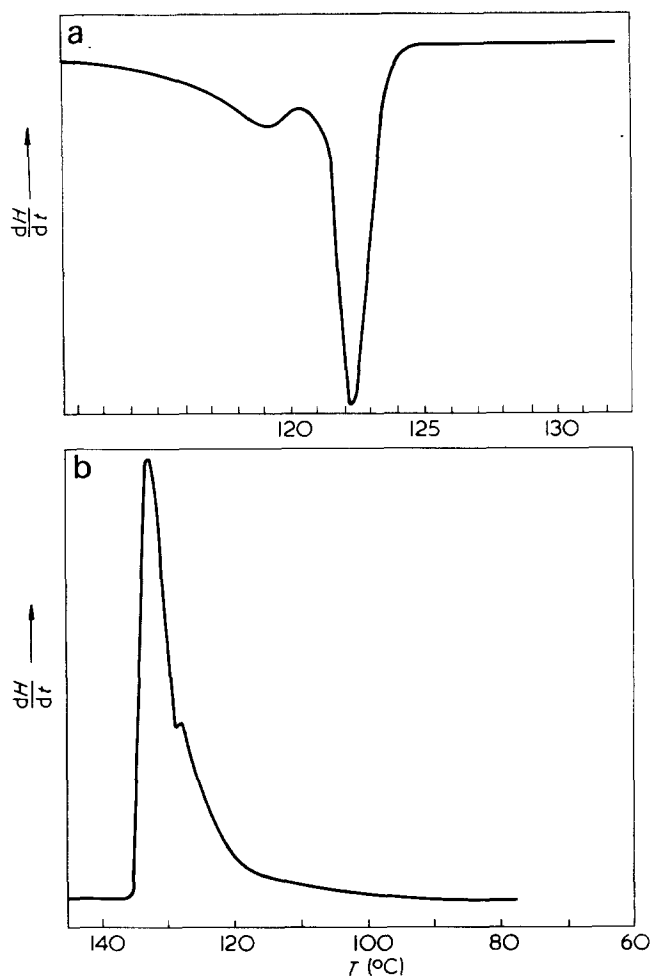

Figure 2 (a) Crystallization exotherm; (b) re-melt exotherm of 50:50 PEH/PED mixture slow cooled at $0.62^{\circ}\text{C}/\text{min}$ from the melt

ably reduces the possibility of phase segregation of the molecules.

We have attempted to reduce the probability of segregation in *slow cooled* samples by choosing a slightly branched PEH polymer, whose thermal characteristics match those of the deuterated material. The temperatures for the start of crystallization, T_s , and peak crystallization rate, T_p , were $T_s = 113.7^{\circ}\text{C}$ and $T_p = 111.7^{\circ}\text{C}$; and $T_s = 113.5^{\circ}\text{C}$ and $T_p = 112^{\circ}\text{C}$ for the PEH and PED materials respectively. These materials were then solution blended in *ortho*-dichlorobenzene as described above, and slow cooled from the press at $\sim 1^{\circ}\text{C}/\text{min}$ after compression moulding. It will be seen from the subsequent discussion that although the matching procedure reduced the segregation or clustering effect, it was not eliminated completely. It is our opinion therefore that it is virtually impossible to prepare unclustered samples of unmatched (i.e. linear) PEH and PED, when these samples are cooled slowly from the melt.

It is important to understand, not only the morphology of melt crystallized polyethylene, but also solution crystallized polymer. For this reason we attempted to also make samples of solution crystallized material. However, d.s.c. measurements on the 50:50 blend of linear PEH and PED, crystallized slowly from *ortho*-dichlorobenzene at 65°C indicated a well resolved shoulder on the d.s.c. endotherm $\sim 8^{\circ}\text{C}$ below the peak of the endotherm (Figure 3). The equivalent melt endotherm of PEH crystallized from solution in the same manner showed no such shoulder. This again indicated the strong possibility of phase separation in

samples of solution crystallized mixtures, and for this reason we did not attempt to proceed with solution crystallized samples at this stage.

For both melt and solution crystallized systems, it is clear that unambiguous conclusions on chain configuration can only be drawn from data which originates from a homogeneous specimen (no phase segregation), where the tagged molecules are statistically distributed throughout the matrix. Fortunately, it is possible to check the latter in a homogeneous specimen as shown in the next section.

SEGREGATION OF TAGGED MOLECULES

The extrapolated forward scattering cross-section, measured in absolute units is a very sensitive indicator as to whether the tagged molecules are clustered or statistically distributed. For the latter case it has been shown^{2,3} that:

$$\frac{1}{cK_N} \left(\frac{d\Sigma}{d\Omega} \right)_{\kappa=0} = \frac{1}{M_w} \quad (1)$$

where

$$K_N = \rho \left[2X \frac{1}{M_{(\text{CD}_2)_x \text{H}_2(1-x)}} (b_D - b_H) \right]^2 N \quad (2)$$

where $\rho = 0.94 \text{ g/cm}^2$ is the density, X is the degree of deuteration of PED chains, $M_{(\text{CO}_2)_x \text{H}_2(1-x)}$ is the mass of a chain segment, N is Avogadro's number, b_D and b_H are the scattering lengths of ^2D and ^1H . The extrapolated forward scattering cross-section is obtained from the usual linear plots of $d\Sigma^{-1}/d\Omega$ vs. κ^2 . Where there is no clustering, M_w determined from the neutron measurement (equation 1) should equal the known molecular weight of the tagged molecules determined by g.p.c. or osmometry prior to blending. When clustering does occur, curves obtained by plotting $d\Sigma^{-1}/d\Omega$ against κ^2 are still linear over a wide range as can be seen by corresponding Figures 4 and 5 but the values of the slope and intercept are changed. In this case the apparent molecular weight obtained from the forward scattering, $(M_w)_{\text{app}}$, is larger than the real molecular weight M_w . The ratio $(M_w)_{\text{app}}/M_w$ is a measure of the number of molecules in a cluster (n).

Figure 3 Melt endotherm of a 50:50 PEH/PED mixture after crystallizing from *o*-DCB solution at 65°C

Figure 4 Plot of $d\Sigma/d\Omega$ vs. κ^2 for sample A6QFigure 5 Plot of $d\Sigma/d\Omega$ vs. κ^2 for sample A6SC

In Table 1 we have summarized the neutron scattering data on polyethylene. Comparing $(M_w)_{app}$ with M_w , there is generally good agreement showing that clustering has been substantially eliminated. The combined error of the comparison is $\sim 25\%$ due to uncertainties in the calibration of g.p.c., SANS and the polydispersity correction¹. One exception to the agreement is sample PE 21 which contains a high concentration (10%) of tagged molecules. It may also be seen that clustering occurs even for matched samples (A3 SC, A6 SC) which are slow cooled from the melt.

MEASUREMENTS OF RADIUS OF GYRATION

For samples without clustering, obtained by rapid quenching from the melt, we obtain from the slopes of the curves such as Figure 4 values of the radius of gyration of statistically distributed molecules in the solid state. In Table 2 we compare values of $\langle S^2 \rangle^{1/2} / M_w^{1/2}$ obtained in the solid state, with those obtained in the melt⁴ and in a θ -solvent. The close agreement between these values shows that the overall size of the molecule is the same in all these systems. The values of radius of gyration measured in the melt are in excellent agreement with the measurements of Lieser *et al.*⁴ and this provides a useful cross-check on the accuracy of the data.

HOMOGENEITY OF THE DISTRIBUTION OF TAGGED MOLECULES IN THE MATRIX

We were concerned to test whether the tagged molecules were preferentially occupying the amorphous regions, as this might have been one explanation for the close agreement between results in the solid and liquid states. To do this we rapidly quenched samples as thin films and etched a selection of this material with nitric acid. This process preferentially removes the amorphous regions of the sample and we would expect a reduction in the deuterium content if this kind of segregation had occurred. The initial and etched samples were therefore analysed using an ARL Multi-Element Plasma Detector, which gives a signal proportional to the deuterium content. Within the experimental error of the measurement ($\frac{1}{2}\%$ in the concentration of tagged molecules, c) no differences was observed. The etched sample showed an increase ($\sim 6\%$) in crystallinity indicating that the amorphous regions had been preferentially removed. Therefore it may be concluded that the deuterated molecules were uniformly distributed throughout the amorphous and crystalline regions.

NEUTRON SCATTERING AT HIGHER ANGLES

We have studied the scattering behaviour at high angles in a similar way to our studies with polystyrene². The most convenient way to present this data is shown in Figure 6 for samples PE 21 at 150°C . It is evident that the results are similar to those obtained for polystyrene. Moreover, sample A6Q, when cooled rapidly at 23°C gives a similar curve as can be seen by comparing Figure 7 with Figure 6. Both curves tend to a constant value at $\kappa \sim 0.15 \text{ \AA}^{-1}$, which may be characterized as follows. Let us define the quantity

$$Q = \lim_{\kappa \rightarrow 0.15 \text{ \AA}^{-1}} \left[\frac{\kappa^2 \langle S^2 \rangle_w \frac{d\Sigma}{d\Omega}(\kappa)}{c K_N M_w} \right] = \lim_{\kappa \rightarrow 0.15 \text{ \AA}^{-1}} [\kappa^2 \langle S^2 \rangle^{1/2}] [|F(\kappa)|]^2 \quad (3)$$

where $F(\kappa)$ is the form factor of the polymer molecule and c is the concentration of tagged molecules. Q is thus a measure of the asymptotic value of the ordinates of Figures 6 and 7. Listed in Table 1 we see that at 150°C and 23°C (for the rapidly quenched material) $Q = 2.3$, very close to that derived from the Debye function⁹ for which $Q \rightarrow 2$ for large κ . The sample PE 21, which contains clusters of tagged molecules, shows a scattering behaviour which is different in the intermediate κ range ($0 \leq \kappa \leq 0.04 \text{ \AA}^{-1}$). Figure 8 shows that in this range the presence of clusters leads to an overshoot of the simple Debye-like curve observed in Figure 7. This overshoot dis-

appears when the sample is melted (Figure 6) and the clusters are dispersed (Table 1).

MODEL CALCULATIONS AND DISCUSSION

It has been shown that the random coil model can fit the neutron data, in the solid state, both with regard to radius of gyration and the whole small-angle scattering function (Figure 7). However, this model is in conflict with the known crystallinity and the SAXS evidence (Figure 1), which shows that long straight sections of the molecule (~ 100 Å) exist. Thus such an extreme model cannot be used to describe the scattering data and other properties of solid polyethylene.

At the opposite extreme of models which might be used to fit the data there are models postulating folding within a given crystallographic plane of the lamella. Such a model has been put forward by Bank and Krimm¹⁰ on the basis of adjacent re-entry. Generally the scattering function of such a configuration would also lead to the observed κ^{-2} behaviour and we have therefore performed model calculations, in which the basic requirement is that the chain folding must occur within a given plane. The molecule is therefore constrained within a plane height, w , length, l , with negligible width. The density of CD_2 molecules of one chain is therefore $\rho_x(x)\rho_y(y)\delta(z)$ with $\rho_x(x)$ and $\rho_y(y)$ constant over distances l and w respectively and zero elsewhere. $\rho_x(x)$ and $\rho_y(y)$ are the mass distribution functions, x and y are the rectangular coordinates within the folding plane, and z is perpendicular to it. The form factor of this chain molecule is:

$$F_x(q_x)F_y(q_y) = \frac{\sin\left(q_x \frac{w}{2}\right)}{q_x \frac{w}{2}} \times \frac{\sin\left(q_y \frac{l}{2}\right)}{q_y \frac{l}{2}} \quad (4)$$

if F_x and F_y are the Fourier transforms of ρ_x and ρ_y of argument q with components q_x and q_y in the x and y directions. The differential cross-section $d\Sigma/d\Omega$ of tagged molecules folded in planes with their normals statistically oriented in space is:

$$\frac{d\Sigma}{d\Omega}(\kappa) = cM_w K_N |F(\kappa)|^2 / |F(0)|^2 \quad (5)$$

with

$$|F(\kappa)|^2 = \frac{1}{4\pi} \int \int d\phi \sin \psi d\psi |F_x(q_x)F_y(q_y)|^2 \quad (6)$$

and

$$q_x = \kappa \sin \psi \cos \phi \quad (7)$$

$$q_y = \kappa \sin \psi \sin \phi$$

The radius of gyration $\langle S^2 \rangle_w^{1/2}$ corresponding to $(d\Sigma/d\Omega)(\kappa)$ is resolvable into two components:

$$\langle S^2 \rangle_w = R_{gx}^2 + R_{gy}^2 = \frac{l^2}{12} + \frac{w^2}{12} \quad (8)$$

where R_{gx} and R_{gy} are the second moments of the mass distributions ρ_x and ρ_y , respectively.

For each chosen pair of mass distribution functions the scattering cross-section $d\Sigma/d\Omega$ was calculated for R_{gy}/R_{gx} ratios of 1, 2, 4 and 8, and hence a value of Q was calculated for each of these ratios. These values of Q are shown in Figure 9, and show that only for a value of $R_{gy}/R_{gx} = 4$, can this model give the measured value of $Q = 2.3$. Using this value of R_{gy}/R_{gx} , Figure 10 shows the curve of $\kappa^2(d\Sigma/d\Omega)(\kappa)$ predicted by the model. The function shows some oscillations which are not important to the main argument, and gives a reasonable agreement to the

Figure 9 Model calculation of Q vs. R_{gy}/R_{gx} for folding in one plane $R_{gy}/R_{gx} = w/l$

Figure 10 Plot of $\kappa^2 \langle S^2 \rangle_w^{1/2} (d\Sigma/d\Omega) (K) / (d\Sigma/d\Omega) (O)$ vs. κ for model with $R_{gy}/R_{gx} = 4$

measured scattering data (Figure 7). For a typical chain with molecular weight $M \approx 140\,000$, the length L , is $\approx 12\,500 \text{ \AA}$ and the radius of gyration $\langle S^2 \rangle^{1/2} = 0.46 M^{1/2} \approx 168 \text{ \AA}$. Thus, assuming $w/l = 4$ we calculate from equation (8) that $l \approx 138 \text{ \AA}$, $w \approx 565 \text{ \AA}$. The distance between adjacent folding segments is then calculated to be:

$$d = \frac{w}{L/l} = 6 \rightarrow 10 \text{ \AA} \tag{9}$$

depending on whether one assumes that all the molecule is within the folding plane, or whether 35% of it is in the amorphous region. Thus this distance of the same order of magnitude to a value of 4.9 \AA calculated by Bank and Krimm¹⁰ for adjacent re-entry within the (200) plane.

According to equation (8), however, $\langle S^2 \rangle = 0.46^2 M_w = l^2/12(1 + 4^2)$ or

$$l = 0.38 M_w^{1/2} \tag{10}$$

This implies a molecular weight dependent fold length, and for a chain with molecular weight $M \approx 60\,000$ we calculate $l \approx 93 \text{ \AA}$; $d = 6 \rightarrow 10 \text{ \AA}$. This raises a particular difficulty for this model because in the neutron experiments l is effectively fixed by the matrix, and yet it is seen that Q remains 2.3, while the tagged molecular weight changes from $60\,000 \rightarrow 140\,000$ (Table 2). It therefore seems that although the model can be made to give a reasonable fit to the data at a given molecular weight, it does not seem

capable of describing the variation of the measured parameters over the whole molecular weight range.

In order to remove the molecular weight dependence of l , which arises from equation (8), the model might plausibly be re-formulated to allow the molecule to pass through several different lamellae. To maintain the κ^{-2} behaviour of $d\Sigma/d\Omega$, the chain would have to crystallize in each lamella in a plane whose dimensions obeyed the relation $w/l = 4$. This relaxes the constraint of equation (8), as the radius of gyration of the molecule is determined by the overall mass distribution of the molecule rather than by equation (8). Such a molecular configuration is shown schematically in Figure 11, for a molecule passing through 4 lamellae. However, a serious argument against this kind of configuration is that l has to be approximately the same as before as this is determined by the matrix. Hence as the ratio w/l has to remain 4 in order to give $Q = 2.3$ (Figure 9), it follows that each folding plane has to have approximately the same dimensions (w, l) as in the previous formulation. Hence the chain has to be distributed over four planes (in the case of Figure 11), of approximately the same size as the original plane. This means that the interchain distance d , has to increase by a factor of 4 and one cannot, therefore, maintain the adjacent re-entry mode of folding.

It seems that the basic problem of this type of model lies in the assumption that the measured value of $Q = 2.3$ in the solid arises from the fact that the molecules fold in planes maintaining $w/l = 4$. This seems a very artificial assumption, which leads to the problems discussed above. It is thus difficult to see therefore how the correspondence with the melt, both in radius of gyration in (Table 2) and the whole scattering function (Figure 7), can be plausibly explained on the basis of adjacent re-entry within a given crystallographic plane for rapidly quenched samples.

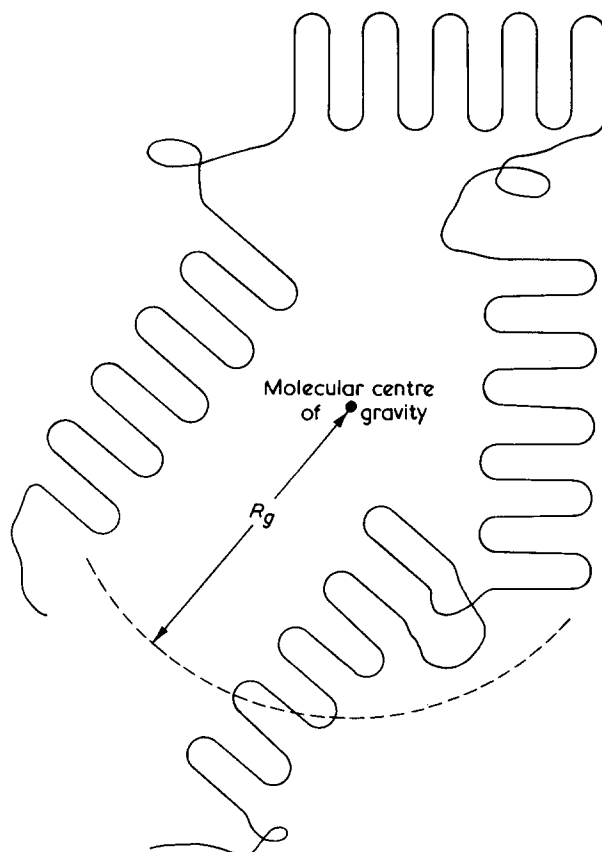

Figure 11 Schematic reformulation of model with molecules folding in one crystallographic plane in each lamella

It seems much more reasonable to propose that the reason for the correspondence of $\langle S^2 \rangle^{1/2}$ with the melt, lies in the fact that on a fast quench, the molecule cannot diffuse sufficiently rapidly to adopt a very different mass distribution of chain elements to that adopted in the melt. The correspondence of Q values in the melt probably arises from a retention in the crystalline state of some of the randomness of the melt.

Beyond these general assertions, we are not in a position of being able to propose a unique configuration for the molecule from the data of *Figure 7*. This is because two extreme models can be fitted mathematically to this data, and hence it is to be expected that there are a whole variety of further models between these extremes which might generate a similar function. It is clear that further data over a wider κ range would be useful for determining the configuration, and such experiments are currently in progress.

In conclusion, it is relevant to discuss the work of Sadler and Keller on single crystal mats¹¹. *Figure 4b* in ref 11 is typical of the results obtained for single crystal mats 0.1 mm thick. The results shown correspond to the translucent material obtained by pressing at 60°C. Sadler and Keller were unable to measure the molecular weight of the tagged molecules from the forward scattering because of the presence of a 'void artefact'. No check for clustering was therefore made, and the evidence from the studies described in this paper would suggest that the system is highly aggregated. A maximum at a value $\kappa \approx 0.08 \text{ \AA}^{-1}$ was observed in the Kratky plots, though we are of the opinion that the shape of this curve is in no way a feature of the structure of PE but a consequence of aggregation

of PED chains. A similar feature was found in sample PE 21 (*Figure 8*) and was shown to be due to clustering of small numbers (2 to 3) of PED molecules. This feature is absent in unclustered samples (*Figure 7*), and the strength of this overshoot in Sadler and Keller's data suggests even greater aggregation effects.

Effect of molecular oxygen on the n.m.r. relaxation times of some aromatic polymers

Michael F. Froix and Andreas O. Goedde

Xerox Corporation, Webster, New York, USA

(Received 5 April, 1976)

Proton spin-lattice (T_1) and spin-spin (T_2) relaxation times are reported for poly(2-vinylpyridine), poly(1-vinylanthracene) and polycarbonate in air, oxygen and *in vacuo*. The results substantiate earlier findings that oxygen complexes with the aromatic rings giving rise to T_1 minima which are not intrinsic to the polymers. This effect appears to be fairly general for aromatic containing polymers. For those polymers containing low temperature relaxations intrinsic to the polymer, the oxygen paramagnetic effect can complicate the relaxation behaviour and, in some cases, totally mask the intrinsic processes. The transitions in T_1 and T_2 , due to the torsional oscillation of the anthracene side group in poly(1-vinylanthracene), is much better defined than the corresponding transitions for previously reported aromatic vinyl polymers. The activation energy for the motion of the side group is comparable to that of polystyrene and poly(*N*-vinylcarbazole).

INTRODUCTION

Recently, it has been shown that some aromatic polymers exhibit anomalous n.m.r.¹⁻⁴ and dielectric^{5,6} relaxations in the presence of oxygen. Prior to this discovery, the origins of these relaxations were the source of much uncertainty. Polyvinylcarbazole (PNVC), poly(*N*-ethyl-3-vinylcarbazole) and polystyrene (PS) were found to complex with molecular oxygen giving rise to low temperature n.m.r. relaxations due to the dipole-dipole interaction with, and spin-diffusion to the paramagnetic oxygen. N.m.r.¹⁻⁴ and dielectric^{5,6} measurements have also shown low temperature relaxations due to the motion of the aromatic side groups which are only observed on interaction with oxygen. In the absence of oxygen, these motions are either of too low amplitude or about a symmetry axis and, consequently, are not observed in the n.m.r. and dielectric data. However, on interaction with oxygen, a dipolar field due to the unpaired electrons of the paramagnetic species is experienced by the polymer protons. At the onset of oscillation of the aromatic ring, the lifetime of the interaction is reduced and transitions in n.m.r. and dielectric relaxations are observed with activation energies corresponding to the intrinsic motions of the polymers.

In this paper, the nuclear spin-lattice (T_1) and spin-spin (T_2) relaxation times are reported for a series of aromatic polymers. The relaxation behaviour of thoroughly evacuated samples is compared with that of samples in air and oxygen, and the results are discussed in terms of the influences of paramagnetic oxygen on the polymer proton relaxation behaviour.

EXPERIMENTAL

The polycarbonate (PC), poly(2-vinylpyridine), and poly(1-vinylanthracene) (PA) samples were obtained from various sources. The relevant data are given in Table 1. All samples were reprecipitated several times before using. Evacuated samples were obtained by pumping the samples to $\sim 10^{-5}$ mmHg at 80°C for 12 h. The n.m.r. tubes were

attached to nylon valves so that samples could be re-equilibrated with oxygen or air at a later time.

The n.m.r. relaxation times were obtained on a Bruker SXP NMR Spectrometer at 90 MHz. The magnetic field was generated by a 12 in shimmed electromagnet operated in the current regulated mode. The temperature was controlled by a gas-flow system thermostatted with a copper constantan thermocouple and controlled to an accuracy of $\pm 1^\circ\text{C}$.

Spin-lattice relaxation times were measured by the $180^\circ - \tau - 90^\circ$ pulse technique⁷. Values of T_1 were derived from a least squares analysis of plots of $\ln[A(\infty) - A(T)]$ as a function of the interval τ between the 180° and 90° pulses, where $A(T)$ is the amplitude of the free induction decay following the 90° pulse and $A(\infty)$ is the value of $A(T)$ for infinite time.

Spin-spin relaxation times were obtained from the free induction decays following the 90° pulse. T_2 was taken as $t_{1/2}/\ln 2$ where $t_{1/2}$ is the time for the magnetization to decay to one-half of its original value. Both values of T_1 and T_2 were determined using a computer program⁸ in which the free induction decays were stored in a Nicolet 1080 computer.

RESULTS

Figure 1 is a plot of T_1 versus temperature for degassed poly(2-vinylpyridine) and poly(2-vinylpyridine) in oxygen. The high temperature T_1 come together at the minimum due to the glass transition. At low temperatures, the sample in oxygen shows a minimum at 210K which is not pre-

Figure 1 A plot of T_1 vs. temperature for an evacuated sample of poly(2-vinylpyridine) (\square) and poly(2-vinylpyridine) in oxygen (\circ)

Figure 2 A plot of T_1 vs. temperature for PA evacuated (\square) and in air (\circ)

sent in the evacuated sample. The T_1 behaviour of PA in air and *in vacuo* is given in Figure 2. The evacuated sample shows a shallow minimum at 400K and the approach to another minimum beginning at 480K. There is no minimum in T_1 for this sample below room temperature; however, the sample in air shows a minimum at 180K three orders of magnitude smaller than the degassed sample. A transition in T_2 at 220 K is observed in Figure 3. The transition in air is slightly more pronounced than that of the evacuated sample. Figure 4 gives T_1 plots of evacuated PC and PC in air. The evacuated sample shows a minimum at 280K while the sample in air exhibits a minimum at 190K and a less in-

tense minimum at 280K which is almost totally masked by the lower temperature minimum. All samples exhibit anomalous minima in air and oxygen. The magnetization recovery on the low temperature side of these minima is non-exponential. This magnetization recovery can be described by a $(\text{time})^{1/2}$ dependence at short times and the plots consist of two straight line segments¹.

DISCUSSION

The low temperature T_1 behaviour of polycarbonate, poly(2-vinylpyridine) and poly(1-vinylanthracene) exhibit enhanced relaxation in the presence of air and oxygen accompanied by the appearance of new minima which are not observed for the evacuated samples. The anomalous minima are accompanied by a non-exponential magnetization recovery on the low temperature side of the minima. The limiting cases of diffusion-limited and rapid diffusion of nuclear spin energy to paramagnetic oxygen have been dealt with previously¹⁻⁴. In diffusion-limited relaxation, the initial magnetization recovery is described by a $(\text{time})^{1/2}$ dependence at short times which gives rise to an exponential dependence at longer times⁹. All of the polymers examined in this study exhibit this type of behaviour in both

Figure 3 A plot of T_2 vs. temperature for PA evacuated (\blacktriangle) and in air (\circ)

Figure 4 A plot of T_1 vs. temperature for PC evacuated (\square) and in air (\bullet)

air and oxygen below the low temperature T_1 minimum. Plots of fractional magnetization recovery are composed of two regions which have been demonstrated to result from surface and bulk oxygen effects¹. Polyvinylcarbazole and polystyrene have been shown to complex with oxygen^{1,3,10} and it appears from the results of this study that this is a general feature of aromatic ring containing polymers. The polymers absorb oxygen both at the surface and in the bulk; however, there appears to be a preference for surface adsorption giving rise to larger concentrations of oxygen on the surface than in the bulk¹. Higher surface area materials have been shown to exhibit shorter values of T_1 in the presence of oxygen and the minimum due to this effect occurs at lower temperatures reflecting the change from diffusion-limited relaxation on the low temperature side of the minimum to rapid diffusion above the minimum¹.

The T_1 minimum at 400K and the corresponding transitions in T_2 at 220K for PA are consistent with maxima in $\tan \delta$ observed for poly(2-vinylanthracene) and poly(α -methyl-2-vinylanthracene)¹¹. Polystyrene^{3,12} and polyvinylcarbazole¹ have been shown to exhibit fairly ill defined minima in T_1 due to torsional oscillation of the aromatic side group. In degassed samples, the corresponding transitions in T_2 are not observed due to the low amplitude of the motion. However, in the presence of oxygen in these systems, changes in T_2 are observed at the onset of re-orientation of the rings due to the averaging of the small dipolar field arising from the proton interaction with the unpaired electrons^{1,3}. In PA, both the T_1 and T_2 transitions are well defined. The T_2 transition is small and is accentuated in air. It is concluded that the T_1 and T_2 transitions correspond to a low amplitude torsional oscillation with an activation energy of approximately 8 kcal/mol. Above 480K, the beginning of another transition in T_1 is apparent. The temperature was not taken any higher in order to avoid sample degradation. The approaching relaxation is probably the $\alpha\beta$ process associated with the glass-transition.

The minimum in T_1 at 280K for degassed PC has been observed previously and is ascribed to methyl group re-orientation¹³⁻¹⁵. Since the position and depth of the T_1 minimum due to the paramagnetic oxygen is known to be a function of the surface area of the sample^{1,3} the position and width of the low temperature minimum can be vastly altered (if T_1 measurements are made in air) depending on the physical state of the sample. This has been shown to be the case for low molecular weight, small particle size polystyrene in air where two minima in T_1 are observed at low temperatures due to the oxygen effect and to the motion of chain ends. When this sample is quenched from the melt, thereby reducing the surface area, both minima merge to form a broad minimum³. Poly(2-vinyl-*N*-ethyl-carbazole) and poly(3-vinyl-*N*-ethylcarbazole) also exhibit a low temperature T_1 minimum due to motion of the ethyl group. It has been shown that in the presence of air, this minimum is totally masked and, as a result, is not observed; however a minimum due to the interaction of oxygen does appear at a lower temperature². In view of these facts, it is not surprising that the minimum due to the methyl group motion is somewhat overshadowed in the PC sample in air. Taking these observations into

account, we have been able to regenerate some previously published T_1 data^{14,15} and to account for their unusually wide and more intense T_1 minimum in terms of the above mentioned oxygen effects.

CONCLUSIONS

Spin-lattice relaxation time measurements have been made on evacuated samples of polycarbonate, poly(2-vinylpyridine) and poly(1-vinylanthracene) and on these polymers in air and oxygen. The results agree with those previously obtained for carbazole containing polymers^{1,2,4} and polystyrene³ in which oxygen is found to complex with the aromatic ring giving rise to a T_1 minimum in these atmospheres which are not intrinsic to the polymers. This effect now appears to be fairly general for aromatic containing polymers. Like low molecular weight polystyrene³ and poly(2-vinyl-*N*-ethylcarbazole)² which exhibit low temperature relaxations due to chain-ends and side chains respectively the oxygen effect in polycarbonate can complicate the low temperature behaviour, in some instances masking the intrinsic processes altogether.

Poly(1-vinylanthracene) exhibits a T_1 minimum and a transition in T_2 due to torsional oscillation of the anthracene side chain. The transitions are more easily discernible than for previously reported aromatic vinyl polymers¹⁻⁶ reflecting either a larger amplitude motion of the side group or a narrower distribution of correlation times associated with that motion. The activation energy for torsional oscillation of poly(1-vinylanthracene) agrees with that of polystyrene and poly(*N*-vinylcarbazole)^{1,3}.

ACKNOWLEDGEMENT

The authors wish to thank John Yanus for providing the polycarbonate and poly(1-vinylanthracene) samples and for all the pertinent data concerning their molecular weights and molecular weight distributions.

Pulsed n.m.r. studies of molecular motion in wet nylon-6,6 fibres

Edward G. Smith

Unilever Research Port Sunlight Laboratory, Port Sunlight, Wirral, Merseyside L62 4XN, UK
(Received 3 February 1976; revised 20 April 1976)

The influence of water molecules on molecular motion in commercial nylon-6,6 fibres has been investigated by pulsed n.m.r. techniques. Transient n.m.r. signals, T_2 and T_1 relaxation times for the fibre protons were measured as a function of temperature and moisture (D_2O) content. Above the glass transition temperature, T_g , of the fibre, separation of the signal into two components, a 'rigid' and 'non-rigid' fraction, was possible. For wet fibres, the temperature at which the 'non-rigid' or 'mobile' component appeared was reduced as the water content was increased and the 'mobile fraction' increased with temperature. This behaviour is explained in terms of the mobilization of amorphous chain segments above the T_g and their ability to be 'plasticized' by water molecules. The effect of D_2O molecules and paramagnetic Mn^{2+} ions on T_1 relaxation of rigid and mobile segments provided further information on the properties of accessible chain segments between and on the crystallite surfaces. A chain folded model of semi-crystalline morphology has been adopted throughout the discussion.

INTRODUCTION

The semi-crystalline structure and properties of polymeric fibres are important in many aspects of textile preparation and applications. It is well known, for example, that the strength, crease recovery and dyeing characteristics of fabrics¹⁻³ depend on the crystallinity and state of orientation in the fibres. Moreover, for fibres such as nylon or rayon, the influence of moisture on these properties is determined by the behaviour of fibre polymer chains in the accessible regions and therefore ultimately by the semi-crystalline morphology. Although numerous correlations have been established between the properties and structure of fibre forming polymers in terms of their degree of crystallinity and orientation^{4,5} more information is required on the dynamic configurational behaviour of the polymer chain segments in both the crystalline and amorphous states. However, the non-crystalline or amorphous structures are of particular interest since it is in these regions that the processes leading to fibre distortions originate^{6,7}, either through mechanical disruption of inter-chain attractions or by the influence of the glass transition temperature, T_g , on molecular mobility. Furthermore, it is known that the penetration of liquids and other low molecular weight substances into fibres⁸ takes place via the inter-crystalline regions and that the rate of penetration is increased above the T_g ⁹. The most popular theory of fibre structure at present is one in which the crystalline or elementary fibril is formed by a polymer chain folding back and forth in a regular manner along its own length¹⁰ with chain ends, loops and tie molecules between crystallite surfaces forming the amorphous regions. Hence, in this case the extent of mobility of an amorphous chain segment above the T_g , unlike that in a completely amorphous polymer depends on its mode of attachment to the crystallite¹¹.

Of the many techniques employed to examine the physical properties and transition behaviour in solid polymers¹²⁻¹⁴ the n.m.r. method is perhaps the one most suited for obtaining direct information on the various molecu-

lar motion processes involved¹⁵⁻²³. The broad-line n.m.r. investigations of Zachmann¹⁸ and of Bergmann¹⁹ on poly(ethylene terephthalate) are representative of recent attempts to analyse the mobility behaviour of the different amorphous arrangements of chain segments in semi-crystalline polymers, while Olf and Peterlin have used the same technique to study orientation²² and the effects of moisture²³ on mobility transitions in nylon-6,6 fibres. Although there have been several pulsed n.m.r. relaxation time studies on polyamides^{21,24} to our knowledge this method has not been used to study chain mobility and thermal transitions in wet nylon fibres. This paper examines the influence of temperature and moisture on chain motion in commercial nylon-6,6 fibres. The n.m.r. relaxation behaviour of polymer segments resulting from penetration of water (D_2O) molecules and paramagnetic electrolyte into the fibres is discussed with reference to the features of a chain folded morphology.

EXPERIMENTAL

Sample preparation

Commercial nylon-6,6 fibres (1.5 denier) were obtained from ICI Fibres Ltd. Fibres were washed several times in distilled water but no attempt was made to remove opacifier or carry out any other purification treatment which might have changed the original morphology. For dry samples oxygen and other volatile materials were removed by maintaining the samples under vacuum for several days. Samples of different water content were achieved by equilibrating fibre samples in various relative humidity chambers (saturated salt solutions in D_2O)²⁵ for about 6 weeks (at 25°C). Saturated fibres and fibres containing manganese sulphate were prepared by soaking fibres in appropriate solutions.

N.m.r. measurements

Pulsed n.m.r. signals and proton relaxation times were measured using a Bruker (BKR 322S) pulsed n.m.r. spectro-

Figure 1 Form of pulsed n.m.r. induction signals for protons of nylon-6,6 fibres (showing 'solid-echo' signals; $t = 0$, end of pulse II.) Dry fibres: (a) at 45°C; (b) at 165°C. Wet fibres: (c) at 45°C, 4% D₂O; (d) at 45°C, 12% D₂O

meter operating at 60 MHz. The temperature was controlled to within ± 1 K. Loss of signal during the pulse and receiver dead time was minimized by examining the induction signals in the form of a 'solid-echo'²⁶ using a $90^\circ - \tau - 90^\circ - 90^\circ$ pulse sequence, where τ , the pulse separation is of the order of several microseconds. Two component signals were found to fit reasonably well the superposition of a Gaussian and an exponential curve of the form:

$$h = h_R \exp [-t^2/2T_{2R}] + h_M \exp [-t/T_{2M}]$$

where h is the signal intensity at time t after the signal maximum and h_R and h_M are proportional to the numbers of chain segments in the 'rigid' and 'mobile' states, respectively. T_{2M} , the spin-spin relaxation time for the mobile component was deduced from the linear portion of the plot of $\log h$ against t and T_{2R} , a relaxation time related to the second moment of 'rigid', Gaussian, component, was estimated from a plot of $\log (h - h_M)$ versus t^2 . T_1 , the spin-lattice relaxation time was determined from the recovery of signal amplitude following a $90^\circ - \tau - 90^\circ$ sequence as τ , the pulse separation, is varied. T_1 values for each signal component could be measured separately.

RESULTS AND DISCUSSION

Influence of water on n.m.r. signals and transitions

Pulsed n.m.r. signals were recorded as a function of temperature for dry fibres and fibre samples containing different amounts of water; a signal contribution from the

water was avoided by using D₂O. The main variations in signal shape obtained for the nylon-6,6 fibres are illustrated in Figure 1, which shows solid echo signals formed after the second 90° pulse ($t = 0$); signal amplitudes are proportional to the total number of protons in the sample. In the dry fibres at temperatures above about 100°C a broader component indicating an increase in molecular motion appears in the signal. This is connected with the α_a process or the onset of 'liquid-like' motions of the amorphous chain segments above their glass transition temperature, T_g . The interesting feature of the n.m.r. behaviour for the wet fibres is that a similar mobile signal component is present at much lower temperatures. Olf and Peterlin²³ have recently investigated a mobile component in broad-line n.m.r. studies of wet nylon filaments which they suggest is a manifestation of the process causing a narrow line in the dry fibres at high temperatures i.e. the α_a process. By comparison we therefore conclude that the pulsed n.m.r. behaviour in the wet fibres is due to mobilization of chain segments in the amorphous regions by water molecules. The temperature at which the mobile component appeared, was found to depend on water content. In an arbitrary manner, transition temperatures for each sample have been deduced from plots of decay time ($1/4$ life) of the bulk signal versus temperature, these curves are presented in Figure 2. It can be seen that the transition occurs at lower temperatures as the water content is increased and in saturated fibres determination of a value below 0°C is probably limited by some freezing of water. From detailed studies of sorption in nylon by Puffr and Šebenda^{27,28} it has been proposed that the progressive uptake of water by nylon occurs in several stages involving water strongly bound across CO groups, loosely bound water forming bridges between neighbouring amide groups and, after further disruption of inter-chain bonds^{29,30}, clustering of water molecules as 'capillary' or included water. Therefore it is not expected that a single mechanism of segment mobilization applies throughout the entire sorption range; the tightly bound water is thought to cause local plasticization of segments connected to CO groups³¹, only above about 3% water content³² can plasticization by water be considered to be of a polymer-diluent type described by free-volume theories^{33,34}.

Apart from recent indications that the transition α_c in the crystalline regions of nylon-6,6 is affected by water²³, it is often accepted that the penetration of water into

Figure 2 Variation of bulk signal decay times (arbitrary scale) with temperature for nylon-6,6 fibres containing different amounts of water (D₂O). Estimation of T_g (n.m.r.). D₂O content: A, 12%; B, 6%; C, 4%; D, 2%; E, 0.6%; F, dry fibres

Figure 3 Estimation of mobile fraction, MF , for nylon-6,6 fibres from analysis of pulsed n.m.r. signal ($t = 0$, end of pulse II). $MF = h_M / (h_M + h_R)^{-1}$ where h_M = mobile component; h_R = rigid component

nylon fibres takes place via the amorphous regions and therefore the molecular motion processes associated with these segments alone are influenced by water. In addition to the influence of water on the normal T_g process it is believed that the firmly bound water gives rise to another transition in the amorphous regions at a somewhat lower temperature, sometimes called the β -transition; (Kapur³¹ *et al* propose that the β -process in wet nylon-6 at low water contents is similar to the mechanical and dielectric transition in ice associated with LI defects). The other important motional process in the non-crystalline regions which can be affected by water is that associated with local movement of the CH_2 groups, as in polyethylene, namely the γ -process^{22,35}. Olf and Peterlin²³ have observed a reduction in hindrance of the γ -motion in wet nylon above -75°C by wide-line n.m.r. due to mobilization of water molecules at this temperature. In the present work, at low water contents it is difficult to determine the relative importance of each mobility process from the signal shape alone, except that at a water content of 2%, which must represent bound water at normal temperatures, a mobile component is produced in the n.m.r. signal at a temperature about 30°C lower than in the dry fibres.

Mobile fraction

At higher water contents and temperatures where the 'rigid' and 'mobile' components can be separated more easily it is possible to estimate the fraction of material

undergoing significant segmental motion and its characteristic decay or relaxation time T_{2M} , as in Figure 3. In this analysis it has been assumed that the 'mobile' component can be extrapolated as a single exponential beneath the 'rigid' signal component and h_M has been taken from the end of the second 90° pulse (the exact position of $t = 0$ for the exponential component probably lies between the two pulses, separation $\sim 4 \mu\text{sec}$, therefore our estimates of h_M will be slightly low). The mobile fraction, defined as the amplitude of mobile signal divided by total signal was plotted against temperature for several water contents, (Figure 4). From these curves it is evident that not all segments in the amorphous regions are able to commence motion at the same temperature and also that the presence of water shifts the curves to lower temperature. This behaviour must be related to the influence of fibre morphology on the properties of chains forming the amorphous regions between the crystallites. Present theories of structures of semi-crystalline fibres, such as chain folding, require that some of the amorphous chain segments belong to chains having at least one end embedded in the crystallites^{11,18} as represented in Figure 5. Hence, in contrast to the beha-

Figure 4 Dependence of mobile fraction, MF , on temperature for nylon-6,6 fibres containing different amounts of water (D_2O): \circ , saturated fibres; \blacktriangle , 12% D_2O ; \square , 2% D_2O ; \bullet , dry fibres

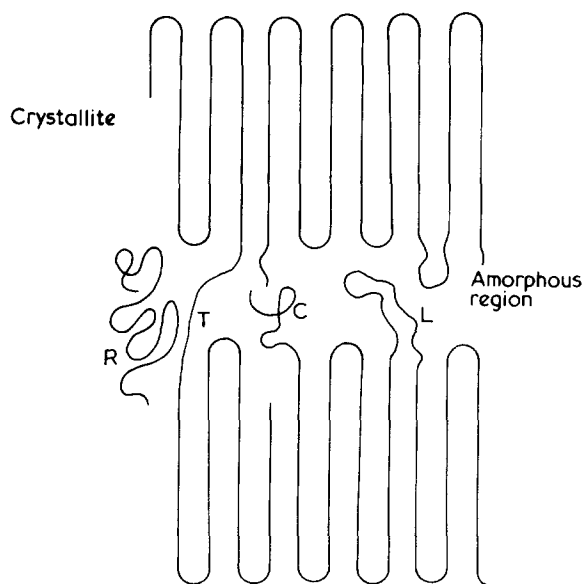

Figure 5 Schematic representation of chain folded structures in a semi-crystalline fibre. C, Cilia (chain end); T, tie molecule; R, rejected chain; L, loop

Figure 6 Plot of log MF against $(T - T_g)^{-1}$ for dry and wet nylon-6,6 fibres: ○, saturated fibres; △, 12% D₂O; ●, dry fibres

viour in completely amorphous materials the presence of the crystalline regions in nylon fibres impose permanent constraints on the ends of amorphous chains at temperatures below the melting point of the crystallites. Zachmann¹⁸ proposes that in poly(ethylene terephthalate), loops of amorphous chain segments (L in Figure 5) protruding from the surfaces of chain folded crystallites take part in significant motion above the T_g only if the ratio of end-end separation to extend length of the loop is less than about 0.5 (in this model, rejected chains and chain ends emerging from crystallite surfaces would, of course, be capable of such motion). Using simple free-volume theories³⁶ to relate n.m.r. mobile fraction to free volume increase viz.:

$$MF = MF_{\infty} \exp [-A(T - T_g)^{-1}]$$

(where T_g is the temperature at which the mobile component first appears and A is a constant which includes the coefficient of expansion) Zachmann extrapolated his n.m.r. data to 'infinite temperature' and obtained estimates of the maximum fraction of chains, MF_{∞} , capable of taking part in motion above the T_g . Our data has been plotted in this form and, for comparison, the curves obtained for dry and wet nylon-6,6 fibres are shown in Figure 6; within experimental error linear relationships were obtained. Although, due to the specific water-polymer interactions in the nylon system, quantitative interpretation of the temperature behaviour becomes difficult, extrapolation of the curves to 'infinite temperature' demonstrates that the fraction of non-crystalline chain segments able to participate in the motion is independent of the method of introducing free volume i.e. whether solvent or thermally induced. The concept of moisture-temperature superposition has been used elsewhere in studies of nylon fibres^{37,38} and in general could be applied to these results, however the method of introducing D₂O into the samples does not preclude the possibility of some droplet formation between individual fibres in the staple pack thereby yielding uncertainties in amounts of water actually absorbed in a fibre.

Relaxation in dry fibres

For dry nylon-6,6 fibres both the T_1 and T_2 processes could be described as single component below the T_g (~100°C); the results are presented in Figure 7. The T_1 behaviour is similar to that found by McCall and Anderson²¹ for dry nylon filaments. The main feature between -100°C

and 100°C is a pronounced T_1 minimum occurring at about 40°C which is attributed to the γ -process in the non-crystalline regions. That T_1 relaxation of the whole sample is influenced by the γ -process suggests that a spin diffusion process³⁹ operates between the crystalline and amorphous regions whereby spin energy of 'rigid' chain segments is propagated by mutual 'spin-flips' between pairs of nuclei to mobile sites capable of relaxing via the normal spin-lattice mechanism. The behaviour is compatible with the arrangements of chains outlined previously in Figure 5 in which the non-crystalline segments are located on the surfaces of the crystallites as chain loops, rejected chains, chain ends or tie molecules adjoining the crystalline regions. These segments, by virtue of either their γ - or α_d -motion, will be able to act as the 'sinks' for the drain of spin energy from the chain folded material to produce an average T_1 for the system. The steady increase in T_2 with increasing temperature up to 100°C is also associated with the γ -process, the signal components of the crystalline and amorphous phases being inseparable in this temperature range. Above ~100°C the T_1 /temperature curve begins to form a second minimum which is accompanied by the appearance of the 'mobile' T_2 component. Here the T_1 values for the two components were determined separately and found to be practically equal, again demonstrating the efficiency of the spin diffusion process between crystalline and mobile amorphous segments above their T_g . (There is likely to be a contribution to the drop in T_1 at this temperature due to the α_c -process²² associated with motion of segments about long chain axes in the crystalline regions.) Approximate T_2 values for each component at the higher temperatures have been determined and are included in Figure 7.

Relaxation in wet fibres

In Figure 8 is shown the recovery of magnetization after the second 90° pulse in a typical T_1 measurement for wet

Figure 7 Dependence of proton relaxation times, T_1 and T_2 , on temperature for dry nylon-6,6 fibres: total signal, ★ (T_1), ☆ (T_2); mobile signal, ● (T_1), ▲ (T_{2M}); rigid component, ○ (T_1), △ (T_{2R}); fibres containing MnSO₄ (□)

Figure 8 Recovery of signal intensity in a typical T_1 experiment ($90^\circ - \tau - 90^\circ$ pulse sequence) for wet nylon-6,6 fibres (at 55°C), $h(\tau)$ = signal intensity at time τ ; $h(\infty)$ = signal intensity as $\tau \rightarrow \infty$. \circ , Wet nylon-6,6 fibres; ----, single exponent

nylon fibres (saturated in D_2O). It can be seen that the form is non-exponential; examination of the curves obtained between 0° and 100°C suggests a distribution of T_1 values⁴⁰. Therefore it appears that in this temperature range spin diffusion is not completely effective in producing an average \bar{T}_1 when some D_2O molecules are present between the chains in the accessible regions. The dependence of relaxation times on temperature is presented in Figure 9. After about 0°C the appearance of the 'mobile' signal component enabled both T_1 and T_2 for the amorphous regions to be measured separately. It is interesting to observe that the lower T_1 curve referring to relaxation of the 'rigid' component retains the minimum characteristic of that produced by the γ -process in the dry fibres. In view of the nature of the morphology being considered this is not surprising since non-crystalline segments contributing to this component over most of the temperature range are those segments capable of acting as 'sinks' in spin diffusion relaxation of crystallite protons i.e. those forming tight loops on the crystallite surface. (The existence of a strong γ -relaxation in highly crystalline nylon-6,6 has recently been noted by Ito, Tanaka and Kayamoto²⁴ and interpreted as arising from crystal defects.) The γ -process may also be responsible for the steady increase in T_2 with temperature for this component although it is possible that the increase includes a contribution from the influence of water on the α_c -process, as indicated in the n.m.r. second moment data of Olf and Peterlin²³. Because of the ability of both moisture and temperature to mobilize chain segments in the amorphous regions it is reasonable to claim that the T_1 minimum observed (Figure 9) for the plasticized segments is a low temperature version of the minimum for the α_c -process commencing after the T_g in the dry fibres. However, in addition, it is realized that the T_1 behaviour for the amorphous component includes relaxation of more and more segments as the temperature is increased. Unfortunately, it is impossible to resolve separate T_1 data for the different types of amorphous chain segments and at present no quantitative treatment can be applied to deter-

mine the relative influences of water on their α_c - and γ -processes.

Effect of paramagnetic ions

When paramagnetic Mn^{2+} ions are introduced into the wet fibre sample only one T_1 is apparent and the T_1 /temperature behaviour is modified considerably as shown in Figure 9. Since there is a reduction in T_1 over the whole temperature range and the fibre diameter is in excess of $10\ \mu\text{m}$ the effect is considered to be due to penetration of some paramagnetic ions into the water accessible regions⁴¹. Below about 0°C some water responsible for plasticization at normal temperatures is frozen; as the temperature is raised above 0°C there must be a dramatic change in correlation frequency for the ions as this water melts. The drop in T_1 as the temperature is further increased arises from the influence of increasing chain mobility in the presence of paramagnetic ions. It is possible that the increase in free-volume with increase in temperature allows more ions to reach tight loops near the crystallite surfaces. The structural features thought to determine relaxation of chain segments between two chain folded crystalline regions are represented schematically in Figure 10. In this model it is expected that amorphous segments plasticized by D_2O molecules remote from the crystallite surface will have a different average motional correlation time, $\bar{\tau}_A$, to those in the chain folded material forming the crystallites (correlation time $\bar{\tau}_C$). The action of D_2O molecules between mobilized chains will result in an inefficient spin diffusion

process across the amorphous regions and hence prevent complete averaging of the T_1 process, i.e. T_{1C} for the crystallites and T_{1A} for mobilized amorphous segments. However, a distribution of Mn^{2+} ions in the amorphous regions, as shown in Figure 10 will relax directly all protons between and on the crystallite surfaces. A single T_1 process is obtained because these ions also determine the relaxation of chain folded material via spin diffusion through the crystallite surface. The influence of paramagnetic sources on the relaxation of chain segments in the region of the transition

for a fibre sample in which the bulk of the water had been removed is shown in Figure 7. Spin diffusion is still effective in producing a single T_1 and it can be seen that compared to the pure dry fibres the drop in T_1 accompanying the increase in chain motion in the vicinity of the T_g is more pronounced. Finally, in order to confirm that paramagnetic effects were responsible for relaxation behaviour in fibres containing manganous sulphate, T_1 values obtained at several temperatures for a sample with non-magnetic Mg^{2+} ions have been included in Figure 9. It can be seen that the presence of these ions has little, if any, effect on T_1 relaxation behaviour.

CONCLUSIONS

For wet nylon-6,6 fibres at ambient temperatures a mobile component is present in the pulsed n.m.r. signal which is similar to that observed in the dry fibres above $100^\circ C$. The temperature at which the mobile component appears was found to depend on water content, the depression in the transition being about $100^\circ C$ on saturating the fibres. This behaviour is due to plasticization of the amorphous regions of the fibre by water molecules corresponding to mobilization of 'non-crystalline' chain segments above their glass transition temperature i.e. the α_g -process. The growth of mobile fraction with increase in temperature and moisture indicates that in contrast to the behaviour for completely amorphous polymers more segments take part in the α_g -process as the free volume is increased after the transition. This is consistent with some of the morphological features of recent chain folded models of fibre structure in which chain loops, chain ends and tie molecules forming the non-crystalline material are constrained to different extents through their attachments to crystallites. The influence of fibre morphology on the mobility properties of chain segments is also reflected in the relaxation behaviour of the fibres. T_1 relaxation of the crystalline segments in dry fibres is dominated by processes occurring in the amorphous regions such as the γ -process, which shows an efficient spin diffusion or relaxation averaging process between both arrangements of chain segments. In D_2O soaked fibres it is concluded that spin diffusion only operates between crystallites and those amorphous segments which are not plasticized by D_2O molecules, i.e. some of the folds on the crystallite surface. When Mn^{2+} ions are introduced into the fibre samples the relaxation behaviour of both the amorphous and crystalline segments is strongly influenced by paramagnetic effects, indicating that some of these ions are able to reach the water accessible segments between and on the surfaces of the crystallites.

Dissolution of polypropylene in organic solvents: 2. The steady state dissolution process

D. A. Blackadder and G. J. Le Poidevin*

Department of Chemical Engineering, University of Cambridge, Cambridge CB2 3RA, UK
(Received 31 March 1976)

This paper is part of a series describing the dissolution of solid polypropylene in organic solvents. A previous paper distinguished between two types of dissolution. (a) At sufficiently low temperatures dissolution is partial and only a limited amount of polymer dissolves, the rate of dissolution falling to zero. (b) At higher temperatures and in suitable solvents dissolution occurs continuously at a constant rate. The present paper is concerned with the details of (b). Steady state dissolution is preceded by an induction period during which solvent penetrates the solid polymer to some characteristic depth. The rate of dissolution is measured by gravimetric analysis of the dilute solution surrounding a rotating disc of solid polymer. The variables considered include polymer density, stirring speed and temperature. From the results it is possible to identify the rate-determining stage of the dissolution. Depending on the conditions this is either the rate at which polymer molecules escape from a solvent-swollen surface layer, or the rate at which solvent penetrates and destroys crystallites in the solid polymer.

INTRODUCTION

Substantial differences exist between the dissolution behaviour of micromolecular and macromolecular substances. The former have been studied in great detail and it is well known that dissolution takes place through a liquid boundary layer with little or no penetration of the solid matrix by the solvent. The concentration of solute at the solid/liquid interface is that of an equilibrium saturated solution at the temperature of the system, and this concentration falls through the boundary layer to the bulk solution value which may be effectively zero.

The molecular entanglement characteristic of high polymers has a pronounced effect on the dissolution rate. Solvent may penetrate deeply into the solid structure while molecules at the surface disentangle themselves sufficiently to 'float' out into the solution. There is certainly a polymer-rich mixed phase in the solid as well as a liquid boundary layer, and some degree of swelling is often observed in the form of a surface gel. Most of the work on polymers so far has been concerned with polystyrene¹⁻⁹ or poly(methyl methacrylate)², both amorphous, or with the very low crystallinity polymer poly(vinyl chloride)¹⁰. The semi-crystalline ester poly(ethylene succinate) has also received some attention^{2,11} and a few results are available concerning the partial dissolution of polyethylene¹². In the present paper it will be convenient to interpret the dissolution of polypropylene on the basis of a comparison with the well-documented features of the dissolution of amorphous polymers. It is therefore necessary to summarize briefly the findings of other authors.

An amorphous polymer dissolves in two stages: an induction period^{1,8,10,13} during which the rate of dissolution build up is followed by a steady state regime where the rate is essentially constant for a fixed area of dissolving polymer. Ueberreiter and Asmussen have identified the

induction period or swelling time as being related to the thickness of the total surface layer system and to an average diffusion coefficient for the solvent penetrant⁸. The stationary state would be represented by a straight line on a plot of penetration depth of solvent into polymer against time, the depth, s , being measured from a fixed reference plane parallel to the flat surface of the receding solid. The slope of the line is \dot{s} , the velocity of penetration, and extrapolation gives the induction time as an intercept on the t axis. Alternatively it is possible to measure m , the mass of polymer dissolved at time t , and this approach would lead to \dot{m} as the measure of steady state dissolution rate. Ueberreiter and Asmussen⁴ have painstakingly described the complicated steady-state system of layers which is built up near the surface of the dissolving polymer, and their model takes account of the influence of temperature. It appears that the flow temperature, glass temperature and gel temperature of the polymer are of particular importance in defining regimes, the last-named being the temperature below which no surface gel is formed.

The dissolution of a semi-crystalline polymer is altogether more difficult to achieve than that of an amorphous polymer, and fewer solvents are suitable. The parallel between crystallization and dissolution has been discussed by many authors since the original suggestions of Tamman¹⁴. In the polymer context it has been shown that under appropriate conditions single crystals of polyethylene will first undergo some dissolution then the dissolved material recrystallizes with a longer fold length than previously^{15,16}. Steiner *et al.*¹¹ used poly(ethylene succinate) to demonstrate a marked correspondence between the temperature of the maximum rate of crystallization¹⁷ and the maximum rate of dissolution. Some work on the effect of hot toluene on polypropylene¹⁸ has shown a dependence on morphology, which is at least qualitatively in line with expectations based on the rate of crystallization.

The present paper considers the steady state dissolution of polypropylene in hot organic solvents, with special refer-

ence to the effects of stirring rate, crystallinity, and temperature. The first paper of the series¹⁹ provided a description of the processes involved in the induction period, and a further paper will discuss the importance of polymer-solvent compatibility on a thermodynamic basis, as well as the effect of the molecular weight of the polymer.

EXPERIMENTAL

Materials

Polymer. The polymer used was a homopolymer, GXM 43, kindly supplied by ICI Plastics Division. The amount of atactic material present was estimated to be about 2 wt %, and the polymer contained the usual small amounts of antioxidant and stabilizer. In view of the relatively high temperatures used in some of the experiments these additives were welcome and no attempt was made to remove them. The polymer was quoted as having a melt flow index of 2.16 and a melt viscosity of 5.0×10^3 N sec/m at 190°C.

Solvents. The *p*-xylene was a 99% product obtained from ICI. The other organic solvents, of SR or AR grade, were used as received.

Procedures

Fabrication of specimens. For the main dissolution experiments it was necessary to prepare polypropylene discs

50 mm in diameter and 4.5 mm thick. 8 g of polymer chips were melted at 210°C for 1 h under vacuum in a special mould. The mould and contents were then quench cooled by immersion in a water bath. Cooling was not particularly rapid and the specimens were typically of density 905 kg/m³. For some purposes specimens were slow cooled from the melt temperature by controlling the input to the heater of the mould assembly. Another method of obtaining higher densities was to anneal quenched specimens for 2 h in the mould itself at an appropriate temperature followed by slow cooling.

Check on polymer degradation. The polypropylene was inevitably subjected to fairly severe conditions during fabrication of specimens and in the dissolution experiments involving hot solvents. It was therefore desirable to check for degradation, and a technique was not adopted on a routine basis until it had been shown that no detectable degradation was caused by the use of that technique. The test was to measure the specific viscosity of a solution of the polymer in a given solvent at fixed temperature and concentration.

Characterization of specimens. Infra-red and density measurements were carried out to assess crystallinity. For the former a Perkin-Elmer Infracord Spectrometer was used, and for the latter a density gradient column with *p*-xylene and chlorobenzene as the column liquids.

Apparatus for dissolution measurements

The apparatus is shown in Figure 1. The flat-bottomed cylindrical vessel was provided with a set of stainless steel baffles designed to prevent the formation of a vortex beneath the spinning disc. The baffle assembly was removable for thorough cleaning between runs. The disc of polypropylene was held in a rimmed plate by means of three retaining screws in the rim. The disc protruded about 1 mm beyond the rim, a slight ambiguity concerning the area of the dissolving polymer being preferable to the possibility of stagnant zones forming if the disc were significantly recessed. Dissolution was assumed to occur over the area represented by one side of the disc. The rimmed plate was attached to one end of an axle with the other end being driven by a variable speed motor.

It was important not to expose a polymer disc to heat or solvent unduly before the start of a timed experiment, having characterized the specimen. The lower surface of the disc was about 40 mm above the bottom of the vessel which held about half a litre of solvent and was thermostatted in an oil bath to $\pm 0.05^\circ\text{C}$. In general runs were terminated when no more than 30% of the original specimen had dissolved.

After reviewing the methods of following the dissolution process used by other workers^{1,10,13,20} and trying a few of these, it was decided to rely on a very simple gravimetric procedure. Up to 10 samples of solution were withdrawn at intervals into a 20 cm³ pipette and transferred to weighed aluminium foil dishes. The solvent was evaporated off in an oven for 12 h at 80°C. The amount of polymer was then found by reweighing. The time of each sample was taken as the midpoint of the 10 sec required for sampling. The initial volume of solvent was generally 550 cm³ measured at room temperature, and corrections were applied to allow for expansion to the operating temperature. The amount of solvent, even after removal of all the samples, was sufficient to ensure that the solution was always very dilute with respect to polymer. Indeed the polymer was

Figure 2 Dissolution of polypropylene in *p*-xylene at 120°C for various densities; stirring speed 1000 rev/min, disc diameter 50 mm. □, Run 1, 904.7 kg/m³; X, Run 2, 909.0 kg/m³; ○, Run 3, 910.8 kg/m³; ●, Run 4, 913.5 kg/m³; ■, Run 5, 913.0 kg/m³; ▲, Run 6, 914.7 kg/m³

virtually dissolving into pure solvent all the time. It is easily shown that m , the amount dissolved after time t , is given by:

$$m = \left[\frac{Vd_A}{vd_B} - (n-1) \right] m_n + \sum_{x=1}^{n-1} m_x$$

In this equation:

- V = initial volume of solvent at room temperature,
- d_A = density of solvent at room temperature,
- v = volume of sample at temperature of experiment,
- d_B = density of solvent at temperature of experiment,
- n = number of samples taken up to time t ,
- m_n = mass of polymer in n th sample,
- m_x = mass of polymer in x th sample.

The weight of polymer in each extracted sample was in the range 5 to 150 mg, increasing with t . Near time zero the error was about $\pm 2\%$ but much less in the later stages of an experiment.

The results of an experiment are in the form of values of m for different values of t and, where appropriate, the slope of a plot of the data, \dot{m} , may be regarded as a good measure of the rate of dissolution. Values of \dot{m} from different experiments are directly comparable because, with the exception of experiments designed to test the effect of disc size, the same type of disc was used throughout. The reproducibility of \dot{m} in separate experiments was better than 5%.

RESULTS AND DISCUSSION

General aspects of the dissolution

Figure 2 shows the dependence of m , the mass of polypropylene dissolved, on the immersion time, t , in *p*-xylene at 120°C for a range of specimen densities, each measured at 23.6°C in the gradient column prior to a dissolution experiment. After an initial period during which the dissolution rate gradually increases, the process enters a steady state in which the rate, \dot{m} , holds constant for several minutes. (Some experiments were continued into a further period of accelerating dissolution rates but these experiments do not appear in Figure 2. Discs subjected to this final stage were deeply pitted by erosion which increased the effective area of exposed surface in an irregular way.) The existence of an induction period followed by a steady rate of dissolution suggests a similarity between the behaviour of amorphous and semi-crystalline polymers. There is, however, a difference in the significance of density for the two kinds of polymers. At any given temperature the density of an amorphous polymer is more or less fixed and predictable, whereas the density of a semi-crystalline polymer is dependent upon its thermal history and is controllable within limits. Figure 2 shows that the dissolution rate of polypropylene tends to increase with decreasing density but in a non-simple manner due to the intrusion of other effects.

Runs 1 and 2 gave similar values of \dot{m} yet the densities of the specimens were different. Since the specimen for Run 1 was prepared by quench cooling it might be thought that a substantial density increase occurred as a result of annealing during the dissolution experiment itself. However, subsidiary experiments with i.r. showed that the crystallinity of both specimens remained unchanged on heating to the temperature of the dissolution experiments. Only on subsequent cooling to room temperature at the end of the experiment did the specimen used in Run 1 show a rise in density, while the density of the specimen from Run 2 remained substantially the same on cooling. The latter observation is explained by the fact that the specimen had experienced a higher temperature (130°C) during the dry annealing which formed part of its initial fabrication than in the subsequent dissolution (120°C). For sufficiently low densities it would therefore appear that the rate of dissolution is actually independent of density and this is borne out by the more detailed results which appear later on.

Runs 4 and 5 also require special comment. The specimens had the same density but were prepared by different methods. (The specimen for Run 4 was quench cooled then annealed at 155°C, while the other was slow cooled from the melt at 10°C/h). The results suggest that for densities of this magnitude the effect of preparative method is wholly subordinate to the effect of density in determining the rate of dissolution.

Figure 3 shows the effect of initial specimen density on the steady dissolution rate, \dot{m} , at various temperatures. Each curve has been extrapolated to intersect the density axis at zero dissolution rate, though it is known from Part 1 of the series¹⁹ that partial dissolution can occur at a slow and ever-diminishing rate even at densities greater than the 'intercept' value for a given temperature. Figure 3 is nevertheless correct in that it shows steady state dissolution rates, and these do genuinely tend to zero at characteristic densities. For a given temperature the dissolution which

Figure 3 Rate of dissolution of polypropylene in *p*-xylene at various temperatures as a function of density; stirring speed 1000 rev/min, disc diameter 50 mm. ■, 130°; ●, 125°; □, 120°; ○, 115°; X, 110°C

can occur at densities above the intercept value is fractional rather than wholesale, and its rate eventually falls to zero for any given specimen.

Figure 4 shows schematically the dependence of dissolution rate on density for both steady state dissolution and fractional dissolution. For the latter runs, characterized by the plot of m against t being concave to the time axis, the recorded \dot{m} is the slope of the tangent at time zero, and it was noticeable that the surfaces of the discs did not recede. Some material evidently dissolved out but the overall structure was maintained by the larger insoluble molecules. The gradual slowing up of any fractional dissolution is due to the fact that removal of soluble polymer becomes increasingly difficult as it has to be leached from deeper levels in the disc.

Figure 5 provides an example where the specimen density of 917.9 kg/m³ slightly exceeded the intercept density of 915.7 kg/m³ read off Figure 3 for the temperature concerned. It is interesting to note that 120°C is virtually the thermodynamic dissolution temperature, T_s , for polymer having the intercept density.

A further demonstration of the nature of fractional dissolution is provided by the following simple experiment. A disc of density 916.2 kg/m³ was suspended motionless in excess *p*-xylene at 120°C. Figure 3 would predict the absence of steady state dissolution for such a specimen. After 4 days the original disc outline remained despite a weight loss of 33%, but the specimen was probably on the verge of dissolving completely in view of the replacement of the smooth surface by a rough gel which could be scraped off easily. Viscometric measurements were carried out on specimens obtained from the original polymer, the interior of the disc after dissolution, and dissolved polymer. For

0.25% w/v solutions in decahydronaphthalene at 135°C the values of η_{sp} were 0.692, 0.738 and 0.250 respectively, thus providing clear evidence for fractionation.

It must be emphasized that the intercepts on Figure 3 have a significance only for relatively short experiments. Considerable morphological changes occur on annealing polypropylene in solvents at temperatures between ambient and T_s (see ref 19). If the dissolution were slow enough it is conceivable that solvent could penetrate right to the back of a disc during an experiment with ambiguous consequences. In addition the excessive swelling so caused could lead to buckling of the disc in its holder. Indeed this tended to occur after 30 min or so however high the dissolution rate, which is a further reason why data such as in Figure 3 should be based on fairly short experiments.

For homopolymers the linear growth rate, G , of spherulites in the vicinity of T_m , the melting point, follows a relation of the form:

$$\ln G = \text{constant} - \frac{C_1 T_m^n}{RT_c(T_m - T_c)^2}$$

where $n = 1$ or 2, C_1 is a term involving interfacial energy and heat of fusion terms, and T_c is the temperature of the crystallization. Qualitatively the curves on Figure 3 appear to follow a similar relationship if T_c and T_m are replaced by

Figure 4 Schematic diagram of dissolution rate as a function of density showing regimes of wholesale and fractional dissolution. ●, Wholesale dissolution; X, fractional dissolution

Figure 5 Fractional dissolution of polypropylene in *p*-xylene at 120°C; specimen density 917.9 kg/m³

Figure 6 Effect of T_{diss} and T_s on the rate of dissolution of polypropylene in *p*-xylene; stirring speed 1000 rev/min, disc diameter 50 mm

T_{diss} and T_s , where T_{diss} is the actual temperature of a dissolution experiment and T_s is the thermodynamic dissolution temperature. Modification of the above equation, putting $n = 1$, gives:

$$\ln \dot{m} = \text{constant} - \frac{KT_s}{(T_{diss} - T_s)T_{diss}}$$

and this is plotted in Figure 6. A good straight line is obtained, but regrettably this does not exclude fractional powers of n around unity, and indeed the fit is only marginally less satisfactory for $n = 2$. It well illustrates the difficulty of matching theory to experiment in this context.

In their work on poly(ethylene succinate) Steiner *et al.*^{2,11} were able to show quite an impressive correlation between the maximum rate of dissolution and the maximum rate of crystallization. In the present work there was no evidence of an identifiable maximum rate of dissolution of polypropylene which is known to crystallize most rapidly round about 75°C²¹. This could well be because it was not possible to cool the relatively massive specimens quickly enough to prevent most of the crystallization occurring at temperatures well above 75°C. If typical water cooled discs were annealed at 110°C there was no change in density and even at 130°C the density change was very small, thus confirming the view that the original cooling allowed crystallization at quite high temperatures.

Modelling the dissolution process

The dissolution process may be described broadly in terms of the following steps which, at the steady state, are occurring at characteristic depths in the dissolving polymer. (a) Penetration and swelling of the non-crystalline regions by solvent. (b) Penetration of the crystalline regions by solvent with subsequent destruction of crystallites. (c) Dilution, disentanglement and final escape of the polymer molecules into solution.

The first step is certainly not rate-controlling: it has been shown previously¹⁹ that the rate of penetration actually increases with specimen density, whereas quite the opposite trend is observed for the rate of dissolution. If step (c) controls, the previous thermal history should be unimportant since the polymer which is exposed to the bulk solvent is essentially in the amorphous state. On the other hand if step (b) dominates, the structure of the specimen

should assert itself and the dissolution rate should be a function of annealing temperature or density. Evidence for separate regimes for control by (b) and (c) is discussed in detail in the next section. At this point it is appropriate to try to identify the fundamental parameter involved in a crystallite destruction controlling step.

The thermodynamic dissolution temperature, T_s , is controlled by fold length as shown by Flory²², and one would certainly suppose that material with a longer fold length would be more resistant to solvent attack. Furthermore, Farrow²³ has established a correlation between fold length and annealing temperature for polypropylene. A six-fold change in fold length was also accompanied by a change of about 20°C in T_s according to the Flory equation. The present results are compatible with these facts since T_s was observed to cover a range of 20°C depending on specimen density or annealing temperature, and the changing fold length can explain this variation if Flory's analysis is sound.

Effect of stirring speed on dissolution rate

For the dissolution of microcrystalline solids many authors have obtained relationships of the form:

$$\dot{m} = n^x + C$$

where \dot{m} is the dissolution rate, C is its value at zero stirring speed and n is the actual rate of stirring. The exponent x lies between 0.4 and 1, with most values around 0.5.

Spalding²⁰ has shown from theoretical considerations that in the laminar regime the rate of a diffusion controlled dissolution is proportional to $n^{0.5}$, all other parameters being fixed. The exponent of 1 sometimes observed²⁴ for higher stirring speeds is probably an indication of non-laminar flow.

Figure 7 shows the effect of stirring speed on the dissolution of polypropylene in *p*-xylene at 120°C. All of the discs were prepared by annealing quenched specimens, and their densities were 909, 913 and 914 kg/m³. There are two distinct dissolution regimes, one in which the rate of dissolution rises with stirring speed and another in which the rate of dissolution is constant.

The fact that the plot of rate of dissolution against stirring speed is linear for the specimen of density 909 kg/m³ suggests that the flow is turbulent. The Reynold's number for a rotating disc is given by

$$\text{Re}_{\text{rot}} = \frac{\Omega \rho d^2}{\eta}$$

where Ω is the rotation speed in radians per unit time, ρ is the fluid density, d is the disc diameter and η the liquid viscosity. Taking η to be the viscosity of the pure solvent, Re_{rot} varied from 1.1×10^5 at 150 rev/min to 7.2×10^5 at 1000 rev/min. For other systems turbulent flow is known to occur²⁰ when Re_{rot} is about 8×10^5 , and in the present apparatus turbulence could be induced at lower values by the presence of flow-disturbing baffles and vibration in the stirrer. It is likely, therefore, that turbulent flow existed.

Ueberreiter and Kirchner¹ have shown that for amorphous polymers the dissolution rate rises with stirring speed. This was attributed to a reduction in the thickness of the swollen layer, rather than to a change in the average diffusion coefficient of the permeant into the polymer since the latter is presumably independent of stirring rate. Likewise crystallite destruction should not depend on stirring speed. In a sense the interplay between disentanglement

Figure 7 Effect of stirring speed on the rate of dissolution of polypropylene in *p*-xylene at 120°C for various densities; disc diameter 50 mm. ○, 909 kg/m³; □, 913 kg/m³; X, 914 kg/m³

Figure 8 Effect of density on the rate of dissolution of polypropylene in *p*-xylene at 120°C for various stirring speeds; disc diameter 50 mm. ○, 1000 rev/min; □, 500 rev/min; X, 250 rev/min

and crystallite destruction mechanisms gives rise to a situation similar to that involving transport processes and chemical reaction, with the destruction of crystallites replacing chemical reaction. At high enough stirring speeds the dissolution rate should flatten off, and this is observed for the 913 and 914 kg/m³ curves on Figure 7. The existence of a regime of rising dissolution rate with stirring speed indicates that the controlling step under these conditions is the disentanglement of polymer chains. It will appear later that this is accompanied by the formation of a gel layer and the polymer therefore resembles amorphous polymer in its behaviour. The similarity is reinforced by Figure 8

which shows the effect of density on dissolution rate at three stirring speeds. At 250 and 500 rev/min the dissolution rate is virtually constant over the density range 905 to 914 kg/m³. This is not the case at 1000 rev/min, though there are signs of flattening out at the lower densities. In regions of constant dissolution rate the fraction of crystalline material (and fold length) does not affect the rate because the stirring speed is too low. It can be imagined that solvent penetrates the polymer very quickly and destroys the crystalline structure, but the amorphous phase so created is still in a very tangled state and the disentanglement process is rate controlling. A result of this is the formation of a gel layer whose thickness actually controls the rate. In other circumstances the rate of destruction of crystallites is the slowest process and so rate controlling. The overall rate of dissolution will decrease with increasing density in this regime because the rate of destruction of crystallites is sensitive to density or fold length. The extent of the gel layer should decrease with increasing density and there is direct experimental evidence for this. A quenched disc, removed from the holder of the dissolution apparatus immediately after a run at 500 rev/min and 120°C, had a surface layer which was extremely tacky and easily scraped off. In addition there were whorls on the surface suggesting bulk movement of a highly viscous gel layer. The amount of polymer which could be scraped off denser discs was smaller and on the specimen of highest density whorls were conspicuously absent. Indeed there may have been no gel layer whatever.

Figure 9 shows schematically the surface layer structure of dissolving polypropylene where ρ_t refers to the density at the transition between constant and changing dissolution rate at a given temperature. The layers are not, of course, individually homogeneous. In the swollen crystalline layer, for example, the crystallinity varies from the dry polymer value on the extreme left to zero at the next interface whatever it might be. It is plausible that when a large amount of solvent is present in the swollen crystalline layer ($T_{diss} \approx T_s$) the macromolecules may be sufficiently disentangled at the outer face of this layer to pass directly into solution without forming a gel layer. Conversely, when the solvent content of the swollen crystalline layer is everywhere fairly low, a gel layer will become necessary to round off the process.

Figure 10 Effect of temperature on the rate of dissolution of propylene in *p*-xylene for various densities; stirring speed 1000 rev/min, disc diameter 50 mm. ○, 904.7 kg/m³; □, 911.0 kg/m³; X, 914.0 kg/m³; ●, 915.0 kg/m³

Effect of temperature on the dissolution rate

Figure 10 shows an Arrhenius plot of $\ln \dot{m}$ against $1/T_{diss}$ for polypropylene and *p*-xylene. Ueberreiter and Asmussen⁴ and Lapčik and Valko¹⁰ have shown that the systems polystyrene–toluene, polystyrene–amyl acetate and poly(vinyl chloride)–cyclohexanone give straight lines when the data are plotted in this manner. For a semi-crystalline polymer such as polypropylene the situation is rather more complicated. It is significant that for a density of 904.7 kg/m³ (the lowest available density, obtained by quench cooling) a straight line can be drawn through the points for the three highest temperatures. In this region each run was repeated at each temperature and the reproducibility was very good.

It is interesting to compare values of the apparent activation energy of dissolution, E_S , for amorphous polymers and polypropylene. E_S can be determined from $\dot{m} = \dot{m}_0 \exp(-E_S/RT)$ where \dot{m} is the observed dissolution rate at temperature T_{diss} and \dot{m}_0 is the value at infinite temperature. For polystyrene–toluene and polystyrene–amyl acetate Ueberreiter and Asmussen⁸ obtained 15.9 and 25.1 kJ/mol for E_S , and Figure 10 gives a value of 31.4 kJ/mol for quenched polypropylene at the higher temperatures. For the poly(vinyl chloride)–cyclohexanone system Lapčik and Valko obtained values of E_S ranging from 30 to 50 kJ/mol depending on the molecular weight¹⁰. When, as in the present work, E_S usually varies with temperature it is instructive to consider the form of the variation. Figure 10 shows clearly that E_S , considered in terms of point values, increases with density at any selected temperature, and varies with temperature for quenched polymer below 120°C and at all temperatures if the density exceeds 909 kg/m³. This can be explained as follows. Higher densities, produced at higher crystallization or annealing temperatures, are associated with crystallites having longer fold lengths^{23,25}. These crystallites may be expected to present larger energy barriers to diffusing molecules.

As the temperature increases the curves on Figure 10 appear to converge, though it is not possible to be sure from the data available. If there is indeed a common line above 137°C or so this would imply that the disentanglement step is controlling regardless of density.

Effect of disc size on dissolution rate

Figure 11 shows $\ln \dot{m}$ plotted against $1/T_{diss}$ for disc diameters of 25 and 50 mm and stirring rates of 500 and 1000 rev/min. Good straight lines of similar slopes can be drawn through the higher temperature points and the values of E_S so obtained range from 27.2 to 31.4 kJ/mol, with an average of 28.9 kJ/mol. The variation is within experimental error, the range of accessible temperatures being only 15°C. Temperatures higher than 135°C were not practicable because *p*-xylene boils at 138°C. Table 1 shows how disc size affects the dissolution rate at fixed stirring speed and temperature. The subscripts refer to the disc diameter in mm. If the local rate of dissolution were the same at all points on the surface of a disc, then doubling the diameter would simply quadruple the exposed surface area and produce a $\dot{m}_{50}/\dot{m}_{25}$ ratio of 4:1. In fact the ratio is about 4.9:1 and direct observation provided an explanation in terms of varying local rates. The 25 mm discs dissolved evenly over the whole surface, while 50 mm discs were noticeably thinned at the edges compared with the centres of the discs.

Figure 12 Swelling time for polypropylene in *p*-xylene at various temperatures as a function of density; stirring speed 1000 rev/min, disc diameter 50 mm. ●, 125°C; □, 120°C; ○, 115°C; X, 110°C

Effect of temperature and density on the swelling time

Figure 12 shows the swelling time, t_q , plotted against the density. (t_q was obtained by extrapolating the linear portion of the plot of m against t to make an intercept at zero m .) Decreasing the temperature and increasing the density both lengthen the swelling time. At low densities t_q is clearly very small (30–50 sec) even with an error of ± 15 sec. At sufficiently high temperatures the induction period for dissolution of poly(vinyl chloride) was virtually non-existent, an important clue to the behaviour of polypropylene. The relative flatness of the curves on Figure 12 at low densities may be associated with the fact that disentanglement controls the ensuing steady state just as for amorphous polymers. On the other hand, as the density increases so does t_q , crystallite destruction being dominant in the resulting steady state. If the crystallites are more resistant to solvent attack when the density is higher, then more swelling is required to bring about their destruction. In its general shape Figure 12 is seen to be an inverted mirror image of Figure 3, thus illustrating a connection between an induction period and the steady state to which it leads.

There are at least two effects which indicate caution in the interpretation of absolute values of t_q . First it might be thought that there are structural differences between the surface of a disc and its interior, but thin sections cut from these places showed that density, at least, was independent of position. Secondly, since discs were not pre-heated before plunging them into hot solvent at the start of a run it might be that swelling time and heating up time are connected. The surface of the disc will heat up almost instantaneously, but there will certainly be a small drop in the liquid temperature due to the thermal capacity of the poly-

mer disc and its holder. In practice it was convenient to set the solvent temperature about 2°C above that actually required for a run, since this offset the fall in temperature. The desired temperature was maintained by adjusting the bath heater. At worst the thermal capacity effect could introduce an uncertainty into t_q of less than 30 sec, and the trend of increasing t_q with increasing density and decreasing temperature is too marked to be obscured by these experimental shortcomings.

CONCLUSIONS

(1) Like amorphous polymers, polypropylene dissolves according to a two-part rate curve. There is first an induction period during which the rate of dissolution gradually increases, and this is followed by a period in which the rate is essentially constant. The length of the induction period increases with increasing density and decreasing temperature.

(2) The rate of wholesale dissolution at a given temperature is constant only over a limited range of lower densities, the breadth of this range being greater at higher temperatures. For any fixed temperature the rate eventually falls for specimens of sufficiently high density, and the rate curve extrapolates to zero at a density value which increases with temperature. This behaviour can be best explained in terms of an increase in the fold length of the chains which accompanies an increase in density. Specimens whose densities exceed the 'zero-rate intersection density' for a given temperature dissolve to some extent, though the process is quite different being a matter of fractionation or selective leaching rather than wholesale dissolution. The rate of a fractional dissolution process inevitably falls off with time since the soluble material (atactic and low molecular weight isotactic) must be leached out from ever deeper levels of the specimen.

(3) For polypropylene discs dissolving in *p*-xylene at 120°C there is a linear relationship between dissolution rate and stirring speed for a specimen density of 909 kg/m³. In these circumstances the rate controlling step appears to be molecular disentanglement in a gel-like surface layer of swollen polymer. At higher densities the linear relationship is visible only at low stirring speeds. When the rate becomes independent of stirring speed it appears that the rate of destruction of crystallites controls the overall rate of the dissolution.

(4) The temperature dependence of the dissolution rate of polypropylene is such that it resembles amorphous polymers only at the highest temperatures and for specimens of lowest density. Otherwise the activation energy for dissolution varies a good deal, and curvature of the Arrhenius plots is attributed to the controlling influence of crystallite destruction.

(5) T_s and T_{diss} are important for dissolution in just the way that T_m and T_c are important for crystallization.

Relative rate constants during the hydrolysis of syndiotactic poly(methyl methacrylate) with base*

Volker Barth and Ernst Klesper

*Institut für Makromolekulare Chemie, Universität Freiburg, D-78 Freiburg, W. Germany
(Received 8 January 1976; revised 5 March 1976)*

The relative rates of appearance and disappearance of triads of monomer units during the hydrolysis of syndiotactic methyl methacrylate/methacrylic acid copolymers in aqueous solution with excess base are studied by proton n.m.r. The relative rate constants are determined from these data using a graphical method. The measured relative rates and rate constants are consistent with a mechanism wherein COO^- retards the attack of OH^- . There is, however, a mechanism change indicated on consumption of OH^- during hydrolysis. The COOH which are then formed apparently participate in an intramolecular mechanism. The change of mechanism is accompanied by a change in copolymer statistics, i.e. from alternation tendency to block character. The lack of temperature dependence of the relative rate constants during the hydrolysis with OH^- as the active species leads to the conclusion that enthalpies of activation are equal for the three reacting triads. Thus the differences found between the relative rate constants are entropic in origin.

INTRODUCTION

Diesters and monoesters of dicarboxylic acids may serve as model substances for the hydrolysis of polymeric esters. Particularly during the hydrolysis of monoesters large cooperative effects influence the kinetics in many instances. These cooperative effects may also be present during the hydrolysis of polymeric esters since with progressive hydrolysis an increasing number of carboxyl or carboxylate groups is introduced. The hydrolysis of the esters of dicarboxylic acids has been frequently studied¹⁻³ and it was found that alkyl esters have widely differing rates for the hydrolysis of the first and the second ester group⁴⁻⁶. This was explained by the electrostatic repulsion between COO^- and the OH^- reacting with the second ester group^{3,7-10}. General base catalysis and nucleophilic attack by neighbouring COO^- appears not to have been found in the alkaline range with alkyl esters of saturated aliphatic dicarboxylic acid. This is in keeping with the known ineffectiveness of COO^- as a general base or nucleophile for the hydrolysis of alkyl esters of saturated monocarboxylic acids¹¹.

For the hydrolysis of atactic methyl methacrylate/methacrylic acid copolymers in aqueous solution with excess base, it has been postulated that the slowing down of the rate and limiting conversion is due to the electrostatic repulsion between the negatively charged carboxylate on the chain and the OH^- attacking the ester groups¹². Copolymers were used as starting materials because poly(methyl methacrylate) is insoluble in aqueous base. For the hydrolysis of syndiotactic methyl methacrylate/methacrylic acid copolymers it was shown by n.m.r. determination of the triads of monomer units that the hydrolysis leads to a statistics of monomer units with a pronounced tendency of alternation^{13,14}. This was attributed also to electrostatic repulsion between the carboxylate and the OH^- attacking the next neighbouring ester group. With

some exceptions^{13,14} most studies of reactions on vinyl polymers relied on measurements of the gross composition of the polymer during the reaction. The probabilities of triads for tactic methyl methacrylate/methacrylic acid copolymers can be evaluated by ^1H n.m.r. and ^{13}C n.m.r.¹³⁻¹⁶. The probabilities of the sequences during hydrolysis gives information on the distribution of hydrolysed and unhydrolysed monomer units along the chain and this is intimately linked with the basic features of the mechanism of hydrolysis. Also, more reliable determinations of the rate constants for the individual sequences might be possible than with measurements of the change of gross composition alone. In this communication the conversion dependent rates of the hydrolysis of triads are studied in detail, (a short account has been previously published¹⁷) and the conversion dependent (relative) rates are evaluated to yield the relative rate constants.

RESULTS

The kinetic runs were carried out with a syndiotactic methyl-methacrylate/methacrylic acid (MMA/MAA) copolymer, possessing Bernoullian (random) compositional statistics. The use of 'prehydrolysed' syndiotactic PMMA, instead of PMMA itself, is necessary to obtain a homogeneous solution of the polymer in the aqueous base. Having Bernoullian compositional statistics is an advantage since it is uniquely defined, easily calculated, and because any cooperative character of the kinetics will be revealed immediately during the kinetic runs by a deviation of the measured sequence probabilities from calculated Bernoullian sequence probabilities. The starting copolymers are characterized by the probability of A-monomer units, $P(\text{A})$, ($\text{A} = \text{MMA}$) the probabilities of configurational triads, $P(\text{ss}) = 0.92$ and $P(\text{is}^+) = 0.08$, and the weight-average molecular weight \bar{M}_w ($s = \text{syndiotactic placement}$, $i = \text{isotactic placement}$; the $^+$ sign indicates inclusion of both forms of the sequence, in this case is and si). The copolymers are then dissolved in aqueous KOH and the kinetic

* Dedicated to Professor H. Kämmerer on the occasion of his 65th birthday.

Figure 1 Probabilities of triad AAA, $P(AAA)$, versus conversion parameter, $P(A)$. Initial Bernoullian copolymer $P(A) = 0.83$. \bullet , 0.5; \blacksquare , 1; \blacktriangle , 1.5; \circ , 3; \square , 5; \triangle , 7 mmol KOH. —, Calculated for Bernoullian statistic from experimental $P(A)$

runs carried out by heating a number of ampoules to 145°C for specified periods. The products were characterized by determining $P(A)$ and the probabilities of the compositional triads [$P(X_sX_sX)$ ($X = A, B$; $B = \text{MAA monomer units}$)] from the α -methyl resonance of the ^1H n.m.r. spectra^{13,14}. In the following, the $P(X_sX_sX)$ are simply written as $P(XXX)$ since only syndiotactic triads are considered. The small amount of $X_iX_sX^+$ is assumed to possess only a small kinetic effect. Plots of $P(XXX)$ versus $P(A)$, the latter being chosen as a convenient conversion parameter, results in graphs which are dependent on relative rates and relative rate constants, but not on absolute rates and absolute rate constants¹⁸.

Starting with a Bernoullian copolymer of $P(A) = 0.83$ with $\bar{M}_w = 100\,000$ (copolymer No. 6 of Table 4) the kinetic runs resulted in $P(XAX)$ vs. $P(A)$ data which are shown as points in Figures 1 to 3. The total amount of KOH (mmol) indicated, is present at the start of the hydrolysis run and includes the amount of KOH necessary for the neutralization of the $-\text{COOH}$ groups of the MAA-units. The broken curves were drawn to give the best fit through the experimental points and, at the same time, to obey the statistically necessary relations¹⁹:

$$P(A) = P(AAA) + P(AAB^+) + P(BAB) \quad (1a)$$

$$P(B) = 1 - P(A) = P(BBB) + P(ABB^+) + P(ABA) \quad (1b)$$

$$P(ABB^+) + 2P(ABA) = 2P(BAB) + P(AAB^+) \quad (2)$$

Equations (1) and (2) are independent of the mode of formation of a copolymer, and are therefore suitable for correcting the experimental triad probabilities for errors which stem from the n.m.r. measurements, particularly the errors caused by incorrect separation of areas of overlapping triad peaks. The full curves in Figures 1 to 3 represent Bernoullian $P(XAX)$ calculated from the measured $P(A)$.

The conversion dependent kinetic behaviour does not depend on the initial amount of KOH, if the amount of KOH is 3, 5 and 7 mmol. Some data collected with 10 and 20 mmol KOH indicated that this appears to hold also for these much higher KOH concentrations. The kinetic behaviour does, however, depend on the amount of KOH when only 0.5, 1.0 and 1.5 mmol KOH are initially present. This dependence of the relative rates on the initial amount of

KOH, at low KOH concentrations, is due to a change in relative rate constants which in turn is due to a change in the cooperative mechanism. The dependence is clearly connected with the consumption of OH^- during the kinetic runs. With 1.0 and 1.5 mmol KOH the excess of OH^- initially present at $P(A) = 0.83$ ($t = 0$) can be calculated to be consumed at $P(A) = 0.61$ and $P(A) = 0.41$. Inspecting Figures 1 to 3 shows that up to these conversions the experimental points for 1.0 and 1.5 mmol KOH follow the main curve, i.e. the common curve for 3, 5, and 7 mmol KOH, and then form separate branches. With 0.5 mmol KOH at $P(A) = 0.83$, there is no excess OH^- present from the start, since all KOH is needed for the neutralization of $-\text{COOH}$. Thus the experimental points immediately form a branch. In summary, it may be concluded that the relative rates are independent of $[\text{OH}^-]$, as long as OH^- is present in excess.

The branches of the main curve, occurring with 0.5, 1.0, and 1.5 mmol KOH, are connected with the fact that not all carboxyl groups of the MAA-units are present as $-\text{COO}^-$ but some are present as $-\text{COOH}$. The proportion of $-\text{COOH}$ increases with increasing hydrolysis, that of $-\text{COO}^-$ remaining constant. The unneutralized MAA-units can partake in the reaction leading to a change in reaction mechanism and relative rates. Comparison with the Bernoullian curves shows that the main curves for excess of OH^- indicate a tendency towards alternation of the A- and B- units, while the branches indicate block character. More AAA and less BAB than corresponds to the Bernoullian curves may be taken as indicating block character and less AAA and more BAB as indicating a tendency towards alternation (Figures 1 and 3). However, no such simple connection apparently exists for AAB^+ (Figure 2). It is worth noting, that a unique relation between

Figure 2 Probabilities of triad AAB^+ , $P(\text{AAB}^+)$, versus conversion parameter, $P(A)$. Initial Bernoullian copolymer $P(A) = 0.83$. Symbols as for Figure 1

Figure 3 Probabilities of triad BAB, $P(\text{BAB})$, versus conversion parameter, $P(A)$. Initial Bernoullian copolymer $P(A) = 0.83$. Symbols as for Figure 1

Figure 4 Probabilities of dyad AB^+ , $P(AB^+)$, versus $P(A)$. Initial Bernoullian copolymer $P(A) = 0.83$. A, 3–7 mmol KOH; B, 1.5 mmol KOH; C, calculated from Bernoullian statistics from experimental $P(A)$; D, 1 mmol KOH; E, 0.5 mmol KOH

$P(\text{sequence})$ and a tendency towards alternation or block character may only be assumed for the behaviour of dyads. This may be seen as follows:

$$P(A) = P(AA) + P(AB) \quad (3)$$

$$P(A) = P(AA)_r + P(AB)_r \quad (4)$$

Where the $P(XX)_r$ are the Bernoullian probabilities. On subtraction:

$$0 = \Delta P(AA) + \Delta P(AB) \quad (5)$$

The $\Delta P(XX) = P(XX) - P(XX)_r$ are the deviations from Bernoullian probabilities at a given $P(A)$. Similarly one obtains:

$$0 = \Delta P(BB) + \Delta P(BA) \quad (6)$$

It follows with $\Delta P(AB) = \Delta P(BA)$ and $\Delta P(AB) + \Delta P(BA) = \Delta P(AB^+)$:

$$\Delta P(AA) = \Delta P(BB) = -0.5\Delta P(AB^+) \quad (7)$$

The deviation of each $P(XX)$ from the corresponding $P(XX)_r$ determines the deviations of the probabilities of the other two dyads at a given $P(A)$. Thus there is a unique relation between the experimentally found deviations from Bernoullian curves and the terms 'tendency toward alternation' and 'block character'. An equation similar to equation (7) does not exist for $P(XXX)$ for the most general case since at a given $P(A)$ the probabilities of three of the triads are independent while only the probability of one dyad is independent.

In Figure 4 the dyad probability $P(AB^+)$ is plotted versus $P(A)$. The $P(XX)$ have been obtained from the $P(XXX)$ by the usual relations based on the principle of stationarity^{20,21}. For $P(AB^+)$ there are two possibilities of reducing the triads to dyads:

$$P(AB^+) = 2P(ABA) + P(ABB^+) = 2P(BAB) + P(AAB^+) \quad (8)$$

for average values equation (9) was employed:

$$P(AB^+) = P(ABA) + 0.5P(ABB^+) + P(BAB) + 0.5P(AAB^+) \quad (9)$$

Inspection of the $P(XX)$ versus $P(A)$ data reveals that the necessary relation equation (7) is reasonably well obeyed. The $P(XX)$ vs. $P(A)$ plots are, together with the $P(XXX)$ data, necessary for the evaluation of relative rate constants.

A second set of kinetic runs was carried out with a Bernoullian copolymer of $P(A) = 0.60$ (copolymer No. 9 of Table 4), in order to show that the relative rate constants do not change when another starting copolymer is used.

In Figure 5 data are plotted for runs with 3, 5 and 7 mmol initial KOH in a similar way as for Figures 1 to 3. The scatter of the points in Figure 5 is reasonable and they are well fitted by the broken curves which have been drawn according to equations (1) and (2). As with Figures 1 to 3, there is no dependence of the data on the amount of excess OH^- .

The conversion dependent kinetics of the triads with excess OH^- , as shown in Figures 1–3, 5, could in principle be dependent on the molecular weight of the copolymers, the ionic strength of the solution, the concentration of the copolymer and the temperature. The molecular weight was varied from $\bar{M}_w = 100\,000$ to 650 000 and the ionic strength changed by the addition of 2 mmol KCl. Moreover, the concentration of copolymer was reduced to 1/2 or 1/4 and the temperature varied from 115° to 175°C. Within the investigated range, none of these variables appears, however, to influence the kinetics to any extent, which is outside the error of measurement.

Assuming that the A-centred triads are the kinetic units for the cooperative hydrolysis, then, if for a given A-centred triad the conformation and/or the solvation state changes with conversion, the rate constants might also change with conversion. A change in conformation and solvation should, however, make itself felt through the ^1H n.m.r. chemical shifts of the copolymers, if the spectra are recorded under conditions similar to hydrolysis. Figure 6 shows the ^1H n.m.r. spectra from $\text{D}_2\text{O}/\text{KOD}$ solutions of syndiotactic copolymers with Bernoullian compositional statistics. The copolymers cover the range of conversion with $P(A) = 0.83; 0.60; 0.37; 0.16; 0.00$. The spectra are recorded from solutions of 100 mg copolymer ($P(A) = 0.83; 0.60; 0.37$) or 50 mg polymer ($P(A) = 0.16; 0.00$) in 1 ml 0.8 N KOD. This is sufficient KOD for an excess of OH^- to prevail after neutralization of all MAA-units. The copolymer concentration is about 5 or 2.5 times the concentration used for hydrolysis, and, the temperature 80°C instead of 145°C. It is unlikely, however, that a change in conformation and solvation with conversion, if present, will appear less strongly at the higher concentration and the lower temperature used for the n.m.r. spectra.

Spectral trace A of Figure 6 shows that at $P(A) = 0.83$ the $-\text{OCH}_3$, $\beta\text{-CH}_2-$ and $\alpha\text{-CH}_3$ resonances are very broad. Decreasing the $P(A)$, however, shows that an acceptable resolution of sequences is possible. A maximum of three peaks appears in the $\beta\text{-CH}_2-$ and a maximum of four peaks in the $\alpha\text{-CH}_3$ resonance. The assignment of the $\beta\text{-CH}_2-$ peaks to dyads is straightforward by observing the change in intensity with changing $P(A)$. On the other hand, the assignment of the $\alpha\text{-CH}_3$ peaks is complicated by coin-

Figure 5 Probabilities of triads versus $P(A)$. Symbols as for Figure 1

cidence of triad resonances. In Table 1 the chemical shifts and relative peak intensities are shown for the peaks in the α -CH₃ resonance of the Bernoullian copolymers and a number of copolymers with alternation character which have been obtained from the kinetic runs. The agreement between the observed relative peak intensities and the expected peak intensities for the proposed assignment leaves little doubt that the assignment of the triads is correct as in Table 1 and trace B of Figure 6. The only strong deviation is seen for the Bernoullian copolymer of $P(A) = 0.60$. This may be connected with the inferior resolution of trace B but also with the possibility that the assignment changes at $P(A) = 0.60$. There exists a self-consistent set of shift differences governing the assignment. Both the replacements $XAX \rightarrow XB X$ (Table 1) ($X = A, B$) and replacements

$BXX \rightarrow AXX$ (Table 1) produce an upfield shift of 0.10 ppm. Having ascertained that the chemical shifts of the triads do not change with the $P(A)$ of the copolymers in the range $0.6 > P(A) > 0$, it is reasonable to assume an absence of change in conformation and solvation of triads in that range. Therefore, an invariance of rate constants with conversion may also be assumed. However, the broadening of the resonances at $P(A) = 0.83$ points to a collapse of the coiled chains with a concomitant reduction in conformational mobility. This collapse is apparently caused by poor solvation of longer blocks of A-units and raises the question of the accessibility of these A-units by the attacking OH^- . Consequently, the reaction rate constants may possibly be variable in the conversion range of $P(A) > 0.60$.

Figure 6 ^1H n.m.r. spectra of syndiotactic MMA/MAA copolymers of Bernoullian compositional statistics and different $P(\text{A})$. A, $P(\text{A}) = 0.83$; B, $P(\text{A}) = 0.60$; C, $P(\text{A}) = 0.37$; D, $P(\text{A}) = 0.16$; E, syndiotactic PMAA, $P(\text{A}) = 0$

DISCUSSION

The treatment of data is limited to that obtained with excess OH^- . The data obtained with less KOH than necessary to neutralize the MMA/MAA copolymers will be the subject of a future communication. With an OH^- excess statistics are obtained which deviate from Bernoullian pointing to cooperative kinetics, i.e. to a kinetic influence of neighbouring monomer units on the hydrolysis of central A-monomer units. Considering only the next nearest monomer units to have kinetic influence and in view of the fact that ester hydrolysis with base is irreversible, the polymer analogous hydrolysis reaction may be reduced to three individual reactions involving the three A-centred triads and their rate constants k , i.e.

From the kinetics of the saponification of low molecular weight alkyl esters it is well known^{2,11} that the rate is first order both in ester and in OH^- . The rate laws in terms of probabilities for overall second order reactions of triads have been established previously^{17,18,22}:

$$\frac{dP(\text{AA})}{dt} = -2k(\text{AAA})[\text{R}]P(\text{AAA}) - k(\text{AAB}^+)[\text{R}] \times P(\text{AAB}^+) \quad (11)$$

$$\frac{dP(\text{AB}^+)}{dt} = 2k(\text{AAA})[\text{R}]P(\text{AAA}) - 2k(\text{BAB})[\text{R}] \times P(\text{BAB}) \quad (12)$$

$$\frac{dP(\text{BB})}{dt} = k(\text{AAB}^+)[\text{R}]P(\text{AAB}^+) + 2k(\text{BAB})[\text{R}] \times P(\text{BAB}) \quad (13)$$

where $[\text{R}]$ is the concentration of reactant, in this case $[\text{OH}^-]$.

There are two more rate laws for the reactions of triads but unfortunately their differential coefficients are written in terms of two triads and may not be simply reduced to

differential quotients of dyads. The differential quotient of the monad A

$$\frac{dP(A)}{dt} = -k(AAA)[R]P(AAA) - k(AAB^+)[R]P(AAB^+) - k(BAB)[R]P(BAB) \quad (14)$$

In order to obtain rate laws which are compatible with the conversion plots, equations (11) to (13) should be divided by equation (14).

$$\frac{dP(AA)}{dP(A)} = \frac{-2k'(AAA)P(AAA) - k'(AAB^+)P(AAB^+)}{N} \quad (15)$$

$$\frac{dP(AB^+)}{dP(A)} = \frac{2k'(AAA)P(AAA) - 2k'(BAB)P(BAB)}{N} \quad (16)$$

$$\frac{dP(BB)}{dP(A)} = \frac{k'(AAB^+)P(AAB^+) + 2k'(BAB)P(BAB)}{N} \quad (17)$$

with

$$N = -k'(AAA)P(AAA) - k'(AAB^+)P(AAB^+) - k'(BAB)P(BAB)$$

The kinetic behaviour shown in Figures 1, 2, 3 and 5 demonstrates that there exists no dependence on $[OH^-]$, as long as an excess of OH^- is available. This lends support to the reaction model embodied in equations (11) to (17). The differential quotients in equations (15) to (17) are affected only by relative rate constants and not the rate constants themselves. For the relative rate constants we choose arbitrarily the definition:

$$k'(AAA) + k'(AAB^+) + k'(BAB) = 1 \quad (18)$$

with, for instance:

$$k'(AAA) = \frac{k(AAA)}{k(AAA) + k(AAB^+) + k(BAB)} \quad (19)$$

The sequence probabilities of a copolymer prepared by a polymer analogous reaction depend only on the relative rate constants and a specified $P(A)$ (and on the sequence probabilities of the starting polymer), but not on the reaction time needed to reach that $P(A)$. Furthermore, only one of equations (15) to (17) is independent since at a given $P(A)$ only one $P(XX)$ is independent. Thus at least two copolymers of differing $P(A)$, prepared under analogous conditions, are needed to determine the two independent relative rate constants. The rate equations (15) to (17), could either be used as such or in their integrated form. We choose to use the former, since it is not simple to establish even the differential equation for a given model of polymer analogous reactions^{22,23}, while it is a formidable task to obtain an integration in closed form without approximations²⁴. Also, an available solution for the irreversible case is difficult to handle²⁵. Thus the differential equations for polymer analogous reactions are important in evaluating kinetic data, particularly with new models. The situation is similar to that for enzyme kinetics where the differential equations are often employed²⁶. The inaccuracy in the determination of the differential quotients by constructing tangents can be kept to levels comparable to or below the inaccuracies caused by the n.m.r. determination of the kinetic curves; both inaccuracies being compared in their effect on the determination of the relative rate constants.

As only one of the equations (15) to (17) is independent, equation (15) has been arbitrarily chosen for evaluating the relative rate constants. Setting $dP(AA)/dP(A) = S$ and substituting $k'(BAB)$ by $[1 - k'(AAA) - k'(AAB^+)]$ one obtains:

$$k'(AAA) = c_1 + c_2 k'(AAB^+) \quad (20)$$

with:

$$c_1 = -\frac{SP(BAB)}{SP(AAA) - SP(BAB) - 2P(AAA)} \quad (21)$$

$$c_2 = \frac{SP(BAB) - SP(AAB^+) + P(AAB^+)}{SP(AAA) - SP(BAB) - 2P(AAA)} \quad (22)$$

Although c_1 and c_2 are functions of $P(A)$, at a given $P(A)$ i.e. for a given copolymer equation (20) yields a linear plot of $k'(AAA)$ versus $k'(AAB^+)$. In order to determine S by the tangent method, not only $dP(AA)/dP(A)$ was determined but also $dP(AB^+)/dP(A)$ and $dP(BB)/dP(A)$, all of them over the available range of $P(A)$ at intervals of $\Delta P(A) = 0.05$. These values are plotted in Figure 7 for the starting copolymer of $P(A) = 0.83$. Differentiating the two generally valid equations $P(A) = P(AA) + 0.5P(AB^+)$ and $P(B) = P(BB) + 0.5P(AB^+)$ with respect to $P(A)$ and $P(B)$, respectively, and considering $dP(A) = -dP(B)$:

$$\frac{dP(AA)}{dP(A)} = 1 - 0.5 \frac{dP(AB^+)}{dP(A)} = 2 + \frac{dP(BB)}{dP(A)} \quad (23)$$

Equation (23) states that the values for the three differential quotients trace out a common curve (broken curve in Figure 7) if a corresponding triple ordinate is used. Any experimental scatter is then due only to errors in constructing the tangents on the $P(XX)$ vs. $P(A)$ curves and on deviations of the $P(XX)$ vs. $P(A)$ curves themselves from the principle of stationarity.

Figure 8 Relative rate constants $k'(AAA)$ and $k'(AAB^+)$ as intersections of straight lines plotted according to equation (20). Bernoullian starting copolymer of $P(A) = 0.83$. $P(A)$ values: A, 0.83; B, 0.80; C, 0.75; D, 0.70; E, 0.65; F, 0.60; G, 0.55; H, 0.50; I, 0.45; J, 0.40; K, 0.20; L, 0.35; M, 0.30; N, 0.25

Figure 9 Relative rate constants $k'(AAA)$ and $k'(AAB^+)$ as intersections of straight lines plotted according to equation (20). Bernoullian starting copolymer of $P(A) = 0.60$. $P(A)$ values: A, 0.60; B, 0.55; C, 0.50; D, 0.45; E, 0.40; F, 0.35; G, 0.20; H, 0.25/0.35

For a random polymer analogous reaction, for which $k'(AAA) = k'(AAB^+) = k'(BAB)$, equation (15) becomes:

$$\frac{dP(AA)}{dP(A)} = \frac{2P(AA)}{P(A)} = 2P(A) \quad (24)$$

However, the second equality holds only if the copolymers formed are Bernoullian, which is always the case for $k'(AAA) = k'(AAB^+) = k'(BAB)$ when the starting polymer

is either a homopolymer or a Bernoullian copolymer. The straight line of equation (24) is seen as the diagonal in Figure 7. As a further test of the precision of the differential quotients the shaded areas F_1 and F_2 must be equal. Considering two polymer analogous reactions, 1 and 2, which differ in their sets of k' but start from the same $P(A)_{start}$ and $P(AA)_{start}$ and end at the same $P(A)_{end}$ and $P(AA)_{end}$, it holds with $P(AA)_{start} - P(AA)_{end} = \Delta P(AA)$:

$$\Delta P(AA)_1 = \Delta P(AA)_2 \quad (25)$$

and

$$\int_{P(A)_{start}}^{P(A)_{end}} dP(AA)_1 = \int_{P(A)_{start}}^{P(A)_{end}} dP(AA)_2 \quad (26)$$

whence:

$$\int_{P(A)_{start}}^{P(A)_{end}} \frac{dP(AA)_1}{dP(A)} dP(A) = \int_{P(A)_{start}}^{P(A)_{end}} \frac{dP(AA)_2}{dP(A)} dP(A) \quad (27)$$

According to equation (27) the areas under the curves traced out in a plot of $dP(AA)/dP(A)$ vs. $P(A)$ for reactions 1 and 2 must be equal. One may regard the hydrolysis with excess OH^- as reaction 1 and the hypothetical hydrolysis with $k'(AAA) = k'(AAB^+) = k'(BAB)$ as reaction 2, because they start from the same $P(A)$ and $P(AA)$ and both end at $P(AA) = P(A) = 0$. The equality holds for Figure 7 with $F_1/F_2 = 1.03$.

The averaged S of Figure 7 (broken curve) and the $P(XAX)$ of $P(XAX)$ versus $P(A)$ curves are taken at intervals of $\Delta P(A) = 0.05$ to plot $k'(AAA)$ vs. $k'(AAB^+)$ according to equation (20). In Figure 8 (starting copolymer of $P(A) = 0.83$) and in Figure 9 (starting copolymer of $P(A) = 0.60$) it becomes apparent that the intersections of the straight lines of differing $P(A)$ show only a reasonable amount of scatter or systematic change. Moreover, the areas in which the intersections occur are about the same for both starting copolymers. In order to evaluate the coordinates of the intersections more closely, the results of Figure 8 are summarized in Table 2; the $k'(AAA)$ values are in the upper right half and the $k'(AAB^+)$ values in the lower left half, the diagonal separating the areas. The intersections of the straight lines of different $P(A)$ in Figure 8 are seen in Table 2 as the intersections of columns and rows. The $k'(AAA)$ and $k'(AAB^+)$ values at the intersections of the columns and rows of $P(A) = 0.60$ to 0.40 can be considered as particularly characteristic for two reasons. First, they stem from a conversion range where Figure 6 shows well resolved spectra with constant chemical shifts of the triad peaks, and second, in this range the difference between different sets of relative rate constants is about the largest both with respect to $P(XXX)$ and $dP(XX)/dP(A)^{18}$. Comparing the fluctuation of the values $k'(AAA)$ and $k'(AAB^+)$ within the rectangle of Table 2 with that of the other values of the same Table, it is apparent that the fluctuation is about the same. The data may be inspected by comparing the $k'(AAA)$ or $k'(AAB^+)$ values running parallel to the diagonal. Immediately adjacent to the diagonal, the values are obtained by intersections of lines which are only $\Delta P(A) = 0.05$ apart. These values are not very reliable since the

Table 2 Values for $k'(AAA)$ and $k'(AAB^+)$ for the intersections of Figure 8, representing the data obtained from a starting copolymer of $P(A) = 0.83$. The intersections of two straight lines of different $P(A)$ in Figure 8 are represented in Table 2 by the intersections of columns and rows of the same $P(A)$.

angles with which the lines intersect are very acute (Figure 8). Once or twice removed from the diagonal, the intersecting lines are $\Delta P(A) = 0.10$ and $\Delta P(A) = 0.15$ apart and the angles less acute, although still far from 90° . A systematic change of the k' values with conversion should appear along these lines parallel to the diagonal. There appears indeed a relatively small increase of $k'(AAA)$ and a corresponding decrease in $k'(AAB^+)$, but in view of the accuracy of the data it is not clear whether one should attach significance to this trend. It should finally be pointed out that intersections for which only lines of $P(A) = 0.35$ to 0.20 participate are those for which the hydrolysis has so far progressed that $P(AAA) = 0$. Then c_1 of equation (21) becomes 1 and the intersections of two such lines becomes meaningless (blank space, lower right corner of Table 2). If, however, only one of these lines participates in a given intersection the values are still useful, although possibly less reliable, since $P(AAB^+)$ has already become small at $P(A) \leq 0.35$ and can only be inaccurately measured (values in broken line rectangles).

In view of the foregoing it appears justified to simply take the median of the values for lines from $P(A) = 0.60$ to $P(A) = 0.40$ for both starting copolymers of $P(A) = 0.83$ and $P(A) = 0.60$ to result in $k'(AAA) = 0.62$ and $k'(AAB^+) = 0.33$. This in turn yields $k'(BAB) = 0.05$. Similar values are obtained when all intersections are evaluated. In view of the experimental error this result may be rounded to 0.6, 0.3, and 0.1, respectively. Apparently, next neighbouring $-\text{COO}^-$ retards the attack of OH^- by electrostatic repulsion. This retardation amounts to about 2 for $k(AAA)/k(AAB^+)$ and to at least 6 for $k(AAA)/k(BAB)$. In view of the relative constancy of the k' values with $P(A)$ it may also be concluded that repulsion by $-\text{COO}^-$ situated on monomer units further removed is not large. It is, of course, also possible to use, besides equation (15), equations (16) and (17) to plot $k'(AAA)$ vs. $k'(AAB^+)$ diagrams. However, the expressions for the intercept and the slopes of the corresponding straight lines are identical with those of equations (21) and (22), as shown for equations (16) and (17) and in accordance with equation (23).

The relative rate constants are not significantly changed in the temperature range 115°C (T_1) to 175°C (T_2). Using the Eyring equation one obtains for T_1 :

$$\left(\frac{k(AAA)}{k(AAB^+)}\right)_{T_1} = \left(\frac{k'(AAA)}{k'(AAB^+)}\right)_{T_1}$$

$$= \frac{(kT_1/h) \exp(\Delta S_1^\ddagger/R) \exp(-\Delta H_1^\ddagger/RT_1)}{(kT_1/h) \exp(\Delta S_2^\ddagger/R) \exp(-\Delta H_2^\ddagger/RT_1)} \quad (28)$$

where S_1^\ddagger and S_2^\ddagger are, for instance, the activation entropies valid for the reaction 1, ($AAA \rightarrow ABA$) and the reaction 2, ($AAB^+ \rightarrow ABB^+$), respectively. Similarly for temperature T_2 :

$$\left(\frac{k(AAA)}{k(AAB^+)}\right)_{T_2} = \left(\frac{k'(AAA)}{k'(AAB^+)}\right)_{T_2} = \frac{(kT_2/h) \exp(\Delta S_1^\ddagger/R) \exp(-\Delta H_1^\ddagger/RT_2)}{(kT_2/h) \exp(\Delta S_2^\ddagger/R) \exp(-\Delta H_2^\ddagger/RT_2)} \quad (29)$$

presupposing, as usual, that ΔS_1^\ddagger , ΔS_2^\ddagger , ΔH_1^\ddagger , and ΔH_2^\ddagger are invariant over a limited temperature range. Since it was found that the approximation:

$$\left(\frac{k'(AAA)}{k'(AAB^+)}\right)_{T_1} = \left(\frac{k'(AAA)}{k'(AAB^+)}\right)_{T_2} \quad (30)$$

holds, it follows from equations (28) and (29) that:

$$\Delta H_1^\ddagger = \Delta H_2^\ddagger \quad (31)$$

and analogously to equations (28) to (30) that:

$$\Delta H_1^\ddagger = \Delta H_3^\ddagger \quad (32)$$

where the subscript 3 is valid for reaction 3 ($BAB \rightarrow BBB$). Thus the activation enthalpies are all equal. From equation (28) it follows that:

$$\frac{k(AAA)}{k(AAB^+)} = \exp \frac{\Delta S_1^\ddagger - \Delta S_2^\ddagger}{R} \quad (33)$$

and similarly that:

$$\frac{k(AAA)}{k(BAB)} = \exp \frac{\Delta S_1 - \Delta S_3}{R} \quad (34)$$

Equations (33) and (34) state that the ratios of the rate constants are determined only by the differences of the activation entropies. From $k'(AAA)/k'(AAB^+) = 0.6/0.3 = 2$

^aAs determined from the α -CH₃ resonance of the ¹H n.m.r. spectra recorded from pyridine solution (100°C) at 220 MHz. For all polymers $P(ii) = 0$ and $P(is^+) = 1 - P(ss)$. ^bAs determined from $[\eta] = 5.2 \cdot 10^{-5} \bar{M}_w^{0.76}$, a relation which has been established for radical initiated (predominantly syndiotactic) PMMA of $\bar{M}_w \geq 35\,000$ at 30°C in benzene²⁹

and $k'(AAA)/k'(BAB) = 0.6/0.1 = 6$ the differences of the activation entropies are found as $\Delta S_1^\ddagger - \Delta S_2^\ddagger = 1.4$ cal/mol K and $\Delta S_1^\ddagger - \Delta S_3^\ddagger = 3.6$ cal/mol K, respectively. The cooperativity of the kinetics is therefore entropic in origin.

EXPERIMENTAL

Syndiotactic poly(methyl methacrylate) (PMMA) was prepared using Ziegler-Natta initiator at -75° to -78°C in toluene, according to the method of Abe *et al.*²⁷ Table 3 lists experimental conditions for 10 preparative runs. The PMMA was prehydrolysed in dioxane/methanol/KOH mixture as described previously¹³. Table 4 lists the copolymers prepared. With one exception the hydrolysis solutions were homogeneous up to the end of reaction time, with the same extent of hydrolysis for all polymer chains. Comparison with Table 3 shows that the \bar{M}_w of the re-esterified copolymers in Table 4 (values without parentheses) are not greatly affected by the prehydrolysis. Moreover, the ¹H n.m.r. spectra of the re-esterified products were the same as those of the corresponding precursor PMMA.

For some copolymers obtained after prehydrolysis it was shown by fractionation, carried out by the incremental addition of HCl from aqueous solution²⁸, that within error of measurement, no heterogeneity with respect to $P(A)$ and $P(XXX)$ ($X = A, B$) existed (Table 5). Thus the copolymers are compositionally homogeneous starting materials for the kinetic runs. For the copolymers obtained after the kinetic runs with excess of OH⁻ it could likewise be shown (Table 5) that no heterogeneity exists with respect to $P(A)$ and $P(XXX)$. Therefore, the sequence data obtained during the kinetic runs with excess of OH⁻ are representative of the statistics of the individual chains¹³. Also, the \bar{M}_w after the kinetic runs are not very different from that of the precursor PMMA or precursor Bernoullian copolymers. The n.m.r. spectra of the PMMA obtained by esterification of the copolymers from kinetic runs are identical with those of the precursor PMMA, showing that side reactions are absent.

For the kinetic runs, 1N KOH was added to multiples of 250 mg prehydrolysed copolymer in an alkali resistant glass ampoule (the amount of KOH specified in this communication always applies to 250 mg of starting copolymer). Sufficient water was added to bring the volume of aqueous KOH to 12 ml for each 250 mg copolymer. As

noted, part of the water was substituted by aqueous KCl solution. The ampoule was flushed with N₂, sealed, and transferred to a circulating air oven at 115°C and after a maximum of 1 h, and shaking every ten minutes, the polymer had dissolved. The $P(A)$ had not changed measurably as determined by n.m.r. The content of the ampoule was then distributed into several smaller ampoules of Duran glass (12 ml solution into each) which contained Teflon thimbles to completely prevent contact of the alkaline solutions with the glass. For the kinetic runs, these ampoules were inserted into well fitting holes of an aluminium block and inserted in a thermostatically controlled oil bath. The time at this instance was taken as $t = 0$; the time needed for the ampoules to reach 145°C (115°C, 175°C) being assumed to be compensated to some extent by the time spent dissolving the copolymer in the dissolution step. The copolymers were isolated after the kinetic runs by diluting

^aArabic numerals 6 and 8 refer to whole (unfractionated) copolymers, of Table 4. d-f refer to whole copolymers, and I and II signify first and second fraction derived from the corresponding whole copolymers. ^b \bar{M}_w in parentheses are determined by viscosimetry from the precursor PMMA, the \bar{M}_w without parentheses apply to fractions which have been determined by re-esterifying with CH₂N₂ to PMMA and determining \bar{M}_w by viscosimetry. ^cThe P values were identical for the whole copolymer and its two fractions. Values of P in parentheses calculated from the experimental $P(A)$ for a Bernoullian statistics. ^dAlternating copolymer, obtained from random copolymer No. 6 (Table 4) with 5 mmol KOH after 4 h at 145°C. ^eAlternating copolymer, obtained from random copolymer No. 6 (Table 4) with 3 mmol KOH after 18 h at 145°C. ^fAlternating copolymer, obtained from random copolymer No. 6 (Table 4) with 5 mmol KOH after 48 h at 145°C

with a ten-fold amount of water and precipitating with concentrated HCl at 80° to 100°C.

The ¹H n.m.r. spectra were recorded on a Varian HR-220 spectrometer operated at 220 MHz. For all the copolymers pyridine was used as solvent; a temperature of 100°C, a concentration of ~10% w/v, and TMS as internal standard were employed. The gross composition of the copolymers was obtained by:

$$P(A) = \frac{\frac{5}{3}I(-OCH_3)}{I(-CH_2-) + I(-CH_3)} \quad (39)$$

where the I values are the areas of the resonance regions indicated in parentheses. The $P(XXX)$ were obtained from the α -CH₃ resonance region by either separating the triad peak areas by hand and measuring the areas by planimeter, or, in most cases, by a Du Pont Curve Resolver 310. For the latter procedure the peak shape was derived from the undisturbed high field flank of the AAA peak which is the α -CH₃ peak situated to highest field. The skew of the peaks was adjusted by observing the skew of the TMS signal.

ACKNOWLEDGEMENTS

Thanks are due to the Deutsche Forschungsgemeinschaft for financial support and to Professor H.-J. Cantow for providing the use of the n.m.r. spectrometer. Spectra were recorded with assistance of H. Bodenstern, H. Bührer, H. Erler, A. Hasenbühl and M. Seiter. Experimental assistance by A. Disch and J. Glaser is gratefully acknowledged.

Rate constants during the hydrolysis of syndiotactic poly(methyl methacrylate) with base*

Ernst Klesper and Volker Barth

Institut für Makromolekulare Chemie, Universität Freiburg, D-78 Freiburg, W. Germany

(Received 5 March 1976)

A procedure is presented for the determination of rate constants for the reaction of triads during the reaction on polymers and the method applied to the base hydrolysis of syndiotactic methyl methacrylate/methacrylic acid copolymers.

INTRODUCTION

For reactions of polymers the relative rate constants for individual sequences are sufficient to determine the distribution of sequence probabilities at a given gross composition for present reaction models. The rate constants themselves yield the same information and in addition the time necessary to obtain a given gross composition and distribution of sequences. The relative rate constants of triads have been determined¹ for the hydrolysis of syndiotactic methyl methacrylate/methacrylic acid copolymers with excess base in aqueous solution. In the present communication a procedure is given for the determination of the rate constants of triads for this hydrolysis reaction. It was found that the values for the rate constants and relative rate constants are compatible and that the rate constants are not greatly affected by conversion, e.g. by the total charge on the chain or by a kinetic effect of pendants.

RESULTS AND DISCUSSION

Syndiotactic methyl methacrylate/methacrylic acid (MMA/MAA) copolymers of Bernoullian distribution of monomer units are used for the kinetic runs in aqueous KOH. PMMA itself could not be employed since it is not soluble in aqueous KOH. Unless otherwise stated, aliquots of 250 mg of copolymer in 12 ml aqueous KOH of specified concentration are kept at 145°C under N₂ in sealed ampoules for periods of time to effect the hydrolysis. The experimental details for obtaining the kinetic data have been described¹. Two gross compositions are selected for the starting MMA/MAA copolymers, i.e. one with a probability of finding A of $P(A) = 0.83$ (copolymer No. 6 of Table 4 in reference 1) and $P(A) = 0.60$ (copolymer No. 9 of Table 4 in reference 1) (A = MMA monomer unit). The molecular weight of the starting copolymers is $\bar{M}_w = 100\,000$, unless otherwise indicated. The probabilities of the configurational triads are $P(ss) = 0.92$ and $P(is^+) = 0.08$ in all cases, where s = syndiotactic and i = isotactic placement. The + sign indicates that both forward and reversed forms of the sequence are included, e.g. is and si. Part of the $P(XXX)$ and $P(XX)$ data presented in this communication (X = A, B; B = MAA monomer unit) have already been evaluated for their dependence of $P(A)$ in a previous communication¹ in which the same hydrolysis reaction was studied,

* Dedicated to Professor H. Kämmerer on the occasion of his 65th birthday.

but with the interest centring on relative rates and relative rate constants. In this communication the time dependent behaviour of $P(XXX)$, $P(XX)$, and also $P(A)$, is of primary concern in order to evaluate the rate constants themselves.

Figure 1 shows the change of gross composition, $P(A)$, with time for the copolymer of $P(A) = 0.83$ with different initial amounts of KOH (at $t = 0$). An amount of 3, 5, and 7 mmol KOH/250 mg copolymer is sufficient to maintain a significant concentration of OH⁻ during the whole course of the reaction, since [KOH] used is more than is needed for the transformation of all -COOH and -COOCH₃ to -COO⁻. The kinetic curves for these OH⁻ concentrations show a monotonous decrease of $P(A)$ with time which depends greatly on [OH⁻]. The runs with 3 mmol initial KOH are considerably slower at the end range of conversion than those with 5 and 7 mmol KOH because a greater percentage of the OH⁻ has then been consumed in the former run.

Kinetic runs are also shown for 0.5, 1.0, and 1.5 mmol initial KOH. With 0.5 mmol KOH, the [KOH] is only slightly in excess of that necessary to transform all carboxyl groups of the starting copolymer to carboxylate (calculated: 0.435 mmol KOH). The kinetic behaviour approximates to that of a straight line. The kinetic curves for 1.0 and 1.5 mmol initial KOH, however, exhibit two points of inflection. During the first part of the reaction the rate de-

Figure 1 Change of gross composition, $P(A)$, with reaction time during hydrolysis of syndiotactic methyl methacrylate methacrylic acid (MMA/MAA) copolymer of Bernoullian compositional statistics and $P(A) = 0.83$. ●, 0.5; ■, 1; ▲, 1.5; ○, 3; □, 5; △, 7 mmol KOH

Figure 2 Slopes of $P(A)$ versus t curves, $dP(A)/dt$, of the curves of Figure 1 for \circ , \square , \triangle , 7 mmol KOH. Slopes are obtained graphically at $\Delta P(A) = 0.05$ intervals

increases greatly to a point which nearly coincides with the point where the excess KOH is consumed during hydrolysis by newly formed $-\text{COO}^-$, i.e. where $[\text{OH}^-] \approx 0$. The calculated points of consumption are $P(A) = 0.61$ with initially 1.0 mmol KOH and $P(A) = 0.41$ with initially 1.5 mmol KOH. The points of consumption are approached slowly, as to be expected for an overall second order reaction in which OH^- partakes, the curves forming thereby a plateau of small slope. The plateau indicates also, that the $-\text{COO}^-$ alone does not sustain the hydrolysis and the slow hydrolysis still prevailing at the plateau leads to an autocatalytic phase which at the end of the reaction levels off again. It is suspected that the active species present after the plateau is connected with the $-\text{COOH}$ formed during the hydrolysis. The final levelling off is connected with the exhaustion of A-units in the copolymer chains. Thus $P(A)$ versus time behaviour is in keeping with the previous finding¹ that at the point of consumption of OH^- the compositional statistics of the copolymers changes from one with alternation character to one with block character. Apparently the plateau separates the hydrolysis with OH^- as the attacking species to one in which the $-\text{COOH}$ partakes in some way. The electrostatic repulsion between OH^- and $-\text{COO}^-$ is likely to create alternation character, while the active species related to $-\text{COOH}$, by being bound to the chain and attacking preferably next neighbouring A-units, will tend to form block character. The following results refer to the hydrolysis in the presence of excess OH^- .

The rate for the hydrolysis of A-units with excess base may be written¹⁻³:

$$\frac{dP(A)}{dt} = -k(\text{AAA}) [\text{OH}^-]^x P(\text{AAA}) - k(\text{AAB}^+) [\text{OH}^-]^x P(\text{AAB}^+) - k(\text{BAB}) [\text{OH}^-]^x P(\text{BAB}) \quad (1)$$

where the $P(\text{XAX})$ designate probabilities in the copolymer chains and the $[\text{OH}^-]$ concentrations in solution. The ex-

ponent x is the reaction order with respect to $[\text{OH}^-]$ and the $k(\text{XAX})$ are the rate constants of the three individual reactions. On transferring $[\text{OH}^-]^x$ to the left of equation (1), the right hand side should be a constant at a given $P(A)$, provided the $P(A)$ uniquely determines the $P(\text{XAX})$, which is the case with a given set of $k(\text{XAX})$ and a given starting copolymer. Then the left hand side of equation (1) can be equated for different $[\text{OH}^-]$:

$$\left[\left(\frac{dP(A)}{dt} \right)_3 \times \frac{1}{[\text{OH}^-]_3^x} \right]_{P(A)_3} = \left[\left(\frac{dP(A)}{dt} \right)_7 \times \frac{1}{[\text{OH}^-]_7^x} \right]_{P(A)_7} \quad (2)$$

where the subscripts 3 and 7 indicate reactions with 3 and 7 mmol KOH and where $P(A)_3 = P(A)_7$. $[\text{OH}^-]_3$ and $[\text{OH}^-]_7$ refer to the momentary $[\text{OH}^-]$ at $P(A)_3 = P(A)_7$. Equation (2) leads to

$$x = \left[\log \frac{\left(\frac{dP(A)}{dt} \right)_3}{\left(\frac{dP(A)}{dt} \right)_7} / \log \frac{[\text{OH}^-]_3}{[\text{OH}^-]_7} \right]_{P(A)_3=P(A)_7}$$

The $dP(A)/dt$ values obtained graphically as slopes from Figure 1 at $\Delta P(A) = 0.05$ intervals are shown in Figure 2 for 3, 5, and 7 mmol KOH. The accuracy of the slope measurements appears to be good since there is little scatter around the broken curves which have been drawn visually through the points for best fit. The $[\text{OH}^-]$ (mol/l) which remains from the initial amount of KOH after hydrolysis to a given $P(A)$ is calculated by:

$$[\text{OH}^-] = \frac{\text{mmol KOH}_{\text{initial}} - \text{mmol KOH}_{\text{consumed}}}{12 \text{ ml}} \quad (4a)$$

The $\text{mmol KOH}_{\text{consumed}}$ is the KOH needed for the neutralization of all MAA units present at a given $P(A)$. Therefore:

$$\text{mmol KOH}_{\text{consumed}} = \frac{250[1 - P(A)_2]}{100P(A)_1 + 86[1 - P(A)_1]} \quad (4b)$$

The $P(A)_1$ is that of the starting copolymer (0.83 or 0.60), while $P(A)_2$ is that of the copolymer for which the $[\text{OH}^-]$ is to be calculated. The $[\text{OH}^-]$ so calculated agreed with the $[\text{OH}^-]$ titrated for a number of copolymers hydrolysed to high conversion. The results for the reaction order x of $[\text{OH}^-]$ are shown in Table 1 for both sets starting from $P(A) = 0.83$ and $P(A) = 0.60$, combining the data for 3 and 7 mmol KOH as well as 5 and 7 mmol KOH. Based on these results, the reaction order is taken to be $x = 1$ and it is interesting that $x \neq 1$ goes unnoticed when evaluating the relative rates as expressed by equations (15) to (17) in ref 1, because $[\text{OH}^-]^x$ has been cancelled in these equations. Also, the determination of x from $dP(\text{XX})/dt$ by equations (13) to (15) is equally possible.

The initial rates of the probabilities do not depend greatly on the concentration of polymer. This can be deduced from Figure 3a where some $P(A)$ vs. t points are shown for 125 and 62.5 mg starting copolymer of $P(A) = 0.83$ hydrolysed

Table 1 Reaction order x for $[\text{OH}^-]$ with copolymers of $P(A) = 0.83$ and $P(A) = 0.60$. The data were combined according to equation (3) for 3 and 7 mmol initial KOH as well as for 5 and 7 mmol initial KOH. The constant C (l/mol h) for transforming relative rate constants $k'(XAX)$ to $k(XAX)$ ($X = A, B$)

$P(A)^b$	Reaction order x of $[\text{OH}^-]$				Constant C^c

^a $P(A)$ of starting copolymer; ^b $P(A)$ during hydrolysis run; ^ccalculation based on $k'(AAA) = 0.60$, $k'(AAB^+) = 0.30$, and $k'(BAB) = 0.10$. Average value of reaction order x of $[\text{OH}^-] = 1.06$; average value of constant $C = 0.51$

by 5 mmol KOH in 12 ml solution. The points may be compared with the drawn out curve of the standard run with 250 mg copolymer under the same reaction conditions.

Since $x = 1$ and the chosen definition for the relative rate constants $k'(XAX)^1$, equation (1) may be written simply as:

$$\frac{dP(A)}{dt[\text{OH}^-]C} = -k'(AAA)P(AAA) - k'(AAB^+)P(AAB^+) - k'(BAB)P(BAB) \quad (5)$$

where C is given by:

$$k'(AAA)C = k(AAA) \quad (6a)$$

$$k'(AAB^+)C = k(AAB^+) \quad (6b)$$

$$k'(BAB)C = k(BAB) \quad (6c)$$

The relative rate constants were previously found to be $k'(AAA) = 0.6$, $k'(AAB^+) = 0.3$, and $k'(BAB) = 0.1$ at 145°C and are not detectably dependent on temperature in the range 115° to 175°C or on the extent of hydrolysis¹. Using the known values for the $k'(XAX)$ equation (5) can be employed to obtain the constant C . The $dP(A)/dt[\text{OH}^-]$ data needed for this purpose are plotted in Figure 4. The $dP(A)/dt[\text{OH}^-]$ obtained for runs with a starting copolymer of $P(A) = 0.83$ are shown in Figure 4a and those for a starting copolymer of $P(A) = 0.60$ in Figure 4b. Because $dP(A)/dt[\text{OH}^-]$ is found invariant with $[\text{OH}^-]$ at a given $P(A)$, averaging curves may be drawn through the experimental points obtained with 3, 5, and 7 mmol initial KOH. The $P(XAX)$ data shown in Tables 2 to 4 however, contain only the primary kinetic data for runs with a starting copolymer of $P(A) = 0.83$. The primary data for $P(XAX)$ of Tables 2 to 4 are not taken as such for the evaluation of C , but are plotted versus time for averaging and interpolation. The C values calculated

Figure 3 (a) Change of gross composition, $P(A)$, with reaction time (h) during hydrolysis of syndiotactic MMA/MAA copolymer of Bernoullian compositional statistics of $P(A) = 0.83$. \square , 125; \circ , 62.5 mg initial copolymer; —, 250 mg initial copolymer from Figure 1. (b) Change of probabilities of A-centred triads, $P(XAX)$, with hydrolysis time. Initially 3 mmol KOH + 2 mmol KCl: \bullet , \circ , $P(AAA)$; \blacksquare , \square , $P(AAB^+)$; \blacktriangle , \triangle , $P(BAB)$ where \bullet , \blacksquare , \blacktriangle represent $\bar{M}_w = 651\,000$ and \circ , \square , \triangle represent $\bar{M}_w = 243\,000$; —, —, —, Represents 3 mmol KOH, $\bar{M}_w = 100\,000$: A, $P(AAA)$; B, $P(AAB^+)$; C, $P(BAB)$

Figure 4 Slopes $dP(A)/dt$ from $P(A)$ versus t curves for: \circ , 3; \square , 5; \triangle , 7 mmole KOH. Data obtained at 145°C from a starting copolymer: (a) $P(A) = 0.83$; (b) $P(A) = 0.60$

for a given $P(A)$ are shown in Table 1. The fluctuation of C with $P(A)$ and with the two starting copolymers of $P(A) = 0.83$ and $P(A) = 0.60$ is within the limits probably to be expected for the errors inherent in the determination of $P(XAX)$. It should be noted that the invariance of C with $P(A)$ excludes the presence of a strong repulsion of attacking OH^- by $-\text{COO}^-$ removed further than one monomer unit along the chain.

The independence of $dP(A)/dt[\text{OH}^-]$ from $[\text{OH}^-]$, was also found for $dP(\text{XX})/dt[\text{OH}^-]$. It should be pointed out that this independence is a test for the chosen kinetic model as embodied in equations (1), (13)–(15) and excludes the presence of a significant overall first order reaction of triads connected with a hydrolysis by neighbouring $-\text{COO}^-$ or by H_2O . An overall first order reaction in the presence of the postulated overall second order reaction with OH^- can be written with respect to kinetic behaviour of A as

$$\begin{aligned} \frac{dP(A)}{dt[\text{OH}^-]} = & - \left[k(\text{AAA})_2 + \frac{k(\text{AAA})_1}{[\text{OH}^-]} \right] \times P(\text{AAA}) \\ & - \left[k(\text{AAB}^+)_2 + \frac{k(\text{AAB}^+)_1}{[\text{OH}^-]} \right] \times P(\text{AAB}^+) \\ & - \left[k(\text{BAB})_2 + \frac{k(\text{BAB})_1}{[\text{OH}^-]} \right] \times P(\text{BAB}) \end{aligned} \quad (7)$$

where the subscripts 1 and 2 denote the rate constants for the overall first and second order reactions. Clearly $dP(A)/dt[\text{OH}^-]$ cannot be independent of $[\text{OH}^-]$ according to equation (5) if the $k(\text{XAX})_1$ possess significant magnitude. Equations analogous to equation (7) may be written for $dP(\text{XX})/dt[\text{OH}^-]$.

Figure 3b shows the averaged $P(\text{XAX})$ of Table 2 (3 mmol KOH and starting copolymer of $P(A) = 0.83$). The points from runs carried out with addition of 2 mmol KCl to starting copolymers of different \bar{M}_w , using otherwise the same reaction conditions show neither a great dependence on molecular weight nor a salt effect. First results (not shown), however, indicate that the counterion might be an influence on the kinetics since with LiOH the rate appears to increase. From the $P(\text{XXX})$ versus t data of Tables 2 to 4 the $P(\text{XX})$ versus t are calculated by the principle of stationarity^{4,5}. The result is shown in Figure 5 as points for the run with 5 mmol KOH. The curves are drawn for best fit and are utilized for graphical determination of $dP(\text{XX})/dt$. A procedure was adopted which allows checking and averaging of the graphically determined differential quotients. On differentiation of the generally valid relations $P(\text{AA}) + 0.5P(\text{AB}^+) = P(A)$ and $P(\text{BB}) + 0.5P(\text{AB}^+) = 1 - P(A)$:

$$\frac{dP(\text{AA})}{dt} = \frac{dP(A)}{dt} - 0.5 \frac{dP(\text{AB}^+)}{dt} \quad (8)$$

$$\begin{aligned} \frac{dP(\text{AB}^+)}{dt} &= 2 \left[\frac{dP(A)}{dt} - \frac{dP(\text{AA})}{dt} \right] \\ &= -2 \left[\frac{dP(A)}{dt} + \frac{dP(\text{BB})}{dt} \right] \end{aligned} \quad (9)$$

$$\frac{dP(\text{BB})}{dt} = -\frac{dP(A)}{dt} - 0.5 \frac{dP(\text{AB}^+)}{dt} \quad (10)$$

From equations (8) and (10) it follows

$$\frac{dP(\text{AA})}{dt} = 2 \frac{dP(A)}{dt} + \frac{dP(\text{BB})}{dt} \quad (11)$$

$$\frac{dP(\text{BB})}{dt} = -2 \frac{dP(A)}{dt} + \frac{dP(\text{AA})}{dt} \quad (12)$$

So, each $dP(\text{XX})/dt$ may be obtained in two additional ways thus compensating the error in drawing the $P(\text{XX})$ versus t curves and in slope measurement.

^aResults of duplicate runs, reproducibility ± 0.01

Figure 5 Change of probabilities of dyads with time of hydrolysis. \circ , $P(AA) = P(AAA) + 0.5 P(AAB^+)$; \triangle , $P(AB^+) = P(AAB^+) + 2P(BAB)$; ∇ , $P(AB) = P(ABB^+) + 2P(ABA)$; \square , $P(BB) = P(BBB) + 0.5 P(ABB^+)$

The appropriate differential equations¹ for $dP(XX)/dt$ are:

$$\frac{dP(AA)}{dt} = -2k(AAA)[OH^-]P(AAA) - k(AAB^+)[OH^-]P(AAB^+) \quad (13)$$

$$\frac{dP(AB^+)}{dt} = 2k(AAA)[OH^-]P(AAA) - 2k(BAB)[OH^-]P(BAB) \quad (14)$$

$$\frac{dP(BB)}{dt} = k(AAB^+)[OH^-]P(AAB^+) + 2k(BAB)[OH^-]P(BAB) \quad (15)$$

Equations (13) to (15) assume first order reaction with respect to $[OH^-]$ and absence of an additional, overall first order reaction of triads.

Equation (13) may be rearranged to the straight line form:

$$k(AAA) = c_1 k(AAB^+) + c_2 \quad (16)$$

with

$$c_1 = -\frac{P(AAB^+)}{2P(AAA)} \quad (17)$$

$$c_2 = -\frac{S_1}{2P(AAA)} \quad (18)$$

where $S_1 = dP(AA)/dt[OH^-]$, and where S_1 , c_1 and c_2 refer, of course, to data at the same time or $P(A)$. Equations (14) and (15) may be rearranged similarly to:

$$k(AAA) = \frac{P(BAB)}{P(AAA)} k(BAB) + \frac{dP(AB^+)/dt[OH^-]}{2P(AAA)} \quad (19)$$

$$k(AAB^+) = -\frac{2P(BAB)}{P(AAB^+)} k(BAB) + \frac{dP(BB)/dt[OH^-]}{P(AAB^+)} \quad (20)$$

In Figure 6 the $k(AAA)$ vs. $k(AAB^+)$ plot of equation (16) is shown for the run with 5 mmol KOH and starting from $P(A) = 0.83$. The $P(XAX)$ for equation (16) are obtained

from $P(XXX)$ vs. t curves drawn through the data of Table 3. Similarly, Figures (7) and (8) show the $k(AAA)$ versus $k(BAB)$ and the $k(AAB^+)$ versus $k(BAB)$ plots. The lines are labelled by their reaction time and vertical parallel lines refer to special cases. When $P(AAA)$ becomes zero during hydrolysis, then according to equations (13) and (14):

$$k(AAB^+) = -\frac{dP(AA)/dt[OH^-]}{P(AAB^+)} \quad (21)$$

$$k(BAB) = -\frac{dP(AB^+)/dt[OH^-]}{2P(BAB)} \quad (22)$$

and $k(AAB^+)$ or $k(BAB)$ can be immediately obtained without plotting. However, additional information is obtained by drawing corresponding vertical lines on the

Figure 6 Determination of $k(AAA)$ and $k(AAB^+)$ according to equation (16). Reaction time (h): A, 0; B, 1; C, 2; D, 3; E, 4; F, 6; G, 9; H, 12; I, 18; J, 24; K, 36; L, 72; M, 48

Figure 7 Determination of $k(AAA)$ and $k(BAB)$ according to equation (19). Reaction time (h): A, 18; B, 36; C, 48; D, 12; E, 9; F, 6; G, 4; H, 3; I, 2; J, 1; K, 0; L, 240; M, 24; N, 192; O, 72; P, 96; Q, 120; R, 144

Figure 8 Determination of $k(\text{AAB}^+)$ and $k(\text{BAB})$ according to equation (20). Reaction time (h): A, 96; B, 120; C, 144; D, 192; E, 240; F, 0; G, 1; H, 2; I, 3; J, 4; K, 6; L, 9; M, 12; N, 18; O, 24; P, 36; Q, 48; R, 72

$k(\text{AAB}^+)$ or $k(\text{BAB})$ axis. When $P(\text{AAB}^+) = 0$, in addition to $P(\text{AAA}) = 0$, then equation (15) becomes:

$$k(\text{BAB}) = \frac{dP(\text{BB})/dt[\text{OH}^-]}{2P(\text{BAB})} \quad (23)$$

Again, $k(\text{BAB})$ may be obtained directly and plotted as vertical on the $k(\text{BAB})$ axis.

There is considerable scatter of the intersections particularly in Figure 6, indicating the limits of accuracy in determining the triad probabilities. Since the two coordinates of the intersections are not normally distributed, the median and the 95% confidence limits of the median were determined. For Figure 6 it was found that $k(\text{AAA}) = 0.34$ (from 0.30 to 0.38) and $k(\text{AAB}^+) = 0.16$ (from 0.10 to 0.18). For Figure 7 it was found that $k(\text{AAA}) = 0.33$ (0.28 to 0.35) and $k(\text{BAB}) = 0.04$ (range less than 0.01), while for Figure 8 the values $k(\text{AAB}^+) = 0.21$ (0.20 to 0.21) and $k(\text{BAB}) = 0.04$ (0.03 to 0.04) were obtained, all rate constants being in (1/mol h). The lack of overlap of the confidence ranges for $k(\text{AAB}^+)$ indicates a systematic error for the triad probabilities.

Plotting the three graphs corresponding to equations (16), (19) and (20) for the data obtained with 3 and 7 mmol KOH (Tables 2 and 4) yields similar values for the rate constants and the same applies to runs starting with a copolymer of $P(\text{A}) = 0.60$ at 3, 5, and 7 mmol initial KOH. Moreover, the value $C_{\text{average}} = 0.51$ of Table 1 agrees reasonably, because this value yields $k(\text{AAA}) = 0.30$, $k(\text{AAB}^+) = 0.15$, and $k(\text{BAB}) = 0.05$ when applied to $k'(\text{AAA}) = 0.6$, $k'(\text{AAB}^+) = 0.3$, and $k'(\text{BAB}) = 0.1$.

The rate constants were determined not only at 145°C but also at 115°C and 175°C, using 5 mmol KOH and a starting copolymer of $P(\text{A}) = 0.83$. The rate constants at 115°C were found as $k(\text{AAA}) = 1.1 \times 10^{-5}$, $k(\text{AAB}^+) = 5.5 \times 10^{-6}$, and $k(\text{BAB}) = 1.9 \times 10^{-6}$, those at 175°C as $k(\text{AAA}) = 6.7 \times 10^{-4}$, $k(\text{AAB}^+) = 3.3 \times 10^{-4}$, and $k(\text{BAB}) = 1.1 \times 10^{-4}$, which compares with $k(\text{AAA}) = 8.3 \times 10^{-5}$, $k(\text{AAB}^+) = 4.2 \times 10^{-5}$, and $k(\text{BAB}) = 1.4 \times 10^{-5}$ at 145°C,

all in (1/mol sec). The set of values for 145°C corresponds to $k(\text{AAA}) = 0.30$, $k(\text{AAB}^+) = 0.15$, and $k(\text{BAB}) = 0.05$ (1/mol h) as derived from $k'(\text{XAX})$ and C .

According to the Eyring equation one may write for the rate constant of each individual reaction (A) $\text{AAA} \rightarrow \text{ABA}$, (B) $\text{AAB}^+ \rightarrow \text{ABB}^+$, and (C) $\text{BAB} \rightarrow \text{BBB}$

$$\log \frac{k}{T} = \log \frac{k}{h} + \frac{\Delta S^\ddagger}{2.303R} + \frac{\Delta H^\ddagger}{2.303RT} \quad (24)$$

The plots of $\log k/T$ vs. $1/T$ are shown in Figure 9 for three temperatures 115°, 145°, and 175°C. The lines for the three rate constants are parallel, i.e. of identical slope, indicating the same ΔH^\ddagger for each of the three reactions. The same conclusion has been reached from the relative rate constants¹. The ΔH^\ddagger was derived from:

$$\text{Slope} = -\frac{\Delta H^\ddagger}{4.576} \quad (25)$$

and found to be 22.9 kcal/mol for the three individual reactions. The ΔS^\ddagger for the three reactions (A), (B), and (C) are then $\Delta S_1^\ddagger = -23.0$; $\Delta S_2^\ddagger = -24.4$, and $\Delta S_3^\ddagger = -26.5$ cal/mol K. This yields $\Delta S_1^\ddagger - \Delta S_2^\ddagger = 1.4$ eu and $\Delta S_1^\ddagger - \Delta S_3^\ddagger = 3.5$ eu which compares with 1.4 and 3.6 eu obtained previously for these differences from the relative rate constants¹. The ΔH^\ddagger possesses a value which is in a higher range than usually found for ester hydrolysis with base⁶. In view of the finding that ΔH^\ddagger is independent of the reacting triad, i.e. its charge, this higher value should be attributed to steric constraints for the attacking OH^- . Clearly, the difference in rates for the three individual re-

Figure 9 Eyring plot (equation 24) for temperature dependence of $k(\text{AAA})$, $k(\text{AAB}^+)$, and $k(\text{BAB})$. \circ , AAA $k(\text{AAA})$; \square , AAB^+ $k(\text{AAB}^+)$; \triangle , BAB $k(\text{BAB})$

actions is due to entropic changes occurring when OH^- is approaching the charged chain to form the transition state. The entropy loss increases from reaction (A) to (C) which indicates that the gain in conformational, and possibly also solvational order of the reacting triads increases with increasing charge of the triad.

(Received 15 March 1976; revised 10 May 1976)

The influence of the thermodynamic interaction parameter on the crystallization of very dilute solutions of polyethylene in decalin, tetralin, α -chloronaphthalene and *p*-xylene has been studied. Depending on the solvent, quantitative kinetics data were obtained at different temperature intervals. In comparison with the crystallization in bulk, higher crystallinity levels were obtained. The overall rate temperature coefficient has been analysed according to the nucleation theory pertinent to polymer-diluent mixtures and the results show that the basal free energy for nucleation is independent of the solvent.

INTRODUCTION

Long chain molecules crystallize in the form of lamellar-like structures of platelets when precipitated from dilute solutions¹⁻³. It has been shown that for linear polyethylene the crystallite size in the chain direction is governed by the nucleation process. In a previous work⁴, the influence of molecular weight and concentration on the crystallization kinetics has been analysed, using a new approach to the nucleation theory for finite chain molecules. It has been shown that the crystallization process in these systems is governed by the nucleation act, so that, when the variation in the interfacial free energy in the (001) face of the crystal with molecular weight is stipulated, the phase transformation is described by a function of the free energy required for nucleation. This analysis was later extended to very dilute solutions⁵ of polyethylene in α -chloronaphthalene and it was found that the basal interfacial free energy of the critical nucleus increases slightly with molecular weight.

Renewed attention has been given in recent years to the effect of solvents on the crystallization of polymers. The relation between the crystallite size and the crystallization temperature^{6,7} and between the dissolution temperature and the mature crystal⁸⁻¹¹ have been studied.

In the present paper we analyse the crystallization kinetics of a high molecular weight fraction of polyethylene in several solvents, utilizing the theory for polymer diluent mixtures. Special emphasis is given to the influence of the thermodynamic interaction parameter on the crystallization conditions.

EXPERIMENTAL

Materials

A linear polyethylene fraction was obtained from unfractionated Marlex 50 using the column fractionation technique¹². The viscosity-average molecular weight was determined from the relation given by Chiang¹³ for decalin at 135°C and corresponds to $M = 100\,000$.

The four solvents used in this work, *p*-xylene, chloronaphthalene, tetralin and decalin, were of high purity

Crystallization

An accurately weighed amount of polymer was introduced into the bulk of the dilatometer and the desired amount of solvent was added to obtain a polymer volume fraction of 0.0030. The dilatometers were so constructed that, after adding the solvent, the bulk was sealed and filled with mercury in a high vacuum line. The total change in the mercury height upon the completion of the crystallization was about 4 cm. Prior to the isothermal crystallization, the polymer in the dilatometer was dissolved by heating overnight at 220°C in the case of α -chloronaphthalene and at about 140°C for the other three solvents. The crystallization was conducted in silicone oil thermostats with the temperature controlled to within $\pm 0.01^\circ\text{C}$. After shaking and complete dissolution of the sample, the dilatometer was quickly transferred to the thermostat set at a preassigned temperature. About 10 min were required for the dilatometer to achieve thermal equilibrium.

RESULTS AND DISCUSSION

Depending on the solvent, quantitative kinetic data could be obtained at different temperature intervals. At this very high dilution ($\nu_2 = 0.003$) comparatively large undercoolings are necessary to obtain kinetics data in a reasonable time period and these undercoolings depend on the solvent. All the isotherms display the same characteristic sigmoidal behaviour.

In order to examine the shape of the isotherms, we analysed the data according to the Gōler-Sachs or free growth approximation¹⁴. For the initial portion of the transformation it is found that:

$$\begin{aligned}1 - \lambda(t) &= (k_3 t)^4 / 4 \\1 - \lambda(t) &= (k_2 t)^3 / 6 \\1 - \lambda(t) &= (k_1 t)^2 / 2\end{aligned}\tag{1}$$

for three, two or one dimensional growth. In these equations $1 - \lambda(t)$ is the degree of crystallinity, k_1 , k_2 and k_3

Figure 1 Double logarithmic plot of degree of crystallinity against t , at different crystallization temperatures, for polyethylene in decalin: \circ , 81.8°; \blacksquare , 82.8°; \square , 83.7°; \blacktriangledown , 85.2°; \bullet , 86.4°; \triangle , 87.2°C

Figure 2 Double logarithmic plot of degree of crystallinity against t , at different crystallization temperatures, for polyethylene in xylene: \blacktriangle , 87.2°; \circ , 88.1°; \square , 89.0°; \bullet , 90.0°C

are the rate constants and t is the time. Equation (1) suggests, that as the simplest analysis, a double logarithmic plot be made of $1 - \lambda(t)$ against time.

Figures 1 to 4 show the experimental results for the four solvents. There is a good adherence of the experimental data to this theoretical development and a linear relation is obtained for a significant portion of the total transformation. At the lower crystallization temperatures, this formulation holds for about 50–60% of the transformation, independent of the solvent. The level of agreement decreases somewhat as the crystallization temperature is increased.

The agreement of the experimental data with the Avrami equation, $\ln(1 - x) = kt^n$, is about the same as with the G6ler–Sachs theory and deviations from either of the theories occurs at about the same level of crystallinity. This conclusion is similar to that obtained previously in the crystallization in bulk¹⁵.

In comparison with the crystallization in bulk, higher crystallinity levels are obtained in solution. For the fraction used in this work, the total crystallinity varies from 90 to 95% and does not depend on the solvent. The slope of the linear portion of the G6ler–Sachs plot, corresponds to the

exponent in the Avrami equation, and these slopes are dependent on solvent. For decalin and *p*-xylene n is four and for α -chloronaphthalene and tetralin n is three. The differences in the exponent n is made clear in Figure 5 where we have superimposed points from two different solvents, decalin and tetralin. Previously, the Avrami exponent for *p*-xylene, decalin and *n*-hexadecane was found to be $n = 4$ in all cases⁶. The simplest interpretation of the exponent $n = 4$ is the occurrence of an homogeneous nucleation accompanied by three-dimensional growth and for $n = 3$, an homogeneous nucleation with a two-dimensional growth. The first fact must be reconciled with the lamella-like crystallites that are observed. The fact that integral values of 3 are obtained in α -chloronaphthalene and tetralin is very important. There is no correlation between the interaction polymer solvent and n and differences observed must remain unexplained at present. How-

ever, the exponent $n = 3$ looks as if it corresponds to poor solvents, in which the molecules freely interpenetrate one another, and the exponent $n = 4$ corresponds to better solvents.

The crystallization rate depends strongly on the solvent. Thus the time necessary for 10% of the transformation to occur at 87.2°C is ~ 3000 min for the polyethylene fraction in decalin while in xylene the time is reduced by a factor of 6. It is tempting to relate this difference to the intensity of polymer-solvent interaction embodied in the parameter χ_1 . Most of the values of χ_1 reported in the literature for these systems, were calculated on the basis of the familiar relationship:

$$\frac{1}{T_m} - \frac{1}{T_m^0} = \frac{R}{\Delta H_u} \frac{V_u}{V_1} v_1(1 - \chi_1 v_1) \quad (2)$$

where T_m^0 is the melting temperature of the undiluted polymer, of infinite molecular weight. As it has been pointed out³ the validity of equation (2) is questionable for very dilute solutions and although it describes the equilibrium, the appropriate thermodynamic quantities may no longer remain constant because of the non-uniform polymer segment distribution throughout the medium. Only when the solvent is sufficiently poor may these aspects be neutralized.

Although different investigations have led to different absolute values for the interaction parameter, they rank in the same order for different solvents, as can be seen in Table 1. Decalin has the lowest value for χ_1 and xylene the highest. Therefore, the crystallization rate, at a given temperature, is lower in the better solvent. However, it is difficult to find a correlation between χ_1 and the magnitude of the crystallization rate as can be seen in Table 1 where χ_1 and the temperature at which 10% of the crystallization occurs in 100 min has been represented for polyethylene in several solvents. The lack of correlation may be due to the fact that the estimation with sufficient accuracy of χ_1 presents serious difficulties. This point will be discussed later.

Nucleation free energy

The free energy of melting of crystalline polymers was calculated by Flory¹⁷ using the lattice model. One of the main contributions to the free energy of melting is the free enthalpy of mixing which for a quasibinary system (single solvent plus multicomponent homologous polymer) is given by:

$$\Delta F/RT = n_1 \ln v_1 + \sum n_i \ln v_i + g n_1 v_2 \quad (3)$$

In the above equation n_1 , n_i are the number of moles and v_1 , v_i the volume fractions of solvent and polymer species i , respectively, $v_2 = \sum v_i$ is the whole polymer volume fraction and RT has its usual meaning. The dimensionless interaction function g is allowed to depend on temperature, pressure and concentration, but not on the molecular weight of any of the species. According to equation (3) the chemical potential of the solvent, referred to its value in the pure liquid is given by¹⁸:

$$\Delta\mu/RT = \ln(1 - v_2) + (1 - x^{-1})v_2^2 + \chi v_2^2 \quad (4)$$

where $\chi = g - v_1 \delta g / \delta v_2$. Moreover, the concentration dependence of χ can be expressed in series form:

$$\chi = \chi_1 + \chi_2 v_2 + \dots \quad (5)$$

A molecular weight dependent contribution to g are the end-group contributions^{19,20} as well as the well-known inherent non-uniformity²¹ of local polymer segment concentration at high dilutions. It has long been recognized that an interaction function g independent of chain length cannot describe the thermodynamic properties of dilute polymer solutions; e.g. the second and third virial coefficients are known to depend on molecular weight. As it is well known two extremes of polymer solutions behaviour can be distinguished. At sufficiently high concentration, we have an enmeshed, intertwined and entangled assembly of chains. Under these conditions, an essentially uniform polymer segment concentration may be assumed throughout the solution and the theoretical treatment leads to equation (2) with an interaction coefficient g that is independent of chain length except for the specific end-group effects. At high dilutions, however, the macromolecules are more or less isolated from each other, only occasionally interacting in small clusters.

Koningsveld *et al.*¹⁸ have considered the dependence of g on molecular weight, by assuming g for a polymer solution of arbitrary concentration as a simple linear combination of the two extreme cases described above. For a strictly binary polymer solution these authors obtain:

$$g = g_{\text{conc}} + \left(\frac{1}{2} - \chi_1 \right) (1 - h(Z))(1 + \lambda)^{-1} \exp(-\lambda_0 x^{1/2} v_2) \quad (6)$$

Table 1 Values of the interaction parameter for different solvents

Solvents	χ_1	T_c

Chloronaphthalene	0.30 ^{8,16}	96
Hexadecane*	0.15 ^{10,11}	105

*Kinetic data from ref 6

The factor $h(z)$ is always less than unity above the θ -temperature and is theoretically related to the average number of nearest neighbour segment-segment contacts between two polymer chains of a binary cluster. λ_0 is given by:

$$\lambda_0 = 4\pi a N_A b^3 V_1^{1/2} / 3 \bar{v}_2^{3/2} \quad (7)$$

where $b = S_i M_i^{-1/2}$, S_i^2 being the mean square polar radius of gyration, a is a geometric factor of order unity and \bar{v}_2 is the effective specific volume of polymer.

The free energy change involved in forming a cylindrically arranged crystalline array of ξ units long and ρ sequences in cross-section, for a diluted system containing N polymer molecules each comprised of x repeating units, in which the volume fraction of polymer is v_2 , is given by⁴:

$$\Delta F_D = 2\pi^{1/2} \sigma_u \xi - 2\rho \sigma_e \ln v_2 - \xi \rho \Delta f'_u + \xi \rho \frac{RT}{x} v_2 - \rho RT \ln \frac{x - \xi + 1}{x} \quad (8)$$

where σ_e is the lateral interfacial free energy per repeating unit as it emerges from the crystal face normal to the chain direction. The third term in equation (8) represents the depressed energy of fusion for the units involved in the transformation. By taking into account equation (6) $\Delta f'_u$ can be written in the following way:

$$\Delta f'_u = \Delta f_u - RT \frac{V_u v_1}{V_1} \left\{ 1 - \left[g_{\text{conc}} + \left(\frac{1}{2} - \chi_1 \right) \times (1 - h(z)) (1 + \lambda)^{-1} \exp(-\lambda_0 x^{1/2} v_2) \right] v_1 \right\} \quad (9)$$

where Δf_u is the energy of fusion per repeating unit for a chain of infinite molecular weight, V_u is the volume unit per repeating unit of the polymer and V_1 is the molar volume of the diluent.

As has been described in a previous work⁴, the surface described by equation (8) contains a saddle point and the coordinates of this point prescribe the dimensions of a nucleus of critical size. These dimensions are given by the relations:

$$\begin{aligned} \rho^{1/2} &= \frac{2\pi^{1/2} \sigma_u}{\Delta f'_u - (RT/x) v_2 - RT/(x - \xi + 1)} \\ \frac{\xi}{2} &\left(\Delta f'_u - \frac{RT}{x} v_2 + \frac{RT}{x - \xi + 1} \right) \\ &= 2\sigma_e - RT \ln v_2 - RT \ln \frac{x - \xi + 1}{x} \\ &= 2\sigma'_e - RT \ln \frac{x - \xi + 1}{x} \quad (10) \end{aligned}$$

and the free energy change, ΔF , involved in forming the critical nucleus is given by:

$$\Delta F = \pi^{1/2} \xi \rho^{1/2} \sigma_u \quad (11)$$

If a bidimensional nucleation is assumed and we use the concepts and notation of a previous analysis, the change in

free energy that accompanies the formation of a bidimensional nucleus, ξ units long and ρ sequences breadth is given by:

$$\Delta F = 2\sigma_u \xi \quad (12)$$

where ξ is expressed by the equation:

$$\xi = \frac{2\sigma'_e - RT \ln \frac{x - \xi + 1}{x}}{\Delta f'_u - \frac{RT}{x} v_2} \quad (13)$$

It is quite clear, independent of the type of nucleation assumed, that the free energy is strongly dependent on the depressed energy of fusion and this magnitude depends on the polymer-diluent interaction. The analysis of g according to the treatment of Koningsveld *et al.*¹⁸ is perfectly feasible in principle, but for its practical implementation a precise specification of the dependence of the second virial coefficient on molecular weight distribution is required. Present experimental and theoretical knowledge is quite limited. We are thus not in a position to evaluate the dependence of g on molecular weight and will use the approximation $g = \chi_1$ in further calculation. Moreover, we should stress that the estimation of χ_1 is a difficult task indeed; as a consequence, different authors obtain different values and the difference between these values are perhaps greater than the contribution to g of the corrections due to the excluded volume effects.

Temperature coefficient

The characteristic strong negative temperature coefficient found in the crystallization of polymer suggests a nucleation controlled crystallization. Taking, $\tau_{0,1}$, the time required for 10% of the crystallization to occur, as a measure of the rate constant and assuming for simplicity that only one type of nucleation process is rate controlling, the data can be analysed by the equation:

$$\ln \tau_{0,1}^{-1} = (\ln \tau_{0,1}^{-1})_0 - \frac{\Delta F}{RT} \quad (14)$$

where T is the crystallization temperature and ΔF is the energy required for the formation of a critical nucleus. If the rate determining step requires the formation of a two dimensional nucleus, then for chains of high molecular weight:

$$\ln \tau_{0,1}^{-1} = \ln (\tau_{0,1}^{-1})_0 - \frac{2\sigma_u \sigma'_e}{T \Delta f'_u} \quad (15)$$

It is clear that $2\sigma_u \sigma'_e$ can be obtained from the straight lines in the plot $\ln \tau_{0,1}^{-1}$ vs. $1/T \Delta f'_u$. The slopes of these lines are clearly dependent on the value taken for χ_1 . Taking as a typical example the polyethylene-tetralin system, if χ_1 for tetralin were taken to be 0.39 as reported by Nakajima *et al.*¹⁰ instead of 0.20, the earlier value given by Quinn and Mandelkern¹⁶, then σ'_e would increase from 3.000 cal/mol, to 4.800 cal/mol (Figure 6) if σ_u is equal to 58 ± 2 cal/mol, as it has been suggested by Mandelkern *et al.*⁶. Similar variations are observed in the other solvents. Therefore it is possible that within the uncertainty of the present

Figure 6 Influence of χ_1 in the coefficient temperature for polyethylene in tetralin

assignment of χ_1 , different values could be obtained for the slopes for each solvent. Consequently relatively high differences in the product of the interfacial free energies cannot be ruled out of this procedure.

It is thus paramount to assign a correct value to the thermodynamic interaction parameter χ_1 . From nucleation theory it is easily shown that equation (15) can be written in the following way:

$$\ln \tau_{0,1}^{-1} = \ln (\tau_{0,1}^{-1})_0 - \frac{2\sigma_u \sigma'_e}{\Delta H_u} \frac{T_s^0}{T \Delta T} \quad (16)$$

where ΔH_u is the enthalpy of fusion per repeating unit and T_s^0 , the equilibrium melting temperature (or dissolution temperature) of the dilute solution. As has been discussed in the literature^{3,8}, this quantity has evaded direct experimental determination and it has been obtained by various extrapolation procedures. The most reliable values of T_s^0 are represented in Table 2. Using these quantities a value of σ'_e equal to 4.800 cal/mol is obtained for polyethylene in different solvents when $\ln \tau_{0,1}^{-1}$ is plotted against $T_s^0/T \Delta T$ (Figure 7). This is the same value obtained by Mandelkern *et al.*⁶ from kinetic analysis and from the crystallite size-crystallization temperature relation⁸.

In order that the plots of Figures 6 and 7 for tetralin are consistent with one another the thermodynamic interaction parameter χ_1 should be 0.39 as has been reported by Nakajima *et al.*¹⁰. For the same reason of consistency we have used for other solvents the values of χ_1 which are summarized in Table 3. These chosen values completely agree with the values reported for decalin, xylene and tetralin and they are higher for chloronaphthalene and hexadecane. By using these values in equations (12) and (13), a set of parallel lines are obtained, and from the slopes a value σ'_e of 4.800 cal/mol is obtained.

The fact that solvents with different interaction parameter χ_1 , such as decalin and tetralin, are characterized by the same slopes in Figure 8 indicates that the interfacial free energies controlling the kinetics of crystallization are independent of the nature of the medium. A similar conclusion has been made earlier by other investigators^{6,7}. This is a very important finding as it enables the temperature solution T_s^0 and the interaction parameter χ_1 for any

Table 2 Values of T_s^0 , the dissolution temperature, for different solvents

Figure 8 Plot of $\ln \tau_{0,1}^{-1}$ against $10^5/T\Delta f'_U$ for the indicated solvents: \circ , decalin; \square , tetralin; \triangle , xylene; \bullet , n-hexadecane; \blacktriangledown , chloronaphthalene

given polyethylene-solvent system to be established if kinetic data are available. Thus, for instance, from our kinetic data we conclude that the equilibrium melting temperature of polyethylene in α -chloronaphthalene should be equal to 122.0°C and χ_1 equal to 0.43. On the same basis, $T_s^0 = 117.6^\circ\text{C}$ and $\chi_1 = 0.38$ for polyethylene in xylene.

It is interesting to analyse the influence of the solvent on the crystallization. The crystallization temperature for 10% of the transformation to occur in a given time, has

been indicated in Table 3. For any given crystallization temperature the depressed free energy of melting depends on $(1 - \chi_1)/V_1$ and as a consequence, the change of free energy involved in forming a critical nucleus increases as $(1 - \chi_1)/V_1$ increases. Therefore, the crystallization temperature should increase as $(1 - \chi_1)/V_1$ decreases as our results show.

With the establishment of the equilibrium dissolution temperature or the thermodynamic interaction parameter χ_1 , it is possible to assess the influence of the crystallizing medium and the temperature on the size of the critical nucleus in the chain direction. By assuming bidimensional nucleation, ξ is given by equation (13) and depends strongly on $(1 - \chi_1)/V_1$. With the values of χ_1 from Table 3, ξ can be calculated from equation (13). It is worthwhile stressing that these values calculated coincide quite well with the mature crystallite thicknesses, which have already been measured as a function of the crystallization temperature¹⁰.

In the analysis of the temperature coefficient of the crystallization process which has been carried out above, we have assumed the same temperature coefficient for both initiation and growth nucleation. This is a fairly standard assumption commonly used. In order to confirm this assumption we compare our results, based on overall temperature coefficient analysis, with the recent results of Cooper and Manley²³, who have measured the growth rates of polyethylene single crystals in xylene as a function of solution concentration, molecular weight and crystallization temperature using the self-seeding method. On increasing the concentration from 0.001 to 0.1%. Cooper and Manley found that the free energy product $\sigma_u \sigma_e$ increases with molecular weight in agreement with our earlier results of polyethylene in chloronaphthalene⁵. If a two dimensional process is assumed, the product $2\sigma_e \sigma_u$ is found to be $5 \times 10^5 \text{ cal}^2/\text{mol}^2$ when the concentration is 0.1%. Although this quantity is about 12% lower than the corresponding one deduced here for overall crystallization, the values can be considered comparable. Therefore, the suggestion is that the temperature coefficient of the overall process is a reflection of the temperature coefficient of lateral crystallite growth.

ACKNOWLEDGEMENT

We thank Professor L. Mandelkern for several helpful discussions on this work.

Effect of intra-chain double bonds on the melt crystallization of aliphatic polyesters

A. Di Meo, G. Maglio, E. Martuscelli and R. Palumbo

Laboratorio di Ricerche su Tecnologia dei Polimeri e Reologia, CNR, Arco Felice (Napoli), Italy

(Received 16 March 1976; revised 10 May 1976)

The influence of intra-chain double bonds on the crystallization rate of a series of linear aliphatic polyesters was investigated. The free energy of formation of a nucleus of critical dimensions decreases with the percentage of double bonds along the chain. The values of the free energy of folding drastically decreases with an almost linear trend with increase in the amount of unsaturation. The results may be interpreted assuming that the increasing chain flexibility decreases the free energy of formation of a nucleus of critical dimensions mainly because of a lamellar surface effect.

INTRODUCTION

The influence of intra-chain double bonds, introduced along the chain of polyamides and linear polyethylene, on the crystallization rate from the melt has been reported previously^{1,2}. The results have shown that both kinetic and thermodynamic quantities such as the half time of crystallization, kinetic rate constant, the free energy of formation of a nucleus of critical dimensions and the surface free energy of lamellar fibrillae of spherulites are dependent upon the chain flexibility, i.e. upon the amount of double bonds distributed along the macromolecular chain.

This investigation has been extended to include crystallization rate measurements for a series of linear aliphatic polyesters with various amounts of double bonds along the chain.

The whole research is part of a general project leading to the study of the properties of some important class of polymers whose chemical structure has been modified³.

EXPERIMENTAL

Materials

The polyesters were prepared by melt polycondensation of 1,16-hexadecandiol with the acid chlorides⁴. They are reported in *Table 1*, along with their composition, inherent

viscosity and number-average molecular weight. From the data reported in *Table 1* it may be deduced that effects of the molecular weight on the crystallization kinetics should be negligible.

Calorimetry

All the measurements were carried out using a Perkin-Elmer DSC-2 differential scanning calorimeter operating under N₂ atmosphere with samples of 4 to 8 mg by wt.

The temperature scale was calibrated against the melting temperature of high purity standards for each of the individual heating rates. For the determination of the heat of fusion indium was used as the standard material. The following procedure was used to record the crystallization exotherm: the sample was kept for 10 min at a temperature 20°C higher than the melting temperature T_m and then cooled rapidly to the predetermined crystallization temperature T_c and the exothermic curve of crystallization was recorded. Furthermore the melting thermograms of the crystals formed in the isothermal crystallization were performed after each crystallization run. The maxima of the melting endotherms were taken to be the melting temperatures. The method used for the determination of the weight fraction of crystallized material at time t , X_t , has been described in detail in previous papers^{1,2}.

Measurement of X-ray diffraction patterns

The wide-angle X-ray diffraction patterns were recorded at room temperature over the range of diffraction angles (2θ) from 2° to 50° with nickel filtered CuK α radiation by

RESULTS AND DISCUSSION

Kinetics and thermal data

Typical examples of crystallization isotherms obtained by plotting X_t versus time are shown in Figure 1. From these curves the half life time of crystallization $t_{1/2}$ was calculated. The variation of $t_{1/2}$ with T_c is given in Figure 2 for each of the polyesters investigated.

For every T_c and for each sample the Avrami exponent n was calculated from the slopes of the lines obtained by plotting the quantity $\log[-\log(1 - X_c)]$ against $\log t^6$ and thereafter the rate constant Z was calculated according to the relation:

$$Z = \frac{\ln 2}{(t_{1/2})^n} \quad (2)$$

Typical Avrami plots are shown in Figure 3.

The values of the equilibrium melting temperature were graphically determined by plotting the melting temperature T_m versus the crystallization temperature T_c by using the well known relation⁷:

$$T_m = T_m^0 \left(\frac{\gamma - 1}{\gamma} \right) + \frac{T_c}{\gamma} \quad (3)$$

where γ is constant.

In Table 3 the values of n and $\log Z$ are given as functions of T_c together with T_m^0 for each polyester examined. The values of n range from 2.8 to 4.1. T_m^0 decreases linearly with the increase in the amount of 4-OD units along the chain. This trend is shown in Figure 4.

For sample P_s, T_m^0 is equal to 382K while for sample P_i the value is reduced to 358K with a percentage lowering of 6.3%. Assuming that the crystallization of polymers from melt is of lamellar type then overall rate constant of crystallization Z can be described in terms of a classical equation^{7,8} which can be written as:

$$\frac{1}{3} \log Z + \frac{\Delta F^*}{2.3KT_c} = A_0 - \frac{\Delta \Phi^*}{2.3KT_c} \quad (4)$$

where ΔF^* is the activation energy for the transport of a chain unit across the liquid-crystal interface and $\Delta \Phi^*$ can be written:

Figure 1 Crystallization isotherms of polyesters with different composition at various crystallization temperatures. (a) Sample P_s, T_c values: A, 346.5K; B, 347.5K; C, 348.4K; D, 349.4K. (b) Sample P_i, T_c values: A', 341.7K; B', 342.6K; C', 343.6K; D', 344.6K

using a Philips diffractometer. The scattering intensities of the crystalline part were obtained by subtracting the contribution of the amorphous part and the incoherent scattering from the total scattering intensity. To separate the contribution of the crystalline part and to calculate the mass crystallinity conventional methods were followed⁵.

The thermodynamic enthalpy of melting ΔH_F has been calculated by means of the simplified relation:

$$\Delta H_F = \frac{\Delta H_F^*}{X_c} \quad (1)$$

where ΔH_F^* is the apparent enthalpy of fusion as deduced from d.s.c. traces and X_c is the X-ray mass crystallinity. In Table 2 the quantities ΔH_F^* , X_c and ΔH_F are reported for each of the samples examined.

Figure 2 Variation of half time of crystallization $t_{1/2}$ with crystallization temperature for aliphatic polyesters. \blacksquare , P₁; \bullet , P₃; \blacktriangle , P₂; \square , P_i; \circ , P_s

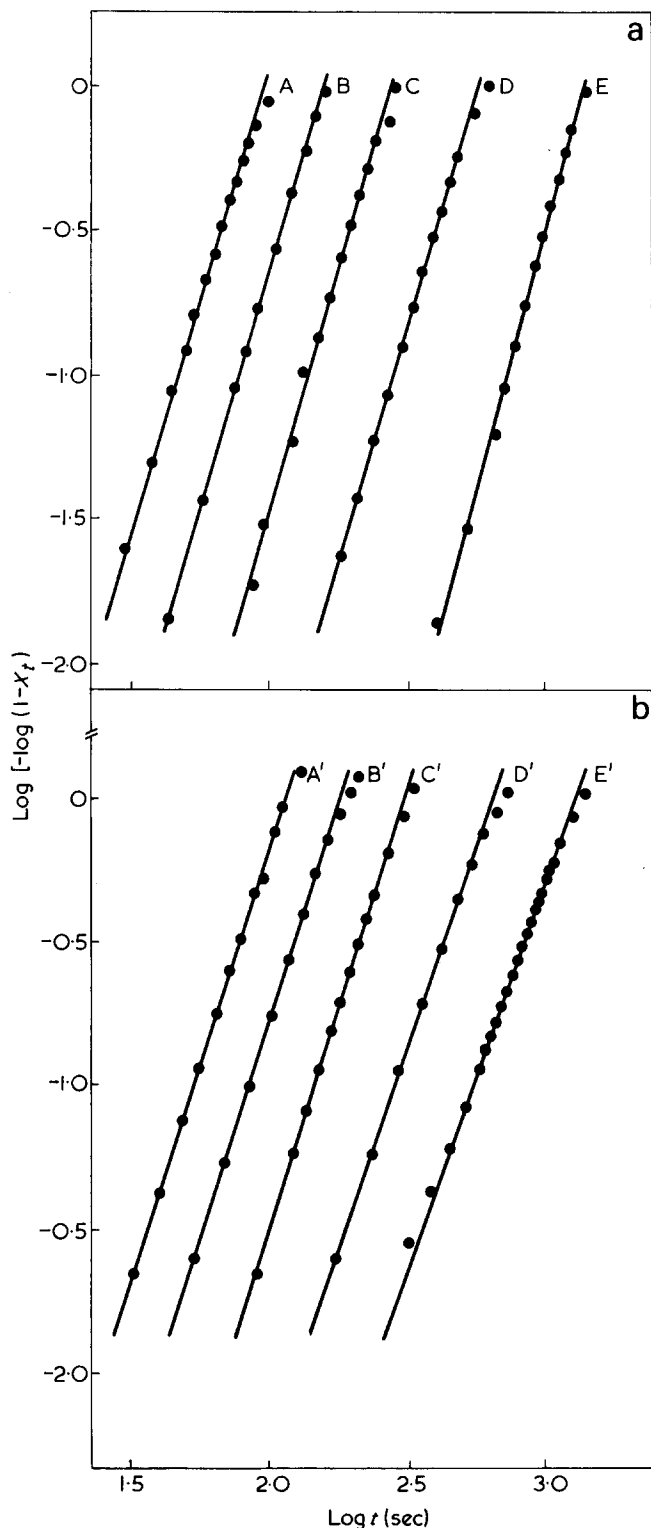

Figure 3 Avrami plots for copolyesters with different composition at various crystallization temperature. (a) Sample P_s, T_c values: A, 346.5K; B, 347.5K; C, 348.4K; D, 349.4K; E, 350.4K. (b) Sample P₁, T_c values: A', 341.7K; B', 342.6K; C', 343.6K; D', 344.6K; E', 345.3K

$$\Delta\Phi^* = \frac{4b_0\sigma\sigma_e T_m^0}{\Delta H_F(T_m^0 - T_c)} = \frac{4b_0\sigma\sigma_e T_m^0}{\Delta H_F\Delta T} \quad (5)$$

where b₀ is the distance of two adjacent fold planes and σ and σ_e are the free energies of formation per unit area of the lateral and end interfaces of the lamellar crystal respectively.

Equation (4) may be rewritten as:

$$\frac{1}{3} \log Z = A_0 - \frac{\Delta F^*}{2.3KT_c} - \frac{4b_0\sigma\sigma_e T_m}{\Delta H_F 2.3KT_c \Delta T} \quad (6)$$

According to equation (6) and taking the term A₀ and ΔF^{*}/KT_c to be relatively insensitive to temperature in the vicinity of the melting point, a plot of 1/3 (log Z) against T_m⁰/T_cΔT should be a straight line of slope 4σσ_eb₀/2.3KΔH_F. Such plots for the series of polyesters investigated are given in Figure 5. A linear trend is observed for all samples of polyesters. The values of the slopes of the straight line drawn through the experimental points are reported in Table 4. The free energy of formation of a nucleus of critical dimensions calculated from the slopes of Table 4 decreases with the percentage of 4-OD units along the chain of the polyesters. This trend is shown in Figure 6 for two different values of the undercooling.

Wide-angle X-ray diffraction analysis of polyesters

Wide-angle X-ray diffraction traces of the polyesters under examination are given in Figure 7. It is well known from literature data⁹ that aliphatic polyesters generally crystallize according to a polyethylene-like monoclinic unit cell with the chains in a *trans* planar conformation.

For sample P_s we assumed a unit cell similar to that of 10–16 aliphatic polyester ($a = 6.47 \text{ \AA}$; $b = 7.38 \text{ \AA}$; $c = 37 \text{ \AA}$; $\beta = 115^\circ$) except for the length of the \bar{c} axis assumed equal to $37 - 2.5 \text{ \AA}$ where 2.5 \AA is the shortening due to the absence of two methylenic groups. According to this consideration it is possible to calculate for the equatorial (110) and (020) reflections; values of spacing of 4.14 and 3.69 \AA , respectively. These values agree very well with the observed spacings of the two most intense reflections on the X-ray traces of the P_s sample, 4.12 and 3.69 \AA , respectively.

These planes are also the most probable fold planes in the case of linear aliphatic polyesters. Sample P_1 shows an X-ray spectrum similar to that of P_s , only a shift toward smaller angles being observed for the (020) reflection.

The unsaturated polyester, sample P_i , has an X-ray diffraction pattern that is totally different from that of the sample P_s . This result is an indication that this polyester crystallizes in a different crystalline unit cell. The X-ray diffraction patterns of the P_2 and P_3 samples (0.57 and 0.75 molar fractions of 4-OD respectively) still show the reflection characteristic of the fully saturated polyester P_s together with some of the more intense reflections characteristic of the fully unsaturated polyester P_i . As observed in the case of the P_1 sample, the (020) reflection of the P_s -like phase shows also for P_2 and P_3 an increasing shift toward smaller angles indicating an expansion of the unit cell along the b -axis. This result is interpreted by assuming that unsaturated units can be incorporated in the P_s crystal lattice as defects. The relative intensities of the reflections lead us to conclude that, for the P_2 and P_3 samples, the fraction of material crystallized with a P_i -like structure is very low. This observation may account for

P_i	3.83	964	8.8	110

Figure 8 Variation of b_0 with the composition of the polyesters

Figure 9 Effect of the copolyesters composition on the value of σ_e (●) and σ (■)

the absence of double peaks both in the fusion endotherm and in the crystallization exotherm.

Moreover to neglect the contribution of the very low amount of the P_i -like phase in the treatment of the thermal and kinetic data should not affect the qualitative trend of the thermodynamic parameters investigated as function of the composition.

For all the polyesters we assumed that the equatorial plane has a smaller spacing than the fold plane. These planes were identified by means of fibre spectra. The fold planes are coincident with the (020) reflection of the saturated polyester phase in the case of sample P_s , P_1 , P_2 , P_3 . For sample P_i we assumed as fold phase that corresponding to the marked peak in Figure 7.

The variation of this spacing, that is coincident with the term b_0 in equation (5), is shown in Figure 8 as function of the percentage of 4-OD units in the sample.

Surface free energies calculation

From the values of $4b_0\sigma\sigma_e/2.3K\Delta H_F$ of Table 4, b_0 and ΔH_F being determined for every samples, it was possible to calculate the quantity $\sigma\sigma_e$. The values are reported in Table 5.

The free energy σ of surfaces parallel to the chain axis of the lamellar crystals was calculated by means of the well known empirical relation⁷:

$$\sigma = \Delta H_F b_0 \alpha \quad (7)$$

where α for polymeric material is assumed equal to 0.1. From the values of $\sigma\sigma_e$ and σ the surface free energy of folding σ_e was obtained. The values of σ and σ_e are reported in Table 5.

As shown in Figure 10 σ_e drastically decreases with an almost linear trend with increase in the amount of unsaturation, whilst σ is practically constant. Values of σ_e of 224 and 110 erg/cm² are obtained for samples P_s and P_i respectively with a percentage reduction of 51%.

It can be concluded that the higher chain flexibility of the more unsaturated chains¹⁰ decreases the free energy of formation of a nucleus of critical dimension mainly because of a lamellar surface effect. This surface effect is probably due to an increase in the values of the surface entropy of folding σ_e . The same result was observed in the case of linear aliphatic copolyamides¹.

Chain conformation of poly-(tetramethylene terephthalate) and its change with strain

I. H. Hall and M. G. Pass*

Department of Pure and Applied Physics, University of Manchester Institute of Science and Technology, Manchester M60 1QD, UK

(Received 1 March 1976; revised 21 April 1976)

In monofilaments of poly(tetramethylene terephthalate) the chain conformation changes reversibly between two forms as the fibre is strained. Both forms and their packing have been determined using the techniques of X-ray diffraction. In the unstrained form the methylene section of the chain has the conformation *gauche-trans-gauche*; on straining this changes to *trans-trans-trans*. The consequences of this change on other structural parameters are discussed in detail.

INTRODUCTION

Poly(tetramethylene terephthalate) is a member of the family of polymers having the structural formula:

and abbreviated n-GT. The best known member of this series is 2GT [poly(ethylene terephthalate)] which has been extensively studied. Other members have received much less attention. The series is of particular interest with regard to relationships between structure and properties of polymers, and previous publications have dealt with comparisons of melting points and glass transitions^{1,2}, with studies of molecular mobility using broad-line nuclear magnetic resonance²⁻⁴ and in a very limited way with crystallographic structure^{2,3,5}.

The present investigation forms part of a study of the relationship between the structure and properties of n-GT for $n = 3, 4$, and 5 , using the techniques of X-ray diffraction and Laser-Raman spectroscopy. It has already been reported that the chain conformation of 3- and 4GT varies by a surprisingly large amount with strain⁶. The conformation of 4GT undergoes a discontinuous change at strains in the region of 4–6%, and in a preliminary publication the unstrained conformation has been described⁷ together with provisional indications of the way it changes with strain. The present paper is a detailed account of the determination of these structures. When it was in an advanced state of preparation the structure of 4GT was published⁸, but it is still of interest to compare the two independent sets of results.

EXPERIMENTAL

Material

4GT polymer chip with an intrinsic viscosity of 0.75 dl/g was made available for this study by ICI Fibres Ltd. It was spun into monofilament at 252°C, the collec-

tion speed being adjusted to give a filament of suitable diameter. The monofilament was drawn over a hot pin (90°C) and plate (170°C), giving a final diameter of 200 μm . A filament as coarse as this was chosen in order that a single fibre could be used in the experiments in which it was strained, and reasonably short X-ray exposures used. The final draw ratio of the fibre was 7:1.

Following drawing, the monofilaments were mounted, just taut, on a frame and annealed for at least 4 h at 202°C. They then had extremely well developed crystallinity and high orientation. After annealing, the birefringence was 0.183 ± 0.007 .

Recording of diffraction data

X-ray diffraction photographs were taken using nickel filtered $\text{CuK}\alpha$ radiation with a camera of the type described by Elliott⁹ and manufactured by G. and D. Searle Ltd. The essential feature of this camera is that a high-intensity, highly monochromatic beam of X-rays of about 40 μm diameter is focused at the film position giving a diffraction photograph of good resolution with comparatively short exposure time. A cylindrical film holder was used and the camera evacuated to eliminate air scatter.

The photographs of the unstrained material revealed biaxial orientation. This has been interpreted qualitatively, but in order to generate true cylindrical symmetry in the photographs used for structural analysis the fibre was spun about its axis whilst the exposure was being made. The specimen holder in which this could be carried out only became available later in the investigation. Some of the intensities were measured from photographs in which the fibre was stationary and may therefore contain some error due to biaxial effects.

To obtain diffraction photographs of the strained fibre, it was strained by 10% whilst mounted in the specimen holder used during the X-ray exposure. This value of strain was chosen because separate experiments had revealed that it was sufficient for most of the material to have adopted the strained conformation, and that diffuseness of the pattern increased at higher strains. The strained fibre was allowed to stand for a few hours so that major relaxation effects could occur before the exposure was made. Experiments

* Present address: ICI Fibres Ltd, Hookstone Road, Harrogate, Yorks, UK.

Figure 1 X-ray diffraction patterns of 4GT fibre. (a) Relaxed; (b) strained at 10%

in which the fibre was re-annealed whilst strained produced negligible improvement in the clarity of the diffraction pattern, and so this procedure was not adopted.

Biaxial orientation persisted in the strained state, and so the fibre was spun on its axis during the exposure. A diffraction pattern of each state of the fibre is shown in Figure 1.

Determination of unit cell parameters

The location of all the diffraction spots on the film was measured, and a reciprocal unit cell that would fit these was determined by trial and error. In the diffraction pattern of the unstrained fibre, the reflections were displaced up and down from the mean layer line positions, indicating that the molecular chain axes were systematically misoriented from the fibre axis by a few degrees, (i.e. the *c*-axis of the unit cell was slightly tilted with respect to the fibre axis). Similar behaviour was reported by Daubeny *et al.* for 2GT¹⁰ and following the method he described, the magnitude and direction of tilt was determined, and it was shown that displacement of all reflections could be explained this way, thereby confirming the correctness of the unit cell. This tilting persisted in the strained form, but not to such a

marked extent. Daubeny *et al.* found with 2GT that annealing under tension would remove the tilt. This did not occur with 4GT.

The unit cell parameters were refined by minimizing the sum of the differences between the squares of the *d*-spacings calculated from the location of the diffraction spots and those calculated from the unit cell. Since a *d*-spacing can be determined directly from the location of a reflection, even though it is displaced from a layer-line, this procedure was particularly convenient.

Determination of intensity of X-ray diffraction spots

The integrated intensity of each reflection was determined using an Optronix 'Photoscan' digital microdensitometer in conjunction with an Optronix 'Photowrite' machine. The technique has been fully described elsewhere¹¹. As far as possible, allowance was made for background intensity, and intensity was apportioned between partly overlapping reflections. Where this could not be done the reflections were treated as an overlapping group.

Determination of chain conformation

Relaxed form. Comparison of the density calculated from the unit cell dimensions with the measured value confirmed that there was one monomer of one molecular chain per cell. This monomer is illustrated in Figure 2 which also defines the symbols used to specify particular angles and bonds. It was assumed that the conformation was centro-symmetric about the points marked. An attempt to confirm this using intensity statistics was inconclusive.

Because of the small quantity and relatively poor quality of the intensity data, it was considered unlikely that a complete structural determination would be possible. Therefore bond lengths and angles were assumed to be the same as those in comparable low molecular weight compounds. Only the chain conformation angles and the orientation of the molecule in the unit cell then remain to be determined.

Bailey¹² and Ohrt *et al.*¹³ have determined the structures of compounds containing many similar bonds to those found in 4GT. Daubeny *et al.*¹⁰ attempted to determine bond lengths and angles in their structural analysis of poly(ethylene terephthalate) as did Tomashpol'skii and Markova¹⁴ from electron diffraction data. Very recently Pérez and Brisse¹⁵⁻¹⁷ have published the structures of ethylene glycol dibenzoate, ethylene glycol di-*para*-chlorobenzoate, and trimethylene glycol di-*para*-chlorobenzoate, all of which closely resemble the 4GT monomer. Bond lengths and angles from all these studies are listed in Table 1 and defined in Figure 2 (values obtained by Tomashpol'skii *et al.* have been omitted because some seem very questionable). Our own choice of assumed values is also given in this Table. Where discrepancies between the various values

1, From structure of diethyl terephthalate¹²; 2, from structure of *trans*-4-*t*-butyl cyclohexanol *para*-bromobenzoate¹³; 3, calculated from atomic coordinates of poly(ethylene terephthalate)¹⁰; 4, from structure of ethylene glycol dibenzoate¹⁵; 5, from structure of ethylene glycol di-*para*-chlorobenzoate¹⁶; 6, from structure of trimethylene glycol di-*para*-chlorobenzoate¹⁷; 7, assumed by Mencik⁸ in structural analysis of 4GT; 8, assumed in the present work.

For identification of bonds, see Figure 2. A blank has been left where no comparable bond exists in the model compound, or where it has not been possible to determine a value from the data given

exist we have used ones similar to those of Pérez and Brisse which are likely to be the most relevant to our work. No bond comparable with C₇-C₆ exists in any of the model compounds and we investigated two possibilities in our trial structures: (a) 1.54 Å which is comparable with the C-C bond in the methylene chain, and (b) 1.50 Å which is comparable with the value found by Pérez and Brisse¹⁵⁻¹⁷ in compounds where the C-C bond is adjacent to an O-C bond. A similar uncertainty exists in the value chosen for α₁₀. The only comparable bond in the compounds listed was in trimethylene glycol di-*para*-chlorobenzoate and was larger than similar bond angles in the methylene chain. The latter value was chosen but the effect of varying it was investigated.

The values chosen by Mencik⁸ are also listed in Table 1. It will be seen that several differ significantly from those chosen by us.

The terephthaloyl residue contributes most of the scattering power of the molecule and is likely to be almost planar. There is only one of these in each unit cell and so its centre was placed at the origin of coordinates, and, assuming it to be planar, the inclination found which gave best agreement between observed and calculated structure factors. Once the inclination of this unit is fixed there are only four different ways in which the section of chain O₁-C₅-C₆-C₇ can be added which will preserve the centre of symmetry, chain repeat length, bond lengths and bond angles. Hence four trial models were generated and the final conformation was found by refinement of these models.

If bond lengths and bond angles are fixed the only degrees of freedom available to the system are the chain conformation angles, τ₁ to τ₄ in Figure 2 (from the as-

sumption of centro-symmetry τ₅ = 180°), and angles which define the inclination of the molecule within the unit cell. This complete set of angles must satisfy the constraints of symmetry and chain repeat length, but subject to this requirement may be varied to minimize the sum of the squares of the differences between the observed and calculated structure factors, these differences being weighted according to some suitable scheme¹⁸. This technique of refinement of polymer structures was described by Arnott and Wonacott¹⁹ and a computer program for performing it was kindly made available for the present investigation by Professor Arnott (The Linked Atom Least Squares Structure Refinement System for Helical Polymers).

For the purpose of computation a model of the chain is built by successively adding atoms, starting at H₁ and proceeding to C₇ (Figure 2). Suppose the atom C₄ has been reached and O₁ is about to be laid down. Its position will be determined by three parameters, the bond length C₄-O₁, the bond angle α₆, and the conformation angle τ₁. The manner in which τ₁ is measured may be understood by reference to Figure 3. In this Figure the section of chain C₂-C₃-C₄-O₁ is held so that C₃-C₄ (the bond about which τ₁ is being measured) is normal to the plane of the diagram with C₂-C₃ (the section already built) above the plane of the diagram and C₄-O₁ (the section about to be built) below. τ₁ is then measured as shown. It is positive if measured clockwise, negative if anticlockwise.

When the chain conformation has been fixed, the molecule still has to be placed in the unit cell. Its location is totally, and its orientation partly, determined by the fact that the centre of a benzene ring lies at the cell origin, and the chain axis coincides with the C-axis. However, the rotation of the chain about its axis is still undetermined. This

Figure 3 Convention for measuring the conformation angle τ

Table 2 Unit cell parameters

Parameter	Relaxed	Strained	Relaxed (from ref 8)
a (Å)	4.8(9)	4.7	5.96

c (Å)	11.6(7)	13.0	11.62
α (degrees)	98.0	102	115.2
β (degrees)	116.(6)	121	99.9
γ (degrees)	110.0	105	111.3

The chain axis is in the c -direction

is specified by the angle θ . The molecule is placed in the unit cell so that the normal to the plane of the benzene ring lies in the (010) plane. θ is the rotation about the chain axis required to bring the molecule into its correct orientation and is positive if this rotation is anticlockwise looking in the negative C direction.

The uncertainty concerning the value of α_{10} has already been mentioned. In general bond-angles might be expected to vary more between compounds than bond lengths. Consequently, when the best models had been obtained by refining τ_1 – τ_4 , α_8 – α_{10} were refined. The choice between 1.50 and 1.54 Å for the bond C_6 – C_7 was based on the results from these final models.

Unobserved reflections were omitted from the refinement procedure and R -factors calculated using only observed reflections.

Strained form. In general the same procedure was followed as with the relaxed form, differences being dictated by the fact that the quality of the intensity data was much poorer in this case.

Refinement of bond angles and lengths was less likely to be conclusive, and so the final refined values from the relaxed form were used. A refinement was attempted, but the results are only quoted to indicate possible changes, not to define a conformation.

Unobserved reflections were included at threshold intensity and only omitted from the refinement if the calculated value was less than this. However, so that R -factors should be directly comparable with those from the relaxed form, the values quoted are calculated on observed reflections only.

RESULTS

Unit cell

The unit cells of both the relaxed and strained fibre were triclinic and the parameters are given in Table 2. Whilst experimental results show conclusively that the change in c occurs discontinuously, they do not show whether the much smaller changes in the other parameters take place discontinuously or not.

The transformation between the two structural forms is known to commence at a fibre strain of about 2%, and as strain is increased above this value progressively more material is transformed until a strain of about 10% is reached at which the transformation is complete²⁰.

At about 6% fibre strain near-equatorial reflections are blurred whilst near-meridional ones remain sharp. This blurring might be due to disorder in the lateral packing of chains, or because two species of unit cell with only slightly differing lateral dimensions are present.

At about 10% strain the 100 reflection remains blurred, but other equatorial ones have sharpened. The (100) planes are fairly close to those of the benzene rings, suggesting that the stacking of these rings is somewhat disordered in the strained state.

A value of 1.286 g/cm³ has been reported for the density of a specimen of 4GT which shows negligible evidence of crystallinity in its X-ray diffraction pattern²¹. The density calculated from the unit cell dimensions of the relaxed material was 1.39(0) g/cm³ and the measured value of the sample used was 1.336 g/cm³. These values correspond to a crystallinity by density of 48%. Since it was not possible to measure the density of the strained sample, no value can be given for this state.

Systematic misorientation of chain axes

The crystallites are tilted by rotation about an axis which lies in the a^*b^* plane at an angle of 42° from the line of intersection of this plane with the ac plane, the angle being measured anticlockwise looking in the negative

Figure 4 Projection of 4GT unit cell down c -axis showing axis about which tilting occurs

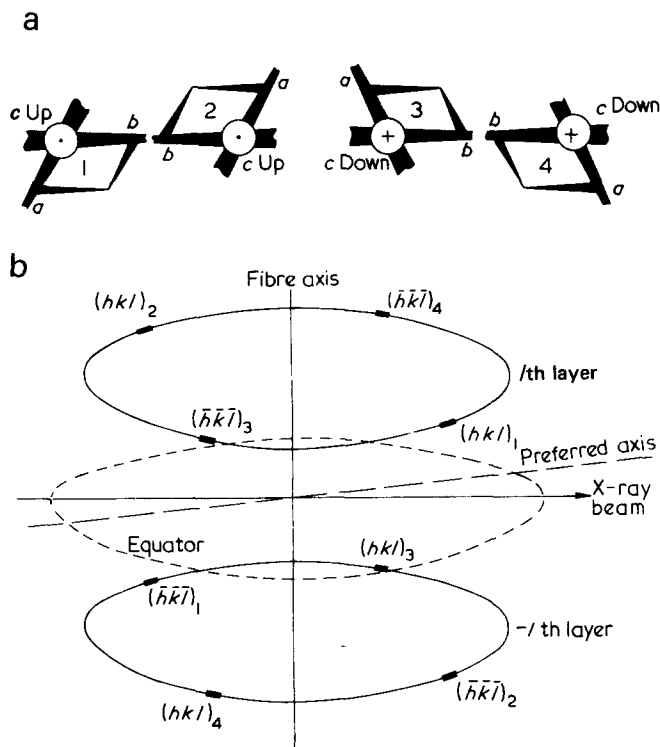

Figure 5 An example, showing four different unit cell orientations having two axial directions common. (a) Projections of the four cells down the c -axis. (It is assumed in this diagram that c and b -projected are the common directions. The direction of tapering indicates the directions in which the axes recede from the observer.) (b) Positions in reciprocal space of the same reciprocal lattice point for each cell

C direction. The magnitude of the tilt is such that the chain axes are, on average, inclined at an angle of $2^\circ \pm 0.2^\circ$ to the fibre axis. Its sense is such that the positive b -axis moves up, whilst the positive a -axis moves down (see Figure 4).

The (310) plane is almost normal to the tilt axis and so will remain vertical on tilting.

Biaxiality

The cross-section of the fibres was elliptical and photographs of stationary (not rotated) fibres showed indications of an axis of a preferred orientation of the crystallites in addition to the c -axis. Since the unit cell is triclinic, in this situation there can be four different possible orientations of the unit cell within the specimen. An example is illustrated in Figure 5a which shows projections of the cell edges on a plane normal to the c -axis and assumes that c and b -projected are the axes of preferred orientation. The plane containing these directions (100) (to be called the preferred plane) has the same orientation in each cell.

Figure 5b shows the positions of equivalent reciprocal lattice spots for each of these cell orientations [$(hkl)_1$ and $(\bar{h}\bar{k}\bar{l})_1$ are equivalent spots for the orientation labelled 1 in Figure 5a, and others are denoted similarly]. If it is assumed that all four orientations are equally probable, then the intensity of each of the illustrated reciprocal lattice points will be the same. Therefore, on a diffraction photograph of a stationary specimen (not rotated), equivalent spots above and below the equator (such as $(hkl)_1$ and $(\bar{h}\bar{k}\bar{l})_2$ in Figure 5b) will have the same intensity. In the general case, this will not be true for equivalent spots either side of the meridian; the relative intensities of these

will depend on their position relative to the sphere of reflection, i.e. on the orientation of the preferred plane relative to the X-ray beam. Their intensities will be equal only in the special case in which the beam is either parallel or perpendicular to this plane.

The intensity of equivalent spots above and below the equator was not equal on the diffraction photographs of the 4GT fibre used in this investigation. Thus the proportion of unit cells in an orientation such as 1 in Figure 5a was different from that in an orientation such as 2, and the proportion in an orientation such as 3 was different from that in 4.

On the other hand intensities of equivalent spots across the centre of the diffraction pattern tended to be similar. This cannot be interpreted without more detailed knowledge of the distribution of intensity in reciprocal space, but if the X-ray beam had been either parallel or perpendicular to the preferred plane, then it would imply that either the proportions in orientations such as 1 and 3 are similar, as are those in 2 and 4, or that the proportions in 1 and 4 are similar, as are those in 2 and 3. Both of these are consistent with the conclusion of the previous paragraph.

These results therefore indicate that there are two directions of preferred orientation in the fibre and that the four different unit cell orientations which are consistent with this do not occur in equal proportion.

To investigate biaxiality further, a sheet was prepared by melting polymer between hot plates under pressure. A section of this sheet was cold-drawn on a tensile testing machine and then annealed under vacuum for 24 h at 202°C . A Weissenberg photograph of the zero layer line showed that the b^* axis lay in the plane of the sheet or was, at most, inclined to it by a few degrees. Comparison of intensities in the different quadrants of a stationary-film photograph showed that all four possible cell orientations were present in approximately equal proportions. The biaxial texture was much more pronounced than with the fibre.

Chain conformation

Relaxed form. After preliminary refinement of the four trial models, it was clear that one gave much closer agreement between observed and calculated structure factors than the others. Subsequent investigations were confined to this model.

In the first stage of refinement, bond angles and lengths were kept constant at the values given in Table 1 and $\tau_1 - \tau_4$ allowed to vary. The values obtained for these angles at the end of this stage are given in columns 1 and 2 of Table 3 for both values of $C_6 - C_7$. In the second stage the bond angles $\alpha_8 - \alpha_{10}$ were allowed to vary as well as $\tau_1 - \tau_4$ and the values obtained at the end of this stage are listed in columns 3 and 4 of Table 3.

In this Table two parameters are given in addition to those defined already. These are not essential to defining the structure but help in visualizing the orientation of the terephthaloyl residue. ϕ is the angle between the bond $C_3 - C_4$ and the c -axis; ψ is the angle the normal to the benzene ring makes with the c -axis.

The different lengths for the bond $C_6 - C_7$ result in negligibly different conformations. If the values of α are kept constant during refinement R increases from 17.2 to 17.3 as the length of $C_6 - C_7$ is reduced from 1.54 to 1.50 Å. If the values of α are allowed to vary then R decreases from

Table 3 Parameters defining chain conformation

(b) Between molecules		
Atom pair	Unit cell translations between molecules	(Sum of radii) - separation, Strained model
H ₁ -C ₂	$a = 0, b = 1$	0.1(8)

17.0 to 16.8 with the same variation in C_6-C_7 . These differences are too small to be significant. However since the conformation in column 4 of Table 3 gave the lowest value of R , these parameters were used in the strained model. Tables and diagrams which refer to the relaxed form, and in which the particular conformation is not defined, are derived from the parameters in column 4.

It was assumed that the Van der Waals radius of the carbon atom was 1.7 Å, of oxygen was 1.4 Å, and of hydrogen was 1.0 Å. Using these values the separations of all pairs of non-bonded atoms were compared with the sums of their radii. Between molecules, all such separations were greater than this sum; within molecules, a few were less and these are listed in Table 4.

The chain conformation and packing within the unit cell is illustrated in Figures 6a-9a.

Strained form. Using values of bond lengths and angles modified according to experience with the relaxed form, four trial models were constructed as already described. Refinement of these again produced one which appeared better than the others. In this case, other factors were introduced as well as agreement between observed and calculated structure factors. (For example, τ_4 is known to move from a *gauche* towards a *trans* conformation²⁰ in

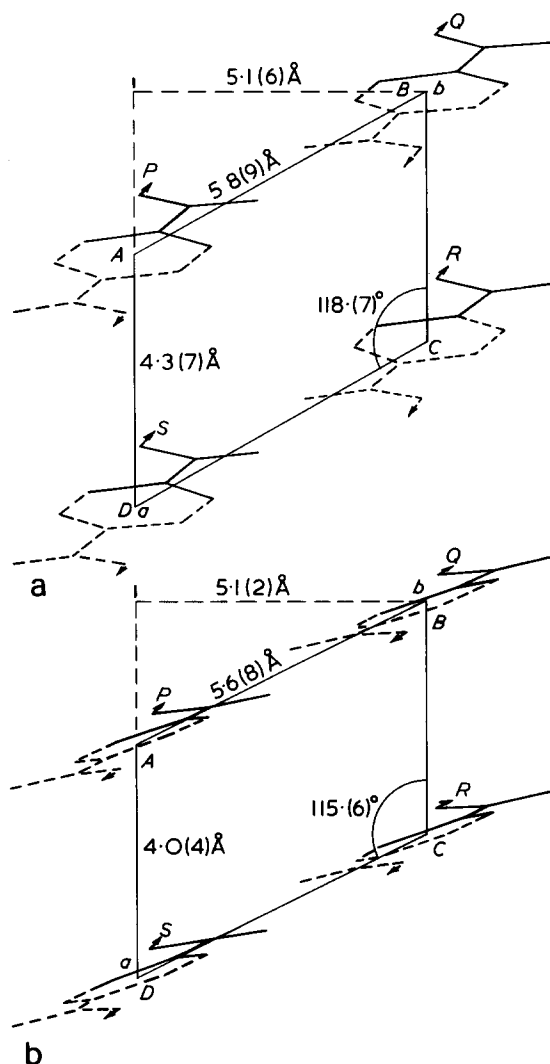

Figure 6 Projection of unit cell and terephthaloyl residue on to plane normal to c -axis. (a) Relaxed; (b) strained at 10%. (The methylene part of the molecule has been omitted from this diagram for clarity)

the transformation from the relaxed form, and the changes in other conformation angles must appear to be reasonable in experiments with molecular models.)

This model was refined by varying $\tau_1 - \tau_4$ but keeping bond angles constant and the values at the end of this stage

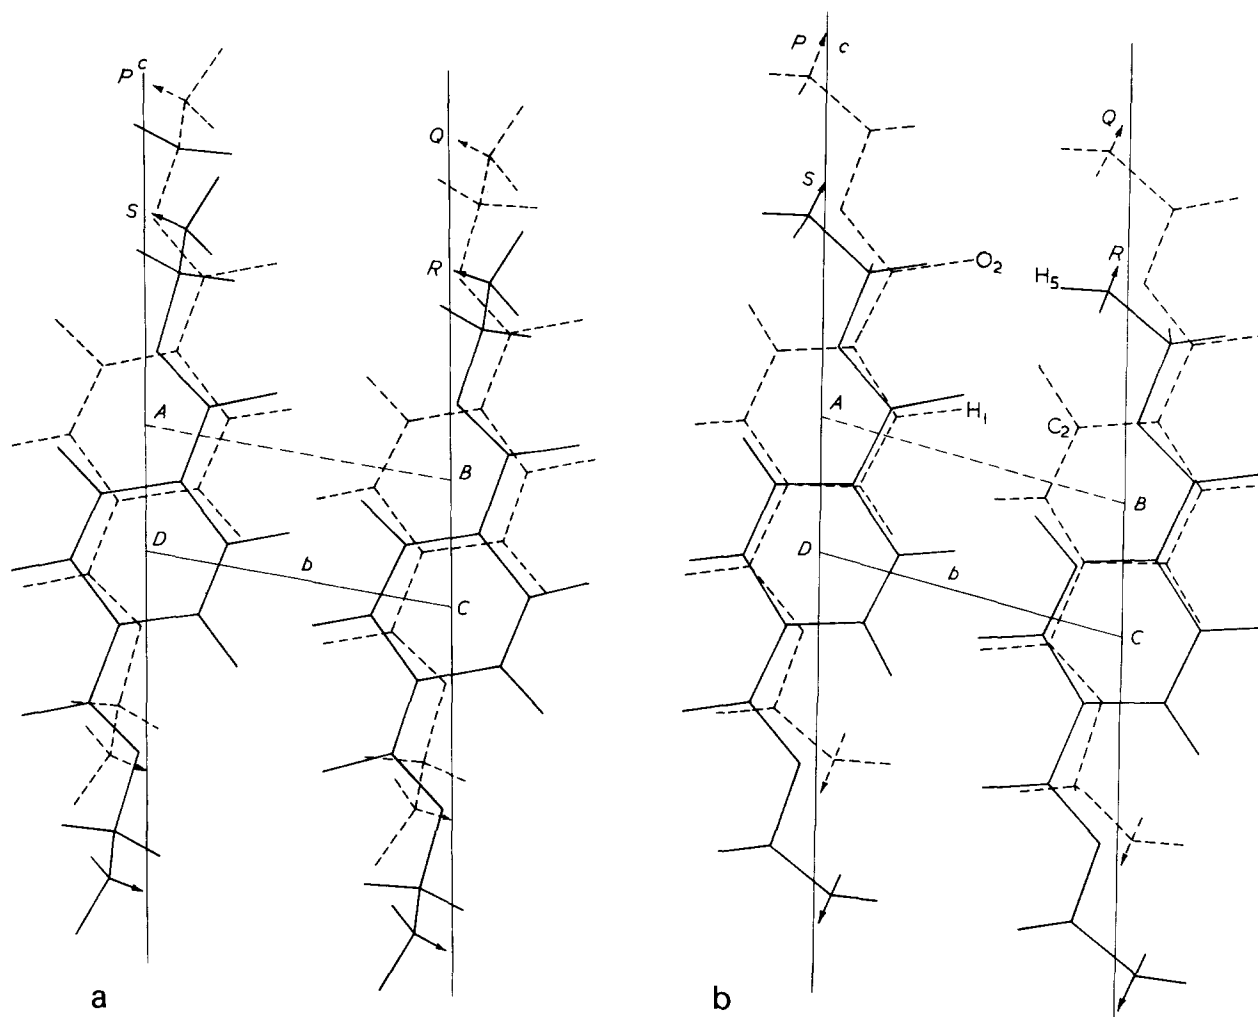

Figure 7 Projection of unit cell and contents onto b^*c plane. (a) Relaxed; (b) 10% strain

are given in column 6 of Table 3. Bond angles α_8 – α_{10} were then allowed to vary as well as τ_1 – τ_4 and the values obtained are given in column 7 of Table 3.

Because of the poor quality of the intensity data, this last conformation is unlikely to be any more accurate than that obtained with the bond angles fixed. It is only included to indicate possible variations in the parameters. Diagrams and Tables refer to the fixed bond-angle model.

The separations of all pairs of non-bonded atoms were compared with the sums of their Van der Waals radii. All cases in which the separation is less than the sum of the radii are listed in Table 4.

The chain conformation is illustrated in Figures 6b–9b.

DISCUSSION

From Table 3 it is clear that the orientation and shape of the terephthaloyl residue is almost the same for each of the relaxed and for each of the strained models. Most of the scattering power of the molecule is concentrated in this residue and so it is likely that this part of the structure has been determined fairly accurately. The other parts of the molecule complete the molecular chain within the constraints imposed, and variations in their parameters have a fairly small effect on the structure factors. Hence there is more doubt about this part of the structure, particularly for the strained form for which fewer reflections were recorded,

and (since they were more diffuse) for which intensities were measured less accurately.

For these reasons, the model of the strained form in which bond angle strain was allowed (column 7 of Table 3) will not be considered here, although this does suggest that bond angles α_8 and α_9 are opened by a few degrees on straining.

With the relaxed form, the terephthaloyl residue is planar, though Daubeny *et al.*¹⁰ found that in 2GT the carbonyl unit was about 10° out of the plane of the benzene ring. Tonelli²² has calculated the potential barrier to rotation about this bond and found it to be low. Deviations from planarity of 10° – 20° might not be surprising. However, in low molecular weight compounds containing this arrangement of atoms^{12–17} the unit is planar.

It has been assumed that there is a centre of symmetry, at the middle of the three bonds joining the methylene groups. Hence this central one must be *trans*, but the others are close to a *gauche* conformation. The conformation of this part of the molecule is shown in Figure 9a.

In 2GT the rotation about the only methylene bond is *trans* but Pérez and Brisse^{15,16} have investigated two low molecular weight analogues and found that in ethylene glycol dibenzoate it is *trans*, whereas it is *gauche* in ethylene glycol di-*para*-chlorobenzoate. In both of these materials τ_3 is nearly 180° whereas it is about -90° in 4GT. In 2GT it is -160° but in poly(ethylene adipate)²³ it is -114° . (In both of these cases the authors quoted values

Figure 8 Projection of unit cell and contents onto ac plane. (a) Relaxed; (b) 10% strain

have been transformed to agree with the conventions used in this paper). These two disparate values suggest a low potential barrier to rotation about this bond which is confirmed by our value. τ_2 is close to 180° in this and all similar structures.

If the structure reported here is compared with that given by Mencik⁸, there is a strong overall similarity with some differences of detail. The unit cells are in close agreement, (see Table 2) except that Mencik has made a different choice of a and b directions from us. Since our cell was the first to be published⁶ we propose to keep to our original convention.

There are some differences in the choice of bond angles and lengths. These are quantities which cannot be determined with high accuracy from studies in the polymeric state, and there must be some doubt in values assumed from similar atomic groups in low molecular weight compounds. However, since the values we take come from studies on compounds which bear a closer resemblance to 4GT than any others yet reported, where differences exist between ourselves and Mencik our values are likely to be the more reliable.

The major differences between the conformation angles found in the two studies are that we find the terephthaloyl residue to be more closely planar and rotation about methylene bond to be closer to *gauche*. To ascertain whether these differences followed from the choice of bond angles and lengths, the parameters given by Mencik

were used to construct a model which was then refined against our intensity data. The final model thus obtained had a closely planar terephthaloyl residue in agreement with our original model, but the methylene conformation angle was roughly midway between the values given by ourselves and Mencik.

Since most of the scattering power of the molecule is concentrated in the terephthaloyl residue the differences in this part probably follow from differences between the two sets of intensity data, but the difference in the methylene conformation is likely to follow from the choice of model parameters and the non-planarity of the terephthaloyl residue.

The R -factor of 14.8 obtained by Mencik was lower than the value of 16.8 obtained by us. However he applied independent scaling to each layer line, whereas we scaled them all by the same factor, and he also used a different formula to calculate R . (We use $R = \Sigma|F_0 - F_c|/\Sigma F_0$ whereas Mencik uses $R = [\Sigma(F_0 - F_c)^2/\Sigma F_c^2]^{1/2}$). The two values are not, therefore, comparable.

The shortest of the interatomic distances, that between O_2 and C_5 (Figure 2 and Table 4) is controlled by the conformation angle τ_2 and the bond angle α_8 (non-planarity in the bonds radiating from C_4 , which was not allowed in our refinement procedure, could also change this distance). τ_2 is nearly 180° which is common to all similar structures. 116° is a typical value for α_8 from similar structures; after refinement we get 119° which should increase this distance.

Figure 9 Conformation of methylene part of molecule. (a) Relaxed; (b) 10% strain

This short distance must, therefore, be a common feature of these structures as are the distances O_2-C_1 and O_1-C_2 which arise from the planarity of the terephthaloyl residue. The other short distances, H_3-C_4 and C_6-C_4 are controlled by the angle τ_3 . As has been pointed out, this varies widely between similar structures indicating a low potential barrier to rotation. Presumably movement to ease these contacts will cause an increase in energy due to the proximity of other atoms, not necessarily in the same molecule.

The main differences between the strained and relaxed conformations are in the values of τ_3 and τ_4 (see Figure 9), and in the planarity of the terephthaloyl residue (τ_1); τ_1 and τ_3 take values very similar to those of equivalent angles in 2GT. The parameters quoted for the strained model are likely to be subject to greater error than those of the relaxed because of the poorer quality of the intensity data.

On transition from the relaxed to the strained form, the unit cell distorts by simple shear along $a-c$ planes accompanied by a reduction in the chain spacings in the a -direction (see Figure 6). There is also some translation of chains in the c -direction. The volume of the unit cell increases from 262.8 \AA^3 in the relaxed state to 268.9 \AA^3 in the strained.

Figure 7 shows that the translation of chains maintains neighbouring terephthaloyl residues in similar positions relative to each other. Thus R and S (Figure 7), which lie alongside each other maintain a position in which the hydrogen atoms on the respective benzene rings interleave. P and S maintain relative positions in which the benzene ring of one sits behind the carboxyl unit of the other. This form of packing is also characteristic of 2GT¹⁰ indicating that the terephthaloyl part of the molecule exerts the controlling influence on their packing.

On straining, the inclination of the plane of the benzene ring changes so that the angle its normal makes with the c -axis increases from 73.7° to 86.9° (Table 3). Thus the perpendicular separation of planes of adjacent rings would increase if the spacing of chains along the a -axis was maintained. This spacing contracts from $4.3(7) \text{ \AA}$ to $4.0(4) \text{ \AA}$ (Figure 6) and the ring normal rotates through 15.1° about the c -axis towards the $b-c$ plane (Table 3). These changes result in the perpendicular separation increasing by a very small amount (from $3.5(7) \text{ \AA}$ to $3.6(7) \text{ \AA}$).

In the relaxed state the plane of the terephthaloyl residue of molecule R (Figure 6) lies roughly midway between those of S and P . The shearing of the unit cell and the rotation of the molecular plane makes S and R more nearly coplanar on straining. From Figures 6–8 it is seen that in the strained state there is a close contact between atoms O_2 and H_5 of molecules P and R . (This is not listed in Table 5a because the atomic separation is about 0.1 \AA greater than the sum of Van der Waals radii.) The shearing movement and twisting would help relieve this contact. These movements, however, cause a close contact between atoms H_1 and C_2 of molecules P and Q . The final positions and orientations of the molecules, therefore, balance these contacts. However, a rotation of the benzene ring in a sense which would improve the planarity of the terephthaloyl residue would also relieve the H_1-C_2 contact. This non-planarity does not, therefore, appear to arise as a consequence of the chain packing.

From the above discussion it is clear that the unit cell dimensions change on straining so as to restore the main features of intramolecular packing with the new conformation.

Since the conformation angles of the strained form are close to those of 2GT, this form might be expected to be stable. The fact that it is not suggests that each conformation represents an energy minimum the relaxed form being the lowest, with the barrier between them being sufficiently low for thermal activation to transform most material to the unstrained form at normal temperatures. The presence of tension reverses the relative heights of these energy levels. Confirmation of this hypothesis must await calculation of the energy of the system, taking into account the proximity of near neighbours. The present study shows that the volume of unit cell of the shortened, relaxed, form is smaller than that of the other, indicating a more economically packed, lower energy, form. However it gives no indication as to why this should be so for 4GT, but not 2GT.

The result from the investigation of biaxiality in a pressed sheet may be combined with the results of the structure determination. It then follows that the chain axis lies in the plane of the sheet, and the plane of the terephthaloyl residue intersects this plane in a line which is within a few degrees of the perpendicular to the chain axis. That is, the two planes are as close as possible to coincidence subject to the constraint that the chain axis also lies in the sheet plane. This finding is in agreement with Menciuk, although he produced his films by a different method.

Consideration of the relative intensity of equivalent diffraction spots has led to the conclusion that the proportions of unit cells in an orientation such as, for example, 1 (Figure 5a) must be different from that in 2, but could be similar to that in either 3 or 4. This suggests that the crystalline objects in 4GT might comprise an orientation such as 1 twinned with either 3 or 4. If this is so the twin plane is likely to be the plane of preferred orientation (which is (100) in the example illustrated in Figure 5), and a twin satisfying this condition is illustrated in Figure 10. It will be seen that this comprises orientations 1 and 3 of Figure 5 (because of the assumed centre of symmetry, the molecular conformation is the same, whether the positive c -axis points up or down) and will so satisfy the requirement that these are present in similar proportions. If an axis normal to the twin plane has a preferred orientation, biaxiality will occur. This axis will correspond to a positive unit cell direction on one side of the twin plane and a nega-

Figure 10 Projection down c -axis of a twin on (100) plane

tive on the other. Should it point with equal probability in both directions along the line of preferred orientation, there will be four unit cell orientations in roughly equal proportions. This was the situation observed in the sheet. Should different proportions point in these directions, one pair of unit cell orientations will occur in greater abundance than the other. This was observed in the fibre.

(It must be emphasized that the choice of preferred plane used in Figure 5a and followed in the above discussion, and in Figure 10, was made solely for convenience of illustration. As already shown, the plane of preferred orientation in 4GT is close to that of the terephthaloyl residue, and if the above suggestion of twin formation is correct, this will be the plane on which twins are formed.)

The cross-section of the fibre was elliptical, and this, together with the biaxiality, was probably caused by lateral compression during drawing at the pin. A longitudinal section containing the major axis of the cross-section might be expected to be equivalent to the sheet plane as far as biaxial orientation is concerned. During pin-drawing there would be a gradient in temperature and pressure normal to this plane which would not occur when pressing a sheet. This might account for the difference in orientation in this direction between the two test-pieces.

There is no apparent relationship between crystalline structure and the tilt of the c -axis with respect to the fibre axis. This is illustrated in Figure 4. Since, on projection down the c -axis, the angles between a and b are similar in 2- and 4GT, it is possible to mark on the diagram the tile axis for 2GT as well as for 4GT. The plane of the terephthaloyl residue, which is the main structure-determining feature, is similar with respect to the a and b axes in each case, but it is seen that the direction of the axis of tilt is very different in the two cases.

ACKNOWLEDGEMENTS

The authors wish to thank Professor I. M. Ward and Dr R. Jakeways of Leeds University for many stimulating discussions and for making the results of their own work readily available. They also gratefully acknowledge the help given by Professor S. Arnott of Purdue University in making a copy of the 'Linked Atom Least Squares' computer program available, and in providing instruction in its use.

One of us (MGP) gratefully acknowledges tenure of a Science Research Council Cooperative Award in Pure Science sponsored by ICI Fibres Ltd, who provided the facilities for making the fibres used in this work.

Note added in proof

After this paper had been accepted for publication, a structural determination of the two forms of poly(tetramethylene terephthalate) was published (Yokouchi, M., Sakakibara, Y., Chatani, Y., Tanaka, T. and Yoda, K. *Macromolecules*, 1976, **9**, 266). The two accounts agree substantially for the relaxed form, but there appear to be significant differences between the proposed structures of the strained form.

Block polymers of poly(*para*-xylelene) and polystyrene or poly(vinyl pyridine) prepared by anionic polymerization

P. K. Wong, A. E. Zachariades and M. Szwarc

Department of Chemistry, State University of New York, College of Environmental Science and Forestry, Syracuse, New York 13210, USA

(Received 6 April 1976)

Anionic polymerization of *para*-xylelene, *p*-X, may be initiated in solution at a low temperature ($\sim -70^\circ\text{C}$) by electron-transfer process. The spontaneous formation of diradicals through dimerization of *p*-X monomers is too slow at these temperatures to initiate the radical polymerization of *p*-X. The anionic polymerization yields a living poly(*p*-xylelene) which is capable of growing further by the addition of vinyl pyridine, VP. In this way block polymers PVP-PpX-PVP were prepared. Alternatively, the addition of *p*-X monomers to living polystyrene, PS, or living poly(vinyl pyridine), PVP, yields at low temperatures the block polymers PpX-PS-PpX or PpX-PVP-PpX. The block polymers prepared by this approach were isolated and characterized. Even small blocks of PpX attached to polystyrene or poly(vinyl pyridine) make the resulting polymers insoluble in boiling solvents below 200°C .

INTRODUCTION

The quinonoid *p*-xylelene hydrocarbon,

discovered by one of us as a product of pyrolysis of *p*-xylene¹, is a highly reactive species which spontaneously polymerizes on any surface exposed to its vapour. Such a surface becomes coated by a tough, crystalline film of poly(*p*-xylelene). In spite of its high reactivity, the *p*-xylelene persists in highly dilute vapour in monomeric form; its stable solutions may be obtained at low temperatures ($\sim -70^\circ\text{C}$) by condensing the dilute vapour of this monomer into a well stirred and chilled solvent², e.g. hexane or toluene, kept at -70°C .

The spontaneous polymerization of *p*-xylelene proceeds through a radical mechanism initiated by the dimerization yielding diradicals, $2\text{CH}_2=\text{C}_6\text{H}_4=\text{CH}_2 \rightarrow \cdot\text{CH}_2-\text{C}_6\text{H}_4-\text{CH}_2\text{CH}_2-\text{C}_6\text{H}_4-\text{CH}_2\cdot$. Low temperature presumably inhibits the latter reaction as well as slows down the subsequent propagation. The high intrinsic reactivity of *p*-xylelene prevents its copolymerization with the conventional vinyl or vinylidene monomers, and hence all attempts of obtaining such copolymers or block polymers were virtually in vain³. However, we expected that the preparation of block polymers of *p*-xylelene with conventional vinyl monomers could be feasible through anionic mode polymerization and, as shown in this paper, this expectation turned out to be correct.

Preparation of *p*-xylelene from *p*-cyclophane

High temperatures of about 800°C – 1000°C are needed to afford the pyrolysis *p*-xylene into *p*-xylelene. Moreover, the resulting monomer vapour is then mixed with an excess of unpyrolysed *p*-xylene and contaminated by some undesirable by-products of pyrolysis. A pure monomer is conveniently obtained by pyrolysing *para*-cyclophane⁴.

Such a pyrolysis takes place at about 600°C , and the vapour of the precursor, maintained at low pressure, is then decomposed cleanly and quantitatively into *p*-xylelene, i.e.

This method has been utilized therefore in the present work.

EXPERIMENTAL

The apparatus used in our studies is depicted in *Figure 1*. *Para*-cyclophane, kindly provided by the Union Carbide Corp., was freshly sublimed in vacuum and placed in the sublimation zone (A). The wide portion (P) of the quartz tube was inserted into an electrically heated furnace, and a thermocouple, placed in a pocket tube, measured the temperature of pyrolysis. The outlet (K) was connected to a pyrex double walled tube (F) through a quartz-to-pyrex graded joint and heated with electric tape to avoid any condensation and polymerization of the monomer on the walls of the outlet system. For the same reason the inner tube of the pyrex double walled tube (F) was also electrically heated. The double walled tube (F) fitted into a round flask reactor (R) equipped with a magnetic stirrer and connected to a high vacuum line. Two evacuated ampoules (B) and (C), or more if necessary, contained the required reagents or solvents. These were equipped with breakseals and magnetic hammers which allowed the introduction of the reagents at the proper time.

After placing a weighed sample of *para*-cyclophane in (A), the left outlet of the pyrolysis tube is sealed and the furnace brought to a desired temperature. The whole unit is then thoroughly evacuated. A solvent, or a solution of a

Figure 1 The schematic drawing of the apparatus used in the preparation of block polymers of PpX

living polymer, is then introduced into the reactor (R) by crushing the appropriate breakseal and the contents are cooled with solid carbon dioxide–isopropanol mixture. The sublimation zone is then heated to about 200°C with electric tape and subsequently the pyrolysis ensues. The resulting monomer vapour passes through (K) and (F) into the reactor (R) where it is dissolved in the stirred liquid that half filled the reactor. Some of the vapour reaches the upper walls of the reactor, above the level of the liquid, coating them with a coherent and insoluble film of poly(*p*-xylene). After completion of the pyrolysis the furnace is switched off and, if desired, the additional reagents are introduced into the reactor by crushing the breakseal of the appropriate ampoule. Finally, air is introduced into the unit, the reactor detached from the outlet of the pyrolysis tube, and its content analysed.

RESULTS

We confirmed that the monomer vapour, *p*-X, when introduced into cold (−70°C) tetrahydrofuran (THF) does not polymerize but forms a clear solution stable as long as the liquid is kept at −70°C. The presence of *p*-X monomer in the solution was demonstrated by pouring the solution into a precooled hexane solution of iodine. The excess of iodine was reduced with thiosulphate, and thereafter 2.2 g of CH₂I.C₆H₄CH₂I were isolated from the organic layer. The amount of the isolated di-iodide shows that 66% of the pyrolysed *para*-cyclophane (1.0 g) was dissolved in THF. The weight of the poly(*p*-xylene) film coating the walls of the reactor was 0.30 g, and hence the material balance is satisfactory.

The identity of the purified di-iodide was established by its n.m.r. spectrum in CDCl₃, δ4.35, (bs, 4), and 7.24 (bs 4).

After establishing the reliability of our procedure the pyrolysis of *para*-cyclophane was repeated and its vapour was introduced into a THF solution of sodium naphthalenide. The dark green solution of the naphthalenide turned rapidly into a light tan suspension. The reaction was completed after 2 h and thereafter the resulting lightly coloured precipitate of apparently living poly(*p*-xylene) was bleached by adding methanol to the reactor yielding a white, dead polymer.

The precipitate was filtered, washed, and dried in a vacuum oven. The conversion of the dissolved *p*-X into the polymer was virtually quantitative and the X-ray diffraction demonstrated that the precipitated poly(*p*-xylene) is in the α-form. We conclude that the electron-transfer initiated

anionic polymerization of *p*-X monomer proceeds rapidly in THF at −70°C, while the initiation of its radical polymerization is too slow to be observed under comparable conditions.

Preparation of block polymers of PpX and styrene

Samples of PpX–PS–PpX block polymers were prepared by introducing the vapour of *p*-X monomer into a THF solution of living sodium polystyryl kept at −70°C. The polystyryl used in these experiments was prepared by the well known anionic technique⁵, initiating the polymerization with sodium naphthalenide. Its molecular weight and molecular weight distribution, determined by the gel-chromatography, were 110 000–120 000 and 1.1–1.2, respectively.

The *p*-X vapour was introduced by the previously described procedure. The red solution of the living polystyrene turned into a redish-brown suspension as the reaction ensued. The pyrolysis was completed after 2 h and the living polymers were terminated then by the addition of methanol to the reactor. The resulting white suspension was then separated from the homo-poly(*p*-xylene) film coating the walls of the reactor. The latter formed 30–40% of the pyrolysed *para*-cyclophane. Repeated centrifugation and decantation yielded a gel that coagulated on addition of water. The coagulate was filtered, washed, and dried for 12 h in a vacuum oven at 110°C. Alternatively, the resulting suspension was gently heated until all the solvent evaporated. This procedure yields white granules from which the soluble fraction (up to 20%) could be extracted with THF, benzene, or toluene. The extractable material, or the solid residue isolated from the decanted THF liquor, was shown to be homo-polystyrene, presumably resulting from the ‘killing’ of some living polystyrene in the course of manipulation preceding the addition of the *p*-X monomer.

The polymers left after extraction were insoluble in boiling benzene, toluene, or chloroform. They could be dissolved in boiling methylnaphthalene (~250°C) but precipitated as the temperature of the solution dropped to about 200°C. The results of the individual experiments are summarized in Table 1. The first two columns give, the respective amounts of pyrolysed *para*-cyclophane and of polystyrene introduced into the reactor. The total amount of the collected polymer, excluding the homo-PpX film, is given in the third column, while the fourth column

Table 1 Preparation of the block polymers PpX–PS–PpX. The polystyrene block, PS, has DP ~ 100

Weight of pyrolysed <i>para</i> -cyclophane (g)	Weight of introduced polystyrene (g)	Total weight of insoluble polymer (g)	Total weight of extractable polymer (g)	Insoluble polymer	
				PS (%)	PpX (%)
1.0	1.0	1.22	0.2	66	34
1.0	1.0	1.19	0.4	50	50
1.0	1.0	1.30	0.2	62	38
1.0	0.5	1.13	0.2	27	73
1.5	0.5	1.10	0.2	27	73

Mechanical losses in the isolation amount often to 10% of the total feed. The percentages are calculated on the assumption that the extractable polymer is a pure PS, subtracting this amount from the PS feed and dividing by the total weight of the isolated, insoluble block polymer. This kind of calculation gives the upper limit for the % of PS

Table 2 Preparation of block polymers of 2-vinyl pyridine and *p*-xylene

	Sample 1, PpX-PVP-PpX	Sample 2, PpX-PVP-PpX	Sample 3, PVP-PpX-PVP

gives the amount of the insoluble block polymer left after extraction of the THF or benzene soluble fraction. The wt% PPX blocks and PS blocks are given in the last two columns and are derived on the basis of material balance.

No attempts were made to prepare block polymers by starting with a suspension of living PpX and feeding it with monomeric styrene. It is known that the initiation of anionic polymerization of styrene by a primary carbanion, e.g. $\text{PhCH}_2^- \text{Na}^+$, is slow as compared with the subsequent propagation, and hence the initiation by $\sim\text{CH}_2-\text{C}_6\text{H}_4-\text{CH}_2^- \text{Na}^+$ was expected to be inefficient. Instead, we decided to produce the two kinds of block polymers, viz. those terminated by the PpX blocks and the other possessing a middle PpX block, by using a monomer that reacts very rapidly with the $\sim\text{CH}_2-\text{C}_6\text{H}_4-\text{CH}_2^- \text{Na}^+$ end groups. 2-Vinyl pyridine was chosen for this purpose.

Preparation of block polymers of *p*-X and vinyl pyridine, VP

Two kinds of block polymers of 2-vinyl pyridine (VP) and *para*-xylene were prepared. The technique used in the preparation of PpX-PS-PpX was applied also in the preparation of PpX-PVP-PpX block polymers. Living poly(2-vinyl pyridine) was prepared in THF by initiating the polymerization with sodium naphthalenide⁶. The solution of the resulting polymer of $DP \sim 100$ was introduced into the reactor and the *p*-X vapour was fed thereafter in the way previously described. The resulting precipitate was extracted with methanol in a Soxhlet and the residue dried in a vacuum oven. The results of two typical experiments are summarized in Table 2. Alternatively, a living PpX was prepared, as described earlier, by initiating the polymerization of *p*-X monomer with sodium naphthalenide. Thereafter, 2-vinyl pyridine was added to the cold solution of the living PpX and the insoluble residue extracted with methanol, dried in vacuum oven and then weighed. A typical result of such a preparation is included in Table 2 (sample 3).

The percentage of PVP in the insoluble fraction was calculated by assuming that the mechanically lost material was proportionally divided between the insoluble and extractable fractions, the latter being assumed to be pure PVP. Thus the composition of the insoluble fraction was calculated as:

$$\text{PpX} = p\text{-X (fed in)} - p\text{-X (in the film of homo-}p\text{-X)}$$

$$\text{PVP} = \text{VP (fed in)} - (\text{corrected weight of the extractable material}).$$

The results of such calculations are given in Table 2 and on this basis we calculated the percentage of N in the block polymers. The calculated results, given in the line before the last, compare satisfactorily with those listed in the last line and obtained by the analysis of the pertinent samples.

I.r. spectra of the studied polymers

All the i.r. spectra reported in this paper were obtained by dispersing the investigated polymers (~ 1 wt%) in KBr and pressing pellets from the mixture. The i.r. spectrum of anionically prepared homo-polystyrene is shown in Figure 2. The two strong absorption bands centred at 758 and 696 cm^{-1} are characteristic of that polymer and distinguish it from the anionically prepared homo-poly(*p*-xylene), the i.r. spectrum of which is shown in Figure 2. The latter has an intense absorption band centred at 819 cm^{-1} .

A typical i.r. spectrum of PpX-PS-PpX block polymer is shown in Figure 3. The absorption bands due to the blocks PpX and PS are clearly seen, proving that both blocks are present in the investigated polymer. To demon-

Figure 2 I.r. spectra of anionically prepared polystyrene (A) and poly(*p*-xylene) (B)

Figure 3 I.r. spectra of block polymers, PpX-PS-PpX. A, the originally isolated polymer; B, the spectrum of the same material after its precipitation from α -methylnaphthalene solution. The block polymer was dissolved in α -methylnaphthalene at 250°C and began to precipitate when the solution was cooled to $\sim 200^\circ\text{C}$

Figure 4 I.r. spectra of block polymers PpX-PVP-PpX (A) and PVP-PpX-PVP (B)

Figure 5 I.r. spectra of PVP-PpX-PVP polymer before (A) and after (B) its precipitation from α -methylnaphthalene solution

strate that the investigated sample contains block polymers and is not a blend of homo-PpX and homo-PS, the following tests were performed. A mixture of homo-PS and homo-PpX, both prepared by anionic technique, were dissolved in boiling α -methylnaphthalene. Precipitation occurred instantly after cooling the solution to about 200°C. The precipitate was isolated and its i.r. analysis showed that it contained PpX only. A similar solution of the PpX-PS-PpX sample afforded on cooling a precipitate, the i.r. spectrum of which is shown also in Figure 3, and its inspection clearly demonstrates the presence of both blocks. Since polystyrene is not occluded in the poly(*p*-xylene) when the latter precipitates from the α -methylnaphthalene solution of the blend, its presence in the precipitate formed from the solution of the block polymer provides an un-

equivocal proof of its block nature. Of course, this test does not preclude the presence of some homo-poly(*p*-xylene) in the material containing a block polymer PpX-PS-PpX.

Comparison of the two i.r. spectra shown in Figure 3 suggests that the percentage of PpX in the dissolved and then precipitated material seems to be higher than that in the original sample. This observation was confirmed by repeating such tests with other samples of the PpX-PS-PpX polymers. The enrichment in PpX could be due to the presence of some homo-PpX in the block polymer, and while the former is insoluble in the cold solvent, the latter could be partly soluble.

The i.r. spectra of the block polymers of PVP and PpX are shown in Figure 4. The presence of the PVP blocks is manifested by the strong absorption bands centred at 745 cm^{-1} and 785 cm^{-1} characteristic for the homo-poly(vinyl pyridine). It is significant to note the presence of poly(vinyl pyridine) in the PVP-PpX-PVP block polymer, an observation confirming the ability of living poly(*p*-xylene) to continue the growth by the addition of vinyl pyridine.

Finally, a sample of PVP-PpX-PVP block polymer was dissolved in boiling α -methylnaphthalene and precipitated by cooling the solution. The i.r. spectra of the original sample and of that obtained from the precipitate are shown in Figure 5. The presence of the PVP blocks in the latter proves again that the original material contained the PVP-PpX-PVP block polymers and not a blend of homo-PVP and homo-PpX.

We tried to develop a quantitative i.r. method of analysis of block polymers. However, these attempts were not yet met with success.

ACKNOWLEDGEMENT

We wish to thank the National Science Foundation for the financial support of these investigations.

Stereoelective polymerization of racemic propylene oxide using a diethylzinc-chiral-1,2-diol system as initiator

Christian Coulon, Nicolas Spassky and Pierre Sigwalt

Laboratoire de Chimie Macromoléculaire associé au CNRS, Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

(Received 4 March 1976)

The polymerization of racemic propylene oxide was performed using a chiral initiator obtained from the reaction of diethylzinc with (–) 3,3-dimethyl-1,2-butanediol. With this initiator *R*(+) enantiomer is preferentially incorporated into the polymer with a stereoelectivity ratio *r* equal to 1.8, the *r* value remaining constant during the polymerization. The polymer was fractionated into a crystalline isotactic part and an amorphous heterotactic part, both optically active. Partial stereoelectivities were determined for both fractions and found to be equal to 2.6 and 1.6 respectively for polymerization at 80°C. Two types of sites, stereospecific and non-stereospecific, formed in the first reaction between monomer and initiator are both active for the stereoelective polymerization. The stereospecificity of the monomer–initiator system increased at low temperatures, but the overall stereoelectivity remained constant and seemed to be an intrinsic property of the system.

INTRODUCTION

Propylene oxide was the first heterocyclic monomer to be polymerized in its optically active form by Price and Osgan in 1956¹, giving an optically active polymer. It was also the first monomer to be involved in an asymmetric selective or stereoelective polymerization in which a racemic monomer is polymerized using an asymmetric catalyst².

Over the last ten years the Japanese school with the groups of Furukawa and Tsuruta have investigated various features of these processes and this work has been reviewed in several papers^{3,4}. The initiator systems which were used in such polymerizations are derived from the reaction between an organometallic compound, usually diethylzinc, and chiral compounds with active hydrogens such as alcohols², amino-acids⁵ or other derivatives.

Most of the results reported up to now were run with a low polymer conversion (generally less than 30%) and under these conditions a linear relationship between optical purity and conversion was established by Furukawa *et al.*⁶ defining the asymmetric selectivity of the catalytic system.

A few years ago we investigated the stereoelective* polymerization of propylene sulphide, and it was found that the initiator systems obtained from the reaction of diethylzinc with chiral 1,2-diols were much more efficient than those obtained using chiral alcohols⁸. We also investigated the stereoelective process at various conversions and have established a theoretical relationship which fitted well with experimental data⁹.

It was interesting therefore to see if this type of initiator was more efficient in the case of propylene oxide than the initiators used previously and also to study the stereoelective process up to high conversions.

EXPERIMENTAL

Materials

Commercial racemic propylene oxide was stored on potassium hydroxide, then distilled on a spinning band column and purified under vacuum on calcium hydride. It was chromatographically pure. A commercial solution of diethylzinc in heptane (Orgmet) was used. It was redistilled and distributed in graduated ampoules under vacuum. The classical EDTA method was used for the zinc content titration; (–) 3,3-dimethyl-1,2-butanediol was prepared as described elsewhere²³.

Polymerizations

All the experiments were carried out in sealed apparatus using high vacuum technique. Diethylzinc was allowed to react with chiral 1,2-diol in heptane solution for 2 h at 80°C, the solvent was evaporated and the initiator dried at 80°C under vacuum for several hours. Then, the monomer was introduced by distillation and the polymerization carried out at a convenient temperature. At the end of the polymerization unreacted monomer was recovered by vacuum distillation. Chloroform and a few drops of acetic acid were added to the residual polymer. The catalyst residue was separated by centrifugation and the solution washed several times with water in order to eliminate all traces of diol. The chloroformic solution was dried on sodium sulphate and finally the polymer recovered and dried under vacuum. Optical activities were measured on a Perkin–Elmer P 141 Polarimeter. ¹³C n.m.r. spectra were observed in CCl₄–C₆D₆ (90:10) solutions on a JEOL PS 100 FT spectrometer.

* Using the terminology introduced by Pino *et al.*⁷ in the case of olefins.

POLYMERIZATION USING DIETHYLZINC/(–) 3,3-DIMETHYL-1,2-BUTANEDIOL (1:1) SYSTEM

Stereoselectivity of the system

Racemic propylene oxide was polymerized using the initiator system derived from the reaction between diethylzinc and (R) (–) 3,3-dimethyl-1,2-butanediol (DMBD) in equimolar ratio. The preparation of the catalyst was carried out under conditions described elsewhere¹⁰ and in all cases we have used an initiator in which the ratio R–M–O/O–M–O between alkylalcoholate and dialcoholate species, was equal to 0.24. The polymerization was carried out in bulk at 80°C. The experimental data are given in Table 1. As one can see, the optical activity α_m of unreacted monomer increases with conversion to polymer, while the optical activity of the polymer α_p is decreasing. The signs of unreacted monomer in pure liquid form and of polymer in benzene solution are both levorotatory. This means that (R)-enantiomer was preferentially incorporated into the polymer chain [poly(|R| propylene oxide) is levorotatory in benzene solution¹] leaving an excess of S(–) enantiomer in the unreacted monomer. This corresponds to the so-called ‘homosteric’ type process as was defined in the case of propylene sulphide¹¹.

If one plots the optical activities of unreacted monomer versus the conversion to polymer as shown in Figure 1, one can see that the experimental data fit well on a curve which corresponds to the following theoretical equation (1), established previously for the stereoselective process⁹:

$$(1-x)^{r-1} = \frac{1 + \alpha/\alpha_0}{(1 - \alpha/\alpha_0)r} \quad (1)$$

where α is the optical activity of unreacted monomer, α_0 the optical activity of pure enantiomer, x the conversion and r the stereoselectivity ratio.

α and x are directly obtained from experimental data and α_0 was deduced from n.m.r. data on the polymer¹² and was taken to be 11.9° (neat, dm). The best theoretical curve fitting the experimental data corresponds to a value of the stereoselectivity r equal to 1.8 as shown in Figure 1.

Similar calculations could be made for the polymer giving the same r value. In all cases we have checked that the optical balance between the recovered monomer and the polymer satisfies the relation (2) proposed previously by Inoue et al.¹³:

$$M[\alpha_m] = \frac{\alpha_{m_0}}{\alpha_{p_0}} P[\alpha_p] \quad (12)$$

where α , α_p , α_{m_0} and α_{p_0} are the optical activities of unreacted monomer, obtained polymer, pure enantiomer and pure polyenantiomer respectively. M is the ratio of recovered to starting monomer and P the yield (%) of optically active polymer. This is shown in Figure 2. The slope of the straight line corresponding to the ratio $\alpha_{m_0}/\alpha_{p_0}$ was found to be 0.34 which is identical to the calculated theoretical value $11.9/35 = 0.34$.

The stereoselectivity ratio found ($r = 1.8$) is one of the highest obtained for propylene oxide. Comparison with the results of Tsuruta and Furukawa is not very easy, because they have usually worked at low conversions where very small variations of optical activity of the monomer produce strong variations in the r value. One can estimate however, that for ZnEt₂/(+) borneol system the stereo-

Polymerization carried out at 80°C, $r = 1.8$. ▲, optical activity of unreacted monomer (neat, dm); ●, optical activity of whole polymer (C = 1, benzene); —, theoretical curves according to equation (1)

Figure 2 Relation between optical activities of recovered monomer and whole polymer. $\alpha_{m0}/\alpha_{p0} = 12/35 = 0.34$

electivity should be close to $1.5-1.6^3$ and the best result for $\text{ZnEt}_2/\text{amino-acid}$ system was found equal to 1.2^5 . A single result for $(\text{FeCl}_3/\text{propylene oxide})$ complex- H_2O catalyst containing *d*-bornylethylether corresponds to $r = 1.71$, however in this case the polymer obtained was optically inactive⁶. In our case both unreacted monomer and resulting polymer fitted satisfactory with the proposed $r = 1.8$ value.

A few experiments were performed in heptane solution. These experimental data fit on the same theoretical curve with $r = 1.8$. The polymerization times are however much longer in solution than in bulk, as expected.

Fractionation of the polymer

Crude polymers were fractionated into crystalline, semi-crystalline and amorphous fractions using selective solubility in acetone at different temperatures.

Using this procedure the following fractions were isolated: a crystalline polymer insoluble in acetone at room temperature; a semi-crystalline polymer insoluble at -20°C and an amorphous polymer, soluble in acetone below -20°C .

Crystalline fractions were of high molecular weight (an intrinsic viscosity of $|\eta| = 7.7$ corresponds to $800\,000\text{ MW}$) and high melting points (varying from 69° to 72°C). Semi-crystalline fractions were of lower molecular weights and lower melting points.

Results of the fractionation are given in Table 2. If one plots $[\alpha]_D^{25}$ of polymers versus conversion one can see that data for the crystalline and semi-crystalline fractions fall on the same curve corresponding to a stereoelectivity ratio equal to 2.6. The data for amorphous fractions, on the other hand, fit well on a theoretical curve corresponding to a much lower stereoelectivity ratio equal to 1.6 (Figure 3).

Effect of temperature on polymerization

A lowering of the temperature from 80° to -8°C (see Table 3) decreased the rate of polymerization by a factor of one hundred if comparing times of polymerization necessary to reach similar yields. The overall stereoelectivity of the system r was not changed significantly. However, distributions between crystalline and amorphous fractions and their corresponding 'partial' stereoelectivities, were considerably modified. Thus, as much as 65% of the crystalline fraction was isolated in the polymerization run at -8°C against only 10% in the polymerization carried out at 80°C . The proportion of semi-crystalline fraction does not alter much as a function of temperature, this fraction resulting probably from an imperfect fractionation. As expected, the proportion of amorphous fraction increased as the temperature increased (Figure 4).

The stereoelectivities of all fractions decreased with decrease in temperature, while overall stereoelectivity remained nearly constant. The semi-crystalline fraction obtained at low temperature has a stereoelectivity very similar to the amorphous fraction, in contrast to their stereoelectivities at 80°C .

Table 2 Fractionation of poly(propylene oxides) obtained in stereoselective polymerizations. Experimental conditions as described in Table 1

Figure 3 Stereoselective curves for whole polymer and its crystalline and amorphous fractions. Polymerization carried out at 80°C. A, $r = 2.6$; B, $r = 1.8$; C, $r = 1.6$; ●, whole; ○, crystalline; □, semi crystalline; ▽, amorphous

According to Tsuruta *et al.*¹⁴ and Furukawa *et al.*¹⁵, racemic stereoregular poly(propylene oxide) could be separated into two fractions of opposite signs with predominant *R*- and *S*-units. The crystalline fraction is therefore a mixture of poly-*R* type chains and poly-*S* type chains in different amounts formed on enantiospecific sites. For other fractions Tsuruta considered a full spectrum of sites having more or less *R* or *S* character^{3,4}.

It is possible to make an estimation of the distribution of various sites knowing the proportion of different fractions and the partial stereoselectivities.

At the beginning of the polymerization the enantiomeric composition of the polymer first formed directly reflects the stereoselective choice of the initiator.

$$[\alpha_p]_r^0 / [\alpha_p^0] = \frac{R/S - 1}{R/S + 1} \sim \frac{r - 1}{r + 1}$$

where $[\alpha_p]_r^0$ is the optical activity of the polymer extrapolated to the origin for a given r ; $[\alpha_p^0]$ is the optical activity of optically pure polymer [we have taken $[\alpha_p^0] = 35(C_6H_6, C = 1)$].

Therefore it is possible to determine the distribution of *R*- and *S*-type species for each fraction of polymer, corresponding to a partial r . Then knowing the amount of each fraction in the whole polymer, one can calculate the percentage of polymer corresponding to different stereoregularities and different chiralities. Calculations were performed using experimental data obtained at various temperatures. Although there is no direct indication that amorphous polymer may be separated into fractions of opposite signs, we have introduced such fractions of both chiralities in our scheme.

Indeed, with a decrease in the temperature of polymerization there is an increase in the stereoregular fraction and with an increase in the temperature a substantial decrease. We consider that there is a full spectrum of sites having different *R*-type and *S*-type characters. The distribution of stereospecific and non-stereospecific sites depends on the experimental conditions, namely on the temperature. At a high temperature (80°C) only 10–15% of active sites are highly stereospecific (giving a crystalline fraction), but the existence of a semi-crystalline polymer fraction is an indication that other sites have potential stereospecificity. With a decrease in the temperature many more sites become stereospecific giving rise to a crystalline polymer (65% of crystalline fraction at –8°C). The latter requires sequences of approximately at least ten successive monomer units of the same configuration incorporated in the polymer chain.

The overall stereoselectivity is not affected by this change in distribution, but a continuous variation of the amounts of different fractions is observed when changing the temperature. The estimated distributions of different polymer fractions calculated from the experimental data are given in Table 4.

As one can see an almost symmetric variation of the percentage of fractions is observed when changing the temperature from –8° to +80°C. Such distributions could directly reflect the spectra of active sites of both chiralities and of different degrees of stereospecificity existing in the polymerization system for given experimental conditions.

Stereoregularity of polymers

The stereoregularity of the different polymer fractions were used as a tool for the study of the stereospecificity of sites in the mechanism of polymerization.

^{13}C n.m.r. was used for the study of the stereoregularity. Schaefer¹⁶ has shown that the tertiary carbon of the poly(propylene oxide) chain is sensitive to triad effects and the methylenic carbon to dyad effects only. The assignment of peaks was reconsidered by Oguni *et al.*¹⁷ and confirmed with the use of optically active monomers by Uryu *et al.*¹⁸ and ourselves¹².

For a random polymer in CCl_4 solution, the i , ($h_i + h_s$) and s triads of tertiary carbon were respectively located at 75.5, 75.4 and 75.3 ppm, while the m and r dyads, corresponding to methylenic carbon, found at 73.5 and 73.1 ppm (from TMS). The methyl carbon was observed as a singlet at 17.6 ppm. The crystalline and the semi-crystalline fractions showed only one type of peak for each carbon, e.g. at 75.5, 73.5 and 17.6 ppm, which indicates that these polymers are highly isotactic. The amorphous fractions, on the contrary, showed a heterotactic structure with predominance of i peak and m peak in triads and dyads respectively (Figure 5).

It was interesting to discover if the tacticity found corresponded to a statistical distribution of R and S units in the chain, the R/S ratio being directly related to the optical activity of the polymer, or whether there was some kind of preferential sequence of units in the chain.

In the first case the arrangement of units should correspond to a Bernoulli type formation of dyads and triads, in

the second case the tacticity found would be higher (or different from) than statistical distribution.

In previous work on propylene sulphide¹⁹ it was demonstrated that the triad distribution could be calculated easily from the enantiomeric composition of a polymer obtained by a non-specific initiation. Thus, if the starting monomer mixture has an enantiomeric composition $R/S = 1/p$ the relative amounts of triads and dyads in the polymer are given by:

$$i = \frac{p^3 + 1}{(p + 1)^3}; \quad s = h_s = h_i = \frac{p(p + 1)}{(p + 1)^3}$$

and

$$m = \frac{p^2 + 1}{(p + 1)^2}; \quad r = \frac{2p}{(p + 1)^2}$$

The enantiomeric composition R/S could be obtained simply from the optical activity of the polymer. Indeed, a linear relationship was found between optical activities of the polymer and of the monomer²⁰ and moreover the optical purity of the latter was determined¹².

The calculation of theoretical amounts of triads and dyads could be carried out easily for our amorphous samples and the comparison with experimental data obtained from ^{13}C spectra showed (Table 5) a satisfactory agreement with tacticity derived from a statistical Bernoulli type process.

Therefore the amorphous fraction is very probably due to non-specific stereoelective sites.

MECHANISM OF POLYMERIZATION

Some mechanistic aspects of stereoelective polymerization of propylene oxide using chiral catalysts have already been described by Tsuruta^{2,3} and Furukawa⁶. The ring-opening occurs almost exclusively at the primary carbon-oxygen bond and a polymer having some stereoregularity is produced.

Using our chiral initiator, we preferentially polymerized the $R(+)$ enantiomer which corresponds to a so-called 'homosteric' choice, i.e. the configuration of the chosen enantiomer is identical to that of the chiral agent used. The result is similar to the result observed previously for propylene sulphide using the same initiator¹¹. Anti-steric type initiators for propylene sulphide in which $R-M-O/O-M-O$ ratio is higher than 3 (excess of alkylalcoholates species) were not able to polymerize racemic propylene oxide under the same conditions. The stereoelectivity found was lower in the case of propylene oxide ($r = 1.8$)

Table 4 Variation of the percentage of polymer fractions of different stereoregularities and chiralities as a function of the temperature of polymerization. Experimental conditions as described in Table 3

Figure 5 ^{13}C n.m.r. spectra of the amorphous part of poly(propylene oxide) obtained is stereoelective polymerization. Amorphous polymer $[\alpha]_D^{25} = -5.8$ ($C = 1$, C_6H_6); spectra run in $\text{CCl}_4/\text{C}_6\text{D}_6$ (90:10) solution at 40°C

than in the case of propylene sulphide ($r = 2.4$). A possible explanation of this result could be found in the difference of 'hardness' or 'softness' of both systems.

The oxygen atom of the oxirane cycle is a 'hard' element, according to the classification of Pearson²¹, while the sulphur is much softer. The association of the latter with the zinc, a soft element, is more favourable and this could play a role in the monomer-initiator interaction during polymerization steps.

The fractionation of poly(propylene oxide) into crystalline (isotactic) and amorphous (heterotactic) parts is a strong support for the existence of different kinds of sites: one, stereospecific, giving isotactic polymer, others, non-specific but stereoelective, giving heterotactic polymer.

Stereospecific sites are enantiomorphic with R -type and S -type chirality. They give through homopolymerization of each enantiomer R -type chains and S -type chains which are in principle separable.

Non-stereospecific sites present an overall electivity corresponding to the preferential choice of one enantiomer.

If one calls C , C_R and C_S the concentrations of non stereospecific sites, or stereospecific R -type sites and S -type sites respectively and k'_R , k'_S , k_R and k_S the global rate constants of polymerization on these sites, one obtains the following kinetic equations for R and S enantiomers:

$$\frac{-d|R|}{dt} = k'_R |C| |R| + k_R |C_R| |R|$$

$$\frac{-d|S|}{dt} = k'_S |C| |S| + k_S |C_S| |S|$$

then

$$\frac{d|R|}{d|S|} = \frac{k'_R |C| + k_R |C_R|}{k'_S |C| + k_S |C_S|} \times \frac{|R|}{|S|} = r \frac{|R|}{|S|} \quad (3)$$

where

$$r = \frac{k'_R |C| + k_R |C_R|}{k'_S |C| + k_S |C_S|}$$

The stereoelectivity ratio r is constant during all the polymerization and equal to 1.8 in our system.

Therefore equation (3) can be integrated and gives the theoretical relation (1) given previously. 'Partial' stereoelectivities could be defined for each type of sites.

The change in the relative proportion of stereospecific and non-stereospecific sites according to polymerization conditions, and particularly temperature, seems to show that there exists a whole spectrum of sites, stereospecific or non-stereospecific, having a relative preference for one of the enantiomers, the rate of each type of site being $\sum_i k'_{iR} C_i$ for non-stereospecific sites choosing preferentially R , $\sum_i k_{iR} C_{iR}$ for stereospecific sites choosing R , and so on.

For pure stereospecific sites, if k_R and k_S are supposed equal, the partial stereoelectivity is:

$$r_{sp} = \frac{|C_R|}{|C_S|}$$

and stereoelection results from unbalanced concentration of R -type and S -type sites

$$|C_R| > |C_S|$$

In our case r_{sp} is equal to 2.6.

For non-stereospecific process the stereoelectivity is given by the ratio:

$$r_{nsp} = \frac{\sum_i k_{iR} C_i}{\sum_i k_{iS} C_i}$$

which is equal to 1.6 for our system.

^aIn benzene $C = 1$; ^bbased on $[\alpha]_D^{25} = 35$ for an optically pure monomer $\alpha_0 = 11.9$ (neat, dm)¹²; ^camorphous part of polymers taken from ref 22

Preliminary results recently reported for propylene oxide and propylene sulphide²² show that the stereoelectivity ratio changed with the enantiomer composition of the monomer used. However, the r values remained constant during the polymerization. This would seem to indicate that active sites are formed only after a reaction of pre-existing sites with the monomer at the beginning of the polymerization.

More data are needed in order to explain the relationship between the global ratio r and partial ratios r_{sp} and r_{nsp} .

Particularly, it is not yet clear why the overall selectivity is constant with temperature and seems to be an intrinsic property of a monomer–initiator system.

CONCLUSIONS

The polymerization of racemic propylene oxide was performed using a chiral initiator derived from the reaction of diethylzinc with (–) 3,3-dimethyl-1,2-butanediol. During the polymerization and up to high conversions, the stereoelectivity ratio, e.g. the preferential choice of the initiator for one of the enantiomers, was constant and a simple relation between the conversion and the optical purity of unreacted monomer remained valid.

The stereoelectivity is equal to 1.8, which is the highest value found up to now for propylene oxide. However this stereoelectivity is lower than that found for propylene sulphide for the same initiator.

The polymer could be fractionated into a crystalline isotactic part and an amorphous heterotactic part both optically active. Partial stereoelectivities could be determined for both fractions, the crystalline one corresponding for example at 80°C to a ratio of 2.6 against 1.6 for the amorphous part.

Two types of sites, stereospecific and non-stereospecific, probably formed in the first reaction between monomer and initiator, are both active for the stereoelective polymerization.

The proportion of stereospecific and non-stereospecific sites depends on the temperature of the polymerization, but the overall stereoelectivity remains constant and seems

to be an intrinsic property of this monomer–initiator system.

Salt effect on cationic copolymerization between *cis*- and *trans*-ethyl propenyl ethers

Kenji Yamamoto and Toshinobu Higashimura

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606, Japan

(Received 15 March 1976)

In order to study the common-ion effect on monomer reactivity ratios, cationic copolymerization between *cis*- and *trans*-ethyl propenyl ethers was carried out at 0°C by using iodine or acetyl perchlorate as initiator. In toluene, the *cis* isomer was several times more reactive than the *trans* isomer regardless of the kind of initiators employed. When a common-ion salt (tetra-*n*-butylammonium iodide, triiodide, or perchlorate) was added to the copolymerization system in ethylene dichloride, the monomer reactivity ratios were changed approaching those observed in a non-polar solvent such as toluene. On the other hand, in nitroethane the monomer reactivity ratios were only slightly affected by the addition of common-ion salts. These noticeable common-ion effects on monomer reactivity ratios in the '*cis*-*trans*' copolymerization were satisfactorily explained on the basis of the steric hindrance between the substituents of monomers and a bulky propagating chain end.

INTRODUCTION

Recently the common-ion effect has been examined with the cationic copolymerizations between vinyl ethers and styrene derivatives and between styrene derivatives initiated by iodine¹ or acetyl perchlorate². When a common-ion salt was added to the copolymerization systems in a polar solvent, it was found that the monomer reactivity ratios approached those observed in a non-polar solvent. These changes in monomer reactivity ratios were interpreted in terms of the depression of the dissociation of propagating species by a common-ion salt, and hence the selectivity of propagating species is dependent upon its dissociation state.

In the cationic copolymerization between *cis*- and *trans*-ethyl propenyl ethers initiated by BF₃OEt₂, it has been reported that the relative reactivities of the two monomers depend greatly on the solvent polarity³⁻⁵. In a non-polar solvent the *cis* isomer is several times more reactive than the *trans* isomer, while in a polar solvent both isomers show nearly the same reactivities.

The addition of a common-ion salt to a polymerization system will vary the degree of dissociation of propagating species without changing its counter-ion in a given solvent^{1,2}. If the change in monomer reactivity ratios by the solvent polarity in the '*cis*-*trans*' copolymerization results from that in the dissociation state of propagating species, the addition of the common-ion salt is also expected to change the monomer reactivity ratios. Therefore, in the present investigation, the common-ion effect on the cationic copolymerization of *cis*- and *trans*-ethyl propenyl ethers in several solvents was examined and the propagation mechanism was discussed on the basis of the experimental results obtained.

EXPERIMENTAL

Materials

Ethyl propenyl ether (EPE) was synthesized by the elimination of ethanol from the corresponding acetal

which was prepared from propionaldehyde and ethanol⁶. The *cis* and *trans* isomers of EPE were separated by fractional distillation through a spinning-band column of over 70 theoretical plates. The *cis* and *trans* isomers were identified by i.r. and n.m.r. spectroscopy. The boiling points of *cis*- and *trans*-EPE were 69° and 75°C, respectively. The spin-spin coupling constants of olefinic α - and β -protons were 6.8 Hz for the *cis* isomer and 13.2 Hz for the *trans* isomer; these values being similar to those for other propenyl ethers⁷. The two monomers were distilled over calcium hydride and then over metallic sodium just before use. The geometric purities of *cis*- and *trans*-EPE were found by gas chromatography to be 99.0% and 98.0%, respectively; each purified monomer containing only its geometric isomer as impurity.

Solvents (toluene, ethylene dichloride, and nitroethane) and *n*-heptane as an internal standard for gas chromatography were purified by the usual methods. Iodine (Merck, Guaranteed Reagent) was used without further purification. Acetyl perchlorate (AcClO₄) was synthesized by the same methods as described in the previous paper⁸. Tetra-*n*-butylammonium iodide (*n*-Bu₄NI) (Wako Pure Chemicals, Guaranteed Reagent) and tetra-*n*-butylammonium perchlorate (*n*-Bu₄NClO₄) (Nakarai Chemicals, Guaranteed Reagent) were used after drying overnight *in vacuo*. Tetra-*n*-butylammonium triiodide (*n*-Bu₄NI₃) was synthesized from *n*-Bu₄NI and iodine⁹.

Procedures

Copolymerizations were carried out under dry nitrogen in the same manner as reported previously¹⁰. The concentration of residual water in the copolymerization system was found to be 0.2–0.3 mmol/l by the Karl-Fischer titration. *n*-Heptane (5 vol%) was added to the reaction mixture as the internal standard for gas chromatography. Copolymer compositions were determined from the amount of residual monomers measured by gas chromatography. Monomer reactivity ratios were calculated according to an improved Fineman-Ross method¹¹. Molecular weights of

all the copolymers obtained were found to be about 3×10^3 (vapour pressure osmometry). Therefore, the conventional copolymer composition equation can be safely applied.

RESULTS

Copolymerization of *cis*-EPE (M_c) with *trans*-EPE (M_t) by iodine

The effect of solvent polarity on the copolymerization of *cis*- and *trans*-EPE was investigated by using iodine as initiator at 0°C . Copolymerizations proceeded relatively slowly in the three solvents. Figure 1 shows the copolymer composition curves. Monomer reactivity ratios (r_c and r_t) are summarized in Table 1. *Cis*-EPE was more reactive than *trans*-EPE regardless of the solvent polarity. As the solvent polarity decreased, r_c increased and r_t decreased.

A common-ion salt for iodine was added to the copolymerization system in a polar solvent. Since it is uncertain whether a counter anion is I^- or I_3^- in the cationic polymerization initiated by iodine¹²⁻¹⁴, both $n\text{-Bu}_4\text{NI}$ and

$n\text{-Bu}_4\text{NI}_3$ were tentatively used as common-ion salts in the present investigation.

Figure 2 shows the copolymer composition curves for the copolymerization in ethylene dichloride and in nitroethane in the presence of $n\text{-Bu}_4\text{NI}$ or $n\text{-Bu}_4\text{NI}_3$. Monomer reactivity ratios are summarized in Table 1. The addition of the common-ion salts in ethylene dichloride affected the monomer reactivity ratios and the resultant copolymer composition curves approached that observed in toluene. Although the effect of $n\text{-Bu}_4\text{NI}$ is not so large as that of $n\text{-Bu}_4\text{NI}_3$, it is clear that the monomer reactivity ratios are changed by the addition of both salts. In nitroethane, a more polar solvent than ethylene dichloride, the monomer reactivity ratios were little affected by the addition of the common-ion salts.

Copolymerization of *cis*-EPE (M_c) with *trans*-EPE (M_t) by AcClO_4

Cis- and *trans*-EPE were copolymerized by AcClO_4 at 0°C . Figure 3 shows the effects of the solvent polarity and of the addition of $n\text{-Bu}_4\text{NClO}_4$. Monomer reactivity ratios are summarized in Table 1. When AcClO_4 was used as initiator, *cis*-EPE was more reactive than *trans*-EPE regardless of the solvent polarity as in the copolymerizations by iodine. As the solvent polarity decreased, r_c increased and r_t decreased. Furthermore, in ethylene dichloride, the addition of $n\text{-Bu}_4\text{NClO}_4$ one hundred times as much as AcClO_4 affected the monomer reactivity ratios and the resultant copolymer composition curve approached that observed in toluene. In nitroethane the copolymerization rate was so large that the monomer reactivity ratios could not be determined.

DISCUSSION

In the cationic copolymerization between *cis*- and *trans*-EPE initiated by iodine or by AcClO_4 , the monomer re-

Figure 3 Effect of solvent and $n\text{-Bu}_4\text{NClO}_4$ on the copolymerization of *cis*-EPE (M_c) with *trans*-EPE (M_t) by AcClO_4 at 0°C . $[M]_0 = 10 \text{ vol}\%$, $[\text{AcClO}_4]_0 = 0.01 \text{ mmol/l}$: \circ , $(\text{CH}_2\text{Cl})_2$, salt free; \bullet , $(\text{CH}_2\text{Cl})_2$, $[n\text{-Bu}_4\text{NClO}_4]_0 = 1.0 \text{ mmol/l}$; \triangle , $\text{C}_6\text{H}_5\text{CH}_3$, salt free

activity ratios were changed by the addition of a common-ion salt in ethylene dichloride, and the resultant copolymer composition curves approached those obtained in toluene. This may be the first example of the cationic copolymerization of α,β -disubstituted olefins, in which the monomer reactivity ratios are affected by the addition of a common-ion salt. The addition of a common-ion salt to a reaction mixture is expected to depress the dissociation of propagating species through the mass-law effect. The propagating species will exist in the form of ion pairs and free ions in ethylene dichloride. When a common-ion salt is added, some of the free ions will be changed to ion pairs and hence the relative reactivities of monomers will approach those in a non-polar solvent such as toluene, in which ion pairs will be the propagating species exclusively.

On the other hand, in the iodine initiated copolymerization in nitroethane the monomer reactivity ratios were little affected by the addition of $n\text{-Bu}_4\text{NI}$ or $n\text{-Bu}_4\text{NI}_3$. The propagating species in nitroethane must be ion pairs in the presence of a common-ion salt. Therefore, the above results suggest that the nature of these ion pairs is similar to that of free ions. The present explanation is based on the same viewpoint as that presented in our previous paper².

It has been shown by ^{13}C n.m.r. measurements and molecular orbital calculations that the π -electron densities of α - and β -carbons are similar to *cis*- and *trans*-EPE¹⁵.

Therefore, it is safe to assume that the magnitude of electrostatic interaction between the propagating carbocation and its counterion does not depend on the geometric structure of monomers. In spite of these, the relative reactivities of *cis*- and *trans*-EPE changed considerably according to the dissociation state of propagating species. This suggests that a factor other than the electrostatic one plays an important role in the determination of relative reactivities in the '*cis*-*trans*' copolymerization.

In a non-polar solvent, the propagating carbocation forms a tight ion pair with its counter-ion, hence the growing chain end must be very crowded. In this circumstance it is probably more difficult for the propagating carbocation to attack *trans*-EPE than *cis*-EPE, because the former carries two bulky substituents on both sides of its olefinic double bond. This will lead to the higher reactivity of *cis*-EPE than that of *trans*-EPE in a non-polar solvent. It is therefore concluded that the changes in relative reactivities of EPE by the addition of common-ion salts result from the difference in steric hindrance of the propagating species in different dissociation states. The above explanation is essentially consistent with the propagation mechanism proposed in our previous paper concerning the solvent effect on the cationic copolymerization between *cis*- and *trans*-EPE initiated by BF_3OEt_2 ⁵.

(Received 10 February 1976)

Experiments on the flow of melts of mixtures of thermodynamically incompatible polymers show that ultra-fine fibrils of one of the polymers form in the matrix of the other in the entrance to the extrusion orifice.

INTRODUCTION

Earlier published papers¹⁻⁵ show that in the flow of melts of mixtures of thermodynamically incompatible polymers under certain conditions ultra-thin fibrils of one of the components form in the mass of the other. Melts of mixtures of polyoxymethylene (POM) with a copolyamide (CPA) show the phenomenon clearly (*Figure 1*).

The experimental results seek answers to the following questions: is the length of elementary ultra-thin fibrils determined by the dimensions of the individual particles of the fibril-forming polymer or are fibrils of considerable length obtained due to the coalescence of the particles of the fibril-forming polymer deformed in the flow? Where does fibrillation take place, at the entrance to the duct, in the duct, or at its exit?

EXPERIMENTAL

The series of extrudates of a mixture of POM + 70% CPA was obtained in a constant pressure gas capillary viscosimeter at temperatures of 173°, 177° and 190°C. The melting point of the POM was determined by d.t.a. and was taken as the melting peak at 171°C. The melting peak at a heating rate of 4°C/min is rather wide⁶, covering the range from 158° to 180°C. The characteristics of the polymers and the conditions under which they were mixed have been described before⁷. Conditions of deformation were as follows: the shear stress at capillary wall was $5.25 \cdot 10^4$ N/m²; diameter of capillary, 0.92 mm; capillary length to diameter ratio, 6. The outflowing extrudate was passed into a mixture of isopropyl alcohol and dry ice (temperature -70°C) or into liquid nitrogen. The copolyamide was extracted from the set extrudate with ethyl alcohol at 75°C in a Soxhlet apparatus. After the removal of CPA the microstructure of thin sections of the extrudates and the remnants of POM were examined under an optical or electron microscope.

RESULTS AND DISCUSSION

Formation of fibrils begins at a temperature 2°C above the melting point of POM: the smallest particles become extended, forming the fibrils (*Figure 2*), but the bulk of POM remains in the shape of undeformed particles. At 177°C fibril formation becomes more pronounced, but large POM particles (=100 μm) still do not stretch, but aggregate. It is from such POM aggregates at increasing volume output, that films form (*Figure 3*). The largest particles do not appear to take part in fibril formation at all, but move in the stream from its axis to the periphery (*Figure 4*) and settle mainly in concentric rings. Conditions can probably be found under which POM in the CPA mass forms only thick films in the shape of concentric cylinders.

The results show that the process of fibrillation takes

Figure 1 Electron microphotograph of an extrudate transversal fracture POM + 70% CPA mixture

* To whom correspondence should be addressed.

Figure 2 Microphotograph of POM after extraction of CPA from the extrudate produced at 173°C

Figure 3 Electron microphotograph of an extrudate fracture. Arrow indicates particle aggregates in the form of films

place by the stretching of POM particles in the direction of the stream and is accompanied by their coalescence, which is the necessary prerequisite for producing long uniform continuous fibrils.

Microscopic analysis of longitudinal sections of extrudates obtained at 177°C confirm the deformation of the particles (Figure 5), and an electron microphotograph clearly shows coalescence of the particles which seem to form a chain of 'Vienna sausages' (Figure 6).

In the case of well pronounced fibrillation the bundles obtained contain $\sim 10^5$ ultra-thin fibrils. Since it is not possible to measure the length of an individual fibril in the bundle, we examined microscopically the POM after the extraction of CPA from the extrudates formed at 177°C, when only a small number of POM particles take part in fibril formation. The individual fibrils, so obtained were several millimetres in length and simple calculations show that the formation of a fibril about 20 μm in diameter and 3.2 mm long requires coalescence of 12 POM particles with a mean diameter of 53 μm . Proof of the coalescence of deformed POM particles in the direction of the stream

is provided also by the formation of ultra-thin fibrils with POM powder of particle diameter $\sim 2 \mu\text{m}$. In this case a bundle of fibrils, obtained after the extraction of CPA from the extrudate, contains no separate particles or short fibrils indicating that the fibrils are continuous in length.

Figure 6 Electron microphotograph of individual POM fibrils after extraction of CPA from the extrudate

Figure 7 Microphotographs of a longitudinal section of a frozen sample from the entrance zone area: (a) along stream axis; (b) parallel to the axis at distance of 200 μm from it. A, entrance to capillary. Arrow indicates direction of the flow

Experiments in which the extrudated stream was frozen in liquid nitrogen were carried out to ascertain the place where formation of ultra-thin fibrils takes place. For this purpose a dismountable capillary consisting of semi-cylinders fastened to the viscometric container charged with polymer mixture was used. The container and capillary were placed in a thermostat at 190°C, a pre-set pressure applied and when the regime of flow stabilized, the container with the capillary was rapidly immersed in liquid nitrogen. Examination of such chilled samples enables the character of POM particle and fibril distribution in the CPA mass, during the flow of the melt in the viscosimetric container, in the entrance zone and in the capillary to be studied.

Figure 7a shows a microphotograph of a longitudinal section of a frozen sample in the entrance zone area, while Figure 7b presents the same results for a section which is parallel to the former, but is situated at a distance of 200 μm away from the stream axis. These data show convincingly that fibrillation takes place in the entrance zone and is due to the effect of tensile stresses which extend and coalesce the POM particles in the direction of the stream lines.

In the zone adjacent to the entrance to the capillary the stream lines form concentric cone-like funnels in which the fibrillation is very pronounced (Figure 8). Nearer to the walls the process becomes weaker and peters out in the dead zones of the container.

Figure 8 Microphotographs of longitudinal sections of a frozen sample, illustrating formation of funnel in entrance zone: (a) along stream axis; (b) parallel to the axis at distance of 0.5 mm from it

Figure 9 Representation of the fibrillation process in the entrance zone and in the ducts

Figure 10 Microphotograph of a longitudinal section of a frozen sample, illustrating the process of fibril shrinkage and loss of parallelism

On the basis of microscopic examinations the fibrillation process can be presented schematically as shown in Figure 9. Under the effect of tensile stresses acting in the direction of the stream the stretching and coalescence of the particles of the fibrillation component takes place in the entrance zone (Figure 9, A). Close to the entrance to the duct the stream narrows sharply (Figure 9, B) and at a definite distance from the entrance (Figure 9, C) the influence of its walls becomes manifest, leading to the intensive development of shear and retardation of the stream. This is apparent in shrinkage (enlargement of diameters) of the fibrils and loss of parallelism in their mutual arrangement as shown in Figure 10. In the zone of shear flow the fibrils become parallel once again (Figure 9, D; Figure 11).

Figure 11 Microphotograph of a longitudinal section of a frozen sample at a zone of stabilized flow

These results show that the formation of ultra-thin fibrils takes place in the entrance zone of the ducts and the effect of tensile stress on the particles and their coalescence in the entrance zone is a prerequisite for the production of continuous fibrils.

ACKNOWLEDGEMENT

The authors are indebted to Dr B. V. Yarlykov, who helped them to stage the tests with the dismantable capillary.

Swelling of linear polymers in mixed swelling agents; predictability by means of solubility parameters

P. E. Froehling, D. M. Koenhen, A. Bantjes and C. A. Smolders
Laboratory for Macromolecular Chemistry, Twente University of Technology, PO Box 217, Enschede, The Netherlands
 (Received 26 March 1976; revised 19 May 1976)

INTRODUCTION

The solubility behaviour of polymers can be predicted to a reasonable extent by applying the Hildebrand relation¹ which connects the energy of mixing of two compounds to their individual energies of vaporization:

$$\frac{\Delta E_{\text{mix}}}{\Phi_1 \Phi_2} = V(\delta_1 - \delta_2)^2 \quad (1)$$

where ΔE_{mix} is the energy of mixing; Φ_1 and Φ_2 , the volume fractions of the components; V , the total volume of one mole of the mixture and δ_1, δ_2 , the Hildebrand solubility parameters of both components, defined by:

$$\begin{aligned} \delta &= (\text{cohesive energy density})^{1/2} \\ &= \left(\frac{\Delta E_{\text{vap}}}{V_m} \right)^{1/2} \end{aligned} \quad (2)$$

where ΔE_{vap} is the energy of vaporization and V_m is the molar volume. From equation (1) it is clear that a smaller difference in δ between two compounds results in a diminished energy of mixing. A decrease in ΔE_{mix} gives a higher degree of swelling and eventually complete solubility may result. The applicability of equation (1) has been extended by Hansen², who divided the solubility parameter into contributions from disperse (δ_d), dipole (δ_p) and donor/acceptor or hydrogen-bond (δ_h) interactions, and represented δ as:

$$\delta^2 = \delta_d^2 + \delta_p^2 + \delta_h^2 \quad (3)$$

which may be taken as a vector sum.

It is possible to express each of the solubility parameter components for a mixture of two solvents as:

$$\delta_{m,i} = \Phi_1 \delta_{1,i} + \Phi_2 \delta_{2,i}; \quad i = d, p, h \quad (4)$$

This relation can be used only when there are no specific interactions upon mixing, since these interactions (e.g. additional donor/acceptor interactions) do not obey the geometric mean rule.

The values of the components of δ have been reported for numerous compounds, and methods to calculate them from other physico-chemical properties of solvents and polymers are progressing rapidly³.

The often encountered enhanced interaction of polymers with solvent pairs can be explained by the vector concept of the solubility parameter, of which a representation is given in *Figure 1*.

The affinity of a solvent mixture X (on the line A-B) with respect to a polymer is inversely proportional to its distance to P, the location of the polymer in the $\delta_d, \delta_p, \delta_h$ space. It is evident that for the given spatial configuration of A, B and P there exists a point M at which the energy of mixing is at a minimum and swelling should reach a maximum. The application of the solubility parameter concept to the interaction of polymers with solvent mixtures has been confined up to now to qualitative aspects of the solubility of linear polymers^{2,4} and the swelling behaviour of cross-linked elastomers⁵. We wish to report here on the application of the same concepts to the swelling of linear polymers by swelling agent/non-solvent mixtures.

The systems studied are shown in *Table 1*. Toluene, trichloroethylene and n-butyl acetate are well-known swelling agents for poly(vinyl chloride), while methanol and nitromethane are strict non-solvents². For the combina-

tion n-butylacetate/nitromethane a deviating behaviour may be expected, as these solvents show mutual interaction on account of their respective electron donating and accepting character⁶. The other two solvent pairs do not show specific interactions which may cause deviations.

EXPERIMENTAL

Poly(vinyl chloride), Breon S 110/10 (BP Ltd), was a very pure preparation according to i.r. spectrum and elementary analysis. From gel permeation chromatography (solvent tetrahydrofuran, stationary phase Styragel-Waters Associates) the molecular weight distribution was calculated as^{7,8} $\bar{M}_n = 28\,000$, $\bar{M}_w = 56\,000$ using calibration samples of PVC from Pressure Chemical Co. All solvents were analytical grade quality.

PVC films were cast from a 15% so-

Figure 1 Spatial representation of solvent mixture/polymer interaction

Table 1 Solubility parameters of PVC and solvents. Values are taken from ref 3

Compound	δ_d	δ_p	δ_h
PVC	9.15	4.9	1.5
Toluene	8.82	0.7	1.0
Trichloroethylene	8.78	1.5	2.6
n-Butylacetate	7.67	1.8	3.1
Nitromethane	7.70	9.2	2.5
Methanol	7.42	6.0	10.9

lution in tetrahydrofuran. The dry films (about 0.5 mm thick) was cut into pieces of ~200 mg. The pieces were immersed in the solvent mixtures, and (after rapid blotting with filter paper) weighed after 2, 6 and 20 h immersion. Equilibrium was attained after 6 h at 20°C. All experiments were carried out in triplicate.

RESULTS

The results of the swelling experiments are plotted in Figures 2–4, together with the calculated polymer/solvent distances in the δ space:

$$\Delta = [(\delta_{p,S} - \delta_{p,P})^2 + (\delta_{d,S} - \delta_{d,P})^2 + (\delta_{h,S} - \delta_{h,P})^2]^{1/2} \quad (5)$$

where the subscripts S and P refer to solvent and polymer respectively.

Values of δ were taken from Koenhen³. The values of the solvent mixtures were calculated according to equation (4). It is clear that for the solvent pairs toluene/methanol and trichloroethylene/nitromethane which do not show donor/acceptor interactions upon mixing, the maximum in the swelling curve coincides with the calculated composition at which the distance in δ -space is minimal. The magnitude of the relative increase in swelling with relation to the pure solvents appears to be proportional to the calculated decrease in Δ .

It should be pointed out that the δ values for PVC as given by Hansen² result in a poorer agreement between the calculated and measured extreme values of Δ and degree of swelling. In the case of the donor/acceptor solvent pair

Figure 2 Calculated interaction parameter Δ and measured relative weight increase of PVC in toluene/methanol mixtures

Figure 3 Calculated interaction parameter Δ and measured relative weight increase of PVC in trichloroethylene/nitromethane mixtures

n-butyl acetate/nitromethane no maximum occurs in the swelling curve, contrary to expectation.

Caution should therefore be exercised in the application of the solubility parameter concept in mixtures of solvent which may interact through donor/acceptor forces.

A method for the calculation of optimum filler content in amorphous and semi-crystalline polymers

S. C. Shea*

Department of Polymer and Fibre Science, University of Manchester Institute of Science and Technology, Manchester, UK
(Received 22 March 1976; revised 13 May 1976)

INTRODUCTION

Currently more and more additives are being used in polymers, particularly the polyolefins. These additives include fillers, flame retardants, pig-

ments etc. Consequently, it is desirable to be able to predict the concentration of additive above which the mechanical properties significantly deteriorate. This communication details a method of calculating an optimum filler concentration using principles well known in the surface coat-

ing industry. While this proposed technique will be illustrated using high density polyethylene, it is thought that since the equations presented here are of a general nature, they may be more widely applicable. Of the many tests available elongation at break is probably the most sensitive and will be used here to compare experimental results with theory.

THEORY

Consider a polymeric material to which

lution in tetrahydrofuran. The dry films (about 0.5 mm thick) was cut into pieces of ~200 mg. The pieces were immersed in the solvent mixtures, and (after rapid blotting with filter paper) weighed after 2, 6 and 20 h immersion. Equilibrium was attained after 6 h at 20°C. All experiments were carried out in triplicate.

RESULTS

The results of the swelling experiments are plotted in Figures 2–4, together with the calculated polymer/solvent distances in the δ space:

$$\Delta = [(\delta_{p,S} - \delta_{p,P})^2 + (\delta_{d,S} - \delta_{d,P})^2 + (\delta_{h,S} - \delta_{h,P})^2]^{1/2} \quad (5)$$

where the subscripts S and P refer to solvent and polymer respectively.

Values of δ were taken from Koenhen³. The values of the solvent mixtures were calculated according to equation (4). It is clear that for the solvent pairs toluene/methanol and trichloroethylene/nitromethane which do not show donor/acceptor interactions upon mixing, the maximum in the swelling curve coincides with the calculated composition at which the distance in δ -space is minimal. The magnitude of the relative increase in swelling with relation to the pure solvents appears to be proportional to the calculated decrease in Δ .

It should be pointed out that the δ values for PVC as given by Hansen² result in a poorer agreement between the calculated and measured extreme values of Δ and degree of swelling. In the case of the donor/acceptor solvent pair

INTRODUCTION

Currently more and more additives are being used in polymers, particularly the polyolefins. These additives include fillers, flame retardants, pig-

ments etc. Consequently, it is desirable to be able to predict the concentration of additive above which the mechanical properties significantly deteriorate. This communication details a method of calculating an optimum filler concentration using principles well known in the surface coat-

ing industry. While this proposed technique will be illustrated using high density polyethylene, it is thought that since the equations presented here are of a general nature, they may be more widely applicable. Of the many tests available elongation at break is probably the most sensitive and will be used here to compare experimental results with theory.

THEORY

Consider a polymeric material to which

* Present Address: Van Leer Research Laboratories, Passfield, Hampshire, UK

pigment is added in increasing amounts. Ultimately a point is reached where just sufficient polymer (binder) is present to fill the voids between pigment particles. This point is defined as the Critical Pigment Volume Concentration (*CPVC*). The term pigment is used here rather loosely and is taken to mean, pigments, fillers and extenders. The term *CPVC*, has been 'borrowed' from the paint industry and hence it is convenient to retain their terminology. According to Patton¹ the *CPVC* represents the densest packing of the particles commensurate with the degree of dispersion and is found to be relatively independent of the binder used (except for polymer emulsions). Hence it can be argued that the *CPVC* is a basic property of the pigment.

Above the *CPVC* insufficient polymeric material is available to bind all the pigment particles, while below the *CPVC* a state of excess binder exists. Associated with this transition, changes can be expected in terms of paint performance, thus for example, high gloss can be achieved below the *CPVC* while above it matt finishes result. Other properties like flexibility and permeability are also affected. It should be appreciated that the *CPVC* is not a sharp point of inflection; properties change gradually, and in general follow sigmoidal shaped curves.

One method of determining the *CPVC* values for pigments and fillers is to use oil absorption figures. The oil absorption (*OA*) is defined as the amount of oil required to wet a particular pigment and depends on particle size distribution and degree of dispersion. It is usually expressed as grams of oil per hundred grams of pigment and can be simply determined by adding oil drop-wise to a known weight of pigment, rubbing with a spatula and considering the end point to be when a uniform film forms. Various other methods to measure oil absorption have been described by Gardner and Sward² and results are slightly dependent on the method used.

The relationship between oil absorption and *CPVC* is given by:

$$CPVC = \frac{100}{\frac{\rho_f}{OA} + \frac{100}{\rho_o}} \times 100\% \quad (1)$$

where ρ_f is the density of filler (pig-

ment); *OA*, the oil absorption (g/100 g) and ρ_o is the density of oil used.

Since oil absorption values are known to be additive¹ it follows that in a blend consisting of many pigments or fillers the following holds:

$$(CPVC)_{Blend} = \frac{V_1(CPVC)_1 + V_2(CPVC)_2 + V_3(CPVC)_3 + \dots + V_n(CPVC)_n}{V_1 + V_2 + V_3 + \dots + V_n}$$

or

$$(CPVC)_{Blend} = \frac{\sum V_i(CPVC)_i}{\sum V_i} \quad (2)$$

where V_i is the volume fraction of a particular pigment or filler.

On applying these equations to polyethylene, it is assumed that the filler is distributed throughout the amorphous regions only, hence if the degree of crystallinity (by volume) of

the base polymer is ϕ it follows that the critical volume fraction of filler, $V_{f\text{crit}}$ is given by:

$$V_{f\text{crit}} = CPVC \times (1 - \phi) \quad (3)$$

This can readily be converted to critical weight fraction of filler, $W_{f\text{crit}}$ by:

$$W_{f\text{crit}} = \frac{(V_{f\text{crit}})\rho_f}{\rho_m(1 - V_{f\text{crit}}) + (V_{f\text{crit}})\rho_f} \quad (4)$$

where ρ_f is the density of filler; ρ_m is the density of polymer matrix and $(1 - V_{f\text{crit}}) = V_m$ (volume fraction of polymer).

In a blend of many pigments and fillers it is necessary to replace ρ_f in equation (4) by $\bar{\rho}_f$ where $\bar{\rho}_f$ is a weighted average density.

The following assumptions are basic to the argument and are discussed in more detail below.

It is assumed that the filler is distributed in the amorphous regions only. In the case of polyethylene the size of the crystallite would appear to exclude any foreign material; with other semi-crystalline polymers some disruption of the crystallites may occur. Other

Table 1 Materials specification

(A) Polyethylene:

assumptions include no volume change on the introduction of the filler and that oil absorption is an accurate measure of the CPVC. Strictly both these statements are incorrect, however they are adequate approximations for this simple theory.

Clearly care should be exercised in using the above equations, which are intended to be a rough guide only.

APPLICATION OF THEORY

The above theory was studied using high density (linear) polyethylene (HDPE) as a matrix together with two different fillers viz. antimony trioxide/chlorinated hydrocarbon in the molar ratio Sb:Cl of 1:3 and alumina trihydrate. Properties of polyethylene and the fillers used are shown in Table 1, the data being taken from the manufacturer's information sheets.

In the case of the antimony/chlorine system the theoretical calculations detailed above gave a critical weight frac-

Figure 1 Elongation at break as a function of amount of additive at Sb:Cl ratio of 1:3

tion of filler of 29%, while from consideration of Figure 1 it can be seen that the elongation at break decreases rapidly after 25% additive.

Regarding alumina trihydrate a critical weight fraction was calculated to be 24%, while Figure 2 indicates a value of 26%.

Thus, while the assumptions used in the theoretical model are somewhat crude it would appear that their use is justified as the practical results indicate.

Figure 2 Elongation at break as a function of amount of alumina trihydrate

Although the theory has only been tested on HDPE it is thought that it could be applied to all polymers as the equations used are of a general nature.

Laser-Raman spectroscopic studies of mechanically-loaded polymers

There has recently been interest in the effect of mechanical stress on the vibrational spectra of polymers with the prime aim of obtaining some insight on the fracture mechanism of polymers. In particular Zhurkov and co-workers^{1,2} using infra-red transmission spectroscopy have examined the effect on skeletal vibrational modes of applying small stresses to thin polymer films or fibres. They observed small frequency shifts which were a linear function of applied stress and agreed with theoretical predictions of Gubonov³; such stress-sensitivity has been confirmed in the i.r. by Roylance and De Vries⁴ and by Wool and Statton⁵.

Recent work in our laboratories has shown that laser-Raman spectroscopy can be used in a similar, but more convenient way to i.r. for the investigation of the effect of stress on polymers. This letter outlines the application, briefly compares the results with the i.r. data, and highlights the advantages which Raman offers for

such studies.

Our investigations have included polypropylene (PP), polycarbonate (PC), polystyrene and nylon-6,6. The samples used are standard 4 in ASTM tensile testing dumbbells which thus allow direct correlations to be made with tensile test data. The dumbbells are stretched *in situ* in a mechanical jig with the orientation shown in Figure 1 and with almost no restrictions of sampling area.

The spectrometer used was the Spex Ramalog 4 with triple monochromator. The 514.5 and 488.0 nm exiting lines of a CRL Ar⁺ laser were used, with Claassen filtering, at a power level of ~200 mW at the sample. Fluorescence presented no problem with PP but PC samples required about an hour to 'burn' out. To check the effect of the laser beam on the polymers some samples were left in the beam for up to three days with neither visible effect nor any further changes in the Raman spectra. The draw direction is

along the direction of polarization of the laser radiation.

We have made an extensive study of all the Raman-active modes in the region 4000 to 10 cm⁻¹ of polycarbonate and polypropylene and preliminary studies on polystyrene and nylon-6,6. We have examined frequency changes, band intensity changes and depolarization ratios for small stresses and large stresses up to the yield point.

In general our experimental results are in agreement with the i.r. data but our much wider coverage of all vibrational modes and to larger stresses suggests that caution must be taken over the early interpretation^{1,2} of the observed changes. Table 1 lists our results for some of the bands of PP, in all cases the data being taken as the average of at least three replicate runs. From this it is clear that the skeletal modes are not the only modes which are stress-sensitive. For the skeletal modes, in concordance with the i.r. studies, we observe a slight decrease in frequencies with applied stress up to neck. After neck we find an increase in frequency often to higher than their initial values. Additionally we have found significant intensity changes usually very sudden at the necking-point, which is not accompanied by a sudden frequency change, the latter being a gradual change between limits. With depolarization ratios we have found a sudden drop in the ratio with small amounts of stress with no change thereafter.

The interpretation of our results will be discussed later in a full paper. However, we feel that the Zhurkov/Gubanov¹⁻³ theory of the stressing of the interatomic bonds in the molecule is an unlikely mechanism and that the modification of intermolecular forces is of greater importance. We thus favour a mechanism along the lines of changes in molecular conformations proposed by Cunningham *et al.*⁶ for

the polarized i.r. spectral changes occurring in poly(ethylene terephthalate) on drawing. From the depolarization ratio measurements it would appear that orientation occurs very early in the stress process and changes very little thereafter. The sudden intensity changes are thought to be a conformational change at neck the preferred conformer on necking being more 'streamlined' than the other.

We hope to have shown the value of laser-Raman as a research tool for stress analysis. The convenience of using bulk samples, in particular standard dumbbells, together with almost no restrictions on sampling area, which allows the ready use of sophisticated stress- and strain-measuring equipment, gives it many advantages over the i.r. technique. However, it should be emphasized that the two methods are complementary rather than competitive and that the use of both i.r. and Raman on the same system is likely to lead to a better understanding of the stress-sensitive phenomena.

Structural Studies of Macromolecules by Spectroscopic Methods

Edited by K. J. Ivin

Wiley, London, 1976, 339 pp. £14.50

This volume is based largely on the contributions to a meeting held at Cranfield Institute of Technology, England, in July 1974. The object of the meeting, and also that of this volume, was to bring together information about the application of some of the more recently developed spectroscopic methods to the study of macromolecules. It consists of sixteen individual chapters, which vary in length from 8 to 69 pages and which may be divided into five groups, of roughly equal total length, dealing with neutron scattering, far infra-red and Raman spectroscopy, X-ray photoelectron spectroscopy (ESCA), n.m.r. (^{13}C and ^1H) and e.s.r. The character of the individual chapters varies quite widely, from one in the review-style on ESCA, which forms the longest chapter of the book, to rather specialized chapters such as that on ^{13}C n.m.r. studies of α -methylstyrene-alkane copolymers. This variation is not a weakness, since the different spectroscopic methods involved are in different stages of development both in terms of their general application and of their more specific application to polymers, and by avoiding any attempt at a rigid style of coverage it has been possible to produce a book of modest length with stimulating and reasonably up-to-date contributions on all the techniques considered.

The book deals with experiments on nearly 100 macromolecules. Most of them are synthetic polymers but very brief descriptions are given of neutron diffraction from collagen, of the overall vibrations of polypeptide chains and protein molecules and of some ^{13}C studies of biopolymers. The techniques described allow information to be obtained about the detailed chemical structure and conformations of macromolecules, about their radii of gyration in the bulk and their segmental and side-chain motions in bulk and in solution, about the rate of collision between the ends in solution and about the vibrational frequencies, crystallinity, lamellar thickness and surface composition in the bulk. Most of the chapters have extensive lists of references.

This is a well-produced book in which all polymer spectroscopists, and indeed most polymer scientists, will find much of interest and value.

D. I. Bower

Macromolecules in Solution

Volume 21: High Polymers, 2nd Edition

Herbert Morawetz.

Wiley, London, 1975, 549 pp. £15.00

The second edition of this well known book is an expanded and updated version of its predecessor but does not deviate from the underlying philosophy of the original volume. As the author makes clear in his introduction, his aim is to present a unified view of macromolecular behaviour in solution regardless of whether the macromolecule is a synthetic polymer or a biopolymer. This eminently desirable aim does carry with it the difficulty of adequately covering a very wide field.

Professor Morawetz starts the book with a chapter entitled 'General Considerations' which deals with the classification, dimensions, dispersity and shape of macromolecules in solution. There follows a chapter on thermodynamic aspects of polymer solutions and one dealing with conformation and the statistics of polymer chains. The next three chapters respectively entitled 'Equilibrium Properties of Dilute Solution'; 'Spectroscopy, Optical Activity and the Scattering of Light and X-rays'; 'Frictional Properties of Dissolved Macromolecules'; present the theoretical but no experimental background into the technique on which we largely base our knowledge of macromolecules in solution. The final three chapters discuss Polyelectrolytes, Molecular Association, and Chemical Kinetics in Macromolecular Solution. Throughout the book considerable

weight is given to biopolymers as illustrative of the various phenomena discussed.

Because of the extent of the field, the author has had to be selective and this has resulted in the omission or scant coverage of certain topics. The author has eschewed the discussion of experimental details, but on occasion missed or insufficiently stressed aspects of theory. Thus, although there is good coverage of the thermodynamic aspects of solubility and miscibility, its underlying importance in the practice of polymer fractionation is not explicitly discussed. There is brief mention of gel-permeation chromatography, but one is left with the impression that this technique inevitably requires the viscometric determination of the molecular weight of the eluted fractions, since there is no mention that columns may be calibrated or even that the Walter's Q factor method may on occasion prove useful. In the chapter on frictional properties there is no mention of the dangers of intrinsic viscosity calibrations when used with samples of differing molecular weight distributions, and the viscosity-average molecular weight is not mentioned. There is some coverage of relaxation techniques, and viscoelasticity is given a brief mention, but dielectric relaxation is hardly touched upon and the use of dipole moment measurements as a tool in studying polymer flexibility not at all.

The author presents numerous interesting examples with references to illustrate the various facets of the field but such mathematical derivations as are given are often over brief. In the case of light scattering the author initially related molecular polarizability to the dielectric constant rather than to the square of the refractive index, not making it clear when these differ, or as an alternative, using the optical frequency form of the Clausius-Mossotti relation and thereby avoiding dielectric constant altogether.

There are a few minor typographical errors, but on the whole the book is well produced and illustrated. Because the author makes extensive use of examples, the book will prove valuable as a source book and reference work. It is a worthwhile acquisition for anyone involved with work on polymers or biopolymers, provided the field is not completely new to the reader. However, for the student embarking for the first time into an understanding of the behaviour of macromolecules in solution, the book is difficult and in some places misleading.

Conference Announcement

IUPAC INTERNATIONAL SYMPOSIUM ON MACROMOLECULES

Dublin, Eire, 17-22 July 1977

The IUPAC International Symposium on Macromolecules will be held in Dublin on 17-22 July 1977.

The symposium will cover the following topics:

(1) Homogeneous Polymerizations, Zwitterions and Coordination Complexes; (2) Fine Structure of Polymers including Biopolymers; (3) Polymers as Reagents and Catalysts and (4) Polymer Chemistry in Polymer Engineering. These topics have been chosen in order to avoid overlapping those proposed for the Macromolecular section of IUPAC XXVI Congress in Tokyo in September 1977. Further details about registration, social events and the full programme may be obtained from: Symposium Officer, Macro Dublin 77, Institute for Industrial Research and Standards, Ballymun Road, Dublin 9, Eire.

Synthesis and characterization of poly(acryloyl morpholine) xerogel networks suitable for the gel permeation chromatography of small molecules

R. Epton, S. R. Holding and J. V. McLaren

Department of Physical Sciences, Wolverhampton Polytechnic, Wolverhampton WV1 1LY, UK
(Received 30 April 1976)

The synthesis and characterization of a crosslinked poly(acryloyl morpholine) network, Enzacryl® Gel KO, calculated to be effective as a matrix for the g.p.c. of small molecules, is described. Chromatographic performance was evaluated in water, chloroform, dimethylformamide and pyridine. Characteristic g.p.c. behaviour was observed for all standards tested although 'additional exclusion' was observed in the case of aliphatic hydrocarbons in the three organic solvents and with aromatic hydrocarbons in chloroform and pyridine. Similar molecular weight fractionation ranges were obtained for poly(ethylene glycols) in the four solvents investigated the molecular weight exclusion limit being less than 1500.

INTRODUCTION

For a polymer network to be effective as a column packing in the gel permeation chromatography (g.p.c.) of small molecules it is essential that the network undergoes gelation in the chromatographic solvent selected as eluent. Matrices which undergo gelation in both water and organic solvents are particularly useful and may be termed 'universal' g.p.c. supports. Three such networks are commercially available. These are the hydroxypropyl ether of crosslinked dextran (Sephadex® LH 20)¹, a crosslinked poly(hydroxyethyl methacrylate) (Spheron® 1)² and a crosslinked poly(acryloyl morpholine) (Enzacryl® Gel K1)³⁻⁴. In water and the more useful organic solvents the exclusion limits of these packings lie in the 3000–4000 molecular weight range. This is rather high for the efficient fractionation of most small organic molecules.

In this paper we report the synthesis of a poly(acryloyl morpholine) network of greatly reduced mean pore diameter. The g.p.c. evaluation of this new bead polymerized column packing (Enzacryl Gel KO) is described. Water, chloroform, dimethylformamide and pyridine were used as chromatographic solvents.

EXPERIMENTAL

Synthesis of Enzacryl Gel KO

The polymerization vessel and stirrer blade used are depicted in *Figure 1*. Stirring was effected by a Citenco continuously variable (0–300 rev/min) stirrer motor (Citenco Ltd, UK).

The bulk phase for the polymerization consisted of light liquid paraffin (5 l) ($\rho^{20} = 0.85 \text{ g/cm}^3$; $\eta^{20} = 3.5\text{--}4.0 \text{ sec/m}^2$) and the surfactant (100 cm³) which was usually sorbitan trioleate (Koch-Light Ltd, UK). In some runs a surfactant mixture (100 cm³) consisting of sorbitan trioleate and polyoxyethylene (20) sorbitan trioleate (Koch-

Light Ltd, UK), volume ratio 19:1, was used. The bulk phase was placed in the polymerization vessel and freed of oxygen by vigorously bubbling nitrogen from a fine jet (0.5 mm) over 3 h with stirring. Subsequently the length of the nitrogen inlet was adjusted to maintain a nitrogen atmosphere over the liquid.

The monomer solution, consisting of acryloyl morpholine (470 g, 3.33 mol), (Koch-Light Ltd, UK), crosslinker, *N,N'*-methylene diacrylamide (52 g, 0.33 mol) and water (500 cm³) as diluent, was deoxygenated by nitrogen bubbling for 1.5 h. The appropriate amount of initiator, potassium persulphate, was dissolved in water (50 cm³) and deoxygenated. Polymerization was started by mixing the initiator solution with the rest of the monomer phase. This mixture was added to the bulk phase in the polymerization vessel and dispersed as droplets by a short period of rapid stirring (100 rev/min). The stirring rate was reduced (25–30 rev/min) and adjusted periodically to maintain most of the droplets within a size range of 50–100 μm .

To ensure complete polymerization, the suspension was left stirring under nitrogen overnight. The hydrated beads of Enzacryl Gel KO so obtained were washed free of paraffin with petroleum spirit (40–60°), further washed with ethanol and dispersed in water.

Preliminary bulk polymerizations were necessary in order to determine optimum initiator concentration. These were carried out using a reciprocating gel timer (Tecam, UK)⁵. An initiator concentration which would cause the gel timer to stop in 10 to 20 min was considered ideal. A temperature maximum was observed in 0.5 to 1 h in the corresponding suspension polymerization at this concentration.

Gradation of Enzacryl Gel KO

Bead gradation was effected by wet elutriation. Up to 1 litre bed volume of the swollen beads was placed in a uniform bore glass elutriation column (9 × 200 cm) fitted with

Figure 1 Polymerization vessel showing stirrer blade geometry: A, polystyrene stirrer blade; B, polystyrene counterweight; C, pivot stop; D, thermometer; E, nitrogen inlet. For clarity, the dropping funnel and stirrer motor have been omitted

a water inlet at the base. The bed was mechanically stirred by means of a polypropylene paddle situated immediately over the water inlet. The paddle (depth 20 cm) had horizontal rectangular slats (1×2.5 cm) cut at 2 cm intervals along each vertical side and each set of slats was staggered with respect to the other. A stirring rate of 40 rev/min was found to give adequate bed fluidization with minimal swirling. The aqueous suspension of graded gel beads was conducted from the top of the column, via a number of siphon tubes, to a wide collecting vessel where the beads settled out. Elutriation times, flow rates and bead size ranges obtained are presented in Table 1.

Gel permeation chromatography

Chromatographic standards. The principle standards used were poly(ethylene glycols) (Carbowaxes) (\bar{M}_n 200, 400, 600, 750, 1000, 1500 and 4000) (Phase Separations Ltd, UK), triethylene glycol, diethylene glycol and ethylene glycol (British Drug Houses Ltd, UK). In addition polystyrene (\bar{M}_n 585), (Digby Chemicals Ltd, UK), t-stilbene, styrene and n-alkanes (pentane, heptane, decane and hexadecane) (British Drug Houses Ltd) were used in organic solvents. Saccharides (stachyose, raffinose, maltose and

glucose) (Koch-Light Ltd, UK) were employed as standards in water.

Column packing. A funnel was attached to the top of each column and the whole assembly filled with a slurry of pre-swelled Enzacryl Gel KO (40–80 μm dry diameter) in the appropriate solvent. In the case of chloroform, packing was effected using an approximate flow rate of $150 \text{ cm}^3/\text{h cm}^2$ throughout. This was necessary in order to prevent flotation of the beads. With other solvents the beads were allowed to settle under gravity for a few minutes before completing packing under flow.

Jobling liquid chromatography columns (1.5 \times 100 cm) (Jobling Ltd, UK) fitted with PTFE end fittings were used throughout.

Elution of columns and effluent analysis. The precise column lengths and flow rates used are given in Table 2. Elution was performed at ambient temperature. Sample volumes applied did not exceed 1 cm^3 and solute concentrations were generally less than 2%.

For aqueous g.p.c. the column was incorporated in a Technicon Auto-Analyzer (Technicon, USA). The proportionating pump of the Auto-Analyzer was used both to operate the column and to regulate the analysis of the column effluent. Analysis was effected by the automatic five-fold dilution of effluent samples with chromic acid reagent⁶, heating and monitoring the colour produced at 440 nm. The flow rate used for column elution was the maximum practical with the Auto-Analyzer.

An alternative system was used with organic solvents. This consisted essentially of a Type R401 Waters differential refractometer (Water Associates, USA), a constant displacement pump (Milton Roy Co., USA) and an injection valve (Jobling Ltd, UK). The flow rates used for elution were those which gave a pressure drop of 14 kg/cm^3 across the column.

The deuterated solvents CDCl_3 , $\text{C}_5\text{D}_5\text{N}$ and $(\text{CD}_3)\text{NCHO}$ were detected in column effluents directly by the differential refractometer. Deuterated water was detected by mass spectrometry⁴.

Table 1 Elutriation parameters used for the gradation of Enzacryl Gel KO

Flow rate (cm^3/min)	Elutriation time (h)	Bead diameter (μm)	
		Hydrated	Dry
70	48	<60	<40
200	24	60–120	40–80
420	8	110–175	70–120
1450	4	>175	>120

Table 2 Column and elution parameters for Enzacryl Gel KO

Solvent used for elution	Column parameter			Bead volume available to solvent (cm^3/g dry polymer)
	Length (cm)	Efficiency (plates/m)	Flow rate ($\text{cm}^3/\text{cm}^2 \text{ h}$)	
Water	95.5	8387	19	1.16
Chloroform	87.5	2354	37	1.42
Dimethylformamide	90.0	3356	12	0.90
Pyridine	93.0	904	30	1.06

Figure 2 Aqueous g.p.c. fractionation of Carbowax 200 on Enzacryl Gel KO. Column dimensions and flow rate are given in Table 2. A, Breakthrough peak; B, $\text{H}(\text{OCH}_2\text{CH}_2)_5\text{OH}$; C, $\text{H}(\text{OCH}_2\text{CH}_2)_4\text{OH}$; D, $\text{H}(\text{OCH}_2\text{CH}_2)_3\text{OH}$; E, $\text{H}(\text{OCH}_2\text{CH}_2)_2\text{OH}$; F, $\text{HOCH}_2\text{CH}_2\text{OH}$

Distribution coefficients. The Wheaton and Baumann⁷ absolute distribution coefficient, K_d , was calculated in the case of all standards chromatographed from the relationship:

$$K_d = \frac{V_e - V_o}{V_i} = \frac{V_e - V_o}{V_s - V_o}$$

where V_e is the elution volume of the given standard, V_o the void volume of the column and V_i the internal volume of the xerogel packing available to a solute able to penetrate the gel with equal facility to the solvent. The void volume, V_o , was determined as the elution volume of Blue Dextran ($M_w 2 \times 10^6$) (Pharmacia Ltd, UK) or polystyrene ($M_n 4 \times 10^5$) (Digby Chemicals Ltd). It was assumed that V_i corresponded to the difference between the solvent elution volume, V_s , and V_o .

Column efficiency. The number of theoretical plates per metre, n , was calculated for appropriate solutes by applying the equation⁸:

$$n = \frac{16}{L} \left(\frac{V_e}{w} \right)^2$$

where L is the column length and w the peak width. The latter was calculated by producing tangents through the points of inflection of a given peak and measuring the distance between the points of intersection with the baseline.

RESULTS AND DISCUSSION

Aqueous suspension polymerization of acryloyl morpholine and N,N' -methylene diacrylamide at the high monomer

concentration necessary to obtain beads of low mean pore diameter proved much more difficult than in the case of other poly(acryloyl morpholine) networks³⁻⁵. The suspension was difficult to stabilize and the aqueous droplets had a marked tendency both to settle and to fuse during polymerization to give 'grape-like' agglomerates.

After numerous empirical trials it was found that the best approach was to use the moderately efficient surfactant, sorbitan trioleate (Span 85) together with slow but very efficient stirring. The geometry of the stirrer blade (Figure 1) and stirrer speed are critical. Inefficient stirring results in a plug of xerogel at the bottom of the reaction vessel whereas stirring too rapidly results in the production of very small droplets at the extremities of the paddle. With some batches of acryloyl morpholine, it was necessary to add a small amount of the more efficient surfactant, polyoxyethylene(20)sorbitan trioleate (Tween 85), to the continuous phase in order to prevent bead agglomeration. Too much Tween 85 resulted in beads too small for chromatographic application.

Enzacryl Gel KO forms denser xerogels in water than the more expanded poly(acryloyl morpholine) networks. Consequently, comparatively high flow rates were required to displace a given bead size range during wet elutriation (Table 1). This was a considerable advantage because grading efficiency is related to the number of column volumes of water which can be passed through the elutriation column during a practical time scale.

A preliminary separation of a poly(ethylene glycol) sample, Carbowax 200, into its constituent oligomers indicated that Enzacryl Gel KO was effective in the g.p.c. of small molecules in water (Figure 2). Aqueous characterization was completed with a series of higher molecular weight poly(ethylene glycols) and oligosaccharides. Chloroform, dimethylformamide and pyridine were selected to complete the g.p.c. evaluation because these solvents all swell the packing efficiently while differing widely in physico-chemical properties. Poly(ethylene glycols) together with aliphatic and aromatic hydrocarbons were employed as g.p.c. standards in these solvents.

For all four solvents used, plots of logarithm solute molecular weight versus K_d were indicative of chromatographic separation by molecular sieving (Figure 3a-3d). Oligosaccharides and aromatic hydrocarbons, being more compact molecules, had relatively higher K_d values than the less compact poly(ethylene glycols) and n-alkanes of similar molecular weight. Late elution of compact solutes in gel permeation chromatography is well established⁹. The fractionation range for poly(ethylene glycols) was similar in all four solvents the molecular weight exclusion limit being less than 1500.

Although reasonable separations were obtained in all four solvents, marked variation in column efficiency was observed (Table 2). The aqueous xerogel derived from Enzacryl Gel KO is considerably softer than those obtained with organic solvents. This allows distortion of the beads on column packing and results in maximal capacity ratio, V_i/V_o , and hence efficiency. The rigidity of the xerogel derived from dimethylformamide was intermediate between that of the aqueous xerogel and xerogels derived from chloroform and pyridine. This is reflected in the efficiency of Enzacryl Gel KO in dimethylformamide even though the internal bead volume corresponding to dimethylformamide is less than that occupied by the solvent component in other xerogels.

Figure 3 Logarithm molecular weight versus K_d relationships for poly(ethylene glycols) (Δ); oligosaccharides (\circ); aliphatic hydrocarbons (\blacktriangle); aromatic hydrocarbons (\bullet) and deuterated eluent (\blacksquare) obtained using Enzacryl Gel KO in different solvents: (a) water; (b) chloroform; (c) dimethylformamide; (d) pyridine

When volumetric parameters alone determine the elution volume of homologous solutes then a plot of logarithm molecular weight versus K_d will extrapolate back through a point close to the coordinates for the isotopically labelled solvent. A linear (isotopically labelled) solvent molecule should emerge from the column slightly earlier than a compact solute molecule of a similar molecular weight. Conversely a compact solvent molecule should emerge from the column later than that of a linear solute. It is clear (Figure 3a–3d) that poly(ethylene glycols) exhibit ideal g.p.c. behaviour in water, dimethylformamide and possibly pyridine. Weak adsorption of ethylene glycol ($K_d = 1.17$) occurs in this solvent. Low molecular weight ethylene glycol oligomers are adsorbed in chloroform.

Marked early elution is apparent in the case of aliphatic hydrocarbons in all three organic solvents and aromatic hydrocarbons in chloroform and pyridine. This is indicative of an 'additional exclusion' mechanism^{10,11} being operative as well as molecular sieving. Altgelt¹¹ has suggested that, in the case of polymeric solutes, 'additional exclusion' arises as a result of the low entropies of mixing between the solvated macromolecular species involved, i.e. between the solvated polymeric solute and the solvated gel matrix. Early elution arises if the entropy term is too small to overcome a positive heat of mixing. We have noted previously that a sufficiently low entropy term is only likely to arise with macromolecular solutes³. We have suggested that 'additional exclusion' of small molecules may be a more subtle, related phenomenon involving solute micropartition being regions of the gel beads consisting of more or less pure solvent and other regions consisting of the constrained solvated polymer chains comprising the gel matrix. The present results are explicable also on this hypothesis.

Synthesis and characterization of poly(ϵ -carbobenzoxy-L-lysyl- γ -benzyl-L-glutamate)

I. Omura*, D. C. Lee**, S. Itou, A. Teramoto, and H. Fujita

Department of Polymer Science, Osaka University, Toyonaka, Osaka 560, Japan

(Received 17 December 1975; revised 26 February 1976)

An alternating copolypeptide poly(ϵ -carbobenzoxy-L-lysyl- γ -benzyl-L-glutamate) was synthesised by polymerizing the *p*-nitrophenyl ester of ϵ -carbobenzoxy-L-lysyl- γ -benzyl-L-glutamate. The highest molecular weight obtained was 570 000 (2370 peptide residues), which had not yet been attained by the active ester method. The polymers were soluble in various organic solvents including those solvents in which the parent polymers were insoluble, i.e. poly(ϵ -carbobenzoxy-L-lysine) and poly(γ -benzyl-L-glutamate), and their conformations were essentially α -helical except in strong acids such as dichloroacetic acid.

INTRODUCTION

According to well-established theories¹, typical average quantities, such as the helical fraction, the number of helix portions, and so forth, which characterize homopolymer conformations in dilute solution, can be expressed in terms of three parameters s , σ , and N , where s is the equilibrium constant between helix and random coil residues, σ is the cooperativity parameter for the formation of a helix sequence, and N is the degree of polymerization of the polymer. Much effort has been made to establish practical methods which allow the parameters s and σ to be evaluated from measurements of thermally or solvent induced helix-coil transition curves, and now little remains to be developed further in this direction, as can be seen for example from our recent review articles^{2,3}.

For both theoretical and experimental studies with copolypeptides one has to face the complexity of two additional factors influencing their conformation. These factors are the composition of different peptide residues and their distribution (or geometric arrangement) in the polymer chain. Furthermore, in general, these factors fluctuate among a bunch of polypeptide molecules in the system under consideration, and this introduces an added complication. To approach the problem of copolypeptides it is therefore desirable to start with systems which involve such complexities as little as possible. One of these systems is an alternating sequential copolymer consisting of two peptide residues A and B, which may be schematically represented by ...ABABAB... In this case, the composition and arrangement of the constituent residues are fixed not only in a particular chain but also among all the individual chains in the system. Thus none of the complexities mentioned appear. The sole effect that distinguishes such sequential copolymers from homopolymers is expected to arise from the interaction between A and B in a given solvent, and it is certainly of interest to investigate either theoretically or experimentally the consequences from this

interaction. The work described in the present paper deals with the synthesis of an alternating copolypeptide and its preliminary characterization.

Since 1963 when DeTar *et al.*⁴ reported a successful synthesis of sequential polypeptides using *p*-nitrophenyl esters, a number of active esters have proved useful for synthesising this class of polypeptides. An obvious motivation of such syntheses has been the hope of acquiring model compounds for the proteins, and much attention has been paid to the preparation of water-soluble species and to the investigation of their conformations in aqueous media. Conformation studies of sequential polypeptides in organic solvents have not always proved easy. Most of the copolypeptides so far obtained were poorly soluble in ordinary organic solvents, making it difficult to characterize them satisfactorily. In fact, dichloroacetic acid (DCA), trifluoroacetic acid (TFA), and their mixtures with chloroform, for example, were the only solvents effective for them. Further, their molecular chains were usually quite short, consisting of at the most 100 peptide residues. It is now well recognized that there is a marked difference in conformation between oligomers and high molecular weight homologues. For this reason it is an important prerequisite for the conformation study of a polypeptide to have samples covering a wide span of molecular weights. To be more precise, such samples must be as homogeneous as possible in molecular weight. The work of Sakakibara *et al.*⁵ on sequential polypeptides of L-prolyl-L-prolyl-glycine is a very impressive example on this point.

The alternating sequential polypeptide chosen for the present study was poly(ϵ -carbobenzoxy-L-lysyl- γ -benzyl-L-glutamate). The choice was made for two reasons. Firstly, there were detailed investigations available on conformational characteristics of the homopolypeptides of its constituent residues, i.e. poly(γ -benzyl-L-glutamate) (PBLG) and poly(ϵ -carbobenzoxy-L-lysine) (PCBL) in various organic solvents^{2,3,6-11}. It was thus hoped that when compared with the data for these parent polymers, measurements on the copolypeptide would provide clear information about the interaction between neighbouring different peptide units. Secondly, Ledger and Stewart¹² had already reported synthesis of this sequential polypeptide by the active ester

* Present address: The Central Research Laboratory, Kurarei Co. Ltd, Kurashiki, Japan.

method and its conformation in the solid state, but little had been mentioned in their paper about the conformation in solution and molecular weight. It is shown below that certain modifications of their method yield samples of poly[Lys(Z)-Glu(OBzl)]* which not only cover a wide range of molecular weight but are also soluble in many organic solvents.

RESULTS AND DISCUSSION

Synthesis of ϵ -carbobenzoxy-L-lysyl- γ -benzyl-L-glutamate *p*-nitrophenyl ester *p*-toluenesulphonate

The scheme of Ledger and Stewart¹² for the synthesis of a dipeptide monomer unit ϵ -carbobenzoxy-L-lysyl- γ -glutamate *p*-nitrophenyl ester *p*-toluenesulphonate (VI) is:

We found that some modifications of this procedure were effective for obtaining the final compound VI in a form of high purity. The modified procedure was as follows.

Cleavage of the Nps-group from the compound II was achieved by treatment with excess HCl, according to Ledger and Stewart¹². The resulting HCl, H-Glu(OBzl)-ONp (III) melted over a rather broad range of temperature. This, together with the result from elemental analysis, suggested that the protecting groups on the side chains might have been partly cleaved. Recrystallization of the crude product from acetonitrile gave the compound III, melting point 157°–160°C, which Ledger and Stewart had described as a hemihydrate. However, our compound III, in agreement with Brack and Spach¹⁴, showed no sign of hydration.

Nps-Lys(Z)-OH (IV) and H-Glu(OBzl)-ONp (III) were coupled to obtain the compound V by the DCCI procedure of Bodanszky and Vigneaud¹⁵ with use of THF or

THF/dioxane as solvent. This choice of solvent was made because racemization of the Glu(OBzl) residue and undesirable side reactions were least likely to occur¹⁶. The compound V recrystallized from acetone/isopropanol had a melting point 10°C higher than the reported melting point for the same compound obtained by the mixed carbonic anhydride method¹². Removal of the Nps-group from the compound V was made by treatment with two equivalents of HCl to the protected peptide, and the resultant hydrochloride was converted to the *p*-toluenesulphonate (VI). The product VI, recrystallized from 0.5% acetonitrile solution, had a melting point of 181.5°–182°C, which indicated its high purity.

Polycondensation

Experimental evidence has indicated that, among various active esters suggested so far for polycondensation, *N*-succinimidyl esters^{14,17–23} and 2-hydroxyphenyl esters^{17,18,24,25} may be least liable to induce racemization. However, the use of these esters yielded polymers which had relatively low molecular weights, at least not high enough for our present purpose. The synthesis of the latter esters involved a lengthy path with relatively poor yields. Although *p*-nitrophenyl esters^{14,22,26–29} and pentachlorophenyl esters^{14,17,22,29,30} were effective for the production of high molecular weights, they induced racemization. The former esters were more satisfactory than the latter with respect to racemization^{14,17,22,29}. Therefore, as a compromise between molecular weight and racemization, we chose *p*-nitrophenyl ester VI.

Recently, König and Geiger^{31–34} have shown that addition of 1-hydroxybenzotriazole (HOBt) was not only largely effective for the condensation of amino-acids and peptides with repressed racemization but also accelerated reactions of active esters to form amide bonds. With the expectation of a similar effect on the polycondensation of active esters, we allowed the active ester VI to polymerize in DMF by treatment with an approximately equimolar amount of base and varying amounts of HOBt. Preparative data are summarized in Table 1.

Samples LG-1 to LG-4 were synthesised under similar conditions in order to observe the effect of HOBt. It was found from an increase in viscosity that the polymerization for LG-1 (with an 0.1 equivalent of HOBt added) was fastest in the initial rate and gave the highest molecular weight when terminated. The polymerization for LG-3 (with no HOBt added) was slower than that for LG-1. These observations appear to substantiate the predicted effect of HOBt on polymerization reaction. Other samples synthesised under similar conditions gave essentially the same results. Furthermore, it was noticed that addition of one equivalent of HOBt had no detectable effect on accelerating polymerization and resulted in a low molecular weight (LG-2). This was probably due to the acidity of HOBt, which is comparable to that of acetic acid.

During the course of these polymerization experiments, we observed that the molecular weights of samples LG-2, LG-3, and LG-4 were quite low when the polymers were precipitated from the reaction mixtures. However the precipitates underwent a remarkable increase in molecular weight when allowed to stand in the solid state. This interesting observation suggests that the precipitated polymers retained the polymerizing activity even in the solid state; the reason for which is as yet unknown to us, because no other samples showed such behaviour.

* Abbreviations used in this article are those recommended by the IUPAC IBU Commission in Biochemical Nomenclature¹³, except that the side chains attached to the α -carbon atom are given in parentheses. All amino-acids referred to in the text are of L-configuration; Bzl, benzyl; Nps, *o*-nitrophenylsulphenyl; Np, *p*-nitrophenyl; TsO, *p*-toluenesulphonate; DCCI, dicyclohexylcarbodiimide; DCHA, dicyclohexylamine; THF, tetrahydrofuran; DMF, *N,N*-dimethylformamide; DCA, dichloroacetic acid; PBLG, poly(γ -benzyl-L-glutamate); PCBL, poly(ϵ -carbobenzoxy-L-lysine); Ala, alanine; Tyr, tyrosine.

^a $[\eta]$ and $[\alpha]_{546}$ measured after three days of polymerization; ^bNEt₃ = triethylamine; ^cN-methylmorpholine

Polymerization of LG-19 was followed by g.p.c. Figure 1 shows the g.p.c. diagrams taken at three intervals of polymerization. It can be seen that the polymerization continued for as long as 7–11 days, with the peak molecular weight increasing gradually from 70 000 to 300 000 and that the low molecular weight oligomers almost disappeared in one week. Other crude samples yielded similarly broad g.p.c. patterns. Thus the samples obtained were quite broad in molecular weight distribution, as expected for polycondensates. A quantitative analysis of these g.p.c. diagrams is deferred until the calibration curve with absolute molecular weights becomes available.

Molecular weights

The molecular weight of 570 000 for LG-3 is the highest of the reported values for polypeptides synthesised by the active ester method. In fact, it far exceeds, e.g. 160 000 for poly[Glu(OBzl)]¹⁴ and 62 600 for poly(Tyr-Ala-Gly)³⁵. Many other samples listed in Table 1 also have molecular weights of a few hundred thousands. This success in attaining high molecular weights may be attributed primarily to the fact that, as observed from its narrow melting range, the crystallizable active ester VI was of high purity and that the resulting polypeptide was very soluble in DMF, the solvent used for polymerization.

Optical purity of polypeptide samples

As is shown below, poly[Lys(Z)-Glu(OBzl)] assumes random coil in DCA, so that the specific rotation $[\alpha]_{546}$ in this solvent may be taken as a measure of the optical purity of the polypeptide. The values of $[\alpha]_{546}$ listed in Table 1 then indicate that all the samples but LG-9 and LG-15 had essentially the same optical purity. Closeness of these $[\alpha]_{546}$ values to those of the parent polypeptides, PBLG and PCBL (Table 2), suggests that polymerization was accompanied by little racemization. In fact, optical rotation measurements on acid hydrolysates gave optical purities of $97 \pm 1\%$ and $98.5 \pm 1\%$ for LG-2 (with a 0.1 equivalent of HOBt added) and $96 \pm 1\%$ for LG-3 (with no HOBt added). These estimates should be accepted with some reservations, because racemization on acid hydrolysis is known to differ between amino-acids and peptides³⁶. Samples LG-9 and FF-3 (fractionated sample) showed somewhat lower optical purities. This is partly because

Table 2 Results from racemization tests

Sample code	$[\alpha]_{546}^a$	Optical purity (%) ^b
LG-2	-22.4	97 \pm 1
LG-3	-22.3	98.5 \pm 1
LG-9	-18.2	91
FF-3	-19.7	93
PBLG ^c	-21 \pm 1	(100)
PCBL ^c	-21.3	(100)

^a $[\alpha]_{546}$ = specific rotation for the wavelength 546 nm in DCA at 25°C; ^b derived from optical rotation measurements on acid hydrolysates; ^c synthesised by the NCA method

Figure 2 Polarized infra-red spectra of an oriented film of poly[Lys(Z)-Glu(OBzl)] (LG-4): —, parallel; - - -, perpendicular

these samples contained low molecular weight impurities, as revealed by g.p.c.

Overall, the present polymerization experiments did not introduce more than a few percent racemization, a conclusion compatible with the previous results from the polymerization of *p*-nitrophenyl esters of γ -benzyl glutamates^{14,17,22,29}. Although HOBt has shown to accelerate polycondensation of compound VI, it had no detectable effect on repressing racemization.

Conformation in solid and in solution

Figure 2 shows the polarized infra-red spectra taken on an oriented film of LG-4. The frequencies and dichroisms of amide I and II bands are recorded in Table 3. From the reported infra-red spectra of synthetic polypeptides³⁷, these data may be viewed as exhibiting characteristic features of the α -helical conformation. Ledger and Stewart¹² have reported essentially the same result, but, differing from their finding, the present spectra show no band attributable to the β -structure or diketopiperazine. This difference is probably ascribed to the fact that the samples used by Ledger and Stewart were of low molecular weight and contained cyclic compounds. Infra-red spectra of LG-4 in ethylene dichloride (EDC) were also characteristic of the α -helical conformation. Thus we conclude that poly[Lys(Z)-Glu(OBzl)] can assume the α -helical conformation in solution as well as in the solid state.

The fact that the intrinsic viscosities of LG-1 were 2.13 dl/g in DCA and 7.13 dl/g in DMF, both at 25°C, suggested that the conformations in these solvents are different. The Moffitt parameters b_0 for LG-1 were 39 in DCA and -575 in DMF at 25°C. The literature values of b_0 for the parent polypeptides are 45 in DCA⁶ and -630 in DMF³⁸ for PBLG, and 3 in DCA and -550 for PCBL⁹. From these

data we may conclude that the conformations of poly[Lys(Z)-Glu(OBzl)] are α -helical in DMF and random coil in DCA, as is the case with PBLG and PCBL. Figure 3 illustrates the o.r.d. curve of LG-1 in trifluoroethanol at 25°C, which displays a negative Cotton effect with a trough at 234 \pm 2 nm ($[m']_{234} = -18\ 600$). The position and depth of this trough are also consistent with the α -helical conformation^{39,40}.

Solubility

Unexpectedly and fortunately, the copolypeptide samples synthesised dissolved in a number of organic solvents, which included either non-solvents or partial solvents for their parent homopolypeptides PBLG and PCBL. Examples of such solvents were THF, methylethyl ketone, and ethyl acetate. This unexpected feature must be a consequence of the interaction between neighbouring different peptide residues, since such interaction is absent in the parent homopolymers. The observation⁴¹ that in CHCl₃ about two thirds of urethane NH groups in the side chains of PCBL were left unbonded would probably account for its poor solubility in less polar solvents. However, the present copolypeptide dissolved in such solvents, despite the fact that the infra-red spectra of LG-4 in EDC suggested the presence of unbonded NH groups comparable in quantity to those of PCBL in CHCl₃. At present, no adequate explanation of the unexpected solubility in terms of molecular concepts comes to mind. For the sake of reference, the intrinsic viscosities and Moffitt parameters of LG-1 in typical solvents at 25°C are compared in Table 4. From these data the conformation of the copolypeptide in the listed solvents except for DCA are supposed to be α -helical. The large intrinsic viscosities obtained might be expected to be largely due to molecular association in these solvents. However, this may be ruled out because the Huggins viscosity constant k' was quite normal (0.4-0.5). Recent light scattering measurements on fractionated samples⁴⁶ have provided more direct evidence for the absence of association in one of the helicogenic solvents, MEK. They have also confirmed the correctness of the molecular weights reported in this paper.

^aMethyl ethyl ketone**Figure 4** Plots of $[\alpha]_{436}$ against temperature for poly[Lys(Z)-Glu(OBzl)] (FF-2) in DCA-EDC mixtures of the indicated vol% of DCA: A, 53; B, 55; C, 58

Helix-coil transition

Figure 4 shows plots of $[\alpha]_{436}$ against temperature for a fractionated sample FF-2 in DCA-EDC mixtures with the indicated DCA volume compositions. It can be seen that the polypeptide undergoes an inverse thermal helix-coil transition in these mixed solvents. For example, the transition temperature in the 58 vol% mixture is about 20°C. Table 5 compares this composition with those of DCA-EDC mixtures for which the transition temperatures of PBLG and PCBL appear at about 20°C. It also includes the transition temperature for an equimolar random BLG-CBL copolymer in CHCl₃ containing 54.4 vol% DCA⁴². The conclusion from this Table is that the stability of the helix of poly[Lys(Z)-Glu(OBzl)] is intermediate between those of PBLG and PCBL and comparable with that of the equimolar random copolymer. Detailed spectroscopic data and an analysis of helix-coil transition curves will be reported in a forthcoming publication.

EXPERIMENTAL

Reagent and solvents

γ -Benzyl-L-glutamate, ϵ -carbobenzoxy-L-lysine, and dicyclohexylcarbodiimide were purchased from the Protein

Research Foundation, Osaka, and used without further purification. *p*-Nitrophenol (the Protein Research Foundation) was recrystallized from toluene. 1-Hydroxybenzotriazole⁴³ was synthesised from *o*-nitrochlorobenzene and hydrazine hydrate, melting point 156°–157°C. *N*-Methylmorpholine and triethylamine were refluxed over sodium metal and fractionally distilled. Other chemicals were purified according to the standard procedures. All the melting points reported below were uncorrected.

γ -Benzyl-L-glutamate *p*-nitrophenyl ester hydrochloride (III)

α -*o*-Nitrophenylsulphenyl- γ -benzyl-L-glutamate, DCHA (I) was synthesised from γ -benzyl-L-glutamate⁴⁴ and recrystallized from dichloromethane, m.p. 160°–164°C, $[\alpha]_D^{25} = -38.4^\circ$ (*c* 1.62, CHCl₃). Literature⁴⁴: m.p. 168°C, $[\alpha]_D = -34.0^\circ$ (*c* 1.2, CHCl₃). The compound I was coupled with *p*-nitrophenol following the procedure of Bodanszky and Vigneaud¹⁵ to give α -*o*-nitrophenylsulphenyl- γ -benzyl-L-glutamate *p*-nitrophenyl ester (II)^{12,44}. The product was recrystallized from EtAc/ether, m.p. 77°–80.5°C, $[\alpha]_D^{25} = -121.3^\circ$ (*c* 1.2, CHCl₃). Literature⁴⁴: m.p. 77°–78°C, $[\alpha]_D = -121.0^\circ$ (*c* 3, CHCl₃). The compound II (69.8 g, 0.136 mol) was dissolved in warm anhydrous dioxane (310 ml), and 4.8 N HCl/dioxane (83 ml, 0.4 mol) was added in one portion to the solution cooled to room temperature. After 3 min, 1.5 l of anhydrous ethyl ether were added to the solution. A white precipitate appeared immediately. The precipitate was washed with ether, dried under reduced pressure, and recrystallized from acetonitrile, yielding 43 g (80%) of the product III, m.p. 157°–160°C, $[\alpha]_D^{25} = 35.2^\circ$ (*c* 1.87, methanol). Literature¹²: m.p. 149°–151°C, $[\alpha]_D = 35.6^\circ$ (*c* 2.0, methanol). Analysis calculated for C₁₈H₁₉N₂O₆Cl: C, 54.76; H, 4.85; N, 7.10; Cl, 8.98. Found: C, 54.5; H, 4.86; N, 7.03; Cl, 8.98; Literature¹⁴: C, 54.43; H, 4.95; N, 6.87; Cl, 9.09; Literature¹²: C, 53.5; H, 5.0; N, 6.9.

α -*o*-Nitrophenylsulphenyl- ϵ -carbobenzoxy-L-lysyl- γ -benzyl-L-glutamate *p*-nitrophenyl ester (V)

α -*o*-Nitrophenylsulphenyl- ϵ -carbobenzoxy-L-lysine, DCHA (IV)⁴⁴ was obtained from ϵ -carbobenzoxy-L-lysine, m.p. 176°–181°C, $[\alpha]_D^{25} = -30.6^\circ$ (*c* 0.61, DMF). Literature⁴⁴: m.p. 184°–187°C, $[\alpha]_D = -29.1$ (*c* 0.7, DMF). α -*o*-Nitrophenylsulphenyl- ϵ -carbobenzoxy-L-lysine isolated from 30.7 g (0.05 mol) of the compound IV was dissolved in THF (250 ml), in which γ -benzyl-L-glutamate *p*-nitrophenyl ester hydrochloride (III) (19.74 g, 0.05 mol) was suspended and cooled to 0°C. Dicyclohexylcarbodiimide (10.3 g, 0.05 mol) dissolved in a small volume of dioxane was added with vigorous stirring, and the suspension was kept stirred for 30 min. *N*-Methylmorpholine (5.06 g, 0.05 mol) diluted with 50 ml of THF was added dropwise

Table 5 Helix-coil transitions in DCA-EDC mixtures

Polypeptide	Transition temperature (°C)	Solvent composition (vol% DCA)
PBLG ^a	20	71
BLG-CBL ^b	16	54.4 (DCA-CHCl ₃)
FF-2 ^c	20	58
PCBL ^d	20	34

^aTaken from Norisuye et al.^{6,7}; ^bdata for an equimolar random copolymer of γ -benzyl-L-glutamate and ϵ -carbobenzoxy-L-lysine in a DCA-CHCl₃ mixture⁴²; ^cfractionated sample of poly[Lys(Z)-Glu(OBzl)]; ^dtaken from Matsuoka et al.⁹

to the suspension in 40 min. The reaction was then allowed to proceed at 0°C for 10 h. The precipitates formed were filtered, and the filtrate was concentrated at reduced pressure almost to saturation. Addition of isopropanol to the solution gave yellow crystals, which were dried at reduced pressure. The product was recrystallized from acetone/isopropanol to yield needle crystals of the compound V in 70% yield, m.p. 143.5°–145.5°C, $[\alpha]_D^{25} = -48.3^\circ$ (*c* 0.77, EtAc). Literature¹²: yield 39% (the mixed carbonic anhydride method), m.p. 134°–136°C, $[\alpha]_D = -49.4^\circ$ (*c* 2.0, EtAc).

Analysis calculated for C₃₈H₃₉N₅O₁₁S: C, 58.98; H, 5.08; N, 9.05; S, 4.14. Found: C, 58.81; H, 5.09; N, 9.25; S, 4.06.

ϵ -Carbobenzoxy-L-lysyl- γ -benzyl-L-glutamate p-nitrophenyl ester p-toluenesulphonate (VI)

The procedure of Ledger and Stewart¹² with some modifications was used to obtain the compound VI. α -o-Nitrophenylsulphenyl- ϵ -carbobenzoxy-L-lysyl- γ -benzyl-L-glutamate p-nitrophenyl ester (V) (15.86 g, 0.0205 mol) was dissolved in 55 ml of anhydrous dioxane at 60°C. To the solution cooled to room temperature was added 4.8 N HCl/dioxane (0.0408 mol). After 7 min, ether was added to the solution, which was kept overnight in a refrigerator. The precipitate was washed with ether, dried at reduced pressure, and dissolved in methanol. To the solution sodium p-toluenesulphonate (8 g, 0.041 mol) was added. Precipitated sodium chloride was filtered. The filtrate was concentrated to saturation, cooled in ice, and diluted with cold water. The precipitated p-toluenesulphonate (VI) was collected, washed with ether, and dried. The product, recrystallized from 0.5% acetonitrile solution, gave colourless needle crystals of the compound VI in 78% yield, m.p. 181.5–182°C, $[\alpha]_D^{25} = -5.5^\circ$ (*c* 1.6, methanol). Literature¹²: 170°–173°C, $[\alpha]_D = -6^\circ$ (*c* 2.0, methanol).

Analysis calculated for C₃₉H₄₄N₄O₁₂S: C, 59.08; H, 5.59; N, 7.07; S, 4.04. Found: C, 58.97; H, 5.60; N, 7.04; S, 4.03.

Polycondensation

ϵ -Carbobenzoxy-L-lysyl- γ -benzyl-L-glutamate p-nitrophenyl ester p-toluenesulphonate (VI) (1.301 g, 1.64 mmol) and HOBt (0.022 g, 0.16 mmol) were dissolved in DMF (1.5 ml). Triethylamine (0.227 ml, 1.64 mmol) was added to this solution with stirring. An appreciable increase in solution viscosity was observed after 1 h, and the viscosity continued to increase for four days, so that subsequently the solution was diluted with DMF. The solution finally diluted to 5% was poured onto 200 ml of water–methanol mixture, yielding a thread-like precipitate LG-1. The product LG-1 was purified by repeated precipitation from DMF solutions and freeze-dried from a dioxane solution in 80% yield. Polymerizations of other samples were performed in a similar way. Aliquots were taken at suitable intervals from the polymerization mixture for LG-19 and the polymers precipitated from them in water–methanol were analysed by g.p.c.

Racemization test

In a sealed tube, a given amount of the polymer mixed with 5.7 N hydrochloric acid or an acetic acid/5.7 N hydrochloric acid mixture (1:1 by volume) was heated at 111°C for 24 h. The optical rotation of the hydrolysate was then measured, after removal of benzyl chloride by centrifuga-

tion if necessary, and compared with that of a similarly treated solution of an equimolar mixture of γ -benzyl-L-glutamate and ϵ -carbobenzoxy-L-lysine. For example, the acid hydrolysate of 0.06 g of LG-2 in 6 ml of 5.7 N HCl gave an optical rotation of $0.343 \pm 0.002^\circ$ for the wavelength 436 nm; $[\alpha]_{436} = 34.4^\circ$. The hydrolysate of the corresponding amino-acid mixture gave $0.318 \pm 0.002^\circ$, which, corrected for the residue weights, led to $[\alpha]_{436} = 34.8^\circ$.

Characterization

Molecular weights were estimated from intrinsic viscosities $[\eta]$ in DCA at 25°C with the use of the $[\eta]$ – degree of polymerization relation for PBLG⁴⁵ as the calibration standard. They actually correspond to the viscosity-average degrees of polymerization multiplied by mean residue molecular weight 241. The accuracy of the estimated molecular weights was confirmed by molecular weight determination of several fractionated samples by osmometry, light scattering, and sedimentation equilibrium⁴⁶. G.p.c. measurements were made on a gel-permeation chromatograph HLC-801A (Toyo Soda) equipped with two columns 2 feet long packed with polystyrene gels of nominal porosities, $1 \times 10^4 \text{ \AA}$ and $1 \times 10^6 \text{ \AA}$, respectively. THF was used as solvent and the molecular weight calibration of the chromatogram was made by using several fractionated samples of known weight-average molecular weights. Infra-red spectra were taken on a Jasco Model 402G spectrophotometer. Optical rotatory dispersion (o.r.d.) and optical rotation measurements were carried out in the manner described previously^{6–9}. O.r.d. data were analysed by means of the Moffitt–Yang equation, with λ_0 being taken to be 212 nm.

ACKNOWLEDGEMENTS

Acknowledgement is made to the Japan Society for the Promotion of Science for the research fellowship awarded to D. C. L. The authors wish to thank Professor H. Yuki and Dr S. Sakakibara for their valuable discussion.

Theory of gelatinization in a starch–water–solute system

J. Lelievre

Agricultural and Food Chemistry Division, Department of Agriculture, Queen's University, Belfast BT9 5PX, UK

(Received 16 June 1975; revised 19 January 1976)

In an attempt to understand the effect of solutes on starch gelatinization the theory of polymer–amorphous phase transitions has been developed to consider melting in a three component system consisting of polymer, diluent and solute. An expression has been derived according to this theory which relates melting temperatures to composition. It is suggested that the expression may be used to explain certain features of gelatinization. However while the theory successfully predicts some of the effects of various solutes on gelatinization temperatures, the fact that the analysis is based on an idealized model of the relatively complex gelatinization transition is emphasized.

INTRODUCTION

When an aqueous suspension of starch granules is heated above a certain temperature the granules swell to form a viscous paste, this process is known as gelatinization. The gelatinization temperature may be defined as the point at which all, or a fraction, of the granules have undergone transformation. Since different experimental techniques for determining this stage give varying results, gelatinization temperatures have arbitrary values when determined by conventional methods. Detailed reviews of starch gelatinization are available in several texts^{1,2}. Many investigators have demonstrated that if gelatinization occurs in the presence of low molecular weight solutes the course of the transition may be altered. For example, polyhydric alcohols raise gelatinization temperatures by an amount that increases as the molarity of the solute is increased³. In the case of monohydric alcohols results are more complicated since lower concentrations of alcohol decrease the values of the temperature at which the transitions occur while in more concentrated solutions these values are raised³. Pasting of starch granules is also possible in non-aqueous systems⁴. Under commercial conditions, gelatinization frequently takes place in solutions containing sugars. The precise effect obtained depends on the concentration of starch and sugar examined^{5,6}. In general, sugar concentrations of less than about 20% w/w appear to have relatively little influence, though in certain instances the temperature at which gelatinization occurs appears to be slightly decreased. As the concentration of sugar is raised above this level gelatinization temperatures are increased, with higher concentrations of sugar producing a disproportionate increment in the temperature at which conversion to a paste occurs^{5,6}. In concentrated sugar solutions there may be relatively large changes in the course of gelatinization. Thus D'Appolonia reported that with a 9% w/w starch suspension the point at which 98% of granules had gelatinized was 24°C higher in an 80% w/w sucrose solution compared to a control⁵. If more concentrated starch suspensions are examined, it is found that sugars tend to cause a greater increase in gelatinization temperatures. Some evidence suggests that disaccharides may cause a larger change in the course of gelatinization than monosaccharides⁷. Despite the industrial significance of starch, the mechanism by

which non-electrolytes influence gelatinization is incompletely understood.

In order to resolve the uncertainties as to how organic solutes influence gelatinization, a detailed knowledge of the structural changes occurring during this process is required. The starch grain consists largely of extensively branched and virtually linear polymers of D-glucose. The chains of these polysaccharides associate to form zones possessing different degrees of order within each granule. However the precise distribution of the numerous types of amylose and amylopectin molecules in the various crystalline and amorphous domains is unknown⁸. In many respects granule structure appears to be quite similar to that of a spherulite crystallized from molten polymer; this might not be expected since polysaccharides are deposited in the starch grain under conditions which are very different from those operating during the crystallization of the synthetic material⁹. Gelatinization occurs when higher temperatures cause the crystalline regions in granules to melt¹⁰, and since these zones possess different degrees of order the transition takes place over a temperature range. When starches are completely gelatinized polymer chains are in an amorphous state, though a fraction of the amylose may complex with traces of lipid^{1,2}. Thus gelatinization entails a change in structure from a partly crystalline to an amorphous form. Previous work has demonstrated that the theory of crystalline–amorphous phase transitions in polymer–diluent mixtures¹¹ may be used to explain certain features of this behaviour in starch¹². The theory provides a means of analysing an idealized model of the gelatinization process, namely that of melting of a partly crystalline polymer in the presence of diluent. The following report describes an attempt to develop the analysis to consider the case of a three component system consisting of polymer, diluent and low molecular weight solute.

THEORY OF MELTING IN POLYMERS

Let the subscripts 1, 2 and 3 refer to diluent, polymer and solute respectively. The expression describing crystalline–amorphous phase transitions relates the melting temperature, T_m , at which liquid crystalline polymer repeat units are in equilibrium, to the composition of the liquid phase.

T_m is the temperature at which the last traces of crystallinity disappear when melting is performed using an extremely slow heating schedule. The condition for equilibrium may be stated as follows:

$$\mu_u^c - \mu_u^0 = \mu_u - \mu_u^0 \quad (1)$$

where μ_u is the chemical potential of the liquid polymer repeat unit with μ_u^c and μ_u^0 the chemical potentials of the polymer in crystalline form and in the standard state. According to Flory¹¹, the left-hand side of equation (1), i.e. the difference in the chemical potential of the crystalline repeat unit and the unit in the standard state may be expressed thus:

$$\mu_u^c - \mu_u^0 = -\Delta H_u(1 - T/T_m^0) \quad (2)$$

where T is the absolute temperature, T_m^0 is the melting temperature of pure polymer and ΔH_u is the heat of fusion of polymer repeat unit. The right-hand side of equation (1) represents the lowering of the chemical potential of the unit in the liquid phase owing to the presence of diluent. For a tertiary system, this may be derived from the following general formula¹¹:

$$\begin{aligned} \mu_2 - \mu_2^0 = RT[\ln \nu_2 + (1 - \nu_2) - \nu_1(x_2/x_1) - \nu_3(x_2/x_3) \\ + (\chi_{21}\nu_1 + \chi_{23}\nu_3)(\nu_1 + \nu_3) - \chi_{13}(x_2/x_1)\nu_1\nu_3] \end{aligned}$$

where μ_2 and μ_2^0 represent the chemical potentials of liquid polymer and polymer in the standard state; R is the gas constant; ν_1 , ν_2 and ν_3 the volume fractions; x_1 , x_2 and x_3 the number of segments per molecule in the respective species and χ_{ij} the pair interaction parameters corresponding to χ_1 in the two component system. An equation for the chemical potential per mole of repeat unit rather than per mole of polymer is required. Dividing by the number of units per polymer molecule, i.e. $x_2 V/V_u$, where V and V_u are the molar volumes of segment and structural unit respectively:

$$\begin{aligned} \mu_u - \mu_u^0 = \frac{RTV_u}{V} [(\ln \nu_2)/x_2 + (1 - \nu_2)/x_2 - \nu_1(x_2/x_1)/x_2 \\ - \nu_3(x_2/x_3)/x_2 + (\chi_{21}\nu_1 + \chi_{23}\nu_3)(\nu_1 + \nu_3)/x_2 - \chi_{13} \times \\ (x_2/x_1)\nu_1\nu_3/x_2] \end{aligned}$$

This expression for the right-hand side of equation (1) may be simplified by making assumptions analogous to those used in deriving the melting point equation for a two component system¹¹. Thus by considering the case of large values of x_2 , and relatively high concentrations of polymer, the expression reduces to:

$$\begin{aligned} \mu_u - \mu_u^0 = RT \frac{V_u}{V} [-\nu_1 x_1 - \nu_3/x_3 + (\chi_{21}\nu_1 + \chi_{23}\nu_3) \times \\ (\nu_1 + \nu_3)/x_2 - \chi_{13}\nu_1\nu_3/x_1] \end{aligned}$$

Let $V = V_1$, and the number of segments per solvent molecule be 1, i.e. $x_1 = 1$. Then:

$$\begin{aligned} \mu_u - \mu_u^0 = RT \frac{V_u}{V} [-\nu_1 - \nu_3/x_3 + (\chi_{21}\nu_1 + \chi_{23}\nu_3) \times \\ (\nu_1 + \nu_3)/x_2 - \chi_{13}\nu_1\nu_3] \end{aligned}$$

The formula may be further simplified by using the relation:

$$\chi_{ji} = \chi_{ij}(x_j)/(x_i)$$

Therefore:

$$\chi_{21} = \chi_{12} \frac{x_2}{x_1} = \chi_{12} x_2$$

Substitution gives:

$$\begin{aligned} \mu_u - \mu_u^0 = \frac{RT}{V_1} V_u \{-\nu_1 - \nu_3/x_3 + [\chi_{12}\nu_1 + (\chi_{32}\nu_3/x_3)] \times \\ (\nu_1 + \nu_3) - \chi_{13}\nu_1\nu_3\} \quad (3) \end{aligned}$$

Combining equation (2) and (3), replacing T by T_m , and rearranging gives:

$$\begin{aligned} \frac{1}{T_m} - \frac{1}{T_m^0} = \frac{R}{\Delta H_u} \frac{V_u}{V_1} \{\nu_1 + \nu_3/x_3 + \chi_{13}\nu_1\nu_3 \\ - [\chi_{12}\nu_1 + (\chi_{32}\nu_3)/x_3] (\nu_1 + \nu_3)\} \quad (4) \end{aligned}$$

This expression relates the melting temperature to the composition as represented by the volume fractions of solvent and monomeric solute. The depression of the melting point is a function of the heat of fusion per repeat unit, the ratio of the molar volumes of this unit and of diluent, the interaction parameters χ_{12} , χ_{13} , χ_{32} and the number of segments per solute molecule.

APPLICATION OF THEORY

While equation (4) provides a means of analysing the effects of solutes on melting temperatures, the expression contains a number of unknown constants and is therefore difficult to use to evaluate experimental situations in an unambiguous manner. Certain of the terms in the equation can be established by considering the case of a two component system; the equilibrium temperature, T_m , is then related to the concentration of diluent by¹⁰:

$$\frac{1}{T_m} - \frac{1}{T_m^0} = \frac{R}{\Delta H_u} \times \frac{V_u}{V_1} (\nu_1 - \chi_{12}\nu_1^2) \quad (5)$$

Values of T_m determined at various volume fractions, ν_1 , may be substituted into this equation and ΔH_u and χ_{12} calculated if T_m^0 is known. However pure starch, like many other naturally occurring polymers, decomposes before melting and hence T_m^0 cannot be determined directly. In this situation it is advantageous to rearrange equation (5) into the form¹³:

$$\left(1 - \frac{T_m}{T_m^0}\right) \frac{1}{\nu_1^2} = \frac{RV_u}{\Delta H_u V_1} \times \frac{T_m}{\nu_1} - \frac{R}{\Delta H_u} \times \frac{V_u}{V_1} \chi_{12} T_m \quad (6)$$

If ΔH_u and the product $\chi_{12} T_m$ are assumed to be constant over the temperature range of concern¹¹, then according to equation (6) the term $[1 - (T_m/T_m^0)]/\nu_1^2$ should be a linear function of T_m/ν_1 . On substituting known values of T_m and ν_1 the magnitude of T_m^0 that gives the best fit to a

Figure 1 Graph of predicted melting temperature as a function of maltose concentration for various starch concentrations. From left to right the curves correspond to suspensions of 110, 100, 90, 80, 70, and 60 g starch in 100 g solution containing the percentage of solute indicated. The symbols refer to corresponding experimentally determined melting temperatures

linear relationship may be established and ΔH_u and χ_{12} can then be calculated.

Two constants remain unknown in equation (4), namely χ_{13} and χ_{32} . However in certain instances it is possible to make assumptions about the values of these parameters. For example, in the particular case of a sugar such as glucose, χ_{32} is approximately zero. In other words, there is a negligible difference between energy of a glucose molecule immersed in starch polymer and the energy of the same molecule surrounded by glucose monomer. On letting χ_{32} equal zero, equation (4) simplifies to:

$$\frac{1}{T_m} - \frac{1}{T_m^0} = \frac{R}{\Delta H_u} \frac{V_u}{V_1} [\nu_1 + \nu_3/x_3 + \chi_{13}\nu_1\nu_3 - \chi_{12}\nu_1(\nu_1 + \nu_3)] \quad (7)$$

Furthermore, for a hexose sugar, χ_{12} is approximately equal to χ_{13} , i.e. the difference between the energy of a solvent molecule in the environment of starch polymer and one surrounded by molecules of its own kind is similar to the difference when a solvent molecule is first in the situation of pure polymer and then pure solvent. Thus in the special case of a sugar, equation (7) may be used to predict the effect of solute on melting temperatures.

The possibility of using equations (7) and (4) to describe certain aspects of gelatinization in starch-water-solute systems was examined in the present study.

EXPERIMENTAL

Starch was isolated from wheat grains according to the method of Adkins and Greenwood¹⁴. Melting temperatures

were determined for starch-water and starch-water-solute systems. Starch suspensions containing Thiomersal (0.01%) to inhibit microbial growth¹⁵ were first annealed by holding at 50°C for at least 72 h. Samples were then heated at a rate of 1°C/3 h. Melting points were detected by loss of birefringence. A minimum of two measurements of T_m were made, results generally agreed to within $\pm 1^\circ\text{C}$. The effects of maltose and glucose on gelatinization were examined.

Equation (7) was used to calculate T_m values as a function of solute concentration when χ_{32} was zero and χ_{13} was equal to χ_{12} . In a further analysis the situation where χ_{13} and χ_{12} had different values was examined. The effect of changing the size of the solute molecule, i.e. varying x_3 was also studied. Finally the case where χ_{32} was not equal to zero was tested. Results were computed using volume fractions calculated from density values of 1.55, 1.50 and 1.0 g/ml for starch, sugar and water respectively.

RESULTS AND DISCUSSION

Results from the starch-water system were analysed according to equation (6) by computing the value of T_m^0 that gave the best fit of the melting temperature and diluent volume fraction data to a linear relationship. Comparison of the experimentally determined melting points with the fitted melting temperatures obtained from this analysis indicated that the expression described results more accurately when diluent volume fractions were of relatively small magnitude. This would be expected as equation (6) was designed to apply to more concentrated polymer solutions. In the range where ν_1 was greater than 0.9 the fitted melting temperatures passed through a minimum as ν_1 increased. Since this was not observed experimentally the expression does not adequately describe melting at such volume fractions as far as the starch examined is concerned. Equation (6) could be modified to consider crystalline-amorphous phase transitions in the presence of relatively large quantities of diluent, however the resultant expression would be more complicated. As the situation where diluent volume fractions have relatively large values is of commercial interest the compromise of analysing data obtained when the diluent volume fraction was less than 0.7 was employed in the present study. From such data T_m^0 was found to be 495 K, ΔH_u to be 6000 cal/mol and χ_{12} to be 0.5, these results are similar to those obtained previously¹². The value of the solvent-polymer interaction coefficient is in agreement with that obtained by other investigators when using different methods of measurement^{16,17}. The similarity between experimental and fitted melting temperatures in the situation where ν_1 is less than 0.7 is illustrated on the y-axis of Figure 1.

The polymer-diluent-solute system was examined in the range of polymer volume fractions where equation (6) was found to describe the behaviour of polymer-diluent mixtures. Equation (7) was used to calculate melting temperatures as a function of solute and polymer concentrations. Figure 1 shows values obtained for the case where the solute was a sugar with a molar volume similar to that of maltose. Results were computed using the assumption that χ_{32} was zero and χ_{12} was equal to χ_{13} . The Figure shows that according to equation (7) sugars increase T_m values under the range of conditions studied, the precise effect depending on starch concentration. Experimentally determined melting points are also illustrated in this diagram. The computed and experimental values are quite

Table 1 Melting temperatures predicted for different molar volumes

50	50	105	100.5	103.9

similar though there is some disagreement at high concentrations of polymer in the presence of relatively large quantities of sugar. The melting points of certain starch suspensions were found to be greater than the boiling point of water as required by theory. When equation (7) was used to predict melting points for smaller sugar molecules such as glucose i.e. molecules having decreased molar volumes but similar solute-polymer and solute-solvent interaction coefficients, the results resembled those in Figure 1 but the curves were shifted to slightly lower temperatures (see Table 1). The computed melting points did not fit the experimentally determined values as well as the results for maltose did, however the discrepancy was usually less than 2°C except at relatively high sugar and starch concentrations where the difference was of the order of 4°C. The assumptions used in deriving equation (7) from equation (4) are probably more accurate for maltose than for glucose, and this may explain the better fit obtained with the former sugar.

The effect of assuming that χ_{32} was zero when calculating melting points was examined. Values of $\chi_{32} \leq \pm \chi_{12}/10$ were substituted into equation (4), this altered results by less than 1°C in all cases. Hence provided χ_{32} is of relatively small magnitude predicted melting temperatures are not significantly changed. Table 2 shows typical results obtained when χ_{32} was zero but χ_{13} and χ_{12} were not equal. In general, if $\chi_{13} > \chi_{12}$ then T_m decreases, and it was only in solutions containing the greatest amount of solute that values increase. When $\chi_{13} \leq \chi_{12}$ or $\chi_{13} < 0$, melting temperatures are increased at all solute concentrations in the range of conditions analysed. As the negative value of χ_{13} increases T_m values increase.

The above results suggest that a theory of crystalline-amorphous phase transitions may be used to explain certain features of gelatinization in a starch-water-sugar system. With other solutes gelatinization temperatures (defined by the point at which the last traces of crystallinity melt) and calculated melting temperatures may correspond when appropriate values of the solute-polymer and solvent-solute interaction coefficients are substituted into the melting point expression. Hence from an analysis based on an idealized model of starch behaviour various qualitative and quantitative aspects of the effect of solutes on gelatinization temperatures may be predicted. However the melting temperature is not strictly identical to the gelatinization point unless suitable experimental conditions are adopted. The term T_m refers to the temperature at which crystalline polymer units are in equilibrium with material in the liquid state. In order to obtain such a condition it is necessary to adopt a very slow heating schedule when melting the polymer. If a slow heating schedule is used annealing occurs which results in the apparent melting temperature increasing in value.

Studies by Kempf¹⁸, Sair¹⁹ and also by Gough and Pybus²⁰ indicate that such a recrystallization process occurs in the starch granule²¹. However the crystallization of starch is a relatively complicated process with high temperatures and low water contents favouring A-type crystallization whereas low temperatures and high water contents favour B-type crystallization²². In addition, branched starch polymers appear to interfere with the crystallization of the linear polymer fraction²³. Thus it is possible that a true equilibrium melting is not achieved even under controlled laboratory conditions. It is clear that with the more rapid heating schedules used under commercial conditions the equilibrium

state is not achieved and hence the point at which gelatinization occurs is not the same as the equilibrium melting temperature.

The application of equation (1) to the analysis of gelatinization is complicated by the fact that the crystalline phase may contain diluent. In this situation, an additional requirement is imposed for equilibrium, namely that the chemical potentials of water in the liquid and crystalline phases be equal. Flory²⁴ has discussed this case with respect to the collagen–gelatin transition and suggested that at the completion of melting part of the diluent is firmly solvated to polar groups while the remainder is in solution, i.e. in the amorphous phase. Under these circumstances, the condition in equation (1) is sufficient to describe the equilibrium and hence equation (5) gives the melting point relation. However T_m now refers to the polymer in a hydrated state. The behaviour of the diluent in the starch crystalline structures is likely to be analogous to that described by Flory for the collagen–gelatin system. There is also the uncertainty as to the precise effect of solutes on the annealing process. In the present study it has been assumed that solutes do not interfere with annealing, however some evidence suggests that in the particular instance of high concentrations of sugars this may not be the case²⁵. A further general problem is that the traces of lipid contained in starch grains may complex with polymer in solution²⁶. The presence of such complexes would influence the chemical potential of the amorphous phase and hence the temperature at which melting occurs would be altered. Lipids complex with approximately ten times their own weight of starch polymer²⁶ and hence the magnitude of the effect may be greater than anticipated from the absolute amount of lipid in the granule. Finally, there is the problem that the analysis is, of necessity, based on a simplified model of the starch granule. This is since the precise distribution and structure of the various amylose and amylopectin molecules in the crystalline and amorphous regions of starch particles is unknown, and hence the framework necessary for a comprehensive treatment of gelatinization is unavailable. Furthermore, even if the required information were available the resultant equations would be too complicated to solve explicitly. Other investigators have also used model structures to interpret crystalline–amorphous transformations in relatively complicated polymers, their results indicate that the principles by which phase transitions in simple polymer systems may be understood apply equally well to more complex situations²⁷.

The results of the present study indicate that some aspects of gelatinization may be explained by treating the process as a general problem in phase equilibria. In particular, the theory of melting in a three component system consisting of polymer, diluent and low molecular weight solute appears to provide a means of analysing certain of the effects of sugars on the starch transition. However the fact that the

analysis is based on an idealized concept of the relatively complex gelatinization process must be stressed. While the foregoing explanation of gelatinization is speculative, it is suggested that the analysis serves to emphasize the fact that starch exhibits crystal–liquid transitions which are analogous to those occurring in other polymeric substances.

Glass transition temperature of ideal polymeric networks

F. Rietsch, D. Daveloose and D. Froelich

Laboratoire de Physique Macromoléculaire, Université des Sciences et Techniques de Lille, 59650 Villeneuve d'Ascq, France

(Received 9 March 1976)

Measurements of the glass transition temperature (T_g) have been carried out on polystyrene networks prepared by the anionic copolymerization of styrene and divinylbenzene, and star-shaped polystyrene of varying functionality. The results show a linear variation of T_g versus M_n^{-1} in all cases. The value of the slope interpreted in terms of the free volume theory shows that the glass transition temperature depends closely on the average functionality of the crosslinks. In order to study the influence of free chains on the glass transition of crosslinked polymers a series of networks were contaminated with increasing ratios of linear polystyrene chains, slightly polydisperse.

INTRODUCTION

The glass transition temperature (T_g) of polymers is an important parameter, as their physical and mechanical properties vary greatly at this temperature. This is why the variation of T_g with molecular parameters has been the subject of numerous experiments¹. In particular, it is well known that the glass transition temperature is a decreasing function of the molecular weight for a linear polymer and of the crosslinking density for crosslinked polymers.

The results published up to now on the variation of T_g with crosslinking density were obtained with samples prepared by a radical process. These samples are poorly defined and their molecular weight between crosslinks, obtained by indirect measurements, is to a great extent polydisperse. In addition to this, the functionality of these networks, i.e. the number of elastic chains produced at each crosslink is a constant figure determined by the chemical nature of the reaction at crosslinking.

The samples studied here are ideal networks prepared by anionic copolymerization². This technique makes it possible to obtain networks for which the molecular weight between crosslinks is only slightly polydisperse and experimentally measurable. It also makes possible the preparation of star-shaped polymers in which the functionality and the molecular weight of the star-points can be varied³. Studies of the temperature variation of glass transition with these two parameters have been carried out. Results have been compared to those obtained on linear polystyrenes and interpreted with the help of existing theories.

EXPERIMENTAL

Polystyrene samples were prepared by anionic copolymerization following the method of Rempp and coworkers². The polymerization of styrene is initiated by the disodium tetramer of α -methylstyrene and gives by the nucleophilic attack of the double bonds, a 'living' polystyrene with reactive organo sodium sites at both ends. The network is obtained by the addition of divinylbenzene (DVB) whose copolymerization is initiated by styryl carbanion. The reactions were carried out in a mixture of 50% toluene and

tetrahydrofuran (THF) at -78°C , in order to obtain a good dispersion of the DVB in the mixture before crosslinking. The gels obtained in this way were deactivated by a solution containing 10% THF and tetrahydrofurfuryl alcohol; its alcoholates were removed by successive washings. Before adding the DVB a calculated amount of linear polystyrene was taken in order to determine the molecular weight and the polydispersity of the chains between crosslinks.

The gels obtained in this way consist of nodules of DVB which are strongly crosslinked and link chains of polystyrene of known molecular weight and slightly polydisperse. It has been shown⁴ that the functionality of the network thus obtained depends on the concentration of DVB per living end. Two series of gels were prepared, with 3 and 10 molecules of DVB per living end. A third series was prepared following the method of Herz⁵ which gives a functionality of three.

In order to study the simultaneous influence of the free ends of the chain and of the crosslink points, we also measured the glass transition of star-shaped polymers with different molecular weight and functionality which were prepared by Rempp and coworkers³. The method used by these researchers consists of preparing living polymers with a reactive organo sodium site at one end only, initiated by a monofunctional initiator. The formation of a star-shaped polymer is obtained by the addition of a variable amount of DVB. The determination of the molecular weight of the initial linear polystyrene and of the star-shaped polystyrene makes it possible to determine the average functionality.

In addition to this, and so as to study the influence of free chains on the glass transition of crosslinked polymers, a series of networks were contaminated with increasing amounts of polystyrene chains of a molecular weight resembling that of the network.

The glass transition temperatures of the polymers were determined on a Perkin-Elmer differential scanning calorimeter (DSC-2). The values of T_g were obtained by the intersection on the baseline of the tangent at the inflection point on the representative curve. It is well known that the glass transition temperature, deduced by calorimetric analysis, depends on the thermal history of the polymer and on the speed of heating and cooling. So as to make the measurements among the different samples comparable, each

of the samples was maintained at 460K for 10 min, then cooled at 40°C/min. With the intention of increasing the reproducibility of the measurements, the T_g were measured for different values of heating-rate and extrapolated at low rate, although this extrapolation has no physical meaning.

RESULTS AND DISCUSSION

Twenty years ago, Fox and Flory⁶ showed that for a series of fractioned linear polystyrene, the glass transition temperature varied linearly with the inverse of the number-average molecular weight of polymers and they proposed an equation of the type:

$$T_g = T_{g\infty} - \frac{K_L}{\bar{M}_n} \quad (1)$$

in which $T_{g\infty}$ is the glass transition temperature of an infinite molecular weight polymer and K_L is a constant. Ueberreiter and Kanig⁷ showed that this equation was an approximation valid for molecular weights up to 2000.

In the same way, Fox and Loshaek⁸ proposed the following semi-empirical equation for crosslinked polymers obtained by radical polymerization:

$$T_g = T_{g\infty} + \frac{K_x \Gamma}{N_A}$$

in which N_A , Γ , K_x represent the Avogadro's number, the crosslink density and a constant characteristic of the polymer. In this equation, the molecular weight of chains between crosslinks does not appear because it is not directly accessible through experiments for this type of network. In our case, where we can measure this molecular weight, we can express the variation of T_g in relation to \bar{M}_n by an equation similar to equation (1):

$$T_g = T_{g\infty} + \frac{K_R}{\bar{M}_n} \quad (2)$$

where $T_{g\infty}$ represents the value of T_g for a network of infinite molecular weight. All the experimental results on linear crosslinked and star-shaped polymers are included in Tables 1 and 2. Following equations (1) and (2) we have plotted in Figures 1 and 2 the values of T_g versus \bar{M}_n^{-1} for linear, cross-linked and star-shaped polymers. In this way we obtained a cluster of straight lines, all passing through $T_{g\infty} = 97.5^\circ\text{C}$ for infinite molecular weight. The convergence of these different straight lines indicates that struc-

Figure 1 Network: Δ , $f = 10-12$; \blacktriangle , $f = 5-7$; \blacksquare , $f = 3$. Linear, \bullet

tural parameters become negligible when the molecular weight \bar{M}_n is high.

The physical interpretation of the value of the slope of these straight lines, in the case of linear and crosslinked polymers, has been the subject of a great many studies based either on the concept of free volume¹, or on statistical theories⁹⁻¹¹. Recently Chompff¹² proposed a theory using the concept of the additivity of free volume, which can be relatively well applied to the experimental results obtained.

The calculation is based on a model made up of three distinct structural elements: free chain ends (index 1), chain segments (index 2) and branch points (index 3). Assuming the additivity of free volumes, we can write:

$$f = \sum_{i=1}^3 f_i \phi_i$$

and $f_i = f_{gi} + \alpha f_i (T - T_{gi})$ with $i = 1, 2, 3$

where f_i are the fractions in free volume of elements i at a given temperature; f_{gi} are the fractions in free volume of elements i at $T = T_{gi}$; T_{gi} are the temperatures of glass transition of elements i ; αf_i are the coefficients of volumic expansion of elements i ; ϕ_i are the fractions in effective volume of elements i and f is the total fraction of free volume.

Considering as Chompff did, that f_3 is negligibly small for $T = T_g$

$$T_g = \frac{\alpha f_1 \phi_1 T_{g1} + \alpha f_2 \phi_2 T_{g2} + f_{g3} \phi_3}{\alpha f_1 \phi_1 + \alpha f_2 \phi_2} \quad (3)$$

Linear polymer

For a linear polymer, the volume fraction ϕ_3 is zero, which enables the volume fraction, ϕ_1 , to be defined by

the equation:

$$\phi_1 = \frac{2\rho N_A \zeta_1}{\bar{M}_n} \quad (4)$$

where ρ is the density of the polymer; N_A is Avogadro's number and ζ_1 represents the effective volume of one chain end.

This equation combined with equation (3) leads to the variation of T_g as a function of \bar{M}_n^{-1} :

$$\begin{aligned} \left(\frac{\partial T_g}{\partial \bar{M}_n^{-1}} \right)_{\substack{\phi_3=0 \\ \phi_1 \rightarrow 0}} &= \left(\frac{\partial T_g}{\partial \phi_1} \right) \left(\frac{\partial \phi_1}{\partial \bar{M}_n^{-1}} \right) \\ &= - \frac{\alpha f_1}{\alpha f_2} (T_{g2} - T_{g1}) 2\rho N_A \zeta_1 = K_L \quad (5) \end{aligned}$$

As is indicated in equation (3), the variation of T_g with \bar{M}_n^{-1} or ϕ_1 is not linear, and equation (5) is an approximation valid only when the molecular weight \bar{M}_n is sufficiently high ($\phi_1 \rightarrow 0$).

From the curve relating to the linear polymer in Figure 1, we have obtained the experimental value of $K_L = 1.5 \times 10^5$. The results obtained by other authors are scattered between 0.70 and 2.1×10^5 ^{6-8,13-16}. This disparity may be linked either to the choice in experimental methods, or to the way in which the results were plotted, or even to the dispersity in the molecular weight of the sample¹⁵.

By identifying the experimental and theoretical values of K_L (equations 1 and 5), it is possible to determine the value of ϕ_1 and thus to know the number of monomer units included in a free end of the chain. To this end, we used the experimental values published by Ueberreiter and Kanig⁷ and by Fox and Loshaek⁸, who obtained respectively the characteristic parameters T_{g1} and αf_1 for oligomers of varying molecular weight.

In Table 3 we have plotted the value of the different parameters appearing in equation (5) as a function of the number of monomer units $\rho N_A \zeta_1 / M_0$ (M_0 is the molecular weight of a monomer unit). The result nearest to the experimental value is obtained when:

$$\rho N_A \zeta_1 = 6M_0$$

This value is twice as great as that obtained by Chompff¹². This difference is essentially due to the experimental value of K_L which was used and to the physical interpretation

Table 3 Parameters from equation (5) as a function of the number of monomer units

$\rho N_A \zeta_1 / M_0$	T_{g1} (°C)	T_{g2} (°C)	$\alpha f_1 \times 10^4$	$\alpha f_2 \times 10^4$	$K_L \times 10^{-5}$

of the characteristic parameters T_{g1} and αf_1 . Clearly this value has no real physical meaning and is only related to the model and its parameters that we have used. It can only be used to compare among themselves the results obtained with different types of polymers.

Crosslinked polymers

For networks obtained by anionic copolymerization we can suppose that $\phi_1 = 0$ (ideal networks) when all the active chain ends have reacted. The volume fraction ϕ_3 is then defined by the equation:

$$\phi_3 = \frac{2\rho N_A \zeta_3}{\bar{M}_n} \tag{6}$$

where ζ_3 represents the effective volume of the crosslinked chain ends. The variation of T_g versus \bar{M}_n^{-1} is expressed by an equation similar to equation (5), with the aid of equations (2), (3) and (6):

$$\left(\frac{\partial T_g}{\partial \bar{M}_n^{-1}} \right)_{\substack{\phi_1=0 \\ \phi_3 \rightarrow 0}} = \left(\frac{\partial T_g}{\partial \phi_3} \right) \left(\frac{\partial \phi_3}{\partial \bar{M}_n^{-1}} \right) = \frac{f_g}{\alpha f_2} 2\rho N_A \zeta_3 = K_R \tag{7}$$

where $f_g = f_{g1} = f_{g2} = f_{g3}$ for $T = T_g$.

This equation is an approximation valid only when the molecular weight \bar{M}_n is sufficiently high ($\phi_3 \rightarrow 0$).

In Table 1 we have included the results obtained for gels of functionality 3, 5-7, 10-12. These results suggest the following remarks.

The slope K_R , as well as the number of segments of ϕ_3 depends closely on the average functionality of the crosslinks. This parameter, which does not appear in an explicit

way in the theory of free volume, reflects the intermolecular interactions near the crosslink points, these are all the more remarkable the higher the functionality. It is therefore very probable that the orientation of the chain segments, near the crosslink nodules is imposed by a volume effect among different chains of the same nodule.

The results we obtained seem to agree with those of other authors^{7,17,18} if we suppose, as Chomppf¹² suggests, that crosslinks prepared by radical means have an average functionality $f = 4$ (Figure 3).

Star-shaped polymers

It is interesting to know the variation of glass transition temperature ΔT_g induced by total or partial crosslinking of linear chains of known molecular weight \bar{M}_n . The T_g increase due to the crosslinking process can be written for a small change in ϕ_1 and ϕ_3 :

$$\Delta T_g = \left(\frac{\partial T_g}{\partial \bar{M}_n^{-1}} \right) \left(\frac{\partial \bar{M}_n^{-1}}{\partial \phi_1} \right) \Delta \phi_1 + \left(\frac{\partial T_g}{\partial \bar{M}_n^{-1}} \right) \times \left(\frac{\partial \bar{M}_n^{-1}}{\partial \phi_3} \right) \Delta \phi_3$$

As T_g is a linear function of \bar{M}_n^{-1} (for ϕ_1 or ϕ_3 small), the variation $\Delta \phi_1$ and $\Delta \phi_3$ for star-shaped polymers is given by:

$$\Delta \phi_1 = -\frac{\rho N_A \zeta_1}{\bar{M}_n}; \Delta \phi_3 = \frac{\rho N_A \zeta_3}{\bar{M}_n}$$

then:

$$\Delta T_g = \frac{1}{2} (K_L + K_R) \bar{M}_n^{-1} \tag{8}$$

In Table 2 the values obtained for star-shaped polymers of functionality 3, 4, 6-7, 10-12, as well as experimental and theoretical (equation 8) values for ΔT_g . \bar{M}_n are given. In Figure 2 the experimental values of T_g versus \bar{M}_n^{-1} are plotted.

Figure 3 ●, Gel anionic; ■, gel radical; ▲, extrapolation to $f = 2$

Table 4 Values of T_g for contaminated gels

$\bar{M}_n = 10450$ $\bar{M}'_n = 7500$	C	C/2	C/5	C/11
Initial concentration $\times 10^2$ (g/cm)	4.20	2.16	0.70	0.38
ρ (%)	13.89	7.52	3.11	2.8
$T_{g\text{contaminated}}$ (found) ($^{\circ}\text{C}$)	98.5	101	102	102.5
$T_{g\text{contaminated}}$ (calculated) ($^{\circ}\text{C}$)	99	100.9	102.1	102.2

Concerning samples of functionality $f = 3$ and $f = 4$, the agreement is still satisfactory, whereas for star-shaped polymers of higher functionality, the disagreement is very important. For all cases the calculated values are lower than the experimental values. This discrepancy can only be interpreted by architectural factors in relation to functionality.

This can be explained if we suppose that the star-shaped molecules the segment density is higher in the vicinity of the nodule than in crosslinked systems where the chains are more extended.

Contaminated gels

In order to study the influence of free chains present in a network on glass transition temperature, we contaminated a sample having a molecular weight between crosslinks $\bar{M}_n = 10450$ at increasing ratio of linear polystyrene with a molecular weight of $\bar{M}'_n = 7500$, slightly polydisperse.

The free polystyrene chains were introduced into the network by a diffusion process in the swollen state. Samples prepared with different concentrations are shown in Table 4.

From the additivity of free volume it is obvious that:

$$T_{g\text{contaminated}} = T_{g\text{linear}}\rho + (1 - \rho)T_{g\text{network}}$$

where ρ is the weight fraction of linear polystyrene in the sample.

As linear polystyrene with a molecular weight \bar{M}'_n slightly different from the network molecular weight \bar{M}_n , has been used, the following correction must be introduced:

$$T_{g\text{contaminated}} = T_{g\text{network}} \left(1 - \rho \frac{\bar{M}_n}{\bar{M}'_n} \right) + \rho \frac{\bar{M}_n}{\bar{M}'_n} T_{g\text{linear}}$$

The results are included in the Table 4. We can see that the agreement between experimental and calculated values is quite good within the experimental errors and justify the assumption of additivity of free volume.

ACKNOWLEDGEMENTS

We wish to thank Dr P. Rempp, Dr J. Herz and Dr C. Strazielle from CRM in Strasbourg for providing us with some gel samples.

Conformation and thermodynamics of adsorbed macromolecules at the liquid/solid interface

Erwin Killmann

Institut für Technische Chemie der Technischen Universität München, 8 München, W. Germany

(Received 20 April 1976)

Calorimetric measurements and results of the adsorption of poly(ethylene glycols) on Aerosil out of solution are reported. With the aid of conformation models for the adsorbed macromolecules and by comparing with the results on low molecular weight model substances, the measured values and their dependence on coverage, molecular weight and solvent are discussed. The resulting structure of the polymer layer, characterized by the adsorbed amount, the number of adhesive segments, the adsorption enthalpy, the thickness and the concentration of the adsorbed layer is verified by i.r. spectroscopic and ellipsometric data.

INTRODUCTION

Most of the experimental work concerning adsorption of macromolecules has dealt with the determination of the amount of adsorption, which is basically necessary for the interpretation of all results from other methods to characterize the conformation of the adsorbed macromolecules. In some adsorption systems information has been successfully obtained on the structure of the layer by spectrometric measurements of the number of adhesive units, and in some other systems by ellipsometric measurement of the thickness and the concentration of the adsorbed layer.

Besides the adsorption layer characterizing parameters, the adsorption enthalpy is also very important in characterizing adsorption behaviour. As we know, direct calorimetric measurements of the enthalpy of adsorption on solid surfaces for polymers were rare until recently¹⁻³. In some investigations enthalpy of adsorption was obtained from the temperature dependence of the adsorption isotherms⁴⁻⁶. The plot of the equilibrium concentration in solution against the reciprocal of the absolute temperature at constant amount of adsorption yields the isosteric Clausius-Clapeyron adsorption enthalpy. This method is very problematical, as the conditions of isostericity and also of reversibility are not fulfilled in the case of polymer adsorption. To demonstrate this an example is given later.

MEASUREMENTS AND DISCUSSION

The enthalpy values reviewed here were measured with an isoperibolic calorimeter (LKB), which is useful for measurements up to 30 minutes. Aerosil 175 and Aerosil 200 were used for the adsorption experiments to achieve the necessary conditions for the method. The Aerosil is non-porous as shown by electron microscopy and has a high specific surface, $\sim 200 \text{ m}^2/\text{g}$. After heating at 10^{-2} – 10^{-1} Torr and 300°C for 6 h the Aerosil was immersed in a solvent or transferred to ampoules under nitrogen and melted off. This procedure yields reproducible adsorbents, shown by i.r. spectroscopy and by calorimetric measurements of the wetting enthalpy in pure solvents. The opti-

imum temperature for preconditioning was found to be 300°C . The wetting enthalpies and the extinction band of the SiOH groups at 3695 cm^{-1} show a maximum (Figure 1). The extinction band of the hydrogen bonds at 3500 cm^{-1} still existing is based partly on hydrogen bonds between neighbouring silanol groups and partly on adsorbed water.

For the calorimetric adsorption measurements poly(ethylene glycols) of different molecular weight were used in comparison with some low molecular weight substances^{1,2}. The solvents were carbon tetrachloride, benzene, water and methanol. Carbon tetrachloride is most important for comparison with i.r. spectroscopic measurements of the number of adhesive segments.

Figure 1 (a) Extinction of the hydrogen bonds $E_{\text{O}-\text{H}-\text{O}}$ and of the SiOH groups $E_{\text{O}-\text{H}}$ versus temperature of heating of Aerosil 200. A, $E_{\text{O}-\text{H}} = 3695 \text{ cm}^{-1}$; B, $E_{\text{O}-\text{H}-\text{O}} = 3500 \text{ cm}^{-1}$. Figure 3 Adsorption isotherms of adsorbed amount A of PEG 6000-benzene at 25°C (○) and 40°C (□)

The adsorbed amounts from CCl_4 and C_6H_6 solutions were measured in the usual way from the difference between the initial concentration weighed in and the equilibrium concentration in the supernatant solution using C-H stretching vibration at 2900 cm^{-1} in CCl_4 and the C-OC valence vibration (oscillation) at 1107 cm^{-1} in C_6H_6 . Figure 2 shows some adsorption isotherms measured in carbon tetrachloride.

The measured adsorption isotherms of poly(ethylene glycol) 6150 in benzene at two different temperatures are given in Figure 3 yielding with the Clausius-Clapeyron evaluation an isosteric endothermic adsorption enthalpy. In contrast to this all calorimetrically measured adsorption enthalpies in all solvents are negative, representing exothermic adsorption. This discrepancy shows that it is impossible to use the temperature dependence of the isotherms and to calculate the adsorption enthalpies according to Clausius-Clapeyron. The reason for this is that the conditions of isostericity and irreversibility are not fulfilled in the case of polymer adsorption, because the conformation of the adsorbed macromolecules is independent of coverage and temperature; this is demonstrated by the i.r. spectrometry and the enthalpy measurements discussed later and by desorption measurements. In the Clausius-Clapeyron evaluation of the adsorption, determination of the enthalpy shows that at the same amount of adsorption the state of adsorption is independent of temperature. This means that at different temperatures at the same amount adsorbed, the macromolecules are adsorbed in the same conformation with the same number of adhesive segments. This condition is not guaranteed by the conformation of the adsorbed macromolecules. The Clausius-Clapeyron enthalpy therefore does not correspond to the enthalpy of adsorption. It contains rather entropic factors, caused

by the variation in conformation and in the number of adhesive segments.

The adsorption enthalpy was measured by breaking an ampoule of 1 ml concentrated polymer solution in an Aerosil suspension of 50 or 100 ml. The desired polymer concentration is given by the amount of the polymer in the ampoule. To obtain the adsorption enthalpy the measured enthalpy must be corrected with the dilution enthalpy, which is measured by separate experiments shown in Figure 4. One can see the strong dependence of the dilution enthalpies on the polymer weight resp. the fraction of OH end groups to the ether groups in the molecules. An example for the correction of the measured enthalpies with the dilution enthalpy to obtain the adsorption enthalpy is given in Figure 5.

The immersion enthalpy was measured by breaking a 1 ml ampoule with the Aerosil under nitrogen gas in a 50 or 100 ml vessel filled with polymer solution. From these procedures one can formulate for the adsorption enthalpy:

$$-\Delta H(\theta) = -n\Delta H_{P,A} + n\Delta H_{L,A} + n\Delta H_{L,P} + \Delta H_{P,P} \quad (1)$$

and for the immersion enthalpy:

$$-\Delta H_I(\theta) = -n\Delta H_{P,A} - (n_0 - n)\Delta H_{L,A} + n\Delta H_{L,P} + \Delta H_{P,P} \quad (2)$$

Figure 4 Dilution enthalpies $-\Delta H_V$ of poly(ethylene glycols): M_w 40 000 (X), M_n 6000 (○), M_n 2000 (●), M_n 600 (□), diethyl ether (+), ethyl glycol (▽), ethanol (△)- CCl_4 -25°C

Figure 5 Measured enthalpy $\Delta H_{\text{Meas.}}$ (○), dilution enthalpy ΔH_V (□), adsorption enthalpy ΔH (▽) versus concentration, C_E

Figure 6 Adsorption enthalpy $-\Delta H$ of PEG 40000-Aerosil 200- C_6H_6 versus adsorbed amount A at $25^\circ C$ (\square), at $40^\circ C$ (\circ)

Figure 7 Adsorption enthalpy $-\Delta H$ of PEG 40000-Aerosil 200- H_2O versus adsorbed amount A at $25^\circ C$ (\circ)

which leads to the general rule:

$$H_I(\theta) = \Delta H(\theta) + n_0 \Delta H_{L,A} \quad (3)$$

The integral adsorption enthalpy equation (1) results from the binding of polymer segments $n\Delta H_{P,A}$ simultaneous displacement of the solvent from the surface $n\Delta H_{L,A}$ and the desolvation of the solvent from the solvation shell $n\Delta H_{L,P}$. In addition to these contributions a possible interaction between polymer segments $\Delta H_{P,P}$ must be regarded. The immersion enthalpy (equation 2) results from the sum of the adsorption enthalpy and the wetting enthalpy of the adsorbent with solvent molecules (equation 3). Neglecting the polymer-polymer interaction the equation states that the integral adsorption enthalpy is proportional to the molar number, n , of adsorbed segments at a defined degree of coverage and to an enthalpy difference ($\Delta H_{P,A} - \Delta H_{L,A} -$

$\Delta H_{L,P}$). The differential adsorption enthalpy, D_M , deviating from equation (1) is proportional to dn/dN ; this means that D_M is a measure of the fraction of adhered segments dn/dN .

In Figures 6-9 the values of adsorption enthalpies obtained are plotted against the adsorbed amount for some different solvents and molecular weights. Because of the convex bent curves the adsorption enthalpies do not increase proportionally with the adsorbed amount. The differential adsorption enthalpy D_M decreases with increasing amount of adsorption. From this one can conclude

Figure 8 Adsorption enthalpy $-\Delta H$ of PEG 40000-Aerosil 200-methanol versus adsorbed amount A at $25^\circ C$ (\circ)

Figure 11 Adsorption enthalpy $-\Delta H$ versus extinction E_{OHO} of the hydrogen bonds of poly(ethylene glycols)- CCl_4 - 25°C -Aerosil 200. \circ , Ethyl glycol; ∇ , poly(ethylene glycol) 600; \square , poly(ethylene glycol) 6000

that the fraction of adhered segments decreases with increasing amount of adsorption, respectively with increasing coverage. This is confirmed by the i.r. spectroscopic measurements of the number of adhered segments on the same Aerosil in CCl_4 ⁷. The plot of the extinction of the hydrogen bonds at 3300 cm^{-1} , responsible for the adsorption of the polyethers, against the adsorbed amount also shows a convex curvature (Figure 10).

The plot of the hydrogen bond extinction against the adsorption enthalpy in Figure 11 shows a straight line. This proves that the adsorption enthalpy and the number or the fraction of adhered segments are proportional. This justifies the neglect of the polymer-polymer interaction contribution in the adsorbed layer in comparison with other enthalpy contributions because the polymer-polymer interaction should increase with coverage, yielding a concave ΔH versus A curve if essentially; but the contrary is measured.

From the analogue curvature of the i.r. measured hydrogen bonds and the adsorption enthalpy it follows clearly that the fraction of adsorbed segments decreases with rising coverage—the conformation of the adsorbed macromolecule depends on coverage. At low coverage the macromolecule on average is bound with more adhered segments in a more flat conformation than at high coverage. At low coverage the macromolecules adsorb unhindered by each other with highest possible contact points, simultaneously desorbing the solvent molecules from the surface and producing the highest exotherm adsorption enthalpy.

With increasing coverage the new adsorbing macromolecule segments are in contact not only with surface places covered with solvent, but also those covered with polymer segments. The number of new contact points decreases. The exchange of segments of adsorbed macromolecules with segments of new adsorbing macromolecules, changing the average conformation of the adsorbed macromolecules, gives no enthalpy contribution. Of course only those segments which adsorb on new solvent covered places give a contribution to the adsorption enthalpy. This change of conformation independent of the concentration of the solution respectively of the coverage also takes effect in the time dependence of the adsorbed amount, demonstrated in Figure 12^{2,7}. At high concentrations normal behaviour is observed: the solution concentration C_L , represented by the extinction of the CH-band, decreases with time indicating the normal increase of the adsorbed amount with time. At low concentrations the opposite behaviour is observed: the solution concentration increases with time indicating a decrease of the adsorbed amount. This behaviour can only be explained by conformation change in the same way as before.

In the solvents CCl_4 , C_6H_6 , CH_3OH and H_2O the immersion enthalpy in polymer solution with adsorption saturation is practically the same, $\Delta H_\infty = 7.2\text{ cal/g}$ adsorbent (equation 2). The wetting enthalpies of the polar solvents H_2O , 6.78 cal/g and CH_3OH , 7.06 cal/g nearly correspond with the immersion enthalpies, the adsorption enthalpy

Figure 12 Concentration of the supernatant solution C_L versus time t at different concentrations in C_E ($\text{g}/100\text{ cm}^3$): A, 0.55; B, 0.45; C, 0.35; D, 0.25; E, 0.15

therefore is very low. The wetting enthalpies of the non-polar solvents CCl_4 , 3.75 cal/g and C_6H_6 , 4.6 cal/g are on the contrary much lower than the immersion enthalpies, the adsorption enthalpy therefore is higher (equation 1).

From the solvent independent immersion enthalpy it therefore follows from equation (2) that the solvent dependent terms $(n_0 - n)\Delta H_{L,A}$ and $n\Delta H_{L,P}$ nearly vanishes in the saturation case. It is considered that this is only possible in the different solvents if both terms are nearly zero. This means that the desolvation contribution for all solvents is small in comparison to the other terms and could be neglected and that in saturation nearly all places are covered with polymer segments, so that $n = n_0$. This interpretation is confirmed by the finding that in case of saturation in CCl_4 practically no more extinction of hydroxyl groups is recognized by i.r.⁷ This interpretation also means that the adsorbed enthalpy of poly(ethylene glycol) on Aerosil in CCl_4 is influenced predominantly by the binding enthalpy and in competition to this, the desorption enthalpy of the solvent. The competition by the desolvation and the polymer-polymer interaction must be of second order.

Relating the measured immersion enthalpy to the number of silanol groups, 2.7 SiOH/100 Å² on the Aerosil surface a binding enthalpy of 9.9 kcal/mol SiOH groups results^{1,7} in good agreement with the enthalpy values of hydrogen bonds in the literature. The value of 9.9 kcal/mol is also confirmed by the fact that also for the low molecular weight substances ethyl glycol, diethyl ether, ethyl alcohol the binding enthalpies are nearly 10 kcal/mol².

From the linear ascent of the adsorption enthalpies with low coverage e.g. in CCl_4 , one can calculate an adsorption enthalpy of 1.76 kcal/mol base units of the polymer. In comparison the adsorbed enthalpy of ethyl glycol at saturation is 4.0 kcal/mol. This consideration shows that at low coverage the fraction of adhered segments of the polymers is $p = 0.5$. This means that the polymer in this state is adsorbed in an extremely flat conformation with 50% adsorbed base units.

In the saturation region from the adsorbed amount and the measured adsorption enthalpy it follows that the frac-

tion of the attached segments is about $p = 0.2-0.25$. This indicates a conformational change of the adsorbed polymer chain with coverage.

The consequences of the high fractions of adsorbed base units are: (1) an extremely flat adsorption layer confirmed by the ellipsometric thicknesses on chrome which are found to be less than 20 Å in the whole coverage region⁸; (2) the extremely small dependence of the adsorbed saturation amounts from the molecular weight²; (3) the state that poly(ethylene glycol) adsorbs almost irreversibly when the molecular weight is high enough, which is demonstrated by desorption measurements⁷.

This paper is restricted mainly to the calorimetric part of our work on polymer adsorption. Extensive i.r. spectroscopic measurements have also been carried out on the same PEG- CCl_4 systems and on low molecular weight materials to obtain direct information about the number of adhesive segments^{2,7}. Also ellipsometric measurements for determining the thickness and the concentration of poly(ethylene glycol), polystyrene, poly(vinyl pyrrolidone), poly(methyl methacrylate), polyisobutylene and poly(vinyl acetate) layers on chrome, platinum and gold surfaces in different solvents have been carried out^{8,9}.

On the reproducibility of T_g measurements on polystyrene using d.s.c.

Marion D. Griffiths and L. J. Maisey

*Rubber and Plastics Research Association of Great Britain, Shawbury, Shrewsbury SY4 4NR, UK
(Received 27 January 1975; revised 29 April 1976)*

In determining the reproducibility of T_g data of a standard polystyrene measured by differential scanning calorimetry (d.s.c.), the effects of d.s.c. trace interpretation method, extrapolation to zero scan rate, polymer sample form, a thermal treatment and a thermal cycling procedure on the results were examined. The results showed that data from scanning at $8^\circ\text{C}/\text{min}$ are preferred to those from extrapolation to zero scan rate while the overall reproducibility was unaffected by the d.s.c. trace interpretation method used. However, the onset of the transition step was selected to define T_g in this work. Similarly, no differences in the reproducibility of data were noted between the overall results for granular or sheet samples, although certain treatments of specific samples did produce changes in some instances. The mean value for T_g at $8^\circ\text{C}/\text{min}$ was found to be 102.3°C . Imposing the thermal treatment on the samples did not significantly alter the reproducibility of the results whereas in contrast, cycling markedly improved the reproducibility of sheet sample data but left that of granules unaffected.

INTRODUCTION

The glass transition temperature (T_g) is a fundamental property of an amorphous or semi-crystalline polymer and is determined by molecular composition and structure. At this temperature, complex rate-dependent molecular processes occur which influence polymer properties both during processing and in service.

Experimental methods of measuring T_g exploit the changes in properties manifested as polymers pass from the glassy to the rubbery state and normally fall into two categories. These are stepwise, steady state methods in which properties are measured under static thermal equilibrium conditions over a temperature range encompassing T_g , and dynamic methods, in which properties are measured during heating the material through T_g . The former approach gives T_g data directly, under approximately isothermal conditions, whilst the latter relies upon an extrapolation procedure in order to generate isothermal (zero scan rate) T_g data. Dynamic methods, however, are becoming increasingly popular on account of their convenience. Differential scanning calorimetry (d.s.c.)¹ falls into this latter category and utilizes the fact that heat capacity changes are observed in a polymer with changes in temperature. Although not intended solely as a technique for determining T_g , d.s.c. is nevertheless widely used for this purpose on account of the commercial availability of suitable equipment, speed of measurement, small sample size requirements and precision of measurement². Currently, many research and development studies use d.s.c. to examine thermal characteristics, structural changes and transitions in polymers. However, no published information which defines the reproducibility of the data generated using this technique is available; it is not known, for example, whether polymer variability is sufficiently low to allow meaningful d.s.c. data to be gathered when small differences between samples are being considered.

The purpose of this paper is to examine the capability of d.s.c. for polymer characterization under normal laboratory conditions; the reproducibility of glass transition data produced for a standard polystyrene will be considered. Sample form, sample thermal history and data interpretation methods are varied. Such a study will permit certain of the polymer/d.s.c. interactions to be quantified, allow a set of data to be produced with which other laboratories may compare their own d.s.c. performances, and finally permit a method to be defined, within the limits of the variables examined, for obtaining the most reproducible d.s.c. data.

EXPERIMENT DESIGN

In an experimental programme of this nature it is important to identify the sources of error and to design the experiment so that the effect of the variables being examined can be readily observed. The present programme recognizes that variations in data result from polymer sample inhomogeneities, instrument/operator errors and data interpretation errors.

In order to minimize d.s.c. data variation due to polymer sample inhomogeneities, a standard polystyrene, supplied by the Polymer Supply and Characterisation Centre (PSCC) at RAPRA was used. This material is homogenized before issue and has a fine particle size (~ 0.5 to 1 mm beads) allowing about 40 individual beads to make up the approximately 10 mg samples used in the study.

There are varying opinions about the method of defining T_g from a d.s.c. trace³⁻⁶. Two methods were used in this work and are shown in *Figure 1*. Both T_i , the intersection point of the projection of the base line with the tangent to the step and T_s , the mid-point between the upper and lower deviations of the step from its tangent were defined. Although glass transitions occur over a temperature range, it is normal practice to quote a single temperature of transition.

Figure 1 (a) T_g taken as the intersection of the extrapolation of the baseline with the extrapolation of the inflection. (b) T_g taken as the inflection point

Also two methods of handling the abstracted data were considered by comparing the reproducibility of the T_i or T_s values obtained at a single calibrated scan rate with those calculated from an extrapolation of transition data from four scan rates.

Amongst the several factors which may affect the reproducibility of d.s.c. data, the following were taken as the controllable variables and were examined in some detail. (A) The effect of sample form, i.e. granules or a thin sheet moulded from the granules. (B) The effect of an imposed, controlled thermal treatment. (C) The effect of thermally cycling the samples in the d.s.c.

The experimental array to examine these three factors is shown in Table 1.

The above were considered to be major practical variables and in order to increase the confidence of data handling, six replications were made of each experimental condition over a period of five months; after three replications had been completed the d.s.c. was serviced. The lengthy period over which the measurements were made, coupled with the instrument service allows the data generated to be considered as typical information, where the instrument/polymer/operator variability encountered will be maximized rather than minimized. It might be argued that the thermal and cycling treatments are not truly independent variables but from a practical point of view and for the purposes of this study they are considered independent.

EXPERIMENTAL METHOD

Material

The polymer used was PSCC polystyrene PS2, a standardized commercial material with number- and weight-

average molecular weights of 145 and 328 g/mol respectively.

Moulding sheet polystyrene

Granules of PS2 were compression moulded to give circular sheets 50 mm in diameter by 1 mm thickness using a manually operated, laboratory Moore press and a semi-positive mould of 100 mm external diameter with a plunger diameter of 50 mm, the cavity depth being 1 mm. Granules were placed in the mould which had been heated to 170°C, the mould was then closed and held at this temperature under a pressure of 18.45 MN/m² for 30 min. The mould was then cooled to and held at 100°C for a further 30 min, and finally slowly cooled to room temperature still under pressure. Three separate sheets of polystyrene were moulded.

Sample preparation

Four different forms of sample were used. These were: (a) the granules as received, samples A and B (Table 1); (b) the granules after they had been given a controlled thermal treatment in the d.s.c., samples C and D; (c) compression moulded sheet formed from the granules, samples 1 and 2; (d) compression moulded sheet as in (c) after having been given the thermal treatment of (b), samples 3 and 4.

Sample selection

Granular material was taken randomly from the stock of polystyrene while the sheet material was taken randomly from the three sheets fabricated; it is possible however that towards the end of the programme sheet sample selection did not fulfil this random condition as only small unidentified remnants of sheet were available for the last few measurements.

Instrumentation

A Perkin-Elmer DSC-1B was used in the programme. Sample size, heating and cooling rates which could be accommodated by this instrument were chosen. All measurements were made under oxygen-free (BOC white-spot) nitrogen gas at a 25 cm³/min flow rate.

D.s.c. operating method

The temperature indicated by the programmer of the d.s.c. is not the true temperature of the contents of the sample pan due to the inherent non-linear character of the programmed temperature range. To allow for this effect calibration of the instrument with pure materials of known melting point was carried out at 8°C/min scan rate and a relationship established between the known melting tem-

Table 1 The experimental array

Sample name	Sample form	Thermal Treatment	Cycled

3	Sheet	Yes	Yes
4	Sheet	Yes	No

peratures and the indicated d.s.c. programmer temperature. Results obtained after scanning the polystyrene samples at 8°C/min could then be corrected using this relationship.

As each polystyrene specimen was scanned at four different rates, viz. 64°C/min, 32°C/min, 16°C/min, and 8°C/min, pure indium was also scanned at these rates and, following Lambert⁷, correction factors to account for the thermal lags at the different scan rates were calculated.

Data abstraction and extrapolation

The transition temperatures were abstracted from the d.s.c. traces as illustrated in Figure 1; the temperatures are given to the nearest 0.5°C.

As has been mentioned previously the experiment requires a comparison of the transition data generated in two ways, viz. that of a single scan rate and that found from extrapolation which involved fitting the logarithms of the T_g values obtained from each set of four scan rates to a first order equation. The basis for this procedure is given elsewhere⁵.

Thermal treatment

The thermal treatment consisted of heating the polystyrene in an open d.s.c. pan until the sample flowed, i.e. from 30° to 200°C at 8°C/min scan rate followed immediately by cooling to 30°C at 2°C/min scan rate. After treatment, the lid was crimped on to the pan. Wunderlich and Bodily⁸ have shown that this type of treatment gives a clear transition upon reheating the sample at a fast scan rate.

Cycling

This was investigated by determining the T_g of the same sample at each of the four scan rates employed and comparing these values with those found when using a fresh sample for each scan rate. Details of these treatments are given below.

(i) The same sample was heated successively to 140°C at 64°C/min, cooled at 16°C/min; to 140°C at 32°C/min, cooled at 8°C/min; to 140°C at 16°C/min, cooled at 4°C/min and finally heated to 140°C at 8°C/min, the T_g being determined during heating at each scan rate. This method is referred to as 'cycling' and samples A, C, 1 and 3 (Table 1) were treated in this manner.

(ii) A fresh sample was used for each of the heating scans at 64°, 32°, 16° and 8°C/min. This treatment is termed 'uncycled' and samples B, D, 2 and 4 (Table 1) were so handled.

Data analysis

Variance ratio and Student's 't' tests were used as appropriate and normally applied at the 5% level of significance.

RESULTS AND DISCUSSION

Effect of extrapolation

The variance calculated from T_i and T_s replications at both the 8°C/min scan rate and the extrapolated zero scan rate are given in Table 2. It can be seen that the 8°C/min results have lower variances in 15 out of the 16 cases given; the probability that this result occurs by chance is 0.24×10^{-3} and it can be concluded that the extrapolation procedure increased the variance obtained. Consequent to this observation the remaining analyses of this work consider only the transition data from the 8°C/min scan rate measurements.

Effect of data abstraction method

Both the T_i and T_s methods of evaluation must produce errors. In order to define the lower intersection point (T_i), tangents to two slopes must be constructed. The errors involved here will be partly dependent upon the gradient of these tangents. To define the inflection point (T_s), the tangent to the transition step must be constructed, the upper and lower points of deviation of the trace from this tangent must be defined and the mid-point between these two determined. It is probable that the errors produced using this method are self-compensating i.e. referring to Figure 1, the errors associated with fixing point A are likely to be similar but in the opposite direction to those involved in fixing point B. It could be anticipated therefore that T_s definition should be more reliable than T_i definition.

Table 2 shows the variance in the replicate measurements calculated for the 8°C/min scan rate using the two graphical methods of determining the transition point. Apart from a single case, no significant differences in variance at the 5% level could be detected between results of each method. Examination at the 20% level of significance however suggests that the intersection (T_i) method may give the better reproducibility. As a result of this observation the T_i method only was adopted for the remainder of this study. It must be emphasized however, that very little difference, if any, exists between the reproducibility of the two methods of data abstraction; a choice has been made only on the grounds of expediency.

A subsidiary experiment where T_i and T_s were determined repeatedly from two different d.s.c. traces showed that T_s was fixed more reproducibly than T_i when temperatures were read to 0.5°C. This finding apparently contradicts the observation from the main experiment where T_i variability is stated to be possibly somewhat less than T_s variability. No contradiction, however, does exist as the variances determined in the main experiment include contributions from sources of error other than those of graphically fixing the T_i or T_s points. It is possible therefore

Table 2 Comparison of variances of means of results from 8°C/min scan rate with those extrapolated to 0°C/min by taking logarithms of T_g

Scan Rate (°C/min)	Data abstraction method	Variance							
		Granules				Sheet			
		A	B	C	D	1	2	3	4
8	Intersection	0.48	0.45	0.95	0.87	0.10	0.70	0.20	2.65
0	Intersection	3.55	1.04	1.45	1.27	3.55	0.75	0.37	5.75
8	Inflection	0.65	0.53	0.36	0.97	0.22	0.57	2.03	5.65
0	Inflection	2.40	3.85	0.75	1.55	0.19	1.45	4.45	7.27

that T_g is more precisely fixed than T_i for a given trace but that overall reproducibility is favoured by using T_i .

Effect of the major variables

Changes in thermal properties are produced on heating and cooling polymeric materials⁴. These are explained by both the free volume and molecular relaxation theories on the basis of molecular configurational changes. All polymer samples handled in this experiment have been subjected at some stage to heating and cooling. It has been reported⁹ that changes in the T_g of polystyrene can be produced by varying the cooling rate of the polymer from the molten condition. Also according to Wunderlich¹⁰ it is only the molten state of linear high polymers that is independent of thermal history. Although Shen and Eisenberg¹¹, in their review of glass transitions in polymers, remark that the effect of thermal history upon T_g is not well characterized, it can reasonably be assumed that differences in heating and cooling rates could lead to differences in the reproducibility of T_g data.

In the case of sample form, differences in reproducibility additionally may arise from differences in sample geometry. A thin disc of sample gives good resolution in the d.s.c. because of the maximization of heat transfer between the sample pan and the sample and this results in more straightforward interpretation of the d.s.c. trace. With a granular material good heat transfer exists only at and near point contacts with the sample pan and unless the granules are extremely fine, the quality of the trace may suffer.

From the above considerations it was expected that the reproducibility of results would be affected by the treatments the polymer received in this work. The effects of the major variables were investigated by calculating and comparing the variances associated with the major variables themselves and also their various interactions. This is shown in Table 3 where F_1 and F_2 represent the two levels of sample form considered i.e. granules and sheet, Th_1 and Th_2 represent thermally untreated and treated samples respectively and C_1 and C_2 represent uncycled and cycled samples respectively.

Considering first the effect of sample form (i.e. F_1

Table 3 The effect of the major variables

versus F_2), the first row of Table 3 gives the variances of the results pooled over the two levels of both the remaining major variables; the next four rows give the variances of the results pooled over the two levels of one of the remaining variables with one level of the other variable, each being considered in turn. The final four rows represent the separate variances for the individual sets of replicates.

The same treatment was given to each of the major variables in turn to complete the array of Table 3.

Those pairs of conditions which display a significant difference at the 5% level can be identified from the Table and the conditions associated with the larger variance in each of these pairs may therefore be taken as those which should be avoided when minimum variance in the data is being sought. These particular conditions are:

- $F_2Th_2C_1$ uncycled, thermally treated sheet,
- $F_2Th_1C_1$ uncycled, thermally untreated sheet,
- $F_2Th_1Th_2C_1$ uncycled sheet,
- and $F_1F_2Th_2C_1$ uncycled, thermally treated material.

Table 3 also shows variance ratios which are suspiciously large indicating that the following conditions possibly should not be used:

- $F_1Th_1Th_2C_2$, $F_1Th_1C_2$ and $F_1Th_2C_2$ (i.e. cycled granules).

The condition $F_2Th_1Th_2C_1$ appears with both of its components $F_2Th_1C_1$ and $F_2Th_2C_1$ and it is clear that uncycled sheet must never be used. It follows therefore from the experimental design that if sheet is used it must be cycled. The position with $F_1F_2Th_2C_1$ however is less clear as only $F_2Th_2C_1$ appears as a separately identified, undesirable component. Since the other component $F_1Th_2C_1$ does not appear as undesirable the use of uncycled, thermally treated granules cannot be excluded on this evidence.

The above treatment of the data merely shows which conditions should not be employed when the best reproducibility of T_g data is being considered. To determine the most favourable experimental conditions a comparison of the lowest values of the variances displayed in Table 3 should be made. This is carried out in the next section.

Minimum variance conditions

By taking the minimum variance shown in Table 3 and comparing it with all the other variances of the array in turn, it may be seen that only five other sets of conditions show a variance ratio which is not significantly different at the

5% level. These are $F_2Th_1Th_2C_2$, $F_1Th_1C_1$, $F_1F_2Th_1C_2$, $F_1Th_1C_2$, $F_2Th_2C_2$, the minimum variance condition being $F_2Th_1C_2$. Using the variance ratio test it is not possible to discriminate further between these six sets of conditions to isolate the one providing the best reproducibility.

It is observed that the condition $F_1Th_1C_2$ appears as both a minimum variance condition and, from above, as one which should possibly be avoided. This apparent contradiction is due to the fact that $F_1Th_1C_2$ possesses a variance which is only suspiciously large when compared with the minimum variance of the array but which is nevertheless a low variance in absolute terms. In fact the variances of all the conditions examined apart from those associated with cycled sheet show up as suspiciously large or significant at the 5% level due to the low variances of the cycled sheet samples.

Preferred experimental conditions

Additional information, which can aid in the choice of experimental procedure, was obtained by a statistical examination of the actual mean values given in Table 4. It was found that the means of samples A ($F_1Th_1C_2$) and 1 ($F_2Th_1C_2$) are significantly different at the 5% level from the remaining means of the array. These particular sets of conditions which lead to anomalous mean values are therefore excluded from those leading to minimum variance. Since experimental simplicity in addition to experimental reliability is desirable, the conditions $F_2Th_2C_2$, $F_2Th_1Th_2C_2$ and $F_1F_2Th_1C_2$ can be eliminated as experimentally complex. Thus the favoured experimental condition giving rise to the best reproducibility is suggested as $F_1Th_1C_1$ i.e. the simple case of uncycled, thermally untreated granules.

It should be noted that elimination of the two anomalous mean values (samples A and 1) does not greatly influence the grand mean value for the whole array. The grand mean for the T_g of PS2 at 8°C/min scan rate using the intersection method of trace interpretation is 102.3°C; exclusion of the two anomalous means shifts this mean value up to 102.6°C.

CONCLUSIONS

None of the major variables of sample form, thermal treatment or thermal cycling of themselves produced a significant difference at the 5% level in the reproducibility of the T_g data. Certain interactions between these variables however are evident and the following conclusions can be drawn from the study.

Table 4 Corrected glass transition data at 8°C/min scan rate, found from the intersection method

Group	Transition temperature (°C)						Mean
	1	2	3	4	5	6	
Sample							
A	102.0	101.5	100.5	102.0	100.5	101.5	101.33
B	102.0	102.0	102.0	103.0	103.0	103.5	102.58
C	101.0	103.5	103.5	102.0	102.5	103.0	102.58
D	103.5	101.5	102.0	103.0	102.5	104.0	102.75
1	101.5	101.5	102.0	101.5	101.5	101.0	101.50
2	103.0	102.5	102.0	103.0	103.0	104.5	103.00
3	102.0	102.0	103.0	102.5	103.0	102.5	102.50
4	99.5	101.5	101.5	102.5	103.5	104.0	102.08
							Grand mean = 102.29

(a) The sheet samples used in the experiment are sensitive to cycling but not to the thermal treatment. It is clear that thermally cycling the sheet samples gives an enhanced reproducibility to the results.

(b) The granules used in the study are not sensitive to cycling or the thermal treatment.

(c) The best reproducibility is associated with an $8^\circ\text{C}/\text{min}$ scan rate as opposed to an extrapolated zero scan rate.

(d) Trace interpretation by the intersection method is preferred.

(e) For experimental convenience uncycled, thermally untreated granules can be used without increasing the variability of the results.

ACKNOWLEDGEMENTS

The authors are grateful to Mr R. H. Norman for his advice on statistics and to Mr C. D. Price for all the experimental work.

APPENDIX

Although the analysis of d.s.c. trace shape was not one of the objectives of this experiment, it was observed that some of the traces showed endothermal peaks superimposed upon the high temperature side of the transition step. The appearance of such peaks has been observed in polystyrene^{4,12} and in PVC where Illers¹³ has presented an

extensive discussion of the phenomenon. Insufficient information is available from our work to allow a critical comparison of our observations with those from Illers' carefully controlled experiments which were specifically designed to study this particular effect. However some of our experimental observations are in agreement with those of Illers and in addition it is probable that some form of correlation exists between the appearance of endothermal peaks and the thermal treatment of PS2. Large peaks appeared on the d.s.c. traces of almost all the granular and moulded sheet samples which had not been thermally conditioned. Cycled and thermally treated samples showed a reduction in both the size and the frequency of occurrence of these endothermal peaks.

It is recognized that the fixing of the mid-point of the T_g step (T_g) will be influenced by the presence of such peaks, with a consequent effect upon the accuracy and precision of the measurement.

As is usually the case in an experiment of this nature, several interesting phenomena have been observed in the course of the study which fall outside the scope of the narrow objectives of the work and which cannot be explained adequately because of the experiment design.

These can be summed up in the questions of why does cycling have such a marked effect upon the reproducibility of results from sheet materials but not upon the reproducibility of results from granules and why does the thermal treatment, which causes melting and flow in both sheet and granules, have no significant effect upon the reproducibility of data? All the materials used in the study have a thermal history whether it has been imposed by the polymerization or moulding stages or by the thermal conditions of the experiment and yet only in certain instances do the differences in thermal history show up as differences in the reproducibility of data.

These observations suggest that the thermal history of the polystyrene samples used is unimportant apart from the single case where sheet is cycled. The only difference between the cycled sheet and cycled granular samples is that the sheet material has been held under pressure in a mould while in the molten state and during cooling.

One is led therefore to the conclusion that the thermal treatment of the experiment maintains but does not improve the reproducibility of the data but that samples which have been melted and cooled once under pressure in some way become more homogeneous when cycled to above T_g but below the polymer melting temperature. Further studies into this specific area are required in order to confirm and explain this particular observation.

Structure-property relationships in amorphous polyamides

John G. Dolden

British Petroleum Co. Ltd, Great Burgh, Epsom, Surrey, UK

(Received 16 May 1974; revised 20 May 1976)

New methods are put forward to explain the numerical values of some useful bulk physical properties of amorphous copolyamides, in terms of parameters related to monomer structure. Polyamides based on adipic, tetramethylsuberic, iso- and tere-phthalic acids, and diamines including isophorone, xylylene, cyclohexane, hexamethylene and its trimethyl derivatives, methylnonane and dodecamethylene diamines were studied. ϵ -Caprolactam and 12-aminododecanoic acid were also used as comonomers. In Part I, an empirical rule is proposed, based on experimental observations which predicts whether a copolyamide has an amorphous or crystalline character. The rule is based on the individual stereochemical contributions of the constituent monomers to the overall polymer chain structure. A relationship between Vicat softening point and monomer composition is derived from experimental data, which seems to be generally applicable to all amorphous polyamides of the diacid/diamine type. Each monomer makes a molar contribution which has been determined experimentally for all the materials studied. An arbitrary set of simple structural rules has been devised which enables the molar contributions of monomers to be related to their chemical structure. This procedure provided a method of predicting the contributions of other monomers for which molar constants had not been measured, and was successfully tested for a limited number of materials. A modified relationship was obtained experimentally to explain the effect of amino-acids on Vicat softening point.

In Part II, the relationships outlined in Part I are combined on the basis of experimental evidence to provide an empirical relationship between composition and impact strength. This relationship predicted the impact strengths of the majority of eighty copolyamides, of widely different chemical structure, with a reasonably good accuracy. Substantial inaccuracy occurred only when a large proportion of a long chain aliphatic monomer was present in the polyamide. Tentative correlations between tensile strength and carbon chain length were observed from a limited number of measurements which suggests that tensile strength may be a constitutive property. The main conclusions of this work are: (a) polyamides are naturally crystalline with high melting points if more than 80% of the monomer units are symmetrical; (b) Vicat softening point and tensile strength decrease linearly with increasing monomer chain length; the softening point is particularly affected by the presence of substituent groups; (c) amino-acids reduce symmetry, impact strength and Vicat softening points of copolyamides; (d) Charpy impact strength increases with the proportion of symmetric monomer units, the rigidity of the acid and flexibility of the diamine structures; (e) tensile strength and flexural modulus correlate with each other in copolyamides of diacids and diamines and both increase as the amount and chain length of aliphatic monomer is reduced; (f) by using the empirical relationships developed in this work, it has proved possible to formulate amorphous polyamides with outstanding combinations of physical properties, when compared with commercially available polymers.

PART I: AMORPHOUS STATE AND VICAT SOFTENING POINT

INTRODUCTION

Polyamides containing aromatic residues are normally very high melting, practically insoluble crystalline materials which are difficult to process. In recent years, a number of more easily processed amorphous polyamides, based on iso- and tere-phthalic acids have been claimed in the patent literature¹⁻¹⁰. Dynamit Nobel market an amorphous polyterephthalamide (Trogamid T) which is suitable for injection moulding¹¹. In general, amorphous polyamides can possess a wide range of good mechanical properties including high tensile and impact strength and high specific modulus which are desirable for engineering applications.

The stereochemistry and the rigidity of the constituent monomer structures will not only determine the bulk physical and mechanical properties of the polyamide, but also

whether it is crystalline or amorphous. There is little published information on the relationship between chemical structure and bulk physical properties of polyamides. Gabler *et al.*¹² reported the effect of using different alkyl substituted hexamethylenediamines on the melting point and physical state of corresponding polyterephthalamides. Ridgeway¹³ showed that incorporating a minimum of 20% of the asymmetric phenylindane dicarboxylic acid into nylon-6,6 rendered the polymer amorphous. Weyland *et al.*¹⁴ discussed a method for predicting the T_g of polymers including some polyamides.

In order to determine the quantitative relationships between chemical composition and bulk physical properties of polyamides, a large number of copolyamides containing from two to five monomers were prepared by melt conden-

sation. The monomers selected for study were chosen principally on the basis of availability, and with the exception of ϵ -caprolactam and 12-aminododecanoic acid, were diacids or diamines. A number of bulk physical properties, including Vicat softening point, tensile strength and notched Charpy impact strength were determined for each polymer. Polyamides were produced to a high molecular weight ($M_n > 20\,000$) in order to minimize the effect of molecular weight on bulk properties. Molecular weight was screened by measuring the inherent viscosity of the polyamides in concentrated sulphuric acid at 25°C. Physical properties were normally measured on polymers with values of $[\eta]_I \geq 0.1 \text{ m}^3/\text{kg}$, as this value corresponded to $M_n \sim 20\,000$ in a few test cases. It was impractical to measure the $[\eta]_I$ versus M_n relationship in every case.

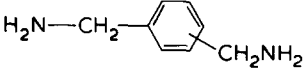

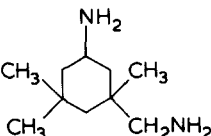

Primary data for about 130 copolyamides are set out in Tables 1–5. Each Table contains a set of polymers with a common acid present.

EXPERIMENTAL

Monomers

All the monomers used in the preparation of polyamides were obtained from commercial sources, with the exception of 12-aminododecanoic acid, 5-methylnonanediamine and 2,2,7,7-tetramethylsuberic acid, which were synthesised in the laboratory.

Abbreviations of monomers studied

IPA	isophthalic acid,
CAP	caprolactam,
PIDA	1,1,3-trimethyl-5-carboxy-3-(<i>p</i> -carboxyphenyl) indane.

Polycondensation

Nylon salts were used as the starting material for the preparation of polyamides. These salts were prepared by dissolving equimolar concentrations of diacid and diamine in water at 60°–95°C, precipitating with isopropanol at ambient temperature and drying overnight under vacuum.

Polymerization was carried out in a 250 cm³ round bottomed flask fitted with a vertical fractionating column, water-cooled condenser and receiver. 0.2 g-mol of salts containing 1% w/w ammonium hypophosphite (reaction catalyst and colour stabilizer), 10 ml water and optionally 0–1.0 mol % benzoic acid to control molecular weight, were charged to the reaction flask. The charge was stirred with a stainless steel rod and heated to a temperature of 270°–300°C under nitrogen over a period of 2 h. Diamine loss was minimized by retaining the fractionating column for a further 2 h at the reaction temperature. The final traces of water of condensation were then removed by venting the flask to the atmosphere for a further hour. The molten polyamide was allowed to cool and recovered by breaking the flask.

This procedure was modified for the preparation of polyterephthalamides, which were difficult to polymerize to a high molecular weight. A precondensation step was introduced, in which the terephthalic acid salts were held under reflux at 220°C for up to 2 h before raising the temperature to 270°–300°C. A small excess (≤ 1 mol %) of diamine was sometimes added to the reaction flask. This method produced polyterephthalamides of very high molecular weight.

Polymer test methods

Test specimens were compression moulded at 220°C using a cycle of 4 min at 0 ton followed by 4 min at 20 ton applied to the 4 in press ram.

Vicat softening point was measured in accordance with BS 2782 1965 Method 102B (Part I), using moulded discs 12.7 mm in diameter and 3.2 mm thick.

Impact strength was measured by the Hounsfield Charpy method at 20°C using compression moulded bars 41.4 mm by 3.8 mm, which were notched after moulding (notched radius = 0.94 mm, notch depth = 0.56 mm). The average value obtained from testing six specimens was taken as the impact strength of the polymer.

Tensile strength was measured at 20°C according to BS 2782, method 301C on an Instron tensile machine at a crosshead speed of 20 mm/min. Dumb-bell specimens 53.4 mm long and between 0.51 and 1.27 mm thick (the actual thickness being recorded) with a control width of 5.39 mm were used in the test. The average value obtained from testing six specimens was taken as the tensile strength of the polymer.

Flexural modulus was measured in accordance with ASTM 790 at 20°C using 6 cm by 1 cm by 0.47 cm specimens with 5 cm between supports and the beam centrally loaded at a rate of 0.127 cm/min.

The following method was used to measure inherent viscosity: ~ 0.04 g of polymer was dissolved in 25 ml of

Table 1 Polyadipamides and polydodecamides

Analar sulphuric acid, ($SG = 1.84$) overnight on a rotating shaker, and subsequently diluted to 0.15% w/v. Flow times were measured in BS 188/U Type D Ostwald viscometers suspended in a viscometer bath controlled at $25^\circ \pm 0.015^\circ\text{C}$. No correction was made for kinetic energy effects etc.

Inherent viscosity was determined from the equation:

$$[\eta]_I = \ln \frac{(t/t_0)}{c}$$

where c , is the concentration (g/100 ml); t , the solution flow time and t_0 is the solvent flow time.

The physical state of polyamides is described in the text as 'amorphous' if the polymer was transparent and possessed a relatively low softening point ($<200^\circ\text{C}$); 'crystalline' is used to describe white opaque polymers which were normally characterized by very high softening points ($>200^\circ\text{C}$). The transition from amorphous to crystalline state normally occurred over a narrow range of composition and was accompanied by a rapid loss of transparency and increase in softening point. It was outside the scope of this work to study these changes by X-ray techniques.

RELATIONSHIP BETWEEN STRUCTURE AND AMORPHOUS STATE IN POLYAMIDES

The objective of the following discussion set out below is to develop an empirical relationship based on experimental data, which will allow the amorphous or crystalline character of a polyamide to be determined on the basis of the individual stereochemical contribution of the constituent monomers to the overall polymer chain structure.

The various degrees of crystallinity found in polyamides prepared from aliphatic diacids and diamines, or ω -aminoacids, and the high melting points which characterize such materials, are the result of the ability of the linear chains to pack in a regular crystal lattice and of the hydrogen bonding which exists between interchain amide links. The inclusion in such materials of in-chain structural units which prevent the formation of crystalline regions within which regular chain packing can occur leads to formation of an amorphous material of generally much lower melting point.

The ability of individual monomers to inhibit crystallization in polyamides can be gauged from the data pre-

sented in Table 6 which has been compiled from published literature. The first two sections of Table 6 show that the structurally planar benzene ring can be accommodated within the polymer chain without interfering with the overall crystalline character of the polyamide formed, and the mono-methyl substitution of an in-chain carbon atom in a linear aliphatic monomer has likewise no effect on the general physical state of the polyamide. The last two sections of the same Table show, however, that the introduction of ethyl or higher substituents along a linear aliphatic chain, or the attachment of more than one methyl group to the same in-chain carbon member, prevents crystallization.

The ability of isophoronediamine to inhibit crystallization is immediately obvious from its structure. The ability of isophthalic acid to do so is less obvious, until it is recalled that the stereochemical configuration of the carbonyl groups adjacent to the benzene ring must introduce a point of inflection into the polymer chain, this being such as to prevent regular chain packing and hence crystallization.

It is interesting to compare the photographs of molecular models of isophthalic acid/hexamethylenediamine units and adipic acid/meta-xylylenediamine units shown in

Figure 1 Molecular model of an isophthalic acid/hexamethylenediamine unit in a polyamide chain

Figure 2 Molecular model of an adipic acid/meta-xylylenediamine unit in a polyamide chain

Figures 1 and 2. In the former case the point of inflection in the chain caused by the stereochemical configuration of isophthalic acid is clearly demonstrated and contrasts with the linear configuration preserved in the xylylenediamine linkages. In both cases, the benzene ring is asymmetrically positioned with respect to the main chain axis and must interfere with the ordered packing of layers within the polyamide crystalline regions. The additional point of inflection created in the linear polyamide chain by isophthalic acid must prevent the growth of ordered layers of crystallite and increase the amorphous character of the polyamide. Since monomers which prevent crystallization all possess some measure of stereochemical asymmetry, it will be convenient to refer to these as asymmetric monomers.

The minimum molar concentration of asymmetric monomers required to produce amorphous polyamides in a number of formulations studied in this work are listed in Table 7.

The number of formulations studied in this way was very limited. Nevertheless it was interesting to note that whereas only 20 mol % of isophoronediamine was required to render the formulations studied amorphous, 30 mol % of trimethylhexamethylenediamine or isophthalic acid were needed to accomplish the same effect, while monomers such as meta-xylylenediamine or 5-methylnonanediamine failed to give rise to amorphous materials at the limit set by their diamine function.

On the basis of this somewhat tentative observation, and a knowledge of the physical state, i.e. amorphous or crystalline, of the polymers listed in Table 6, it was decided to attempt a speculative classification of asymmetric monomers into three groups, and attach to this classification a summative numerical index based on type and molar concentration from which the physical state of the polyamide could be predicted. The following three groups of asymmetric monomers, AM, were distinguished,

Type AM1: Monomers whose presence alone, either as a diacid or diamine, do not seriously interfere with the linearity of the polyamide chain and hence do not affect the crystallinity of the polyamides, e.g. linear aliphatic diamine having one or more monomethyl substituted carbon atoms in the main chain—3-MeHMD, 2,5-DMeHMD etc. and MXD (Table 6).

Type AM2: Monomers whose presence alone, either as a diacid or diamine, would interfere stereochemically with the ability of the linear polyamide chains to pack in a crystalline manner e.g. linear aliphatic diacids or diamines having ethyl or higher substituents along the linear aliphatic chain, or the attachment of more than one methyl group to the same in-chain carbon member—3-EtHMD, 2,2,7,7-TMeSA and 2,4,4-TMeHMD (Table 6). Aromatic diacids also come within this group because of the stereochemical restriction imposed by the rigid benzene nucleus flanked by two carbonyl groups.

Type AM3: Monomers whose stereochemical configuration causes a gross distortion of the linear polyamide chain e.g. isophoronediamine and 1,1,3-trimethyl-5-carboxy-3-(*p*-carboxyphenyl) indane (PIDA). The latter at a concentration of 20 mol % prevents crystallization in nylon-6,6¹³.

The results already presented in Table 7 have shown that different amounts of each type of monomer are required to produce amorphous properties, and hence the transition point between the amorphous and crystalline state cannot be related to the simple sum of the molar concentrations of the so called asymmetric monomers. It was decided intuitively to sum the molar concentrations of the asymmetric monomers expressed in percentages according to the relationship:

$$\Sigma[\text{AM}] = [\text{AM1}] + 2[\text{AM2}] + 3[\text{AM3}] \quad (1)$$

A contribution from the asymmetric monomers of Type AM1 has been included here in order to allow for the possibility of an amorphous product being produced as the result of the combination of diacids and diamines of this type in the same polymer chain. The result of carrying out this procedure is shown in Table 8, from which it can be seen that polymers with a summed asymmetry value of less than 60 are crystalline, while materials with a higher molar asymmetry contribution are amorphous. Examples where the value given by equation (1) was used to predict the physical state of a polyamide before it had been prepared are indicated by an asterisk.

It is interesting to compare formulations 2 and 7 in Table 8. The former contains dodecamethylenediamine in

combination with isophoronediamine, and the latter 5-methylnonanedi-amine in combination with isophoronediamine. The last mentioned only required the addition of 5 mol % isophoronediamine to render it amorphous, whereas the other material did not become amorphous till almost 20% isophoronediamine had been added. This would seem to indicate that monosubstituted monomers do make a finite contribution towards the amorphous state.

Insufficient data are available at the time of writing to extend this concept to polyamides containing caprolactam as a comonomer. Values of the asymmetry index have been calculated for about one hundred experimental polymers. These values have been transformed into the more convenient concept of a symmetry index (*SI*), which is defined by the relationship:

$$SI = 1 - \frac{\Sigma(AM)}{300}$$

From the former discussion, it is clear that we should expect a polymer with a symmetry index >0.80 to be crystalline. From the data presented in Table 11, this normally appears to be the case.

There is a simple rule for deciding to which group an asymmetric monomer should be assigned. If the monomer can interfere with chain packing by distortion in one direc-

A = amorphous; C = crystalline

tion only, either along the chain or at right angles to it, then it belong to Type AM1. If it can interfere with chain packing by causing distortion in two different directions at right angles to each other, irrespective of how it is rotated about the chain axis, then it belongs to Type AM2. Similarly if the stereochemical configuration of the monomer causes distortion in three different non-coplanar directions it must belong to Type AM3.

STRUCTURE-VICAT SOFTENING POINT RELATIONSHIP IN AMORPHOUS POLYAMIDES

Review of experimental data and derivation of molar constant concept

A linear relationship between Vicat softening point and composition for a series of amorphous copolyamides containing ϵ -caprolactam and six of the nine salts which can be prepared from adipic, terephthalic, and isophthalic acids with isophorone-, trimethylhexamethylene- and *m*-xylylene-

diamines is shown in *Figure 3* and demonstrates that the softening point decreases linearly as the proportion of ϵ -caprolactam in the copolyamides is raised. This dependence of softening point upon the caprolactam molar concentration can be described by the equation:

$$V = V_0(1 - \alpha m) \quad (2)$$

where V is the Vicat softening point of the copolyamide; V_0 , the Vicat softening point of the corresponding polyamide containing no caprolactam; m , the molar concentration of caprolactam and α is a constant.

Similar behaviour is observed for copolyamides containing 12-aminododecanoic acid (*Figure 4*).

A linear dependence of softening point upon molar composition has also been observed for multi-component copolyamides prepared from mixtures of diacids and diamines. This is shown graphically in *Figure 5* for the dodecanedioic acid/hexamethylenediamine/isophoronediamine system, in which the ratio of the two diamines is varied, and in

phthalic acid/terephthalic acid/hexamethylenediamine/isophoronediamine system, using concentration ranges of terephthalic acid and isophoronediamine which yielded amorphous products. A relationship was established between softening point and composition of the form:

$$V = b_0 + b_1(\text{TPA}) + b_2(\text{IPD}) \quad (3)$$

Values of 0.143 and 1.38 were found for b_1 and b_2 respectively.

The softening point is therefore not only related to the concentration of a single diacid/diamine pair, as in the caproamide copolymers referred to earlier, and to the linear combination of two or more such diacid/diamine pairs (see *Figures 3-6*), but also to a linear combination of the individual diacids and diamines in the polyamide formulation. It follows that the softening point of an amorphous copolyamide is related to its constituent diacid/diamine pairs by the expression:

$$V = m_1V_1 + m_2V_2 + \dots + m_nV_n \quad (4)$$

where m_1, m_2, \dots, m_n are the mole fractions of the diacid/diamine pairs which form polyamides of softening points V_1, V_2, \dots, V_n .

In addition:

$$V_n = (K_a)_n + (K_b)_n \quad (5)$$

where $(K_a)_n$ is the molar constant of the diacid in the n th diacid/diamine pair and $(K_b)_n$ is the molar constant of the diamine in the n th diacid/diamine pair.

Substituting equation (5) into equation (4) yields:

$$V = m_1(K_a)_1 + m_2(K_a)_2 + \dots + m_n(K_a)_n + m_1(K_b)_1 + m_2(K_b)_2 + \dots + m_n(K_b)_n \text{ etc.}$$

which can be written more conveniently in the form:

$$V = \sum m_a K_a + \sum m_b K_b \quad (6)$$

K_a and K_b values for terephthalic acid and isophoronediamine are given in equation (3) as b_1 and b_2 respectively. Since K_a and K_b values can be derived from the softening points of polyamides, it is only necessary to assign a unique value to one such component in order to calculate values for all other diacids and diamines. From the data contained in *Table 9* it can be seen that isophoronediamine has a much more marked effect on the Vicat softening point than terephthalic acid, and for this reason the value of b_2 quoted for isophoronediamine was considered to be the better reference standard. It will be convenient in the discussion to follow to write K_b as $100b_2$.

The K_b values for isophoronediamine can now be used to calculate the K_a values for diacids in two component polyamides, and the procedure progressed through other polyamide formulations to yield further K_a and K_b values. Unfortunately, a large number of salts cannot be easily polymerized due to the formation of polymers of very high softening points, e.g. terephthalic acid/isophoronediamine, and reliable softening point measurements cannot be made. In many cases a crystalline polymer is formed and the softening point is not a true measure of the monomer contributions because of crystal lattice forces. In both cases molar constants can be calculated from ternary copoly-

amide softening point data. The extrapolation of softening point to zero concentration of ϵ -caprolactam in copolyamides is a particularly useful method of obtaining molar constants.

Molar constants are listed in *Table 10* and are quoted in $^{\circ}\text{C}/\text{mol}$, to an accuracy of $\pm 5^{\circ}\text{C}$. By using these values to determine the intercepts of the best straight lines through the experimental points shown in *Figure 3* for copolycaproamides, it was found that a slope of -0.8 satisfactorily characterizes the relationship between softening point and ϵ -caprolactam concentration in every series of copolycaproamide studied. The softening point of these polymers can therefore be predicted from the equation:

$$V = V_0(1 - 0.8[\text{CAP}]) \quad (7)$$

providing V_0 is known or can be predicted from molar constants.

Table 11 compares softening points calculated from equation (5) using the values of the molar constants given in *Table 10* with measured softening points of polyamides containing up to five monomers. The predicted values agreed to within 5% of the experimental values in most cases except when the polyamide was crystalline, and amply demonstrate the utility of the molar constant concept for amorphous polyamides.

The simple additivity of the molar constant concept would appear to indicate that the rigidity and cohesive energy forces of the polymer chains are determined solely by the number and frequency of different monomeric structural units present in the molecular chain. From the data contained in *Figures 3* and *4* there is also evidence to indicate that a reversal in the arrangement of amide groups by the introduction of an amino-acid into the diacid/diamine copolymer creates additional steric hindrance which further reduces the ability of chains to pack together and lowers the softening point of the polymer. Because of a much more regular and closer packing arrangement in crystalline polyamides the cohesive energy between chains is much greater, and the softening points are much higher than for amorphous polyamides.

Extension of the molar constant concept to the prediction of Vicat softening point from functional group contributions

The Vicat constants K_a and K_b of a range of diacids and diamines have been calculated in the manner described above. The chemical structure of the various diacids and diamines, together with their associated Vicat constants, are presented in *Table 10*. The objective of the discussion to follow will be to determine whether the individual groups within these monomers can be assigned a constant fractional contribution to the already characterized monomer Vicat constant.

The chemical formula of a linear polyamide chain may be written in the form:

In the discussion, it is proposed to consider the polyamide chain as being built up of structural units $\text{---NH.O.C.X.CO.NH---}$ and ---Y--- . These units were chosen in order to simplify the discussion.

Linear polyamides derived from aliphatic diacids and diamines contain structural units in which X and Y repre-

Figure 7 Relationship between the Vicat constant K_N and the monomer structural unit factor N . \circ , Linear diamine unit; Δ , linear diacid unit; \bullet , branched diamine unit; \blacktriangle , branched diacid unit

sent a chain of methylene groups $(-\text{CH}_2-)_n$. If the total number of atoms in a structural unit which lie along the chain axis of the polyamide is given by N , then $N = n + 4$ for the linear structural unit $-\text{NH}.\text{OC}.\text{X}.\text{CO}.\text{NH}-$ and $N = n$ for the linear structural unit $-\text{Y}-$.

Figure 7 shows that a linear relationship exists between the Vicat constants for the various aliphatic diacids and diamines listed in Table 5, and their individual N values derived as above. The line shown is fitted by the equation:

$$K_N = 78 - 6.7N \quad (8)$$

where K_N is the Vicat constant characterizing both diacids and diamines in terms of the common structural unit factor N .

The monosubstitution of in-chain atoms remote from the polar amide groups, would not be expected to significantly affect the value of K_N . This is found to be the case with 5-MeNDA whose K_N value is close to that predicted for the unsubstituted nonanediamine. On the other hand, methyl substitution at in-chain carbon atoms adjacent to the amide groups would be expected to cause a steric effect, and hence some change in K_N relative to the value of N computed from the number of in-chain atoms within the structural units. This is indeed observed when the data contained in Figure 7 for 2-MePMD and 2,2,4-TMeHMD are plotted against the respective diamine N values. However, if for such monomers the apparent chain length N is reduced by the number of methyl groups substituted on in-chain carbon atoms which occupy the α or β position relative to the amide bond, agreement with the previously established relationship is obtained. The same rule when applied to 2,2,7,7-TMeSA reduces the apparent chain length from 10 to 6, and as can be seen from Figure 7, gives a better fit to the linear relationship proposed.

Additional empirical rules which might govern the application of equation (8) to cyclic diacids and diamines should next be considered. Since only six such monomers are listed in Table 10, two being alicyclic and four aromatic, it will not be possible to test adequately any proposed structural rule.

Applying equation (8) to diaminomethylcyclohexane yields a value of $N = -4$. Since from the previously established rule for aliphatic diamines the two exocyclic methylene groups contributed $n = 2$, the alicyclic ring must contribute $n = -6$ to the overall value of N . Thus for isophoronediamine, the alicyclic ring must contribute $n = -6$, tetra-substitution of the two ring atoms $n = -4$, and the exocyclic methylene group $n = 1$. Isophoronediamine has therefore a derived structural unit factor $N = -9$, and coordinates $K_N = 140$, $N = -9$ which allow placement in Figure 8 according to the relationship given in equation (8). In neither of these calculations has any account been taken of the nature of the ring substitution. The general application of the proposed group contribution to the structural unit factor, N , cannot be further tested here because of the lack of experimental data on other alicyclic diamines.

In considering how aromatic monomer might be placed on the same K_N versus N relationship, it is convenient to make the purely arbitrary selection of terephthalic acid as the aromatic standard. Terephthalic acid has a K_d value of 105, and therefore to fit the required data line it must have a structural unit factor of $N = -4$. If instead of assigning an arbitrary value to the aromatic ring we count each carbon atom in the shortest chain through the aromatic nucleus as -1 , and add -1 for each carbonyl group directly attached to the aromatic ring, terephthalic acid can be assigned a structural unit factor of -4 (by previous rules each of the nitrogen atoms attached to the carbonyl groups

Figure 8 Extension of the relationship between the Vicat constant K_N and the monomer structural unit factor N to cyclic monomers

must be counted as +1). In the same way isophthalic acid yields a structural unit factor $N = -3$, and 4,4'-diaminodiphenylmethane a factor $N = -7$, both of which fit the desired relationship fairly well. *m*- and *p*-Xylylenediamine with a Vicat constant $K_b = 80$ and a *m*-/*p*-ratio of 70/30 also provides a fairly close fit to the K_b against N plot contained in Figure 8, by having a calculated value of $N = -1.3$.

From the discussion set out above it is clearly possible from the simple structural rules derived to calculate the Vicat constant for a diamine or a diacid, and hence predict the Vicat softening point of a polyamide containing that component. The computational procedure adopted is arbitrary. Nevertheless, a limited amount of success has been achieved in predicting values for the structural unit N

which would have yielded by interpolation, values of K_a and K_b close to the values derived from experimental observation. Most of the polyamides listed in Table 5 were prepared to provide additional data to support the relationship shown in Figure 7.
