(Received 13 June 1975)

The structure and the structure change of the melt crystallized oligourethanes, $\text{CH}_3\text{CO}-\text{-(CH}_2)_5\text{NHCO-}_n\text{OCH}_3$, having strictly homogeneous molecular weight, were studied. The crystal system of every melt crystallized oligourethane was similar to that of the single crystal of $n = 2$. In the case of $n = 2$, crystalline rearrangement by annealing does not occur, although the number of hydrogen bonds increases. On the other hand, rearrangement occurs for $n = 3$ and higher oligomers. It was considered that the rearrangement for $n = 3$ was the transformation from the spherulite to the plate-like crystal, whilst for those of $n = 5$ and 8 the growth of the new spherulitic type of crystal by secondary crystallization occurs. For $n = 10$ and the polymer crystal the thickening was accompanied by an increase of ordered regions.

INTRODUCTION

The synthesis and the fine structure of oligourethanes have been previously studied by Kern¹ and Zahn². The structure and the physical properties of solid state of oligomer, however, have not been investigated in detail.

In previous papers^{3,4}, the dependence of the degree of polymerization on the crystal structure of the solution grown crystal of oligourethane was elucidated. In this paper, the structure and the structure change of the melt crystallized oligomer have been studied.

EXPERIMENTAL

Acetoxy-oligopentamethyleneurethane, $\text{CH}_3\text{CO}-\text{-(CH}_2)_5\text{NHCO-}_n\text{OCH}_3$ with $n = 2$ to 10, synthesized by a stepwise addition polymerization method⁵ and having strictly homogeneous molecular weights and the polymer having $\bar{M}_n 5.3 \times 10^4$, were used as samples.

The melt crystallized samples were prepared as shown in Table 1.

The thermal properties were determined by differential scanning calorimetry (d.s.c.) and differential thermal analysis (d.t.a.).

Infra-red spectra was measured by the KBr and Nujol method.

Wide angle X-ray scattering (WAXS) was measured with a diffractometer at room temperature.

Small angle X-ray scattering (SAXS) was measured with a Kratky type U-slit camera using $\text{CuK}\alpha$ radiation and a scintillation counter with pulse height analyser.

Density was measured by the floatation method using a mixture of n-heptane and carbon tetrachloride.

The dependence of the specific volume on temperature was measured by dilatometry.

RESULTS

Infra-red spectra of unannealed and annealed samples are shown in Figure 1. The intensity of the absorption band of $3400-3500 \text{ cm}^{-1}$, which is due to the free hydrogen bonds, was reduced by annealing for every sample.

Figure 2 shows WAXS patterns of the unannealed and annealed samples. In the case of $n = 2$ to 8, the intensity of two strong diffraction peaks of the annealed sample does not change. On the other hand, for $n = 10$ and the polymer the diffraction peak shifts into the wide angle side on annealing, namely the same angle as that obtained with oligomers of $n = 8$ and lower. This means that the crystal system of every melt crystallized sample is similar to that of $n = 2$.

Densities of the before and after annealing are shown in Table 2.

Figure 3 shows d.s.c. thermograms. Those of $n = 2, 10$ and the polymer show only a simple endothermic peak,

Table 1 Preparation condition of sample

that of $n = 3$ shows two endothermic peaks and one exothermic peak. Exothermic and endothermic peaks appear for $n = 5$ and 8. By annealing a simple endothermic peak appears in every sample.

Plots of the specific volume against temperature are shown in Figure 4.

The long periods calculated from the results of SAXS pattern by Bragg's law is shown in Figure 5.

DISCUSSION

The process of heating in the d.s.c. measurement corresponds to the annealing and the d.s.c. thermogram of $n = 2$ shows only a simple endothermic peak. The infra-red spectra shows an increase in the number of hydrogen bonds in the sample. Therefore, it is considered that the rearrangement of the whole crystal solid by annealing does not occur, although the number of hydrogen bonds increases.

The d.s.c. thermogram of $n = 3$ shows exothermic and endothermic peaks and by annealing for 5 h at 80°C , the thermogram shows only an endothermic peak on the higher temperature side as shown in Figure 3.

As seen in Figure 5 specific volume increases and decreases abruptly at temperatures close to those of the endothermic and exothermic peaks, respectively. The above results show that the rearrangement of crystallites occurs in the $n = 3$ sample.

To study the rearrangement of the $n = 3$ sample the influence of heating rate on the d.t.a. thermogram and dilatometry was measured. Figure 6 shows the dependence of the endothermic peak temperature on the heating rate. At heating rates higher than $5^\circ\text{C}/\text{min}$ one endothermic peak on the higher temperature side disappears and the other on

Table 2 Degree of polymerization and density

the lower temperature side remains. At very low heating rates, which corresponds to annealing, only one peak appears on the higher temperature side. As shown in Figure 2, the annealed and unannealed samples show almost same WAXS pattern. These results suggest that the metastable crystalline structure at lower temperatures transforms to the stable one at higher temperatures which have the same value of the long period with the metastable one and the same crystal system.

To elucidate the nature of the metastable and stable crystals, the volume contraction was observed by dilatometry, and the volume contraction versus time curves were analysed by using the Avrami equation⁷:

$$\ln \frac{h_0 - h_\infty}{h_t - h_\infty} = kt^n$$

where h_0 is the initial height of mercury in the dilatometry, h_∞ is the final height, h_t is the height at time t and k and n are constant. In the case of the volume contraction for isothermal crystallization at 65°C, the slope of the Avrami plot was 3.2 (Figure 7). This value indicates the formation of spherulitic type of crystal. On the other hand, the spherulitic type of crystal packed in the dilatometer, at 85°, 88° and 92°C, corresponding to the exothermic peak

temperature in the d.s.c. thermograms, expands and then contracts as shown in Figure 8. This volume contraction versus time curve was also analysed by using the Avrami equation. The slope of this Avrami plot was 2.0 and this value may mean that the growth of new crystal is two dimensional, or plate-like crystal. These results suggest that the rearrangement from the metastable to the stable crystal is the transformation from the spherulite to the plate-like crystal.

It is clear that the specific volume either increases or decreases at temperatures close to those of the endothermic and exothermic peaks, respectively. Each annealed sample shows a simple fusion curve (Figures 3 and 4) and thus the rearrangement also occurs in these samples.

When the temperature was kept at the maximum point of the plot of specific volume and temperature curve, the slope of the Avrami plot calculated from the volume contraction was about 3.5 as shown in Figure 9. It is thus reasonable to consider that the new spherulitic type of crystal grows from the amorphous parts by secondary crystallization in the samples of $n = 5$ and 8.

As shown in Figure 5, the long periods of $n = 10$ and polymer increase by annealing. The calculated spacing⁴ ($0k0$) assuming that the unit cell expands along \vec{b}_s of sub-cell axis, the length of repeating unit, $-\text{O}(\text{CH}_2)_5\text{NHCO}-$, having that of the planar zigzag configuration is also shown in Figure 5. The Figure shows the thickening phenomena of the crystal of $n = 10$ and polymer by annealing. Furthermore, the $2\theta = 24.8^\circ$ diffraction peak, which corresponds to the lattice plane composed of the molecular sheet connected side by side, shows a decrease of this lattice distance on annealing. Therefore, in the unannealed sample the disordered region changes into the ordered region, or the intermolecular sheet distance decreases. Consequently, density increases as shown in Table 2.

In addition to the endothermic peak for quenched sample a new endothermic peak on the lower temperature side appears in the d.s.c. thermogram for isothermal crystallization at 125°C (Figure 10). The area of the new peak increases with increasing crystallization time and both the long period of the $n = 10$ and polymer increase as shown in Figure 5. Therefore, it is considered that the crystal is thickened gradually during the long period of isothermal crystallization. The decrease of the endothermic peak temperature in the d.s.c. thermogram may be explained if the entropy difference between the solid state of crystal and the melt increases with increasing time.

ACKNOWLEDGEMENTS

The authors express their grateful thanks to Dr Y. Iwakura of University of Tokyo and Dr K. Iwata of Central Institute of Teijin Co. Ltd for donating the sample.

Reaction field in anisotropic dielectrics

K. H. Lau and K. Young

Department of Physics, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong
(Received 3 June 1975)

Drawn polymers are often characterized by dielectric anisotropy. This is determined by the anisotropy in the molecular polarizability, averaged over the distribution of polymer chains. Since each dipole in the dielectric is situated in a macroscopically anisotropic medium, corrections arise from the anisotropic cavity field and reaction field. The necessary reaction field correction is explicitly evaluated for an axially symmetric dielectric with negligible electronic polarizability and is found not to exceed 2–3%. This shows that the *ad hoc* anisotropic generalization of Onsager's equation used in the literature need only be corrected for the cavity field effect in the manner recently discussed.

INTRODUCTION

A useful tool for determining the orientation function in a drawn polymer is the measurement of dielectric anisotropy. From the measured permittivity tensor ϵ_{ij} , one first obtains the molecular polarizability $\overline{\alpha_{ij}}$, where $\overline{\quad}$ denotes an average over the polymer chain distribution. Comparison with the polarizability α_{ij} of a single molecule yields the orientation function. Our purpose here is to examine in some detail the relation between ϵ_{ij} and $\overline{\alpha_{ij}}$; this relation for the isotropic case is the Onsager equation¹. Previous analyses of anisotropic data^{2–4} have not used a proper anisotropic generalization of the Onsager equation. This is particularly worrying because (a) it is the anisotropy, rather than the average value, which is of main interest in polymer physics, and (b) the likely size of the error involved has not hitherto been estimated.

We give a systematic formulation of dielectric theory in the anisotropic case and show that two effects need be taken into account: (a) the cavity field effect recently discussed⁵; and (b) the reaction field. The latter is the main concern of this paper, and the necessary correction is evaluated for an axially symmetric dielectric with negligible electronic polarizability. Our main result is that the reaction field correction turns out to be very small. It is fortunate, but not *a priori* obvious, that this should be so.

The rest of the paper is organized as follows. In the next section, we consider the response of an isolated molecule to an external field and define the polarizability α_{ij} . Next the response of a molecule in a medium is considered and a general expression is found for the permittivity ϵ_{ij} . In both cases, the example of an axially symmetric material with negligible electronic polarizability serves to illustrate the main ideas. Finally, the reaction field is studied for this special case and the correction is estimated.

MODEL FOR AN ISOLATED MOLECULE

General formulation

The molecular dipole will be assumed to be made of two parts: a rigid permanent dipole of magnitude μ_0 and a bound electron of charge $-e$:

$$\vec{\mu} = \mu_0 \vec{a} - e\vec{x} \quad (1)$$

Here \vec{a} is a unit vector specifying the direction of the permanent dipole and \vec{x} is the position of the electron. The generalization to several electrons is straightforward. The thermal average of the dipole moment is:

$$\langle \mu_i \rangle = \frac{\int \mu_i \exp(-\beta U) d^3x d\Omega}{\int \exp(-\beta U) d^3x d\Omega} \quad (2)$$

Here Ω denotes the orientation of the unit vector \vec{a} , $\beta = (kT)^{-1}$ and U is the energy of the dipole. For an isolated molecule, U is taken to be of the form:

$$U = \Delta(\vec{a}) + \frac{1}{2} x_i k_{ij} x_j - \vec{\mu} \cdot \vec{E} = U_0 - \vec{\mu} \cdot \vec{E} \quad (3)$$

Here $\Delta(\vec{a})$ is the orientation energy of the permanent dipole, the symmetric matrix k_{ij} represents an anisotropic 'spring' binding the electron and \vec{E} is an external electric field. To first order in \vec{E} , equation (2) may be written as:

$$\langle \mu_i \rangle = \alpha_{ij} E_j \quad (4)$$

where the polarization tensor α_{ij} is:

$$\alpha_{ij} = \beta \frac{\int \mu_i \mu_j \exp(-\beta U_0) d^3x d\Omega}{\int \exp(-\beta U_0) d^3x d\Omega} \quad (5)$$

A special case

We shall focus attention on a special case of equation (5) in order to bring out the essential physics. First, we assume the electronic contribution can be ignored, so that equation (5) reduces to:

$$\alpha_{ij} = \beta \mu_0^2 \frac{\int a_i a_j \exp(-\beta \Delta) d\Omega}{\int \exp(-\beta \Delta) d\Omega} \quad (6)$$

Define

$$Q(\Omega) = \exp(-\beta \Delta) \quad (7)$$

which is just the Boltzmann distribution function for the permanent dipole. Further assume that $Q(\Omega)$ is axially symmetric about the chain axis (of the monomer molecule). If

the angle between the chain and the dipole \vec{a} is denoted by γ , $Q(\Omega)$ may be written as:

$$Q(\Omega) = \frac{1}{4\pi} \sum_l Q_l P_l(\cos \gamma) \quad (8)$$

Putting these into equation (6) gives:

$$\alpha_{ij} = \frac{\beta\mu_0^2}{4\pi Q_0} \sum_l Q_l \int a_i a_j P_l(\cos \gamma) d\Omega \quad (9)$$

In a frame where the z-axis coincides with the chain, α_{ij} takes the diagonal form:

$$\alpha_{ij} = \alpha(\delta_{ij} + \nu\eta_{ij}) \quad (10)$$

where η_{ij} is the matrix (matrices will be denoted by $\hat{\eta}$)

$$\hat{\eta} = \begin{pmatrix} 1 & & \\ & 1 & \\ & & -2 \end{pmatrix} \quad (11)$$

Thus $\alpha = \text{tr } \alpha_{ij}/3$ is the average value (over the principal directions) of the polarizability and ν is a measure of the anisotropy. Taking the trace of equation (9) and noting that $a^2 = 1$, we get:

$$\alpha = \beta\mu_0^2/3 \quad (12)$$

which is the classical result of Langevin and Debye⁶, here found to be unmodified so long as we talk about the average. For the anisotropy we obtain:

$$\nu = -\frac{1}{5} \frac{Q_2}{Q_0} \quad (13)$$

It is to be noticed that α_{ij} is insensitive to Q_l with $l > 2$; therefore measurement of the polarizability will yield no information on the higher Q_l . This comes as no surprise since α_{ij} is a rank two tensor and therefore involves only $l = 0$ and 2.

Averaging over the chain distribution

Let us now transform to a frame suitable for macroscopic discussion: we take the z-axis to be the draw direction (rather than the chain direction). In this frame, let the direction of the dipole be Ω and that of the chain be Ω' , with the angle between them being γ . Then equation (8) becomes, by the addition theorem for spherical harmonics*.

$$Q(\Omega) = \sum_{lm} \frac{Q_l}{2l+1} Y_{lm}^*(\Omega') Y_{lm}(\Omega) \quad (14)$$

We are interested not so much in $Q(\Omega)$ as in its average value $\bar{Q}(\Omega)$ over the chain distribution. Let the chains be distributed according to $f(\Omega')$; this is, of course, the orientation function one wants to study. Let $f(\Omega')$ be axially symmetric about the draw direction:

$$\begin{aligned} f(\Omega') &= \frac{1}{4\pi} \sum_l f_l P_l(\cos \theta') \\ &= \frac{1}{(4\pi)^{1/2}} \sum_l \frac{1}{(2l+1)^{1/2}} f_l Y_{l0}(\Omega') \end{aligned} \quad (15)$$

Here θ' is the polar angle between the chain and the draw direction. The distribution (15) is normalized to unity if $f_0 = 1$. With these definitions in hand, $\bar{Q}(\Omega)$ can be evaluated:

$$\begin{aligned} \bar{Q}(\Omega) &\equiv \int Q(\Omega) f(\Omega') d\Omega' \\ &= \frac{1}{4\pi} \sum_l \frac{1}{2l+1} Q_l f_l P_l(\cos \theta) \end{aligned} \quad (16)$$

where we have used equations (14) and (15) and the orthogonality of the spherical harmonics.

Comparing with equation (8), we see that Q_l has been replaced by $Q_l f_l/(2l+1)$. Thus if we parametrize the average polarizability as:

$$\bar{\alpha}_{ij} = \bar{\alpha}(\delta_{ij} + \bar{\nu}\eta_{ij}) \quad (17)$$

then $\bar{\alpha} = \alpha$, which is physically obvious. The average anisotropy $\bar{\nu}$ can evidently be obtained from equation (13) with the replacement $Q_l \rightarrow Q_l f_l/(2l+1)$:

$$\bar{\nu} = -\frac{1}{5} \frac{Q_2 f_2/5}{Q_0 f_0} = -\frac{1}{25} \frac{Q_2 f_2}{Q_0 f_0} \quad (18)$$

Again $l > 2$ is not involved. The proportionality to f_2 is physically reasonable: it expresses the fact that no matter how anisotropic each molecule is, there will be no average anisotropy $\bar{\nu}$ if the molecules are randomly oriented.

THE MOLECULE IN A DIELECTRIC MEDIUM

General formulation

We next consider a substance with N such molecules or monomers per unit volume. Our treatment will draw on the method of Fröhlich⁷. In contrast to the case of the isolated molecule, it will be necessary to consider interaction between molecules. We consider a sphere of radius R containing one molecule; this molecule will be treated microscopically while the rest of the medium will be treated macroscopically as a dielectric with permittivity ϵ_{ij} . An alternate but equivalent method is to consider a larger sphere containing many molecules but to neglect the short range interaction between these molecules. Thus we are not concerned here with Kirkwood's generalization⁸ of the Onsager equation to include short range effects.

Now the energy of the molecule in question will still have the intrinsic pieces $\Delta(a) + \frac{1}{2} x_i k_{ij} x_j$ of molecular origin. In addition, there will be the energy used to set up the dipole:

$$-\int_0^{\vec{\mu}} \vec{F} \cdot d\vec{\mu} \quad (19)$$

where \vec{F} is the electric field at the origin, other than that due to the dipole itself, i.e. \vec{F} is defined by:

$$\phi(r) = \frac{\vec{\mu} \cdot \vec{r}}{r^3} - \vec{F} \cdot \vec{r} + O(r^2) \quad (20)$$

as $r \rightarrow 0$, where ϕ is the electrostatic potential. The linearity of the dielectric can be used to write \vec{F} as the sum of two

* We shall not explicitly indicate the Ω dependence of Q .

terms respectively proportional to the external field \vec{E} and to μ :

$$F_i = X_{ij}E_j + Y_{ij}\mu_j \quad (21)$$

The first term, known as the cavity field, is the field at the origin when the external field is E and the cavity contains no dipoles:

$$\begin{aligned} \phi(r) &\rightarrow -\vec{E} \cdot \vec{r} & r \rightarrow \infty \\ \phi(r) &\rightarrow -(X_{ij}E_j)r_i + O(r^2) & r \rightarrow 0 \end{aligned} \quad (22)$$

The second term, known as the reaction field, is the field at the origin when there is no external field, but with a dipole μ in the cavity:

$$\begin{aligned} \phi(r) &\rightarrow 0 & r \rightarrow \infty \\ \phi(r) &\rightarrow \frac{\mu \cdot \vec{r}}{r^3} - (Y_{ij}\mu_j)r_i + O(r^2) & r \rightarrow 0 \end{aligned} \quad (23)$$

The symmetric matrices X_{ij} and Y_{ij} are completely defined by equations (22) and (23) and will be functions of the macroscopic permittivity ϵ_{ij} . For reference, we quote the well-known isotropic result:

$$X_{ij} = \frac{3\epsilon}{2\epsilon + 1} \delta_{ij} \quad (24)$$

$$Y_{ij} = \frac{2}{R^3} \frac{\epsilon - 1}{2\epsilon + 1} \delta_{ij} = \frac{8\pi}{3} N \frac{\epsilon - 1}{2\epsilon + 1} \delta_{ij} \quad (25)$$

where in equation (25) we have made the usual assumption $(4\pi/3)R^3N = 1$. We are of course concerned here with the anisotropic case. The form of X_{ij} for this more complicated situation has recently been found and its effect discussed⁵. The rest of the paper will concentrate on the effect of Y_{ij} .

If we now substitute equation (21) into equation (19), we get:

$$-\int_0^{\vec{\mu}} \vec{F} \cdot d\vec{\mu} = -\mu_i X_{ij} E_j - \frac{1}{2} \mu_i Y_{ij} \mu_j \quad (26)$$

so that the total configuration energy is now:

$$\begin{aligned} U &= \Delta(\vec{a}) + \frac{1}{2} x_i k_{ij} x_j - \frac{1}{2} \mu_i Y_{ij} \mu_j - \mu_i X_{ij} E_j \\ &= U_1 - \mu_i X_{ij} E_j \end{aligned} \quad (27)$$

This can now be inserted into equation (2), which is valid in general, to yield the following result to first order in \vec{E} :

$$\langle \mu_i \rangle = \beta \frac{\int \mu_i \mu_j \exp(-\beta U_1) d^3 x d\Omega}{\int \exp(-\beta U_1) d^3 x d\Omega} X_{jk} E_k \quad (28)$$

Recall that the permittivity tensor ϵ_{ij} is defined by:

$$4\pi N \langle \mu_i \rangle = (\epsilon_{ik} - \delta_{ik}) E_k \quad (29)$$

so that comparison with equation (28) gives:

$$\epsilon_{ik} - \delta_{ik} = 4\pi N Z_{ij} X_{jk} \quad (30)$$

or in matrix notation:

$$\hat{\epsilon} - \hat{1} = 4\pi N \hat{Z} \hat{X} \quad (31)$$

where:

$$Z_{ij} = \beta \frac{\int \mu_i \mu_j \exp(-\beta U_1) d^3 x d\Omega}{\int \exp(-\beta U_1) d^3 x d\Omega} \quad (32)$$

Comparison with equation (5) shows that Z_{ij} differs from α_{ij} by the replacement $U_0 \rightarrow U_1$. Physically this just means that the presence of the dielectric modifies the configuration energy, and hence the response to an external field. It is precisely the difference between \hat{Z} and $\hat{\alpha}$ that concerns us here.

It will in fact be instructive for the reader to evaluate equation (32) for the isotropic case (where $\Delta = \text{constant}$; \hat{X} , \hat{Y} are given by equations (24) and (25) and $k_{ij} = k\delta_{ij}$) and thus show that equation (31) reduces to the usual form of the Onsager equation. Indeed such a derivation of the Onsager equation avoids the introduction of various ambiguous concepts such as the 'effective dipole'.

Special case

Again, to simplify matters, we ignore the electronic contribution, then equation (32) becomes:

$$Z_{ij} = \beta \mu_0^2 \frac{\int a_i a_j \exp(-\beta \Delta) \exp(\frac{1}{2} \beta \mu_0^2 a_i Y_{ij} a_j) d\Omega}{\int \exp(-\beta \Delta) \exp(\frac{1}{2} \beta \mu_0^2 a_i Y_{ij} a_j) d\Omega} \quad (33)$$

Note that in the isotropic case $a_i Y_{ij} a_j \propto a^2 = 1$ is independent of Ω and hence can be dropped. Thus the reaction field has no effect in the isotropic limit when the electronic contribution is ignored; it is a specifically anisotropic effect. This is in fact physically obvious: in the isotropic case, the reaction field \vec{E}_R is necessarily in the same direction as the rigid dipole, therefore the torque tending to orient the dipole: $\tau = \mu \times \vec{E}_R$ vanishes. When the medium is anisotropic and $Y_{ij} \neq Y\delta_{ij}$, \vec{E}_R is no longer parallel to μ , so there is a non-zero torque.

The matrix Y_{ij} is of course a function of ϵ_{ij} . We consider a case where ϵ_{ij} is symmetric about the z-axis:

$$\hat{\epsilon} - \hat{1} = (\epsilon - 1) [\hat{1} + u\hat{\eta}] \quad (34)$$

with $\hat{\eta}$ defined as in equation (11). Here:

$$\epsilon = \text{tr} \hat{\epsilon} / 3 \quad (35)$$

is the average value (over the principal directions) of the permittivity, while:

$$u = \frac{\epsilon_{xx} + \epsilon_{yy} - 2\epsilon_{zz}}{6(\epsilon - 1)} \quad (36)$$

is a measure of dielectric anisotropy*. We have calculated

* The parameter u here corresponds to u in ref 5.

Y_{ij} in terms of ϵ and u , using a method similar to that in ref 5, with the result:

$$Y_{ij} = \frac{2}{R^3} \frac{\epsilon - 1}{2\epsilon + 1} \left\{ \delta_{ij} + u \frac{3}{10} \frac{1}{2\epsilon + 1} \eta_{ij} + O(u^2) \right\} \quad (37)$$

It is anticipated that the $O(u^2)$ contribution will be negligible; this is the case with X_{ij} , which we have previously calculated to $O(u^2)$ ⁵.

Insert equation (37) in equation (33) and note that the δ_{ij} piece in Y_{ij} affects only the overall normalization and may be dropped. Thus:

$$Z_{ij} = \beta\mu_0^2 \frac{\int a_i a_j \bar{Q}(\Omega) \exp(Au a_i \eta_{ij} a_j) d\Omega}{\int \bar{Q}(\Omega) \exp(Au a_i \eta_{ij} a_j) d\Omega} \quad (38)$$

where we have made the replacement, $\exp(-\beta\Delta) = Q \rightarrow \bar{Q}$, as discussed earlier and where A stands for:

$$A = \frac{3}{10} \frac{\beta\mu_0^2}{R^3} \frac{\epsilon - 1}{(2\epsilon + 1)^2} \quad (39)$$

Since the calculation will be carried only to first order in the anisotropy u , we only need A to zero order in u , i.e. for the isotropic case. In that case, equation (30) is:

$$\epsilon - 1 = 4\pi N \frac{\beta\mu_0^2}{3} \frac{3\epsilon}{2\epsilon + 1} \quad (40)$$

so that comparing equations (39) and (40) gives:

$$A = \frac{1}{10} \frac{(\epsilon - 1)^2}{\epsilon(2\epsilon + 1)} \quad (41)$$

Note that A does not exceed 0.05.

Let us parameterize Z_{ij} as:

$$\hat{Z} = \alpha(\hat{1} + w\hat{\eta}) \quad (42)$$

then solving for w from equation (38) gives:

$$w = - \frac{\int P_2(Z) \bar{Q}(Z) \exp(-2AuP_2(Z)) dZ}{\int \bar{Q}(Z) \exp(-2AuP_2(Z)) dZ} \quad (43)$$

where we have used:

$$a_i \eta_{ij} a_j = -2P_2(\cos \theta) = -2P_2(Z) \quad (44)$$

For reference note that the usual treatment in the literature^{2,3} ignores the anisotropy in the reaction field and corresponds to putting $A = 0$. Provided that neither the reaction field correction (owing to $A \neq 0$) nor the cavity field correction (owing to $\bar{X} \neq X\bar{1}$) is too large, the two corrections may be independently applied. The cavity field correction has already been discussed⁵, so in this paper we take \bar{X} to be isotropic as in equation (24) and concentrate on the reaction field. Thus comparing anisotropies in equation (31), we find $u = w$. Hence equation (43) now reads:

$$u = - \frac{\int P_2(Z) \bar{Q}(Z) \exp(-2AuP_2(Z)) dZ}{\int \bar{Q}(Z) \exp(-2AuP_2(Z)) dZ} \quad (45)$$

Thus we have derived an implicit equation relating u to

molecular parameters embodied in $\bar{Q}(Z)$. It remains to investigate how a non-zero A affects equation (45).

The reaction field correction

We expand the exponential in equation (45) and also insert equation (16) to get:

$$u = - \frac{\sum_n \sum_l \frac{Q_l f_l}{2l+1} \frac{(-2Au)^n}{n!} \int P_2(Z)^{n+1} P_l(Z) dZ}{\sum_n \sum_l \frac{Q_l f_l}{2l+1} \frac{(-2Au)^n}{n!} \int P_2(Z)^n P_l(Z) dZ} \quad (46)$$

Since $A < 0.05$ and $|u| < 1$, we terminate the series at $n = 1$:

$$u = - \frac{N_0 - 2AuN_1}{D_0 - 2AuD_1} \quad (47)$$

where:

$$N_0 = \sum_l \frac{Q_l f_l}{2l+1} \int P_2(Z) P_l(Z) dZ = \frac{2}{25} Q_2 f_2$$

$$N_1 = \sum_l \frac{Q_l f_l}{2l+1} \int P_2(Z)^2 P_l(Z) dZ$$

$$= \frac{2}{5} Q_0 f_0 + \frac{4}{175} Q_2 f_2 + \frac{4}{315} Q_4 f_4$$

$$D_0 = \sum_l \frac{Q_l f_l}{2l+1} \int P_l(Z) dZ = 2Q_0 f_0$$

$$D_1 = \sum_l \frac{Q_l f_l}{2l+1} \int P_2(Z) P_l(Z) dZ = \frac{2}{25} Q_2 f_2 \quad (48)$$

Notice that since

$$\int P_2(Z)^n P_l(Z) dZ = 0 \quad (49)$$

for $l > n$, by terminating the sum over n we automatically terminate the sum over l as well.

We are now in a position to look at the properties of equation (47). Recall that the molecular polarizability determines $Q_2 f_2$ by means of equation (17), but does not determine $Q_4 f_4$, which appears in N_1 . This is an interesting breakdown of classical dielectric theory, where 'normally' molecular polarizability determines the permittivity. In practice, however, this will not be an important effect, since the coefficient of $Q_4 f_4$ is small. So in the rest of the discussion, we shall set $Q_4 f_4$ to zero. This will be discussed in the Appendix.

Ignoring $Q_4 f_4$, and relating $Q_2 f_2$ to \bar{v} by equation (18), equation (47) can be written as:

$$u = \frac{\bar{v} + Au \left(\frac{2}{5} - \frac{4}{7} \frac{\bar{v}}{v} \right)}{1 + 2Au\bar{v}} \quad (50)$$

Solving for \bar{v} :

$$\bar{v} = u \left[1 + A \left(2u^2 + \frac{4}{7}u - \frac{2}{5} \right) \right] \quad (51)$$

where $O(A^2)$ terms have not been kept. In practice, one measures the anisotropy $u = [\epsilon_{xx} + \epsilon_{yy} - 2\epsilon_{zz}]/[6(\epsilon - 1)]$ and determines \bar{v} from it, so equation (51) is the experimentally useful equation. (The determination of the orientation function from \bar{v} is standard and will not be discussed here; see for example ref 5.) The square bracket in equation (51) is the correction factor to be applied to the naive result $\bar{v} = u$ often used in the literature; the correction is of course proportional to A . In view of the bound $A < 0.05$, the correction never amounts to more than 2–3% and is totally negligible at the present level of experimental accuracy.

Thus the only significant correction, of up to 10%, comes from the cavity field effect⁵.

CONCLUSION

Our main result is that the reaction field correction is small; if a correction is nevertheless desired, equation (51) may be applied. It is well to recall the limitations of the present calculation. First, we restricted our attention to axially symmetric systems. This is the most common situation in polymer physics, and in any case it is inconceivable that the qualitative conclusion of this paper will be altered if one removes this restriction. Secondly, electronic polarizability has been ignored. Thus we expect our result to be applicable in detail only if $|\hat{\epsilon}_0| \gg |\hat{\epsilon}_\infty|$ (where the subscript denotes the frequency) or if we consider the dispersion $\Delta\hat{\epsilon} = \hat{\epsilon}_0 - \hat{\epsilon}_\infty$, which should be due to the permanent dipoles alone. Whether the reaction field has any appreciable effect on the birefringence (i.e. the anisotropy in $\hat{\epsilon}_\infty$) is a separate question to be looked at.

Note added in proof

Similar problems have been considered in the context of liquid crystals by Bordewijk (*Physica* 1974, **75**, 146). We thank Dr Bordewijk for bringing this work to our attention.

APPENDIX

Here we wish to justify the neglect of Q_4f_4 , which, we stress again, cannot be calculated from the polarizability. If we keep the Q_4f_4 term in equation (48), (51) acquires an extra term:

$$\bar{v} = u \left[1 + A \left(2u^2 + \frac{4}{7}u - \frac{2}{5} + \xi \right) \right] \quad (51')$$

where $\xi = 4/315 (Q_4f_4/Q_0f_0)$. By the positive of f , we can deduce

$$|f_4| = \frac{9}{2} \left| \int f(Z)P_4(Z)dZ \right| \leq \frac{9}{2} \int f(Z)dZ = \frac{9}{2} f_0$$

since $|P_4(Z)| \leq 1$. A similar bound applies to Q_4 , hence

$$|\xi| \leq \frac{4}{315} \left(\frac{9}{2} \right)^2 = \frac{9}{35}$$

Therefore the inclusion of ξ does not alter the fact that the correction will be quite small, on account of $A < 0.05$.

Comparative study of crystallization rates by d.s.c. and depolarization microscopy

C. F. Pratt and S. Y. Hobbs

General Electric Research and Development Center, P.O. Box 8, Schenectady, NY 12301, USA

(Received 17 June 1975; revised 20 September 1975)

Markedly slower crystallization half times for poly(butylene terephthalate) and poly(ethylene terephthalate) are found by d.s.c. than by depolarization microscopy although similar values are obtained for isotactic polypropylene. In both the microscopic and calorimetric experiments an Avrami analysis of data on each polymer gives $n \sim 3$ (predetermined nucleation, spherulitic growth), over the range of crystallization temperatures investigated. Possible reasons for the observed discrepancies are discussed.

INTRODUCTION

Measurements of isothermal crystallization rates by the depolarization of light in the hot stage microscope have been reported by several authors¹⁻⁵. In this method the light transmission through crossed polarizers, is monitored as a function of time with a photocell and chart recorder. Crystallization half-times can be interpolated directly from the I versus t profiles or, as suggested by Magill^{1,2}, from normalized light transmission/time plots of the form $(I_c - I_t)/(I_c - I_0)$ vs. $\log t$ where I_0 and I_c are initial and final intensities and I_t the intensity at time t . Rate constants can be calculated from the Avrami equation:

$$\theta = e^{-kt^n} \quad (1)$$

where θ is the fraction of untransformed material, k is a constant and n an integer depending on the type of nucleation and growth⁶⁻⁷. With $\theta = (I_c - I_t)/(I_c - I_0)$, n can be obtained directly from $\ln(-\ln\theta)$ vs. $\ln t$ plots.

In spite of the widespread use of this technique it is not obvious that the depolarized light/time traces should provide a correct measure of polymer crystallization rates or should give the proper Avrami exponent. Binsbergen has shown, for example, that only when it is assumed that the birefringent entities in the crystallizing aggregates increase in number and length with time, (probably a reasonable model for spherulite development), is there a linear relationship between the birefringence and volume of crystalline material⁸. Other analytical techniques may show a similar sensitivity to the details of the crystallization process. Godovsky has recently indicated that for some polymers calorimetry may give $n = 2$ while dilatometry gives $n = 3$ ⁹. In explanation he suggests that the first technique is more sensitive to the development of two-dimensional lamellae while the second reflects the formation of three-dimensional spherulites. Gilbert and Hybart have noted a similar but smaller difference in d.t.a. and dilatometric measurements of aliphatic polyester crystallization rates¹⁵. In general, however, when different analyses give similar Avrami exponents on a given system other kinetic parameters such as the crystallization half-times are found to be comparable.

Some recent studies of the crystallization kinetics of isotactic polypropylene, poly(butylene terephthalate) (PBT), and poly(ethylene terephthalate) (PET) by differen-

tial scanning calorimetry (d.s.c.) and depolarization microscopy, have been reported. Our calorimetric data on PBT are in quantitative agreement with those recently presented by Shultz and Stang¹⁰. The comparative results are noteworthy in that the two polyesters appear to exhibit similar Avrami kinetics but quite different crystallization half-times when examined by the two techniques. In contrast, similar $t_{1/2}$ values are obtained for polypropylene by the two methods.

EXPERIMENTAL

PBT samples were obtained from the GE Plastics Division (Pittsfield, Mass.) (Valox® 310 resin, $[\eta]$ at 25°C in hexafluoroisopropanol (HFIP) = 1.32 dl/g), PET from Cellomer Associates ($[\eta]_{\text{HFIP}}^{25^\circ\text{C}} = 0.67$ dl/g), and polypropylene from the GE Capacitor Department in Hudson Falls (Rexene PP41E3 resin). All calorimetry was carried out in a DSC-2 calorimeter and all microscopy in a Zeiss polarizing microscope equipped with a Mettler FP-2 hot stage. Light transmission between crossed polarizers was monitored as a function of time using a beam splitter and photocell whose output was channeled into a Hewlett-Packard $x-y$ recorder. Both instruments were calibrated over the temperature range 30°–300°C using the following standards: naphthalene, (80.24°C ± 0.05°C); adipic acid, (151.46°C ± 0.05°C); 2-chloroanthraquinone, (208.95°C ± 0.05°C); anthraquinone, (284.23°C ± 0.05°C). Equilibrium temperatures were determined by scanning the standards at increasingly slower rates and extrapolating to zero cooling rate. In the hot stage these values were checked using a copper-constantan thermocouple sandwiched between 9 mil glass cover slips. The values agreed within ±0.2°C.

All samples were melted for 2 min prior to crystallization; polypropylene at 210°C, PBT at 250°C, and PET at 290°C. No changes in the measured crystallization rates were observed on increasing the melting temperature or time and it is assumed that in all cases crystallization proceeded from the equilibrium melt. In both the calorimeter and the hot stage the samples were first cooled to an intermediate temperature* sufficiently high that no measurable crystallization took place, equilibrated for 1 min, and then dropped

* For polypropylene 140°C, PBT 210°C, and PET 240°C.

to the crystallization temperature. This procedure allowed any thermal stresses to be relieved and permitted more rapid equilibration at T_c . Indicator lights on the two pieces of apparatus were found to give an accurate measure of temperature stabilization. Other investigators employing the depolarization technique have used two furnaces, one at T_m and one at T_c and transferred the sample into the low temperature furnace to initiate crystallization. Our experiments with imbedded thermocouples have indicated that a fairly large but variable time may be required to reach thermal equilibrium using this technique (see Figure 1), giving rise to appreciable uncertainty in the determination of t_0 . By dropping the entire stage temperature with a cool nitrogen jet, t_0 could be accurately fixed although the maximum measurable crystallization rate was somewhat reduced.

The calorimetric data were reduced by setting $\theta = \Delta H_c^t / \Delta H_c^0$ where ΔH_c^t is the integral heat of crystallization at time

t and ΔH_c^0 the total measured heat of crystallization. The depolarization data were reduced as described by Magill. In both cases (see Figures 3 and 5) the times in the $\ln(-\ln\theta)$ vs. $\ln t$ plots include induction times. Slopes were determined graphically over the range $\theta = 0.2-0.8$ to avoid difficulties associated with unusual birefringence variations during the

Figure 4 Crystallization half times for polypropylene. \circ , D.s.c.; \square , hot stage

early, non-spherulitic stage of crystallization and truncation effects near the end of crystallization. Independent linear regression analyses of the data gave slopes within ± 0.05 of the graphical values.

RESULTS

Avrami plots obtained by d.s.c. and depolarization microscopy for polypropylene are shown in Figures 2 and 3 and the crystallization temperatures and the corresponding n values for each polymer are listed in Table 1. In the polypropylene samples crystallized in the hot stage above 127°C the diameters of the growing spherulites become comparable to the film thickness and two-dimensional growth ensues. This change is reflected as a shift from 3 to 2 in the slopes of the Avrami plots as shown in Figure 3. In all other cases the slopes of the isotherms remain approximately equal to 3.

The crystallization half times for the three polymers are presented in Figures 4–6. In the case of polypropylene the agreement is excellent between the two techniques over the range of crystallization temperatures investigated, whereas there is considerable disparity in the case of PBT and PET. (The log scale on the ordinate minimizes the displacement in the curves which is approximately a factor of 2.) Crystallization half times for PBT samples with different thermal and processing histories as measured by the two techniques are shown in Figure 6. (The key 450/70, etc. indicates the

melt and mould temperatures respectively in °F.) Again the $t_{1/2}$ values obtained from the depolarization experiments are approximately half of those measured by d.s.c. although the data appear to show some convergence at higher crystallization temperatures. In all cases the measured Avrami n values ranged from 2.8–3.0. It is noteworthy that there is a considerable increase in the crystallization rate of PBT resin which has been injection moulded although very little change in the viscosity average molecular weight is observed. Very likely the nucleation density is increased in these samples.

A comparison of our data with those obtained by dilatometry on Profax 6513E¹¹ polypropylene and by depolarization microscopy on Shell Carbona White polypropylene² is presented in Figure 7. The respective values for $t_{1/2}$ are conveniently replaced with the respective values for Avrami's k since $n = 3$ in all cases. The three sets of data show surprisingly good agreement for independent measurements on three different polymer samples using three analytical techniques.

DISCUSSION

At the present time we cannot offer a totally satisfactory explanation for the differences in the $t_{1/2}$ vs. T plots obtained for PBT and PET by calorimetric and depolarized light techniques. Repeated measurements showed that the differences are real and reproducible. Although it appears that the curves can be nearly superimposed by a shift along the temperature axis, repeated calibration of both instru-

ments with melting standards indicate that there is less than 0.5°C temperature error in the data points. Similarly there is no evidence that the differences can be attributed to differences in sample configuration or to heterogeneous nucleation on the glass cover slips. The observed spread in $t_{1/2}$ values was maintained when microtomed films of identical thickness were used in the hot stage and calorimeter. Similar half times were measured for unfilled- and glass-filled polyester resins in the calorimeter and no preferential nucleation could be observed on the glass cover slips in the optical microscope.

It has been suggested that the value of I_c obtained from the depolarized light intensity curves may be too low because of improper correction for scattering. This argument finds some support as there are other reports of anomalous maxima in some intensity time traces which may be attributed to competing depolarization and scattering effects. These peaks occur most commonly in samples which are excessively thick or which crystallize extremely rapidly. It is not considered that such effects lead to major errors in the present analyses. Data points were collected only from sigmoidal curves showing no decrease in intensity after reaching maximum height. The half-times normally fell in the steepest section of the traces requiring an unacceptably large 'error' in I_c to displace $t_{1/2}$ to the values obtained by calorimetry. Furthermore, it is unlikely that such competing effects could combine to give 'correct' integral Avrami exponents. Another common reported problem in these experiments is in the selection of τ , the induction time, as the slopes of the $\ln(-\ln\theta)$ vs. $\ln t$ plots are very sensitive to the value of τ . However, we would expect such errors to show up as fluctuations in the Avrami n well before deviations in $t_{1/2}$ are observed. Such variations were not observed. Furthermore inbedded thermocouples indicate that t_0 , the time at which equilibrium temperature is obtained, is accurate 3% or better even in the most rapidly crystallized samples.

Stein has found upon annealing quenched samples of PBT that considerable non-birefringent crystallization may occur which is detectable by low angle light scattering and density measurements but which is not detectable in the optical microscope¹². It is possible that the rate of primary spherulitic development is given accurately by the depolarization measurements while the calorimetric data more accurately reflects the overall rate of crystallization. The latter may include contributions from numerous small crystals which mirror the development of more well developed spherulites but do not contribute appreciably to increases in birefringence. In support of this argument we note that significant heat output is observed in the calorimeter, before the first signs of birefringence develop in the hot stage, especially at higher temperatures. It is also likely that secondary growth processes which proceed at a much lower rate than spherulite development make substantial contributions to the heat of crystallization but only small contributions to increased birefringence. This explanation is undoubtedly oversimplified in that several theoretical treatments have indicated that substantial secondary crystallization should introduce a large fractional component to the Avrami exponents^{13,14}. This result is partly attributable to the fact that such growth is proportional to the time a given volume element has resided in a growing spherulite. We hope that more extensive light scattering experiments, in which contributions from primary spherulite growth are separated from other types of crystallization, will help to explain the observed discrepancy in half-times.

A rapid technique for the qualitative analysis of polymers and additives using stop-and-go g.p.c. and i.r.*

Francis M. Mirabella Jr[§] and Edward M. Barrall II[†]

Institute of Materials Science and Department of Chemistry University of Connecticut, Storrs, Connecticut 06268, USA

and Julian F. Johnson[‡]

IBM Research Laboratory, San Jose, California 95193, USA

(Received 23 May 1975)

The use of gel permeation chromatography operated in a stop-and-go mode combined with an infra-red spectrometer detector permits rapid qualitative and quantitative analysis of additives in polymers. Additionally, the chemical composition of the polymer and its molecular weight and molecular weight distribution may be determined. The method does not require any preliminary separation steps.

INTRODUCTION

Polymers are often modified with various additives to improve their usefulness. Plasticizers, such as phthalate esters, phosphate esters, fatty acid esters and sulphonamides, are added to improve processability and flexibility of the compounded polymer. Antioxidants, such as phenols, aromatic amines, and condensation products of amines and aminophenols with aldehydes, ketones and thio compounds, are added to prevent or inhibit the oxidation of the polymer. Other additives include colorants, flame retardants and stabilizers. The analysis of polymeric materials routinely includes the qualitative and quantitative analysis for these additives.

The additives present in polymeric materials have been determined in various ways. One of the most common techniques is extraction followed by infra-red spectroscopic analysis¹. The extraction techniques, generally, involve the preparation of a thin film of the sample, e.g. by slicing in the microtome. The films are then extracted in a Soxhlet, Kumagawa or similar apparatus with a solvent that leaches out the monomeric additives present without dissolving, essentially, any of the polymeric material. The polymer and additives, thus separated, can then be analysed separately. Extractions are generally continued for 8–10 h and drying of the polymeric films is done overnight¹. Thus this method is not rapid. A more rapid technique involves the dissolution of the entire sample in a suitable solvent followed by the ultra-violet spectroscopic (u.v.) analysis of the solution². The u.v. spectrum is usually scanned from 200–400 nm and the additive identified and then quantified by direct calibration with the use of standard curves. The solvent and polymer must not absorb u.v. radiation in the region where the additive absorbs. This is a rapid

method but has the disadvantage that the identification of the additive is not readily determined from a u.v. spectrum alone. This would be further complicated if the polymer were unknown. Thus, the method is usually used with known polymers when only one of several additives are suspected as present. A similar u.v. technique has been described by Luongo³, using thin compression moulded films of the polymer. It is subjected to the difficulties mentioned for the solution technique, except there is no solvent which can interfere.

This paper describes a rapid technique for the determination of the chemical composition of the polymeric portion of the sample and the identification of the additives present. The technique can be extended to allow the molecular weight (*MW*) averages and molecular weight distribution (*MWD*) of the polymeric portion of the sample to be determined and to permit the quantification of the additives present, also. This method involves the dissolution of the entire sample in a suitable solvent, followed by the separation of the components on a gel permeation chromatograph. Then using the stop-and-go g.p.c./i.r. method, previously described⁴, the infrared (i.r.) spectrum of each component is scanned while the g.p.c. flow is stopped. This allows for the identification of the polymeric and additive portions of the sample.

EXPERIMENTAL

The experimental apparatus has been described in detail, previously⁴. It consisted of a simple gel permeation chromatograph with a 4.0 cm³ injection loop, stainless steel, 6.35 mm (0.25 in), 1 m columns, packed with Bioglas (Richmond, Cal. USA) glass beads and a Perkin-Elmer 21 infrared spectrometer as a detector. The i.r. detector was fitted with a refracting beam condenser, a 3 mm pathlength, 50 μ l flow-through cell and a 3 mm pathlength, adjustable reference cell.

Two columns sets were employed. Column set 1 consisted of three, 1 m, 6.35 mm (0.25 in) columns packed with 1000, 200 and 200 Å nominal exclusion limit glass beads respectively. Column set 2 consisted of five, 1 m, 6.35 mm

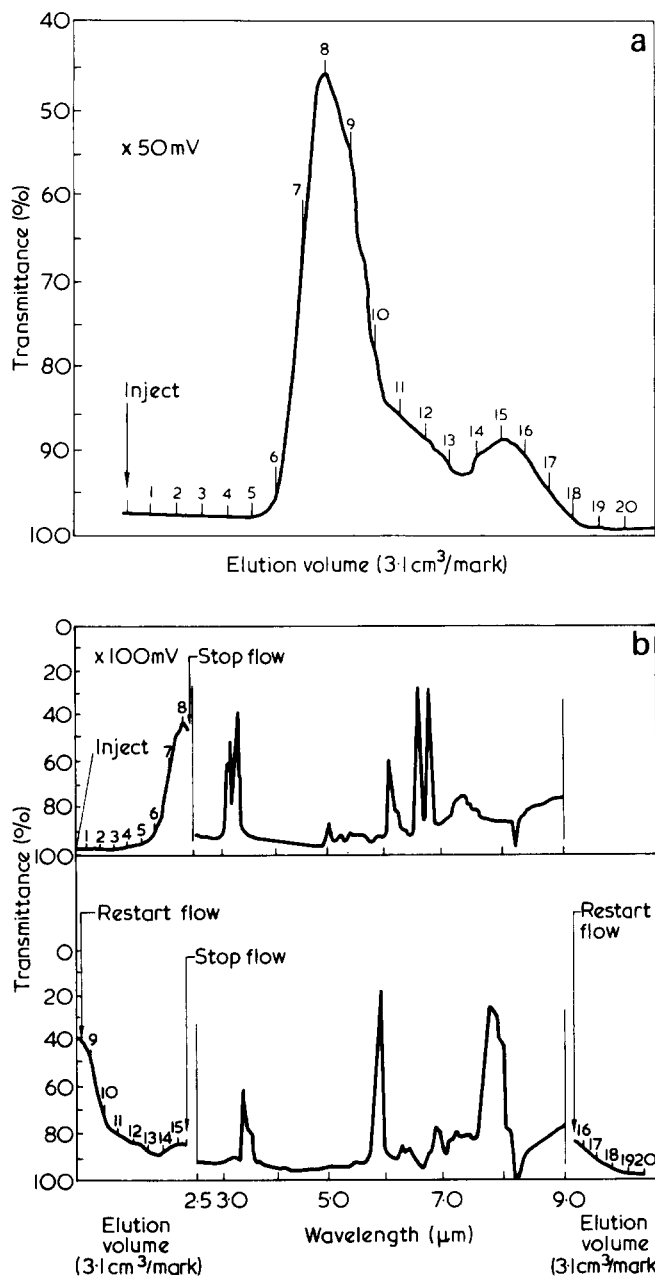

Figure 1 (a) G.p.c. of sample 1 (polystyrene and dibutyl phthalate) on column set 1; see text for details. (b) Stop-and-go g.p.c. of sample 1 on column set 1, showing the i.r. spectra of the polymeric portion and additive portion of the sample

(0.25 in) columns, packed with 1250, 370, 2000 and 1000 glass beads, respectively. Particle sizes of the glass beads used ranged from 50 to 400 mesh.

Column set 1 was used to demonstrate rapid qualitative analysis. Column set 2 was used to demonstrate the feasibility of higher resolution quantitative analysis.

Chromatograms and i.r. spectra were both recorded on a Varian A-25 recorder. Wavelength calibration of the i.r. spectra was performed manually, using the wavelength counter of the spectrometer as a reference.

The following polymer formulations were prepared to demonstrate the method of analysis. All formulations were made using a broad *MWD* polystyrene. Sample 1 contained 7.2% w/w dibutyl phthalate in polystyrene. Sample 2 contained 3.2% w/w didecyl phthalate in polystyrene. Sample 3 contained 1.0% w/w BHT, (2,6-di-*t*-butyl-4-methyl phenol), in polystyrene. Each sample was dissolved at a

concentration of 15 mg/cm³ (based on polymer) in tetrachloroethylene (Fisher Scientific Co., technical grade) which was freshly distilled prior to use. This same solvent was used as the g.p.c. solvent.

The solutions were syringed up through a Millipore filter to remove any insoluble materials. They were chromatographed at a flow rate of 0.8 ml/min and at room temperature. Since 4.0 ml of each solution were injected, the sample load was 60 mg of polymer.

RESULTS AND DISCUSSION

Figures 1a and 1b show, respectively, the g.p.c. of sample 1 (15 mg/cm³ in tetrachloroethylene of polystyrene containing 7.2% w/w dibutyl phthalate) and the stop-and-go g.p.c. of sample 1, showing the i.r. spectra of the polymeric portion and the additive portion of the sample. The g.p.c. were run on column set 1, as described above. The spectra were scanned from 2.50 μm (4000 cm⁻¹) to 9.00 μm (1111 cm⁻¹) since a continuous 'window' was obtained within these limits for tetrachloroethylene solvent. Figures 2a and 2b show standard spectra of polystyrene and dibutyl phthalate in tetrachloroethylene, respectively. Comparison of Figures 2a and 2b with Figure 1b indicates how this method permits the qualitative identification of both polymer and additive. Total analysis time was 1½ h for running one chromatogram and two i.r. spectra.

Figure 2 (a) I.r. spectrum of polystyrene, 1 mg/cm³ in tetrachloroethylene, 3 mm pathlength solution versus 3 mm pathlength tetrachloroethylene reference. (b) I.r. spectrum of dibutyl phthalate, 1 mg/cm³ in tetrachloroethylene, 3 mm pathlength solution versus 3 mm pathlength tetrachloroethylene reference

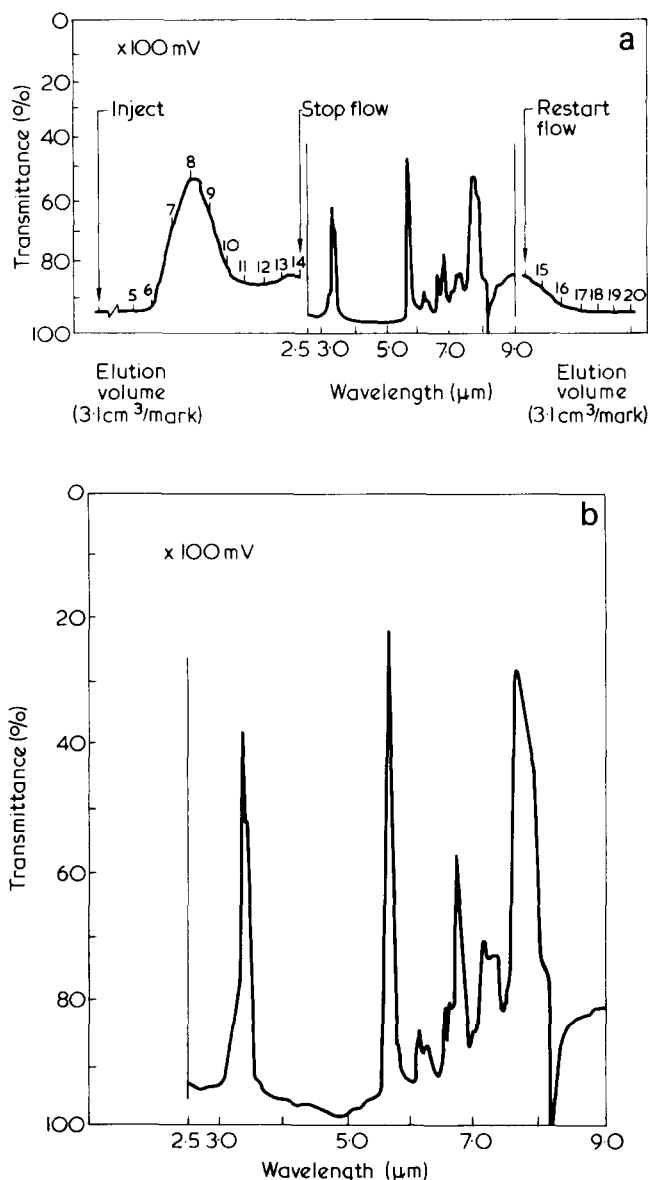

Figure 3 (a) Stop-and-go g.p.c. of sample 2 (polystyrene and didecyl phthalate) on column set 1, showing the i.r. spectrum of the additive peak; see text for details. (b) I.r. spectrum of didecyl phthalate, 1 mg/cm^3 in tetrachloroethylene, 3 mm pathlength solution versus 3 mm pathlength tetrachloroethylene reference

Analogous rapid analyses for samples 2 and 3 are shown in *Figures 3* and *4*, respectively. The i.r. scan of the polymer peak is not shown. *Figures 3a* and *3b* show the stop-and-go g.p.c. of sample 2 (15 mg/cm^3 in tetrachloroethylene of polystyrene containing 3.2% w/w didecyl phthalate) with the i.r. spectrum of the additive peak and a standard spectrum of didecyl phthalate in tetrachloroethylene, respectively. *Figures 4a* and *4b* show the stop-and-go g.p.c. of sample 3 (15 mg/cm^3 in tetrachloroethylene of polystyrene containing 1.0% w/w BHT) with the i.r. spectrum of the additive peak and a standard spectrum of BHT in tetrachloroethylene, respectively.

Comparison of the standard spectrum in each of *Figures 3b* and *4b* to the spectrum obtained for the additive peak in each case, again shows the application of this technique to qualitative analysis. The additional peaks observed in the i.r. spectrum of the additive peak in *Figure 4a* are due to polystyrene which was not resolved on the g.p.c. columns. However, the additive can be identified as BHT from the

other peaks, not interfered with by the residual polystyrene, especially the hydroxyl absorption at $\sim 2.70 \mu\text{m}$ (3700 cm^{-1}).

Polymer formulations which contain more than one polymer and/or additive could be analysed by this method with somewhat more difficulty in interpreting the i.r. spectra.

The method can be extended to the quantitative analysis of both polymeric and additive portions of the sample. This was demonstrated for sample 1 using column set 2, as described in the experimental sections. *Figure 5* shows a stop-and-go g.p.c. of sample 1, showing the i.r. spectrum of the additive peak. Under these higher resolution conditions the polymer peak was well resolved from the additive peak. Thus the *MW* averages and *MWD* of the polymeric portion of the sample could be determined in the usual way. The concentration of the additive could be determined by direct calibration with standard solutions of the additive chromatographed on the same system in order to obtain a

Relationship of temperature to composition of copolymers of α -methylstyrene and maleic anhydride

Raymond B. Seymour and David P. Garner

Department of Chemistry, University of Houston, Houston, Texas 77004, USA

(Received 19 August 1975; revised 16 September 1975)

Alternating copolymers of α -methylstyrene and maleic anhydride were prepared in good yields in a decalin solution at temperatures below 80°C. Random copolymers with large percentages of α -methylstyrene were obtained in good yields at higher temperatures. These results were in accord with the charge transfer complex which was characterized by n.m.r. and u.v. spectrophotometry and shown to exist below 80°C. The copolymers were characterized by pyrolysis/gas chromatography and differential scanning calorimetry. The glass transition temperature of poly(α -methylstyrene) and the random copolymer of this monomer and maleic anhydride were approximately 450 and 458 K respectively.

INTRODUCTION

Polymers of α -methylstyrene¹ and maleic anhydride² as well as alternating copolymers of these two monomers³ have been described. Likewise, the alternating copolymer of styrene and maleic anhydride was one of the first recognizable copolymers⁴. Both block copolymers and random copolymers of this system have also been described^{5,6}.

The formation of block copolymers is the result of the addition of excess styrene monomer to styrene-maleic anhydride macroradicals⁷. The formation of random copolymers has been attributed to the decomposition of the charge transfer complex at elevated temperatures⁸. It is assumed that this complex is formed when the electron-poor maleic anhydride accepts a charge from the electron-rich styrene⁹. Absorbance bands attributable to this complex and not characteristic of either monomer species have been observed in the u.v. spectra of a solution of these monomers¹⁰. The presence of this complex has also been demonstrated by n.m.r. techniques¹¹.

EXPERIMENTAL

Copolymers of α -methylstyrene and maleic anhydride were prepared from freshly distilled α -methylstyrene and maleic anhydride, which had been crystallized from benzene. Mixtures of these monomers as a 10% w/w solution in purified decalin were polymerized in oxygen-free sealed containers at specified temperatures. Azobisisobutyronitrile (AIBN) was used as the initiator.

The decalin was washed with concentrated sulphuric acid, washed with water, dried over sodium and freshly distilled. Yields of better than 90% w/w of alternating copolymers were obtained in the presence of 2.5% w/w AIBN. However, it was necessary to increase this concentration to 10% w/w in order to obtain comparable yields of random copolymers at higher temperatures.

U.v. absorbance data were obtained from 0.001 M solutions of the monomeric mixtures in decalin using a Carey Model 14 spectrophotometer. N.m.r. data were obtained from solvent free α -methylstyrene, 10% w/w solution of maleic anhydride in carbon tetrachloride, and 10% w/w

solution of the maleic anhydride/ α -methylstyrene complex in carbon tetrachloride using a Varian T-60 spectrophotometer. The d.s.c. data were obtained on a Perkin-Elmer Differential Scanning Calorimeter 1B.

Pyrolysis/g.c. data were obtained from small samples of copolymers which were thermally decomposed by a current of 8 A for 6 sec in a Varian Aerograph A-25 pyrolysis unit. Helium at a flow rate of 60ml/min was used as the carrier gas for the decomposition products in a Varian Aerograph A 100 C Gas Chromatograph.

RESULTS

Charge transfer complex of α -methylstyrene and maleic anhydride

Since α -methylstyrene is a better electron donor than styrene, it forms a stronger charge transfer complex with maleic anhydride as shown below:

As shown in *Figure 3*, the n.m.r. absorbance for maleic anhydride has shifted from 7.1 δ (*Figure 1*) to 5.9 δ in the mixture of this monomer and α -methylstyrene. The n.m.r. absorbance for the latter is shown in *Figure 2*.

Effect of temperature on the charge transfer complex

Since the effect of temperature on the charge transfer complex is not readily determined by n.m.r. techniques, u.v. spectrophotometry was used to investigate this effect. The change in the absorbance band at 291 nm in the u.v. spectrum was followed with the change in temperature. As shown in *Figure 4*, the intensity of this absorbance decreased as the temperature was increased. Extrapolation of these

Figure 1 N.m.r. spectrum of maleic anhydride

Figure 2 N.m.r. spectrum of α -methylstyrene

Figure 3 N.m.r. spectrum of an equimolar mixture of maleic anhydride and α -methylstyrene

Figure 4 Effect of temperature on absorbance of α -methylstyrene-maleic anhydride charge transfer complex at 291 nm

data showed zero absorbance at temperatures above 85°C. Since the formation of an alternating copolymer is dependent on the presence of a charge transfer complex, the composition of the copolymer is independent of compositions at temperatures below 85°C.

Copolymers of α -methylstyrene and maleic anhydride

As shown in Table 1, good yields of decalin insoluble alternating copolymers were obtained when 10% solution of equimolar ratios of α -methylstyrene and maleic anhydride in decalin were heated at temperatures below 80°C for 72 h in the presence of 2.5% AIBN. These compositions were determined by pyrolysis/gas chromatography. Typical pyrograms are shown in Figure 5.

As shown in Table 2, the composition of the copolymer was independent of the monomer ratio in the feed at temperatures below 80°C. However, random copolymers with large proportions of α -methylstyrene were obtained at 100°C

CHARACTERIZATION OF COPOLYMERS

The d.s.c. thermograms, shown in Figure 6, indicate that the copolymers prepared at 100°C were random copolymers while those prepared at temperatures less than 80°C (B) were alternating copolymers. Scan A for poly(α -methylstyrene) shows a glass transition temperature of approximately 450 K, which corresponds well with the previously obtained range of 446–453 K¹².

Table 1 Effect of temperature (60°–80°C) on composition of copolymers of α -methylstyrene (α -MS) and maleic anhydride (MA)

Temperature (°C)	Feed ratio (α -MS/MA)	Polymer composition (α -MS/MA)
60	1:1	1:1
70	1:1	1:1
80	1:1	1.1:1

Figure 5 Typical g.c. pyrograms of copolymers of α -methylstyrene and maleic anhydride. A, 1:1 ratio; B, 20:1 ratio of monomers

Table 2 Effect of temperature (60°–100°C) on composition of copolymers of α -methylstyrene (α -MS) and maleic anhydride (MA)

Temperature (°C)	Feed ratio (α -MS/MA)	Polymer composition (α -MS/MA)
60	5:1	1:1
70	5:1	1:1
80	5:1	1:1
100	10:3	7:2
100	50:3	20:1

No transition at $\sim 450\text{K}$ was observed for the alternating copolymer (B), which melted at about 480K . Scan C for the copolymer produced at 100°C resembles scan A. However, since α -methylstyrene does not form a homopolymer at temperatures above 61°C , and g.c. pyrograms showed the presence of two monomers in a 7:2 ratio, this scan is for a random copolymer.

Figure 6 D.s.c. thermograms of α -methylstyrene-maleic anhydride copolymers. A, poly(α -methylstyrene) $T_g = 450\text{K}$; B, alternating copolymer prepared at 70°C ; C, random copolymer (7:2) prepared at 100°C

A study of molecular orientation in drawn and shrunk poly(ethylene terephthalate) by means of birefringence, polarized fluorescence and X-ray diffraction measurements

J. H. Nobbs, D. I. Bower and I. M. Ward

Department of Physics, University of Leeds, Leeds LS2 9JT, UK

(Received 21 July 1975)

Amorphous tapes of poly(ethylene terephthalate) (PET) containing the fluorescent additive 4,4'-(dibenzoxazoly) stilbene, prepared by a method previously described, were drawn around a 'pin' at 80°C to draw ratios, λ , of 2.0, 2.5, 3.4, 3.5 and 4.2. Values of $\langle P_2(\cos\theta) \rangle$ were determined for samples from the tapes, either as-drawn or shrunk and crystallized in air under various conditions. $P_2(\cos\theta)$ is the second order Legendre polynomial, θ is the angle between a chain axis and the draw direction and the angle brackets denote an average value. Measurements of refractive index and of the intensity of X-ray scattering were used to derive $\langle P_2(\cos\theta) \rangle_{\text{opt}}$ and $\langle P_2(\cos\theta) \rangle_c$ which refer, respectively, to the whole polymer and to the crystalline regions only. By making certain assumptions, values of $\langle P_2(\cos\theta) \rangle_a$ for the amorphous regions only, were derived from measurements of the intensity of polarized fluorescence. The expected relationship between the three measures of orientation and the degree of crystallinity was verified, which justified the assumptions made in deriving $\langle P_2(\cos\theta) \rangle_a$. The PET samples appeared to behave as a rubber with 5.6 freely-jointed links between crosslink points when drawn and shrunk at 80°C for $\lambda < 2.5$. For higher λ , although the shrinkage was dramatically reduced, it was always associated with considerable disorientation of the amorphous regions, which suggests that this is the primary mechanism of shrinkage.

INTRODUCTION

In a previous paper¹ we have presented the theory of the polarized fluorescence method for studying molecular orientation in polymers, together with quantitative results for a series of uniaxially drawn amorphous tapes of poly(ethylene terephthalate) (PET), in which molecules of the fluorescent compound 4,4'-(dibenzoxazoly) stilbene were dispersed. This previous investigation was deliberately concerned with oriented polymers of low crystallinity, so that the effects of crystallization were minimized. By comparing the fluorescence results with measurements of optical birefringence it was shown that, although the fluorescent molecules were more highly oriented than the polymer segments, the two distributions of orientations maintained a constant relationship.

The most useful application of polarized fluorescence is, however, to study the distribution of orientations within the amorphous regions of a semi-crystalline polymer, if, as is believed, the large fluorescent probe molecules are too bulky to be accommodated in the crystal lattice of the polymer. In the present paper, we describe a study of similar PET tapes which were first drawn and then shrunk under various conditions, some of which induced crystallinity. The results confirm that the fluorescent probes are indeed located in the amorphous regions of the polymer and provide valuable information about the shrinkage and crystallization processes. In this investigation, fluorescence measurements, have been combined with X-ray diffraction and optical measurements which provide direct measures of the orientation of the crystalline regions and of the overall molecular orientation, respectively.

ORIENTATION AVERAGES

For transversely isotropic samples we define an orientation average $\langle P_2(\xi) \rangle$, the mean value of $P_2(\xi)$, where ξ is the cosine of the angle θ between the axis of a structural unit in the polymer and the draw direction and $P_2(\xi) = \frac{1}{2}(3\xi^2 - 1)$ is a second order Legendre polynomial.

The optical orientation averages, which are determined from measurements of refractive index and which we call $\langle P_2(\xi) \rangle_{\text{opt}}$, relate to the overall chain axis orientation to a good approximation. This has been confirmed directly by infra-red² and Raman³ spectroscopic studies, where it has been shown that there is an excellent correlation between the optical orientation averages and those obtained from intensity measurements on infra-red or Raman lines assigned to specific benzene ring vibrational modes.

It will be assumed that the semi-crystalline polymer can be regarded as a two-phase system consisting of a mixture of crystalline and amorphous phases. Although it has to be borne in mind that the state of order required to produce X-ray diffraction is not necessarily the same as that required to exclude a fluorescent molecule it will be assumed, as a first step, that it is the same. In the previous paper¹ a set of equations was developed which enables the determination, from suitable measurements of fluorescent intensities, of $\langle \cos^2\theta_M \rangle$ and $\langle \cos^4\theta_M \rangle$, the average values of $\cos^2\theta_M$ and $\cos^4\theta_M$, where θ_M is the angle between a unique axis M in a typical molecule of the fluorescent additive and the symmetry axis of the sample. As explained later, $\langle P_2(\xi_M) \rangle = \frac{1}{2}(3\langle \cos^2\theta_M \rangle - 1)$ can be used to estimate the value of $\langle P_2(\xi) \rangle_a$, where the subscript a signifies that the average extends only over the polymer chains in the amorphous

regions. A similar average, $\langle P_2(\xi) \rangle_c$, for the crystalline regions can be obtained from X-ray diffraction measurements, in a manner to be described.

If the assumptions made are correct the three orientation averages $\langle P_2(\xi) \rangle_{\text{opt}}$, $\langle P_2(\xi) \rangle_a$ and $\langle P_2(\xi) \rangle_c$ should be related by:

$$\langle P_2(\xi) \rangle_{\text{opt}} = f_c \langle P_2(\xi) \rangle_c + (1 - f_c) \langle P_2(\xi) \rangle_a \quad (1)$$

where f_c is the fraction of polymer in the crystalline phase. The accuracy with which the experimental values satisfy this equation is a measure of the adequacy of the underlying assumptions and of the accuracy of the three measures of orientation.

EXPERIMENTAL

Specimen preparation

Amorphous tapes of PET, approximately 1.5×10^{-3} m by 1.0×10^{-4} m in cross-section and containing the photo-stable compound 4,4'-(dibenzoxazoly) stilbene as the fluorescent additive, were prepared by the method described in the previous paper¹. Tapes containing the compound at a concentration of 50 or 200 ppm by wt, were subsequently oriented by drawing around a smooth stationary 'pin' to produce a series of tapes with draw ratios 2.0, 2.5, 3.4, 3.5 and 4.2. The 'pin' was heated to a temperature of $80 \pm 1^\circ\text{C}$ and was located between feed and wind-up rollers rotating at different rates.

In the first set of experiments, tapes with an initial draw ratio, λ , of 2.0 were shrunk in a controlled way at a temperature of 80°C to a series of final effective draw ratios in the range 2.0 to 1.0 by passing them through a hot-air oven held at 80°C and located between the feed and wind up rollers of the frame originally used to draw them. The oven was constructed from sections of expanded polyurethane foam and consisted of two regions. The tape was first led through a slit into a region fed with hot air at 80°C and then passed through a slot to a second region fed with air at 10°C . The air flow rate through both regions was 200 ft³/h. The temperature in the hot region was monitored by a thermocouple and was found to be within 1° of 80°C throughout the hot region. Each part of the tape took approximately 30 sec to travel through the hot region and a similar time to travel through the cold region.

For the second group of experiments, drawn tapes were placed in a conventional air oven and allowed to shrink free from constraints. The tapes were in the oven for various lengths of time within the range 5–1000 min, for a series of temperatures from 70° to 180°C .

Refractive index measurements

The refractive indices of the samples for light polarized with the electric vector parallel to the draw direction, n_z , or normal to this direction but parallel to the plane of the tape, n_x , were measured using an image-splitting interference microscope (Zeiss Zena Interphako) with accurately calibrated immersion liquids. All measurements were made at 551 nm. The results are shown in Tables 1–6.

$\langle P_2(\xi) \rangle_{\text{opt}}$ can be most simply obtained from the refractive index data using the relationship⁴:

$$\frac{\Delta\alpha}{3\alpha_0} \langle P_2(\xi) \rangle_{\text{opt}} = \frac{\phi_z^e - \phi_x^e}{\phi_z^e + 2\phi_x^e} \quad (2)$$

where $\phi_i^e = (n_i^2 - 1)/(n_i^2 + 2)$, $\Delta\alpha$ is the difference between the electronic polarizabilities of a polymer repeat unit parallel and perpendicular to the chain axis, and α_0 is the isotropic polarizability.

In the present work $\Delta\alpha/\alpha_0$ was estimated from measurements on a series of drawn amorphous samples. A plot of $(\phi_z^e - \phi_x^e)/(\phi_z^e + 2\phi_x^e)$ against $\langle P_2(\xi_M) \rangle$, measured by polarized fluorescence, was extrapolated to the point where $\langle P_2(\xi_M) \rangle = 1$. The corresponding value of $(\phi_z^e - \phi_x^e)/(\phi_z^e + 2\phi_x^e)$, 0.106 ± 0.005 , was taken as $\Delta\alpha/(3\alpha_0)$. The assumption here is that the axes of the fluorescent molecules are fully aligned only when the polymer segments are fully aligned. It is further assumed that the value of $\Delta\alpha/(3\alpha_0)$ is the same for polymer segments in the crystalline and amorphous phases.

As in previous studies^{1,2}, the assumption of transverse isotropy was checked by calculating the refractive index of isotropic amorphous PET, n_d^0 , from n_z and n_x using the relationship:

$$\frac{n_d^{02} - 1}{n_d^{02} + 2} = \frac{\rho_d^0}{3\rho} \left[\frac{n_z^2 - 1}{n_z^2 + 2} + \frac{2(n_x^2 - 1)}{n_x^2 + 2} \right] \quad (3)$$

where ρ is the density of the sample and ρ_d^0 is the density of an isotropic amorphous sample. The values of n_d^0 obtained are shown in Tables 1–6 and are essentially constant.

Fluorescence measurements

The fluorescence experiment consists of measuring the intensity and polarization of light emitted by the sample when the fluorescence is excited by linearly polarized light. The same theory, apparatus and method of analysis of the intensity measurements were used in this study as are described in a previous paper¹ and reference should be made there for further details.

In the previous investigation it was concluded that there was a unique relationship between the birefringence of the sample and $\langle \cos^2\theta_M \rangle$ for PET samples of low crystallinity containing the same fluorescent additive as used in the present work. In Figure 1, $\langle P_2(\xi_M) \rangle$ is plotted against $\langle P_2(\xi) \rangle_{\text{opt}}$. Note that $\langle P_2(\xi_M) \rangle$ and $\langle P_2(\xi) \rangle_{\text{opt}}$ take the value unity simultaneously as a result of the method used to derive $\langle P_2(\xi) \rangle_{\text{opt}}$. In this paper it will be assumed that the relationship between the distribution of orientations of the fluorescent molecules and the polymer chains in the amorphous regions of semi-crystalline PET is the same as that in completely amorphous PET. This assumption will be adopted as a working hypothesis, to be justified by detailed comparison of measurements of orientation obtained from optical, fluorescence and X-ray diffraction measurements. With this assumption Figure 1 can be used to obtain a value of $\langle P_2(\xi) \rangle_o$ from the measured value of $\langle P_2(\xi_M) \rangle$. For example, a value of $\langle P_2(\xi_M) \rangle$ of 0.25 corresponds to a value of 0.119 for $\langle P_2(\xi) \rangle_o$.

X-ray diffraction measurements

The distribution of orientations of a particular crystal-plane normal for the crystallites in a semi-crystalline polymer can be determined from X-ray diffraction measurements⁵. Figure 2 illustrates schematically the experimental arrangement used, in which the X-ray source, S, the detector, D, and the centre of the sample, O, all lie in the same horizontal plane. \angle TOD formed by the transmitted beam, OT, and the line OD from the centre of the sample to the detector we call 2β . The angle between the bisector of

Figure 1 $\langle P_2(\xi_M) \rangle$ compared with $\langle P_2(\xi) \rangle_{opt}$ for samples of low crystallinity. Δ , Samples from previous work¹ drawn at 80°C to various draw ratios; \blacktriangle , samples from previous work¹ drawn to draw ratio 2.66 at various temperatures between 65 and 90°C; \circ , samples from present work drawn at 80°C to various draw ratios; \bullet , samples from present work drawn and shrunk at 80°C

\angle SOD and the draw direction of the sample, Oz, is called χ . Oz lies in the horizontal plane.

To determine the distribution of orientations of a particular plane normal, the value of 2β is fixed so that the detector is at the peak of the diffraction profile for that plane. The intensity of the diffracted beam, $I(\chi)$, is measured as χ is varied by rotating the sample about a vertical axis. $I_0(\chi)$ is derived from the measured intensity $I(\chi)$ by subtracting the background intensity (noise and amorphous scattering) and correcting for any variation with χ of the volume of sample illuminated with X-rays or of the absorption by the sample due to changes in its orientation with respect to the incident and diffracted beams.

This procedure involves the assumption that the peak intensity, $I_0(\chi)$, is directly proportional to the amount of crystalline material having the particular plane normal in the direction χ . This is justified if the peak intensity is proportional to the total intensity integrated over a range of values of 2β around the peak.

The orientation averages are calculated from the observed intensity function by means of the equation:

$$\langle P_n(\cos\chi) \rangle = \frac{\int_0^\pi I_0(\chi) P_n(\cos\chi) \sin\chi d\chi}{\int_0^\pi I_0(\chi) \sin\chi d\chi} \quad (4)$$

The unit cell of PET is triclinic with the direction of the molecular chain axis parallel to the crystallographic c -axis. Unfortunately there are no planes whose normals are parallel to the c -axis and which strongly diffract the X-ray beam. The diffraction from the $(\bar{1}05)$ plane was therefore used and the results were corrected to allow for the angle

$\delta (= 9^\circ 46')$ between the $(\bar{1}05)$ plane normal and the c -axis.

We require to obtain the orientation averages $\langle P_2(\xi) \rangle_c$ and $\langle P_4(\xi) \rangle_c$ which characterize the orientation of the crystallographic c -axes in the specimens. If we assume that there is no preferential alignment of the a and b crystallographic axes about the c -axis, the Legendre addition theorem gives:

$$\langle P_2(\cos\chi) \rangle = \langle P_2(\xi) \rangle_c \langle P_2(\cos\delta) \rangle \quad (5)$$

$$\langle P_4(\cos\chi) \rangle = \langle P_4(\xi) \rangle_c \langle P_4(\cos\delta) \rangle \quad (6)$$

X-ray samples were prepared from the tapes by first cutting across each tape at right angles to the initial draw direction and then glueing the two halves together to form a tape twice as thick. This composite tape was then cut in two and the halves glued together to form a four-layer tape. This process was repeated until a stack of tape 32 layers high was formed. The stack was then trimmed to form a 3 mm long rod with a square cross-section of side 1.5 mm in such a way that the initial draw direction was parallel to one of these short sides. A poly(vinyl alcohol) adhesive was used since it was found to give a strong bond, produced very little background scatter and no discrete X-ray diffraction peaks. Microscopic examination of samples produced in this way showed that the draw directions of the tapes within the stack were parallel to each other to within one degree.

The sample was mounted on the goniometer stage of a Siemens K4 recording X-ray diffractometer and aligned so that the centre of the sample was at the centre of rotation of the diffractometer stage and the draw direction of the sample was in the horizontal plane (see Figure 2.) The $\text{CuK}\alpha$ radiation passed through a nickel filter and a slit system so that an X-ray beam that almost fully illuminated the sample yet diverged less than $15'$ from parallel was formed. The effective solid angle sampled by the diffractometer was ellipsoidal in shape. It was estimated from the diffractometer dimensions that the detector sampled plane normals within approximately $\pm 1/2^\circ$ of χ in the horizontal plane and $\pm 1 1/2^\circ$ in the vertical plane. This was not corrected for, since the ranges of angles involved are far smaller than the smallest half-width of the intensity *versus* χ plots. The corrected values of $\langle P_n(\xi) \rangle_c$ would be slightly greater than the uncorrected values. The diffracted beam was detected by a scintillation counter and the signal passed through a pulse-height selector to eliminate background pulses before being recorded by a chart recorder.

Daubeny *et al.*⁶ have given the lattice parameters of the PET crystal as $A = 4.56\text{\AA}$, $b = 5.94\text{\AA}$, $c = 10.75\text{\AA}$, $\alpha = 98^\circ 30'$, $\beta = 118^\circ$ and $\gamma = 112^\circ$. These values, together with a value of 1.5416\AA for the wavelength of the radiation, give

Figure 2 Schematic diagram of arrangements for X-ray diffraction measurements. S, source; D, detector; O, centre of sample; Oz draw direction in sample

Figure 3 Diffracted X-ray intensity as a function of 2β in the region of the $(\bar{1}05)$ plane diffraction for sample 3f

$2\beta = 42.8^\circ$ for the $(\bar{1}05)$ plane diffraction. For our samples 2β was found to lie between 42.9 and 43.6° .

When the diffraction peak was recorded the detector was rotated at twice the rate of rotation of the sample, in the usual way, so that the same set of crystal planes was potentially able to give rise to Bragg 'reflection'. The intensities observed for the angular range $2\beta = 37^\circ$ to 49° for $\chi = 0^\circ$ and $\chi = 90^\circ$ are shown in Figure 3 for sample 3f. The amorphous background intensity was determined for each sample from the distribution of diffracted intensity as a function of 2β for $\chi = 90^\circ$ by drawing a straight line through it in the regions well away from the diffraction peak. The height of this line at the diffraction peak was taken as the background intensity and the ratio of this height to that at $2\beta = 37.5^\circ$ was called C . The background intensity at the diffraction peak for any other value of χ was found by multiplying the observed background at $2\beta = 37.5^\circ$ by C . Figure 4 shows the observed intensities as a function of χ for $2\beta = 43.3^\circ$ and 37.5° for sample 3f. For this sample $C = 1.11$.

The values of $\langle P_n(\xi) \rangle_c$ were obtained from equations (4), (5) and (6) by performing the integration by Simpson's method. A total of 27 points was used in the range 0° to 90° ; the range 0° to 20° was divided into 10 intervals, 20° to 60° into 10 intervals and 60° to 90° into 6 intervals. The corresponding range from 0° to -90° was similarly divided.

In order to determine whether the peak intensity $I_0(\chi)$ was proportional to the intensity integrated over a range of values of 2β around the peak, the diffraction peak from sample 3f was recorded for several values of χ . For each peak the corrected intensity $I_0(\chi)$ was integrated from $2\beta = 41.5$ to $2\beta = 45.5^\circ$ and the integral was plotted against the corrected intensity of the diffraction peak. A least squares fitted straight line gave a correlation factor of 0.995, confirming the proportionality.

No correction was made for the change with χ of the effective volume or absorption of the sample. The rod-shaped samples were almost completely illuminated with

radiation and the correction was expected to be small. The background-corrected intensity from a highly crystalline sample with randomly oriented crystallites was found to be independent of χ , which further justifies the neglect of the correction.

Determination of crystallinity

A comparison of X-ray, infra-red and density measurements of crystallinity by Farrow and Ward⁷ showed poor agreement between the crystallinity as measured by density and the crystallinity measured by X-rays for drawn yarns of PET. They concluded that for drawn oriented yarns it is not permissible to regard the non-crystalline material as having a constant density and suggested that the density of these regions increases as the orientation of the chains increases. We have made an estimate, using a simple model (see Appendix), of the way in which the density, ρ_a , of the amorphous material should vary with orientation of the amorphous regions, and the curve in Figure 5 shows the estimated variation. f_c , the fraction of polymer in the crystalline regions, is given by $f_c = f_v \rho_c / \rho$, where f_v is the volume fraction that is crystalline and ρ_c is the density of

Figure 4 Diffracted X-ray intensity as a function of the orientation of the draw direction for sample 3f. A, $2\beta = 43.3^\circ$; B, $2\beta = 37.5^\circ$

Figure 5 The curve shows the estimated relationship between density and $\langle P_2(\xi) \rangle_a$ for amorphous PET. The points show the relationship for samples of low crystallinity. Δ , Samples from previous work¹ drawn at 80°C to various draw ratios; \blacktriangle , samples from previous work¹ drawn to draw ratio 2.66 at various temperatures between 65 and 90°C ; \circ , samples from present work drawn at 80°C to various draw ratios; \bullet , samples from present work drawn and shrunk at 80°C

Figure 6 $\langle P_2(\xi) \rangle_a$ plotted against final effective draw ratio for samples drawn at 80°C to draw ratio 2.0 and then shrunk at 80°C to controlled final effective draw ratios. The curve represents a smooth line through points (not shown) for all samples from the previous¹ and present work which were drawn at 80°C but not subsequently shrunk

the crystalline fraction. Now

$$f_v = (\rho - \rho_a)/(\rho_c - \rho_a)$$

Hence, using the known crystalline and estimated amorphous densities, f_c may be obtained from:

$$f_c = (\rho_c/\rho)(\rho - \rho_a)/(\rho_c - \rho_a) \quad (7)$$

This method of obtaining the crystallinity involves assuming that there is a unique relationship between the density of the amorphous regions and their orientation, which may not be quite correct. We have, however, only used the calculated crystallinities in verifying equation (1) for samples for which either the crystallinity or the amorphous orientation was low and any errors in the estimated crystallinity values should be small for such samples.

RESULTS

Tables 1–6 contain the complete list of results for all the samples, including details of the mechanical and heat treatment and the sample density, crystallinity, refractive index, $\langle P_2(\xi) \rangle_{\text{opt}}$, $\langle P_2(\xi) \rangle_a$ and $\langle P_2(\xi) \rangle_c$. The calculated values of the isotropic refractive index, n_a^0 , are also shown. The values of n_a^0 were the same within experimental error for all samples, which confirmed that the samples were uniaxial and that the assumptions used in deriving equation (2) were probably justified. Several samples were also checked by means of wide-angle X-ray photographs, which confirmed that the crystallite distribution was uniaxial for these samples.

For sample 4e, $\langle P_2(\xi) \rangle_c$ was determined for three different X-ray specimens made from different parts of the same tape and the results were the same to within 0.012. Samples 3u and 3i underwent the same mechanical and heat treatments but contained 200 ppm and 50 ppm by wt of the fluorescent molecules respectively; the results were the same to within experimental error. The concentration used was 200 ppm for all samples except 3a–3g and 3i, for which it was 50 ppm.

For seventeen out of the twenty-six samples 3a to 3u and 4a to 4e the values of the three averages $\langle P_2(\xi) \rangle_{\text{opt}}$, $\langle P_2(\xi) \rangle_a$ and $\langle P_2(\xi) \rangle_c$ were determined. These values do not generally satisfy equation (1). If we temporarily denote the experimental values by a superscript m , then in general,

$$\langle P_2(\xi) \rangle_{\text{opt}}^m \neq f_c^m \langle P_2(\xi) \rangle_c^m + (1 - f_c^m) \langle P_2(\xi) \rangle_a^m$$

There is no simple way of deciding which of the measured quantities are in error and lead to the inequality. We can, however, calculate a set of values $\langle P_2(\xi) \rangle_a$, $\langle P_2(\xi) \rangle_c$, $\langle P_2(\xi) \rangle_{\text{opt}}$ and f_c which satisfy equation (1) exactly and at the same time minimize the sum

$$S = (E_a/D_a)^2 + (E_c/D_c)^2 + (E_t/D_t)^2 + (E'_c/D'_c)^2 \quad (8)$$

where the E 's are defined as:

$$E_a = \langle P_2(\xi) \rangle_a - \langle P_2(\xi) \rangle_a^m$$

$$E_c = \langle P_2(\xi) \rangle_c - \langle P_2(\xi) \rangle_c^m$$

$$E_t = \langle P_2(\xi) \rangle_{\text{opt}} - \langle P_2(\xi) \rangle_{\text{opt}}^m$$

$$E'_c = f_c - f_c^m$$

and the D 's are estimates of the standard deviation of the corresponding measured values. The degree of agreement between this calculated set of values and the corresponding experimental ones may be taken as a measure of the reasonableness of the assumptions made in deriving the experimental values.

In this investigation the values of $\langle P_2(\xi) \rangle_a^m$, $\langle P_2(\xi) \rangle_c^m$, $\langle P_2(\xi) \rangle_{\text{opt}}^m$ and f_c^m were calculated as described above and the standard deviation of all these values was arbitrarily assumed to be the same. The sum S in equation (8) was minimized by computer and the corresponding best fit values of $\langle P_2(\xi) \rangle_{\text{opt}}$, $\langle P_2(\xi) \rangle_a$, $\langle P_2(\xi) \rangle_c$ and f_c were derived and they are shown below the corresponding measured values in Tables 1, 4, 5 and 6.

DISCUSSION

Rubber-like behaviour for low initial draw ratio

Figure 6 is a plot of $\langle P_2(\xi) \rangle_a$ against the final draw ratio for essentially non-crystalline samples ($f_c < 0.03$). The curve is derived from the results given in Tables 2 and 6 of our previous paper¹ for samples which were simply drawn at 80°C. The values of $\langle \cos^2 \theta_M \rangle$ in these Tables have been converted to $\langle P_2(\xi_M) \rangle$ and then to $\langle P_2(\xi) \rangle_a$ by means of the curve in Figure 1. The curve in Figure 6 is a smooth curve drawn through these values and the points shown are the results for samples 1a to 1g (Tables 1 and 2), which lie on the curve within experimental error. These samples were drawn at 80°C to a draw ratio of 2.0 and subsequently shrunk to various predetermined final effective draw ratios. The reversibility of the deformation and the dependence of the distribution of orientations only on the final effective draw ratio suggests that the PET tape is behaving as a rubber for uniaxial deformations at 80°C up to at least a draw ratio of 2.0.

Using the inverse Langevin approximation to the rubber model, Roe and Krigbaum⁸ have derived the following

Table 1 As-drawn samples

Figure 7 B plotted against $\lambda^2 - 1/\lambda$ for samples drawn and shrunk at 80°C . Linear region for rubber model

relationship between $\langle P_2(\xi) \rangle$ and draw ratio:

$$\langle P_2(\xi) \rangle = \frac{1}{5N} \left(\lambda^2 - \frac{1}{\lambda} \right) + \frac{36}{875N^2} \left(\lambda^4 + \frac{\lambda}{3} - \frac{4}{3\lambda^2} \right) + \frac{108}{6125N^3} \left(\lambda^6 + \frac{3\lambda^3}{5} - \frac{8}{5\lambda^3} \right) + \dots \quad (10)$$

where N is the number of freely jointed links between crosslink points. This equation can be simplified by setting:

$$B = (1/N) \left(\lambda^2 - \frac{1}{\lambda} \right) \quad (11)$$

to obtain the following approximation to equation (10):

$$\langle P_2(\xi) \rangle = \frac{1}{5} B + \frac{36}{875} B^2 + \frac{108}{6125} B^3 + \dots \quad (12)$$

Figure 8 B plotted against $\lambda^2 - 1/\lambda$ for samples drawn at 80°C . \circ , Samples drawn but not shrunk, present and previous work¹; \bullet , samples drawn to draw ratio 2.0 and shrunk at 80°C

Equation (12) gives $\langle P_2(\xi) \rangle$ within 1% of the value given by equation (10) for $\lambda < 3$ and $N = 6$, which is close to the value of N found in the present work.

By plotting a graph of $\langle P_2(\xi) \rangle$ against B , a value of B can be read off for each experimental value of $\langle P_2(\xi) \rangle_a$. The rubber model predicts that a plot of B against $(\lambda^2 - 1/\lambda)$ should be a straight line of gradient $1/N$. Figure 7 is a plot of B against $(\lambda^2 - 1/\lambda)$ for samples 1a to 1g. The plot is a straight line of slope $1/5.6$, which corresponds to a rubber network with 5.6 freely jointed links between crosslink points. Figure 8 is a plot of B against $(\lambda^2 - 1/\lambda)$ for all samples from the present and previous¹ work that were drawn at 80°C and were subsequently not shrunk or were shrunk at 80°C . Initially the plot is linear, with a gradient of $1/5.6$. However, for values of $(\lambda^2 - 1/\lambda)$ greater than 6, the results deviate from the straight line. This value of $(\lambda^2 - 1/\lambda)$ corresponds to a draw ratio of 2.53, which is in the region of maximum extension for a rubber network with $N = 5.6$, since the maximum draw ratio of a rubber network with N freely jointed links between crosslink points

is approximately equal to $(N)^{1/2}$. The value of 5.6 compares well with the value of 5.3 deduced by suitably averaging values previously reported from stress-optical data⁹ on higher and lower molecular weight polymer and with the value 4.8 previously obtained by means of infra-red measurements². If the previous data are re-evaluated using equations (11) and (12) above, values of 6.2 and 5.7 are obtained from the stress-optical and infra-red measurements, respectively.

The density measurements showed that samples 1a to 1h had very low crystallinity. When freely shrunk in an air oven at higher temperatures, specimens 1i to 1k (Table 3) returned to their original length. The final crystallinities were, however, no longer low. Sample 1k was shrunk at the highest temperature and had a crystallinity of 0.45 after ten minutes in the air oven held at 180 $^{\circ}\text{C}$.

The tapes 2b to 2c (Table 3) were drawn to an initial draw ratio of 2.5, which is very close to the maximum rubber-like extension ratio of 2.4 calculated on the basis of 5.6 freely jointed links between crosslink points. These tapes shrank back to very nearly their original length when placed in the hot air oven for 10 min, and generally behaved in a similar way to the tapes with an initial draw ratio of 2.0.

Shrinkage of samples with higher initial draw ratio

The third series of tapes, 3a to 3u were drawn to an initial draw ratio of 3.4₄ (3a to 3i) or 3.5 (3j to 3u). This was well beyond the extension limit of the equivalent rub-

ber network. These tapes were studied in greater detail and refractive index, density, polarized fluorescence and X-ray diffraction measurements were made.

Samples 3b to 3i (Table 4) were freely shrunk in an oven for 10 min at 8 different temperatures in the range 70 $^{\circ}$ to 180 $^{\circ}\text{C}$. The as-drawn sample, sample 3a, had a crystallinity of 0.06, and consequently the crystalline orientation $\langle P_2(\xi) \rangle_c$ had a large uncertainty arising from the low diffracted X-ray intensity for this sample. The percentage shrinkage, the crystallinity, $\langle P_2(\xi) \rangle_{\text{opt}}$, $\langle P_2(\xi) \rangle_a$ and $\langle P_2(\xi) \rangle_c$ are plotted against oven temperature in Figure 9. As the temperature of the oven was increased, the amount by which the samples shrank increased. This was accompanied by a decreasing amorphous orientation and increasing crystallinity and crystalline orientation. The overall average orientation initially decreased in step with the amorphous orientation, then increased as the fraction of the more highly oriented crystalline material increased.

Samples 3k to 3o (Table 5) were all freely shrunk at 80 $^{\circ}\text{C}$ for various times in the range 5 to 1000 min. The results are plotted against time in Figure 10. The shrinkage initially increases with the length of time the sample spends in the oven until a plateau is reached after 20 min oven time. Each sample which spent longer than 20 min in the oven had a similar value of crystallinity, shrinkage, $\langle P_2(\xi) \rangle_{\text{opt}}$, $\langle P_2(\xi) \rangle_a$ and $\langle P_2(\xi) \rangle_c$. Results for samples 3p to 3t (Table 5) are shown in Figure 11. They were freely shrunk at 120 $^{\circ}\text{C}$ in the oven for the same range of times as samples 3k to 3o and they behaved in a similar way to that

set except that the plateau was reached more quickly, after about 8 min, and the final shrinkage was greater than for the corresponding sample shrunk at 80°C.

The final series of samples had an initial draw ratio of 4.2. The four samples 4b to 4e were freely shrunk for 10 min in the air oven at temperatures in the range 80° to 180°C. The behaviour of this series was similar to that of the corresponding series drawn to an initial draw ratio of 3.44.

The behaviour of the two series of tapes initially drawn to draw ratios of 3.44 (or 3.5) and 4.2 were very different from those initially drawn to draw ratios of 2.0 and 2.5. At 80°C the latter two series shrank back to their original length, whereas the former two series shrank by less than 25% at this temperature. The significant fall in shrinkage is attributed to the increased crystallinity of the more highly drawn tapes, even though the level of crystallinity is still very low (<10%).

Figure 11 $\langle P_2(\xi) \rangle_c$ (Δ , \blacktriangle), $\langle P_2(\xi) \rangle_{\text{opt}}$ (\circ , \bullet), $\langle P_2(\xi) \rangle_a$ (\square , \blacksquare), f_c and shrinkage plotted against time in oven for samples 3p to 3t, which were initially drawn to $\lambda = 3.5$ and subsequently shrunk freely in an air oven at 120°C for various times. Solid points denote experimental data; open points denote best fit to equation (1)

Intercomparison of shrinkage with amorphous, crystalline and overall orientation

For seventeen out of the twenty-six samples 3a to 3u and 4a to 4e the value of $\langle P_2(\xi) \rangle_c$ was measured, enabling a second set of values of $\langle P_2(\xi) \rangle_a$, $\langle P_2(\xi) \rangle_c$, $\langle P_2(\xi) \rangle_{\text{opt}}$ and f_c to be calculated for a best fit to equation (1). These best fit values are displayed below the corresponding measured values in Tables 1, 4, 5 and 6 and are plotted as open points in Figures 9, 10 and 11.

Comparison of the experimental and best fit results throughout the series reveals a systematic error. This can be interpreted as a systematic error in one or a number of the experimental results and such an error is not surprising considering the number of assumptions involved in deriving each of the four quantities from the data. Taking this into account, the agreement between the experimental and best fit values is reasonable. This result supports the hypothesis that the fluorescent molecules are excluded from the crystalline regions and that the relationship between the distribution of orientations of the fluorescent molecules and

that of the polymer chains in the amorphous regions of the crystalline polymer is the same as in the completely amorphous polymer. We are therefore justified in interpreting $\langle P_2(\xi) \rangle_a$, determined from measurements of the fluorescence intensities in the way described, as the value of $\langle P_2(\xi) \rangle$ for the amorphous regions of the polymer.

Figures 9, 10 and 11 show both the shrinkage and the crystallinity of the samples. The results in Figure 9 for samples originally drawn to draw ratio 3.4 are the most revealing because they show a separation between the shrinkage and crystallization processes. For this series of samples the shrinkage increases very markedly, from zero to 15%, as the temperature of the oven rises from 60° to 90°C and then increases less rapidly with temperature. The crystallinity, on the other hand, shows a more gradual increase over the whole range of oven temperatures from 60° to 180°C. It is notable that $\langle P_2(\xi) \rangle_{\text{opt}}$ shows a clear minimum for oven temperatures near 80°C. We can conclude from this that shrinkage is associated with a decrease in overall molecular orientation, whilst for these samples crystallization produces an increase in molecular orientation and that this is the major effect above 100°C. These results and those for the samples of lower draw ratio shrunk at 80°C, which do not crystallize, show that there can be no doubt that at the lower temperatures shrinkage is primarily due to the disorientation of the amorphous regions, as was concluded from a much earlier study of the dichroism of dyestuffs incorporated in PET¹⁰. It has been proposed¹¹⁻¹³, notably by Statton *et al.*¹³, that shrinkage should be attributed primarily to the refolding of chains which have been pulled out in the drawing process. The present results for shrinkage at 80°C, however, support the dichroism studies^{10,14} and the view of Wilson¹⁵ that the shrinkage of PET is essentially associated with the disorientation of the amorphous regions and that crystallization occurs at a later stage. The observed rise in orientation of the crystalline regions can be explained either by Wilson's suggestion that the molecules in the amorphous regions preferentially crystallize onto pre-existing more highly oriented crystallites or by the assumption that shrinkage forces in the amorphous regions cause re-orientation of the crystallites. Both of these processes may occur.

At higher temperatures the separation between the shrinkage and crystallization processes is not so clear cut. Figure 11 indeed suggests that the rates of these processes are roughly comparable at 120°C, although our results cannot rule out a very fast component of shrinkage taking place in times of the order of a few minutes, or even less, as found by Wilson. Although it may well be that the driving force for shrinkage is still molecular disorientation rather than chain folding, these two processes seem to be occurring simultaneously in the samples for which the results are shown in Figures 10 and 11.

Figure 12 $\langle P_4(\xi) \rangle$ plotted against $\langle P_2(\xi) \rangle$. \circ , $\langle P_4(\xi_M) \rangle$ plotted against $\langle P_2(\xi_M) \rangle$ for all the samples of low crystallinity from the present and previous¹ work, including those drawn to draw ratio 2.0 and shrunk at 80°C; \bullet , X-ray data for $\langle P_4(\xi)_c \rangle$ against $\langle P_2(\xi)_c \rangle$; \blacksquare , fluorescence data for $\langle P_4(\xi_M) \rangle$ against $\langle P_2(\xi_M) \rangle$ for the shrunk samples 3b to 3i and 3l, 3n, 3q, 3s, 3u and 4e. —, —, —, mathematical upper and lower bounds on the value of $\langle P_4(\xi) \rangle$ for any value of $\langle P_2(\xi) \rangle$; —, relationship predicted by the pseudo-affine deformation scheme¹⁶.

Fourth-order orientation averages

The fluorescence method can provide¹ values of $\langle P_4(\xi_M) \rangle = 1/8(35\langle \cos^4\theta_M \rangle - 30\langle \cos^2\theta_M \rangle + 3)$ as well as values of $\langle P_2(\xi_M) \rangle$, and the X-ray method can give similar and higher-order orientation averages for the crystallites, as already explained.

Figure 12 shows, as open circles, the values of $\langle P_4(\xi_M) \rangle$ plotted against the corresponding values of $\langle P_2(\xi_M) \rangle$ for all the samples of low crystallinity from the present and previous¹ work, including those drawn to draw ratio 2.0 and shrunk at 80°C. The continuous line, which they lie close to, is the relationship between $\langle P_4(\xi) \rangle$ and $\langle P_2(\xi) \rangle$ predicted according to the pseudo-affine deformation scheme¹⁶ for the preferential orientation of a set of unique axes. As previously suggested¹, the agreement between the points and this line may be fortuitous. Also shown in Figure 12 are values of $\langle P_4(\xi_M) \rangle$ plotted against $\langle P_2(\xi_M) \rangle$ and $\langle P_4(\xi)_c \rangle$ plotted against $\langle P_2(\xi)_c \rangle$ for all the shrunk samples for which X-ray measurements were made. The upper broken curve is the theoretical upper limit on $\langle P_4(\xi) \rangle$, which corresponds to $\langle \cos^4\theta \rangle = \langle \cos^2\theta \rangle$ and thus to a distribution in which the unique axes lie parallel or perpendicular to the draw direction. The lower broken curve corresponds to the lower theoretical limit, where $\langle \cos^4\theta \rangle = (\langle \cos^2\theta \rangle)^2$ and the unique axes lie on a cone around the draw direction with semi-angle θ .

The fluorescence points lie in general between the upper limit and the pseudo-affine curve and the X-ray points between this curve and the lower limit. The first of these results suggests that it may not be quite correct to deduce $\langle P_2(\xi)_a \rangle$ for the amorphous regions in the semi-crystalline polymer from the curve in Figure 1, which refers to non-crystalline samples, since the natures of the distributions of orientations of the fluorescent molecules for the two kinds

of samples appear to be different. Since, however, the points for the semi-crystalline sample do not lie far from the pseudo-affine curve the approximation may be reasonably good.

The fact that the fluorescence and X-ray points for the shrunk samples lie on opposite sides of the curve on which the original drawn samples lie suggests the possibility that points representing the overall distribution of molecular orientations after shrinkage might also lie on this curve. To test this hypothesis it is first necessary to deduce values of $\langle P_4(\xi)_a \rangle$. This may be done by making two assumptions. The first is that $\langle P_4(\xi)_a \rangle$ is related uniquely to $\langle P_4(\xi_M) \rangle$, which is similar to the assumption made in deriving $\langle P_2(\xi)_a \rangle$. The second is that $\langle P_4(\xi)_a \rangle$ may be deduced approximately for totally amorphous samples from the value $\langle P_2(\xi)_a \rangle = \langle P_2(\xi) \rangle_{\text{opt}}$ by taking the corresponding value on the pseudo-affine curve. We do not imply here that the mechanism of orientation is in fact that of the 'floating rod' model to which the pseudo-affine curve applies exactly; on the contrary, we have already shown that for low orientation the rubber model is appropriate. It is only necessary for the present purpose to note that the two models do not differ greatly in their prediction of the relationship between $\langle P_4(\xi) \rangle$ and $\langle P_2(\xi) \rangle$. It thus seems very likely that the use of the pseudo-affine curve, which is well-defined for all degrees of orientation (in contrast to the curve for the rubber model, which applies only for low orientation) will lead to values of $\langle P_4(\xi)_a \rangle$ for amorphous samples which are correct to a good approximation.

Once $\langle P_4(\xi)_a \rangle$, $\langle P_4(\xi)_c \rangle$ and f_c are known, a value of $\langle P_4(\xi)_0 \rangle$ for the overall distribution of molecular orientations may be derived using a similar equation to (1). In Figure 13, $\langle P_4(\xi)_0 \rangle$ is plotted against $\langle P_2(\xi) \rangle_{\text{opt}}$ (which also refers to the overall distribution of orientations), $\langle P_4(\xi)_c \rangle$ is plotted against $\langle P_2(\xi)_c \rangle$ and $\langle P_4(\xi)_a \rangle$ is plotted against $\langle P_2(\xi)_a \rangle$ for samples 3a–3i. Despite the scatter of the points, the values of $\langle P_4(\xi) \rangle$ and $\langle P_2(\xi) \rangle$ for the overall distribution are indeed seen to lie closer to the pseudo-affine

Figure 13 $\langle P_4(\xi) \rangle$ plotted against $\langle P_2(\xi) \rangle$ for samples 3a to 3i. \blacksquare , X-ray data for $\langle P_4(\xi)_c \rangle$ against $\langle P_2(\xi)_c \rangle$; \square , $\langle P_4(\xi)_a \rangle$ against $\langle P_2(\xi)_a \rangle$; \bullet , denotes $\langle P_4(\xi)_0 \rangle$ against $\langle P_2(\xi) \rangle_{\text{opt}}$ (which both refer to the overall distribution of orientations). —, —, —, and — as in Figure 12

curve than the corresponding values for either the amorphous or crystalline regions. This is consistent with the view that shrinkage takes place before crystallization so that the overall orientation is reduced by the polymer re-tracing the orientation states through which it passed during drawing, prior to subsequent crystallization.

Although much further work is required in order to deduce the precise nature of the changes in molecular orientation which take place during shrinkage, the present results illustrate clearly the importance of developing methods such as the fluorescence method which can give more information about amorphous orientation than $\langle P_2(\xi) \rangle$, which is the only information deducible from, for instance, birefringence or dichroism, whether optical or infra-red.

CONCLUSIONS

The results of the present work show that for the fluorescent-molecule-polymer system used in the experimental work, the fluorescent molecules are excluded from the crystalline regions in the semi-crystalline polymer and confirm that the unique relationship between the distribution of orientations of the fluorescent molecules and that of the chain axes, reported previously, still applies to a good approximation in the amorphous regions of the semi-crystalline polymer. We conclude that the fluorescence method is capable of characterizing quantitatively the distribution of chain orientations in the non-crystalline regions of semi-crystalline polymers.

The samples of PET studied appear to behave as a rubber with 5.6 freely joined links between crosslink points when uniaxially drawn and shrunk at 80°C, provided the draw ratio is less than 2.5. At higher draw ratios strain-induced crystallization occurs and the shrinkage is significantly reduced.

In all cases it can be concluded that shrinkage is associated with the disorientation of the amorphous regions. The results suggest that further crystallization takes place independently of the disorientation process.

APPENDIX

The following simple ideas have been used to estimate the dependence of the density of the amorphous regions on the value of $\langle P_2(\xi) \rangle_a$.

A unit volume of amorphous polymer is imagined to be divided into two parts, V_c and ΔV . Thus

$$1 = V_c + \Delta V \quad (\text{A1})$$

V_c is defined as the volume of the same mass of material if it were fully crystalline. It follows that ΔV is the volume of the sample that is orientation dependent. In *Figure 14*, the two unit vectors S_1 and S_2 represent two adjacent polymer chains. We assume that the shaded area, A , is proportional to the volume that is reduced to zero when S_1 is completely aligned with S_2 . If G is the angle between S_1 and S_2 the area A is equal to $\frac{1}{2} \sin G$. It follows that

$$\Delta V = k \langle \sin G \rangle \rho_a / \rho_a^0 \quad (\text{A2})$$

where k is a constant of proportionality and $\langle \sin G \rangle$ is the average value of $\sin G$ for the amorphous sample.

From equation (A1) we obtain:

$$\Delta V = 1 - \rho_a / \rho_c \quad (\text{A3})$$

and if R is defined by:

$$R = \langle \sin G \rangle / \langle \sin G \rangle_0 \quad (\text{A4})$$

where $\langle \sin G \rangle_0$ refers to an isotropic amorphous sample, it can be shown from equations (A2) and (A3) that

$$\rho_a = \rho_a^0 \rho_c / [\rho_a^0 + R(\rho_c - \rho_a^0)] \quad (\text{A5})$$

If we assume that there is no correlation between the position and orientation of a chain it follows from the Legendre addition theorem that for a sample with a uni-

Figure 14 The unit vectors S_1 and S_2 represent two adjacent chains in the amorphous regions of a polymer. The shaded area is assumed to be proportional to the volume that is reduced to zero when S_1 is completely aligned with S_2

axial distribution of chain orientations,

$$\langle P_2(\cos G) \rangle = [\langle P_2(\xi) \rangle]^2 \quad (\text{A6})$$

It is not possible to obtain an exact expression for $\langle \sin G \rangle$ in terms of $\langle P_2(\cos G) \rangle$ and we have therefore used the approximation

$$\langle \sin G \rangle = |1 - \langle \cos^2 G \rangle|^{1/2} = \left| \left\{ \frac{2}{3} [1 - \langle P_2(\cos G) \rangle] \right\}^{1/2} \right| \quad (\text{A7})$$

which gives in fact the maximum value for $\langle \sin G \rangle$ for a given $\langle P_2(\cos G) \rangle$, since by Schwartz's inequality $\langle \sin^2 G \rangle$ is greater than or equal to $(\langle \sin G \rangle)^2$. The same approxima-

tion was used for $\langle \sin G \rangle_0$ in an attempt to reduce the error in R .

For PET appropriate values are $\rho_d^0 = 1.3375$ and $\rho_c = 1.445$. Thus equation (A5) becomes:

$$\rho_a = 1.9327 / (1.3375 + 0.1075R) \quad (\text{A8})$$

The curve in *Figure 5* corresponds to this equation. The points shown are for all the samples, from this and the previous work¹, which were drawn at 80°C and which are believed to be of low crystallinity. The general relationship between the points and the curve suggests that, despite the simplicity of the ideas and approximations used to derive it, the curve may be sufficiently good to be used for deriving values of f_c for oriented samples.

Trajectory of polyethylene chains in single crystals by low angle neutron scattering

D. M. Sadler and A. Keller

H. H. Wills Physics Laboratory, University of Bristol, Bristol BS8 1TL, UK

(Received 9 May 1975; revised 1 September 1975)

Measurements of coherent neutron diffraction of oriented single crystals of blends of hydrogenous and deuterated polyethylene have been undertaken in order to study the mutual arrangements of the crystalline 'stems' of the same molecule. In the appropriate range of diffraction angle, the scatter is fully consistent with thin lamellae, the planes of which contain the stems. The thickness of these lamellae agrees with that expected for neighbouring stems of one molecule being restricted to the same (110) plane. The density of deuterium atoms in the lamellae is consistent with largely adjacent re-entrant folding; for crystals grown at low supercooling there is a possibility of some segregation according to isotope. Outside the above range of diffraction angle, effects are observed which are attributable to the finite lateral dimensions of the proposed lamellae. At the smallest angles of measurement an artifactual signal attributable to voids can be observed, which can be avoided by suitable sample treatment.

INTRODUCTION

In the period following the discovery of chain folding in crystallizable polymers, there has been a continuing effort to define the degree and nature of crystal disorder and, in addition, how the chains thread through the crystalline lamellae. Two newly applied techniques promise to provide some evidence on the second of these two related matters: both infra-red (i.r.) and low angle neutron diffraction are sensitive to the 'trajectory' of an isotopically labelled chain in its unlabelled matrix. I.r. results¹ suggest that in single crystals composed of blends of polyethylene (PE) and deuterio-polyethylene (DPE), nearest neighbour chains along the $\langle 110 \rangle$ direction are of the same isotopic composition. This indicates adjacent re-entrant folding, leading to one molecule forming a slab along the growth face. This was the chain trajectory proposed when chain folding was first discovered. *Figure 1* shows a chain folded in this manner, with crystal 'stems' (i.e. those parts of the chain passing through the crystals) adjacent to one another. Other modes of folding will result in the stems of the same molecule being arranged differently, and in the case of labelled chains the coherent neutron scattering will depend on the resulting spacial arrangement of these stems. *Figure 2* illustrates several possibilities; the position of each stem in the plane of the crystal being indicated. It should be emphasized that the degree and nature of the disorder in the crystal is not directly in question here, since the scattering will only be affected to a minor extent by the chain sequence in any disordered regions (e.g. in the fold surface).

Preliminary results² on bulk crystallized material, in conjunction with a study on molten PE, concern very small angles of diffraction (equivalent Bragg spacings in the region of 500 Å). These results lead to molecular weights and radii of gyration of the deuterated particles consisting of molecules or groups of molecules in the PE matrix. The present results concern crystals grown from solution; the angles of diffraction correspond to equivalent Bragg spacings of 200–15 Å, in which case the intensities of diffraction depend on the variations of scattering density according to the stem arrangements as outlined above.

Figure 1 Diagrammatic representation of a polyethylene crystal, showing how adjacent re-entrant folding leads to lamellar diffracting objects

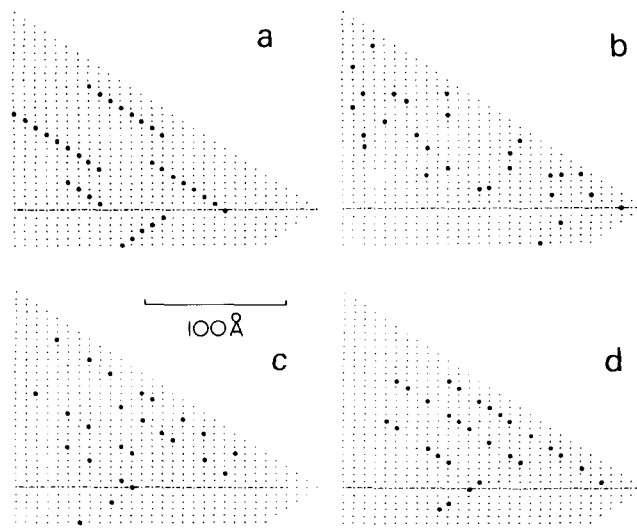

Figure 2 Representation of the positions of intersections of stems (i.e. chain sequences passing through the crystalline region) and a (001) plane. The small points represent PE chains, the large points DPE. The examples of chain trajectory are: (a) adjacently re-entrant folding; (b) randomly re-entrant folding; (c) and (d) other forms of folding restricted to (110) planes; (c) large gaps between stems; (d) small gaps. The broken line indicates a fold sector boundary

Figure 3 Example of data used for the analysis. In general only at larger values of 2θ were the total counts as high as shown on the ordinate: for smaller angles the values plotted were calculated using shorter times of counting. These data were interpolated and analysed as explained in the text to give Figures 4 and 6. Some measurements were taken at even higher 2θ than shown, and were fully consistent with the way in which the two spectra, PE and PE with DPE, were subtracted to give a measure of coherent scattering from the DPE component. Results from the diffractometer at Harwell⁴.

The results presented here have been analysed with a view to testing whether the diffraction could be from lamellar structures (e.g. as in Figure 1). It remains to be tested how much of the labelled stems are in lamellae only one molecule in thickness, and in addition to investigate to what extent alternative structures can be excluded.

EXPERIMENTAL

DPE from Merck Sharpe and Dohme was specified as being of 99% isotopic purity; the PE used was Rigidex 9. The DPE was dissolved by boiling in xylene together with PE; the mixing in solution was continued for at least 1 h. Total concentration of polymer was 0.04% w/v, the weight fraction of DPE in the polymer being 0.13. The solution was poured into thin-walled tubes held at 70° or 85°C. For the crystallization temperature $T_x = 85^\circ\text{C}$ a seeding procedure was employed³ in order to produce a uniform crystal size. The crystal suspension was filtered (at 85°C in the case of that crystallization temperature) so that the final filtrate consisted of a concentrated sludge on filter paper. This was dried so as to produce flat mats about 0.1 mm thick. For $T_x = 70^\circ\text{C}$ the dry mat was pressed at 60°C so as to produce a translucent material. For $T_x = 85^\circ\text{C}$ one of the samples remained white in colour. The isotopic composition of the samples was monitored by i.r. The sample sheets were cut and mounted in aluminium holders, usually with the mat planes (hence the crystal layers) parallel to the plane of the holder. In these cases an area of 7×20 mm was uniformly filled with a weighed amount of polymer (~130 mg). In two instances, mentioned in the text, the mats were cut into strips and mounted with the mat normals in the plane of the holder. Two small angle scattering instruments were used: at Harwell⁴ where the normal to the holder was held at an angle of θ to the incident beam (where 2θ is the angle at which the scattering is being measured) and at the high flux reactor of the Institut Max von Lane–Paul Langevin at Grenoble⁵ where the normal to the holder was parallel to the incident beam. The aperture defining the beam at the sample was slightly larger than the area defined by the sample. Orientations of the crystal layers and the crystal lattice within the mats were monitored by low- and wide-angle X-ray diffraction, respectively. The layer normals are concentrated within about 30° to

the normal to the mats. The 110 arcs were equatorial (most intense along a direction parallel to the plane of the mats). The long spacing l was 107 Å for $T_x = 70^\circ\text{C}$ and 132 Å for $T_x = 85^\circ\text{C}$.

RESULTS

Figure 3 shows the variation of neutron count rate as a function of 2θ , for a mat of PE and of a blend of 0.13 DPE and 0.87 PE using the scanning diffractometer⁴. The former show scatter which is almost independent of 2θ , which corresponds to the high H content and high incoherent scatter. The latter shows an additional intense scatter attributable to the DPE component. The latter contribution was separated by taking the difference between the signal from the blend, and the signal from PE which is rescaled slightly so that it corresponds to the same total incoherent cross-section as in the blend. To enable this to be done accurately, the PE scatter was measured for several sample thicknesses. A (small) desmearing correction⁶ was applied to the difference curve to allow for the finite size of the sample and of the counter aperture. The resultant measure of diffracted intensity I decreases sharply with 2θ ; the results are conveniently expressed as a plot of $I s^2 \cos \theta$ versus s , where

$$s = 2 \sin \theta / \lambda \quad (\lambda, \text{neutron wavelength})$$

Such a plot is shown in Figure 4.

Figure 5 shows results on mats mounted edgewise ($T_x = 85^\circ\text{C}$) using the high flux reactor device. The total scatter from the blend is shown since these samples do not have a uniform thickness, so that background subtraction cannot be accurate. Figure 5a corresponds to a mat as dried, i.e. white in colour and containing large numbers of voids. The scatter in a direction parallel to the mat normals (broken line) is much higher than that at right angles to the normals (solid line). This is not consistent with scatter from PE–DPE contrast from any of the models of the type shown in Figure 2 (see below). Figure 5b shows the corresponding results for mats which have been pressed at 60°C so as to remove most of the voids; a translucent sample then results. The anomalous signal in a direction parallel to the mat normals has been removed. We tentatively

Figure 4 Plot of the data as $I s^2 \cos \theta$ versus s after background subtraction, desmearing, and corrections for attenuation and preferred orientations (see text). The units of I are arbitrary, being expressed as $I_{\text{diff}}/I_{\text{D}}$ where I_{diff} is the count rate difference from Figure 3. I_{D} is the sum of the coherent diffraction intensities for the same number of labelled individual atoms as in the PE and DPE blend, calculated on the basis of the vanadium calibration. (a) $T_x = 85^\circ\text{C}$, mat unpressed; (b) $T_x = 70^\circ\text{C}$, mat pressed. For the effect of pressing see also Figure 5

Figure 5 Dependence of uncorrected scattered intensity (in counts per cell of the multidetector array) on orientation of the mats. —, direction in the plane of the mats; ----, direction parallel to the mat normals. $T_x = 85^\circ\text{C}$; (a) mat as dried, containing many voids; (b) after pressing at 60°C to minimize voids. The intensity scale of (a) relative to (b) is arbitrary. Results from the high flux reactor, Grenoble⁵

attribute the anomalous signal to multiple total internal reflection at interfaces between voids and stacks of crystals.

General considerations

The small angle scatter from the DPE component of PE-DPE blends is clearly significant (the intensity is quantified in the discussion below). If the DPE was segregated into blocks much larger than 200 \AA , most of the diffraction would not be included within the measured range, and would be at very small angles and at wide angle peaks. Much of the DPE must be dispersed in particles of a size of the order of magnitude of 100 \AA .

The reader is referred to Guinier and Fournet⁷ for the detailed interpretation of low angle intensity measurements. For the present purposes it is convenient to quote some formulae in the form below, which are relevant to samples where the scattering particles take up a range of orientations.

Rods of radius R_0 and length L . For $s \gg 1/L$ diffraction occurs only for s perpendicular to the direction of the rod; the intensity is then given by:

$$I = (N\sigma n_L / 2s \cos \theta) \exp - (2s^2 \pi^2 R^2) \quad (1)$$

where N is the number of scattering centres defined as the number of deuterium atoms, σ is the corresponding coherent cross-section, n_L is the number of centres per unit length, and the exponential factor applies for $s \ll 1/R_0$. R is analogous to the usual radius of gyration: $R \equiv r^2$ where r is the distance of each centre from the centre line of the rod.

Lamellae of thickness $2H$ and width W . For $s \gg 1/W$ diffraction only occurs for s parallel to the lamellar normals, and the intensity is given by:

$$I = (N\sigma n_A / 2\pi s^2 \cos \theta) \exp - (4\pi^2 D^2 s^2) \quad (2)$$

where n_A is the number of centres per unit area, and the exponential factor applies for $s \ll 1/2H$. $D \equiv z^2$ where z is the distance of a scattering centre from the central plane of the lamella. In these equations the additional $\cos \theta$ term arises in order to avoid the restriction to small values of 2θ ⁷.

For both particle shapes a preferred particle orientation will result in scattered intensities which are higher in a direction either perpendicular to the rod direction or parallel to the lamellar normals.

The validity of these two equations depends not only on whether rods or lamellae are suitable structural models (see Figures 2b and 2a respectively). In addition the range of s must be examined. The maximum value of s measured was 0.07 \AA^{-1} , so that both conditions $s \ll 1/R_0$ and $s \ll 1/2H$ (see above) are likely to be satisfied. The length of a stem (approximately equal to the fold length l) is, however, within the experimental range of $1/s$. Equations (1) or (2) can therefore only be valid as asymptotes. To predict the variation of I with s for values of $s \lesssim 1/l$, numerical calculations would be necessary. These would need to allow for the distribution of orientations and the dimensions l and l_1 (see Figure 1). Qualitatively, it may be said that I may be both above or below the asymptotic value for $s \approx 1/l$ (Fig. 8⁷). For $s \ll 1/l$ will be below the asymptotic value.

It must be considered whether interference caused by the phase relationship between the scattering from neighbouring rods or lamellae should be significant for the prediction of I . For non-overlapping spheres spaced at random it has been calculated⁷ that the importance of interference effects, depends on the concentration and the relative value of $1/s$ compared with the average sphere separation. For a DPE concentration of 0.13, the average spacing between stems arranged randomly within the crystal would be of the order of 11 \AA , and between rows of stems (i.e. lamellae) about 30 \AA . These estimates are made from simple geometry based on the cross-sectional area per stem of 18 \AA^2 . Based on these figures, estimates of interference effects which are analogous to previous calculations⁷ suggest that for lamellae (equation (2)) they should be small, for s more than about 0.03 \AA^{-1} , but that for rods should be quite significant for all s measured.

Finally, in order to be able to deduce values of n_L or n_A from the equations, it is necessary for all the DPE to be dispersed within the crystals. Some partial segregation would of course lead to low measured values.

DISCUSSION

It is immediately apparent that equation (1) (using $R \approx 2\text{ \AA}$ i.e. for a single chain) bears no relation to the experimental results (Figure 4) since $I s^2$ decreases and not increases as a function of s . It must be borne in mind, however, that interference between different stems (see above) has not been considered, so that equation (1) cannot be expected to predict accurately the scatter from structures such as shown in Figure 2b. Equation (2) predicts a decrease of $I s^2$ for larger values of s ; to test this equation further $I s^2 \cos \theta$ is plotted on a log scale against s^2 (Figure 6). The predicted variation for infinitely wide sheets [corresponding to (110) pleated sheets: $D = 1.57\text{ \AA}$; $n_A = 0.35\text{ \AA}^{-2}$] is also shown. The absolute calibration of I was estimated from a measure of the (incoherent) scatter from a vanadium sheet; very similar results are obtained by using the incoherent scatter from PE. Corrections were also made for beam attenuation (a factor of 2) and for preferred orientation (a factor of 0.45 for $T_x = 70^\circ\text{C}$ and 0.66 for $T_x = 85^\circ\text{C}$).

It can be seen that the experimental curves as plotted in Figure 6 are linear for large s , hence the results are consistent with sheet structures. In addition, the linear portions of the experimental curves are approximately parallel to the predicted one. Hence the thickness of the sheets (as specified by D) is that predicted on the basis of the

Figure 6 The data of Figure 4 replotted as $Is^2 \cos \theta$ on a logarithmic scale versus s^2 . (a) $T_x = 85^\circ\text{C}$ (b) $T_x = 70^\circ\text{C}$. ----- predicted for (110) adjacent re-entrant folding for 100% of DPE in the form of stems. No account is made for finite width of sheet, or intersheet interference (see text)

Table 1

Single crystals	$D(\text{\AA})$	$n_A(1/\text{\AA}^2)$
Calculated	1.57	0.35
$T_x = 70^\circ\text{C}$	2.2	0.29
$T_x = 85^\circ\text{C}$	1.9	0.18

The calculated values of n_A assume that all the deuterium in the blend is in the form of rows of stems of the same length. The folding has been assumed to be on (110) planes for this calculation. Other directions of folding [e.g. on the (100) plane] would give slightly different values. The measured results are obtained from the experimental curves in Figure 6, as discussed in the text

stems of a DPE molecule being restricted to the same (110) plane. Of such structures (Figures 1, 2a, 2c, and 2d) only those where the interstem spacing within the sheets is not too high, i.e. with few gaps of more than two stems in the folded sequence will still scatter as sheets in the observed range of s .

Table 1 shows predicted values for D and n_A for adjacent re-entrant folding, together with values derived from the linear portions of the experimental curves. (For $T_x = 70^\circ\text{C}$ there is an uncertainty introduced by the slight concavity of the measured curve; the tabulated D and n_A values refer to the slope at the highest values of s^2 , for which, unfortunately, the experimental uncertainties in I are greatest.) As discussed above, the dimension D (related to the slopes in Figure 6) agrees well with those predicted. For $T_x = 70^\circ\text{C}$, there is also good agreement for n_A , when it is borne in mind that any measured value of n_A should be about 20% lower than that shown for (110) folding in the Table, because of exclusion of DPE chains into a superficial amorphous layer, and because of variations in stem length⁸⁻¹⁰.

For $T_x = 85^\circ\text{C}$, the measured value of n_A is rather low on this basis. There are a number of reasons why this should be so, for example gaps in the rows of stems (Figure 2d). We suggest that a likely hypothesis for this discrepancy is partial segregation according to isotope or molecular weight at $T_x = 85^\circ\text{C}$. This is not unreasonable since $T_x = 85^\circ\text{C}$ represents a lower supercooling than $T_x = 70^\circ\text{C}$, and hence sensitivity to slight thermodynamic differences. This interpretation is consistent with measurements of overall PE/DPE contents¹¹. If there is partial segregation, no information is available as to the folding within the aggregates. A second explanation which cannot be excluded is less efficient dispersal in xylene prior to crystallization for this sample.

It remains to consider qualitatively the intensities at

low s when neither equations (1) nor (2) are likely to be valid. For $T_x = 85^\circ\text{C}$, the sample used for the data in Figures 4a and 6a had not been pressed. In addition its degree of orientation was such that a few lamellae were edge-on to the beam. Thus an artifactual signal from voids is to be expected (see above); the sharp increase of Is^2 with decreasing s at small s is therefore attributed to voids. By comparison, for $T_x = 70^\circ\text{C}$, for which the mats had been pressed, Figures 4b and 6b show a decrease in Is^2 at small s . The value of s at which the decrease commences (0.01\AA^{-1}) is fully consistent with the sheets containing the stems only being 100\AA wide⁷.

At $s \approx 0.02 \text{\AA}^{-1}$ there is, especially for $T_x = 70^\circ\text{C}$, still an increase of Is^2 above the asymptotic line (Figure 6). Some such departure could be expected for $1/s$ slightly smaller than l or l_1 (see above). Another, perhaps more likely, possibility is intersheet interference.

Experiments are continuing, employing both instruments, in order to test the generality of these results and to investigate to what extent alternative structural models can be eliminated.

CONCLUSIONS

The intensity of coherent neutron scattering from a blend of DPE in PE agrees with that expected for lamellae (equation (2) for $0.03 < s < 0.07 \text{\AA}^{-1}$). Table 1 shows, furthermore, that these lamellae have a thickness as predicted for rows of stems along (110) planes. The density of deuterium atoms in the lamellae is consistent with predominantly adjacent re-entrant folding along (110) in the case of crystals grown at high supercooling. At low supercooling there is a possibility of partial segregation of the deuterated chains in the hydrogenous matrix.

It seems that at low angles of diffraction there can be an artifactual signal originating from voids.

ACKNOWLEDGEMENTS

Thanks are due to Dr D. L. Worcester whose generous assistance made these experiments possible. Among those with whom we have had valuable discussions, we would like to thank in particular M. V. Luzzati, Professor G. Allen and Dr J. S. Higgins. Thanks are due to Dr C. G. Vonk for a listing of his deconvolution program. The work is supported by the Science Research Council.

Pulsed n.m.r. of a SBS 'macroscopic single crystal'

G. E. Wardell

Physical Laboratory, University of Dublin, Trinity College, Dublin 2, Eire

and D. C. Douglass and V. J. McBrierty

Bell Laboratories, Murray Hill, New Jersey 07974, USA

(Received 2 September 1975)

Pulsed n.m.r. T_1 , T_2 and $T_{1\rho}$ results are reported for a macroscopic single crystal of styrene-butadiene-styrene copolymer, recorded as a function of the angle between the extrusion axis of the sample and the magnetic field direction. The data confirm the absence of molecular orientation in either component of the copolymer. T_1 and $T_{1\rho}$ results indicate a coupling via spin diffusion, between the polystyrene and polybutadiene regions. These spin diffusion effects are analysed in terms of a simple model, presented earlier, which demonstrates a stronger spin diffusion coupling in the rotating frame than in the laboratory frame.

INTRODUCTION

Styrene-butadiene-styrene (SBS) is a three block copolymer which may be extruded into a material of unique morphological character, in which the dispersed polystyrene (PS) component is in the form of cylinders, parallel to the extrusion axis, and arranged in a hexagonal array within a continuous polybutadiene (PB) matrix¹⁻³. This form of the copolymer is referred to as a macroscopic 'single crystal'¹. Although such systems are anisotropic in their optical and mechanical properties⁴ experimental observations so far indicate a random molecular orientation in both the PS and PB components⁵.

EXPERIMENTAL

In the work reported here, T_1 , T_2 and $T_{1\rho}$ relaxation times have been recorded over a wide temperature range for a SBS single crystal of the type described above. The sample, kindly provided by Professor A. Keller of the University of Bristol, was in the form of an extruded plug made from the copolymer Kraton 102 (Shell). The molecular weights of the PS and PB components were 10^4 and 5.5×10^4 , respectively⁶. The sample was annealed at $\pm 150^\circ\text{C}$ for 16 h in order to enhance the features of the macrolattice³. Measurements were carried out for orientation angles $\gamma = 0^\circ$, 54° and 90° between the extrusion direction (cylinder axis) and the direction of the applied magnetic field.

Data were recorded on a Bruker B-KR301 spectrometer operating at a resonant frequency of 20 MHz with a recovery time of about 9 μsec . A 90° pulse was of 2.5 μsec duration. The Bruker temperature control facility provided sample temperatures to an accuracy of $\pm 1^\circ\text{C}$. Rotating frame data were recorded at a r.f. field, H_1 , of 10 G. The details of data acquisition and analysis have been described previously^{7,8}.

RESULTS AND DISCUSSION

The single crystal results are presented in Figures 1 to 3 along with data on homopolymers of comparable molecular weights. Connor's rotating frame data ($H_1 = 10$ G) for PS,

of molecular weight 1.08×10^6 , have been used for comparison⁹.

It is immediately apparent from the data that there is no T_1 , T_2 or $T_{1\rho}$ dependence on the orientation angle γ . This result implies that there is no measurable molecular orientation, in a n.m.r. sense, in either region of the polymer, which is in agreement with earlier conclusions from infra-red measurements⁵.

Figure 1 T_2 data for a SBS single crystal: \circ , $\gamma = 0^\circ$; \triangle , $\gamma = 54^\circ$; \square , $\gamma = 90^\circ$; -----, data for PS homopolymer; data for PB homopolymer

Figure 2 T_1 data for a SBS single crystal: -----, data for PS homopolymer;, data for PB homopolymer. ———, values predicted by the spin diffusion model (see text). Data points for orientations $\gamma = 54^\circ$ and 90° which are essentially the same as for $\gamma = 0^\circ$ have been omitted for clarity

The T_1 and T_2 results for the single crystal are similar to those for the comparable unextruded material⁸, at least up to 150°C , which is the upper limit of the earlier work. From this, it would appear that the molecular motions in this temperature region are insensitive to the *shape* of the PS domains in the copolymer. There are a number of additional features in the more comprehensive single crystal data, not included in the detailed treatment presented earlier, which require explanation.

The minimum in the short $T_{1\rho}$ component at -50°C is the $T_{1\rho}$ analogue for the T_1 minimum at -20°C and the sharp transition in the long T_2 component in the region of -40°C ; they are all manifestations of the PB first order transition⁸. The high temperature T_2 transition from 2 msec at $+140^\circ\text{C}$ to 3.6 msec at $+180^\circ\text{C}$ is associated with the PS glass transition. Furthermore, the constraints on the motion of the PB chains which are in force below the glass transition temperature T_g are removed⁸. This may be deduced from the magnitude of the plateau, which is greater than would be expected from the onset of the glass transition in PS, alone. There are indications of a correspondingly high temperature minimum in the short $T_{1\rho}$ component, although the exact location of the minimum is not possible. A short $T_{1\rho}$ component was just detectable in the temperature range -20°C to $+150^\circ\text{C}$ but the intensity was too small to permit a reasonable quantitative assessment of its magnitude. Above $+150^\circ\text{C}$ the intensity was of the order of 25%.

The variation in the component intensities indicates that it is most probable that there is coupling, via spin diffusion, between the PS and PB regions at these temperatures. A consequence of this would be a recorded $T_{1\rho}$ minimum for the glass transition process in PS which is greater in magnitude than the predicted value of 60 μsec in the absence of spin diffusion¹⁰.

The T_1 and $T_{1\rho}$ data indicate that spin diffusion is operative between the PS and PB components in the region of the minima associated with the first order transition in PB. This effect has been treated in detail in an earlier paper⁸, on the basis of a simple spin diffusion model in which a uniform spin temperature is assumed in each region of the copolymer and, in addition, the geometry of the interface is neglected. The strength of the coupling between the two regions is controlled by the parameter K , the only variable of the model. The solid lines in Figures 2 and 3 indicate the computed magnitudes of the T_1 and $T_{1\rho}$ components, respectively, which are seen to be in good agreement with the experimental results. The intensities of the long components in each case, which are also spin diffusion controlled, compare favourably with the measured values (see Figures 4 and 5). In order to achieve this fit, however, different values had to be assigned to the coupling parameter K for the T_1 and $T_{1\rho}$ data, respectively; for the T_1 data $K = 4.4$ as compared with the value of $K = 20$ for the $T_{1\rho}$ results.

Figure 3 $T_{1\rho}$ data for a SBS single crystal: -----, data for PS homopolymer, (due to Connor⁹);, data for PB homopolymer. ———, Values predicted by the spin diffusion model (see text). Data points for orientations $\gamma = 54^\circ$ and 90° which are essentially the same as for $\gamma = 0^\circ$ have been omitted for clarity

Figure 4 Intensity of the T_1 long component as a function of temperature. —, theoretical predictions from the spin diffusion model (see text)

Figure 5 Intensity of the $T_{1\rho}$ long component as a function of temperature. —, theoretical predictions from the spin diffusion model (see text)

While this variation may derive from inadequacies of the model, there is also longstanding recognition that the spin diffusion coefficient can depend upon field strength for applied fields comparable to the dipolar fields¹¹⁻¹³. Since the coupling parameter is proportional to the spin diffusion coefficient, D this result implies an increased D in the rotating frame. Measurement of relaxation in normal alkanes indicates that D does indeed increase with decreasing field in the resonant rotating frame¹². This result is consistent with the intuitive notion that additional paths for spin exchange become energetically possible when the Zeeman and dipolar energies are comparable. However, no data on calculations directly applicable to comparison of spin diffusion in the rotating and laboratory frames seem to exist.

ACKNOWLEDGEMENTS

Mr S. Doherty provided valuable assistance throughout the course of the work. The research was supported in part by a grant from the National Science Council of Ireland.

Structural order in heat treated vinyl chloride polymers

A. Gray* and M. Gilbert

Institute of Polymer Technology, University of Technology, Loughborough, Leicestershire LE11 3TU, UK
(Received 3 June 1975; revised 16 July 1975)

Three vinyl chloride polymers were annealed at temperatures in the range 40–160°C for times varying from 0.5 to 5 h. Structural changes occurring in the polymers were examined by density measurement, differential thermal analysis and X-ray diffraction. It was shown that the three polymers varied in their original crystallinity. Attempts to totally remove this crystallinity, were unsuccessful; further crystallinity could be introduced by annealing above T_g . Changes induced by annealing below T_g were not due to crystallization. Methods used to measure crystallinity in poly(vinyl chloride) (PVC) were assessed.

INTRODUCTION

Several workers^{1–6} have investigated the morphological changes which can be induced by suitable heat treatment of poly(vinyl chloride) (PVC). Methods used for such investigations have included density measurements^{1–4}, X-ray diffraction⁴, infra-red spectroscopy⁵ and differential scanning calorimetry (d.s.c.)^{2–6}. Changes in various mechanical properties have also been reported^{1–3,7}. Phillips *et al.*¹ have attributed property changes caused by heat treatment near and above the glass transition temperature T_g to changes in free volume. Foltz and McKinney have interpreted their d.s.c. results in a similar manner. Again, most of their samples were given heat treatments at temperatures below T_g . Rybníkář⁴ and Witenhafer⁵ have heat treated at higher temperatures (up to 180°C in the latter case) and have attributed observed changes to crystallization. Rybníkář and Juijn *et al.*^{3,8} distinguish primary and secondary crystallization processes, the latter workers discussing the thermal analysis of PVC polymers in some detail. Illers² also used this technique extensively, and compared structural changes occurring under various conditions. He suggested that heat treatment above T_g caused crystallization, while heat treatment below T_g caused decrease in free volume. Crystallinity changes were shown to have a greater effect on density, solvent sorption and shear modulus than free volume changes.

The present work was carried out as part of a project investigating the relationships between thermal history, crystallinity and properties for PVC polymers containing different types and levels of additives in an attempt to find the effect of structural changes occurring in PVC during processing. Initially the effects of time and temperature of annealing on the crystallinity of three PVC polymers have been examined. The polymers selected are a commercial suspension PVC homopolymer, a copolymer in which crystallization would be expected to be hindered, and a polymer prepared at –30°C which has increased syndiotacticity, hence increased crystallinity⁹.

* Present address: BP Chemicals International Ltd, Sully, Penarth, Glamorgan, UK.

EXPERIMENTAL

Materials

Details of polymers used are given in *Table 1a*. Molecular weights were obtained by gel permeation chromatography (g.p.c.), at 25°C using tetrahydrofuran as solvent. The copolymer and PVC 2 homopolymer could be dissolved at room temperature. While the low temperature PVC apparently dissolved under these conditions, two peaks were observed in the g.p.c. trace. The high molecular weight peak was attributed to incomplete solution of PVC mole-

Table 1a Polymers examined

PVC 2	160	180	3	200
PVC/PVAC copolymer	140	140	3	175
low temp. polymerized PVC	170	200	3	220

cules. After heating the polymer at 90°C for 5 days in a sealed tube the size of this peak became insignificant and the resulting trace was used to obtain the molecular weights quoted for this polymer.

To obtain a measure of syndiotacticity, the diad concentrations shown were calculated from spin decoupled ¹³C n.m.r. spectra using the method described by Carman *et al.*¹⁰. The figure for the copolymer is an approximate one since some peak overlap occurred; however, it suggests that the copolymer is virtually atactic.

Glass transition temperatures were obtained by thermo-mechanical analysis as described below.

Sample preparation

Four parts per hundred (w/w) of dibasic lead stearate were added to each polymer as stabilizer and lubricant. Each compound was dry blended, milled, then compression moulded to form sheets 0.5 mm thick. Details of milling and moulding conditions are shown in columns 2–4 of *Table 1b*. The moulded samples were cooled under pressure to room temperature.

Temperatures were selected to be high enough to achieve fusion of PVC particles. Scanning electron micrographs obtained by Pezzin *et al.*⁷ for PVC polymers milled at various temperatures suggest that temperatures used should give adequate fusion. An acetone immersion test indicated that samples were homogeneous. If fusion is inadequate, individual PVC particles are observed and fragmentation of the sample occurs on swelling in acetone.

Heat treatment

In an attempt to destroy existing crystallinity, and to ensure a uniform thermal history, all samples were subjected to a 3 min pre-treatment under nitrogen, prior to crystallization. Pre-treatment temperatures are shown in column 5 of *Table 1b*. These temperatures were the highest that could be used without degradation occurring. Samples were quenched in an ice/water mixture, then immediately subjected to annealing or stored at about –50°C until the annealing treatment was carried out. Density and d.t.a. measurements on the stored samples indicated that no detectable changes occurred during this period.

Subsequently samples of all three polymers wrapped in aluminium foil were packed in a glass tube which was suspended in a thermostated bath controlled to ±0.15°C. Annealing treatments (under nitrogen) varied from 0.5 to 5.0 h at temperatures of 40°–160°C. Some samples were stored at room temperature for longer periods of time.

Differential thermal analysis (d.t.a.)

Thermograms were recorded using a Du Pont 900 Thermal Analyser fitted with a d.s.c. cell. Samples of 10 ± 1 mg were heated at 30°C/min from –40°C. In order to convert peak areas into energy units the instrument was calibrated using indium (melting temperature 157°C, heat of fusion 28.4 J/g). The reproducibility of the method was estimated by obtaining results for ten similar samples. The standard deviation on the mean was found to be 5%.

Glass transition temperatures of the quenched polymers were measured using the thermal analyser fitted with a thermomechanical analyser (t.m.a.) attachment. The penetration probe used was loaded with a weight of 10 g and the t.m.a. trace was recorded from –50°C, using a heating rate of 5°C/min. The temperature at which the probe first star-

ted to penetrate into the polymer was taken to be the glass transition temperature, T_g .

Density measurement

Sample densities were measured at 23°C using a Davenport density gradient column filled with an aqueous solution of calcium nitrate. Each measurement was made by averaging results from four samples. In order to find the density of the PVC in the samples, measured values were corrected to allow for the 4 pph of dibasic lead stearate (density 2000 kg/m³) present.

Crystallinity X_d of the PVC was calculated from the equation

$$X_d = \frac{\rho_c}{\rho} \frac{\rho - \rho_a}{\rho_c - \rho_a} \times 100\%$$

where ρ_c is density of totally crystalline polymer = 1530 kg/m³¹¹, ρ_a is density of totally amorphous polymer = 1373 kg/m³¹², and ρ is the density of the PVC in the samples. Although values of X_d have been calculated for polymers annealed at 40°C (*Table 5*) it is considered that the true crystallinities of these polymers are equal to the crystallinities of quenched samples (see Discussion).

X-ray diffraction

X-ray diffractometer traces were obtained from compression moulded sheets of the polymers using Ni filtered CuK α radiation (40 kV, 20 mA). Order factors were calculated as described by Rayner and Small¹³. To obtain diffractometer traces for amorphous PVC, templates were prepared from the graphs in ref. 12 using a horizontal scale corresponding to that of the experimental traces. Each trace was then analysed by fitting the appropriate template which touched the experimental curve as shown in *Figure 5b*.

$$\text{Then, order factor} = \frac{A_x}{A_x + A_a} \times 100\%$$

No corrections were made for the variation of scattering intensity with θ .

RESULTS

Differential thermal analysis

A typical series of thermograms for the commercial homopolymer (PVC 2), annealed for 5 h is shown in *Figure 1*. The thermogram of a quenched sample (i.e. one heated at 200°C for 3 min and quenched in ice–water) is shown in *Figure 1(A)*, and is similar to that reported by Illers² for samples subjected to similar treatments. A baseline shift due to the glass transition at about 84°C is followed by an exotherm peaking at approximately 107°C which has been attributed to crystallization². A broad melting endotherm is observed in the 120°–200°C range. For a quenched sample of the low temperature polymerized PVC the trace is similar but the exothermic peak is smaller and the melting endotherm extends to 220°C. In both cases the three transitions merge into one another.

It can be noted that owing to the relatively high heating rates used for these measurements, the glass transition temperatures are higher than those obtained from the t.m.a. experiments.

Figure 1 Thermograms for PVC 2: A, quenched, and annealed for 5 h at B, 40°; C, 55°; D, 70°; E, 100°; F, 115°; G, 130°; H, 145°; I, 160°C

Figure 2 Enthalpy changes of low temperature polymerized PVC as a function of annealing time. Annealing temperatures: X, 100°, ■, 115°; ▲, 130°; ●, 145°; ▼, 160°C

Sharper endotherms are observed in thermograms of the annealed polymers, the peak temperature occurring at approximately 20°C above the annealing temperature in each case. Peak temperatures for PVC 2 are listed in Table 2. It is apparent that the peak temperature is also influenced

to some extent by annealing time. Results for the low temperature polymerized PVC were very similar, peak temperatures being 1°–2°C lower at the lower annealing temperatures, and 1°–2°C higher at the higher annealing temperatures.

For samples annealed at 100°C and above (i.e. above the glass transition temperature) the main features of the thermograms are the baseline shift due to the glass transition and the endotherm described above. No exothermic peak is observed. For samples annealed in the 40°–70°C region or stored at room temperature, the exothermic peak present in the quenched samples is still present [e.g. Figure 1(B)]. For the samples annealed at 55°C and 70°C the endothermic peak and glass transition occur very close together so that it is difficult to make any accurate measurements of area or temperature [Figure 1(C and D)]. In these cases peak areas were estimated by superimposing d.t.a. traces for quenched samples on those for the annealed samples.

Endotherms increase in area as annealing time is increased. In Figure 2 enthalpy changes are plotted as a function of time for the low temperature polymerized PVC. The corresponding plot for PVC 2 is similar except that the highest enthalpy changes are observed after heat treatment at 130°C.

The relationship between enthalpy change and temperature is shown in Figure 3 for PVC 2, and in Figure 4 for the low temperature polymerized PVC. Results for samples

stored at room temperature for longer periods of time are shown in *Table 3*.

Although endotherms were observed in thermograms of the PVC/PVAC copolymer after annealing, these were very much smaller than those observed for the other two polymers. It was not possible to anneal above 130°C as at higher temperatures acetic acid is released from the vinyl acetate units present. This volatilizes, causing voids in the sample. Results obtained for the copolymer annealed for 5 h at temperatures shown are listed in *Table 4*; again, peak temperatures are similar to those observed for the other two polymers.

Density results

The calculated crystallinities (X_d) for the two polymers are shown in *Table 5*. The time and temperature dependence of the density changes is similar to that of the enthalpy changes although the densities of samples annealed at 160°C are lower than would be expected from the observed enthalpy changes. Also, density results for PVC 2 showed a considerable scatter although four measurements were averaged to obtain each result. The lower reliability of the density measurements is thought to be partly due to the very small density changes being measured. A minor amount of degradation could have a significant effect on density measurements, but less effect on the order measured by thermal analysis. Since the density measurements for the low temperature polymerized PVC showed less scatter than those for PVC 2, the former polymer appears more thermally stable under the conditions used.

X-ray diffraction

Order factors calculated by the method described are shown in *Table 6*. As expected, the low temperature poly-

Table 6 Effect of annealing on order factor for vinyl chloride polymers

Annealing temperature ($^{\circ}\text{C}$)	PVC 2 annealed 0.5 h	PVC 2 annealed 5 h	low temp PVC annealed 0.5 h	low temp PVC annealed 5 h	PVAC annealed 5 h

160	11.6	11.9	27.5	23.1	

merized PVC is the most crystalline of the three polymers, while the copolymer is the least crystalline. For PVC 2 the order factor for a quenched sample (i.e. before annealing) was found to be 8.7. Heat treatment in the 40° – 70°C range did not appear to alter crystallinity significantly, while heat treatment above 70°C increased crystallinity by a factor of approximately 1.6. Diffractometer traces for samples of PVC 2 annealed for 5 h at 100°C and 40°C are shown in *Figure 5(B and C)*. No significant differences in order factor were observed when annealing time was increased from 0.5 to 5 h, nor at different temperatures in the 100° – 160°C range. For a quenched sample of the low temperature polymerized PVC the order factor was 20.1. Annealing at 100°C and above increased the figure by a factor of approximately 1.2, but results were rather erratic particularly after annealing for 5 h. A diffractometer trace for this polymer annealed for 5 h at 100°C is shown in *Figure 5(A)*. Diffraction maxima assignments are those reported by Garbuglio *et al.*¹⁴

DISCUSSION

Effect of pre-treatment and quenching

A pre-treatment and quenching procedure was used prior to annealing in an attempt to destroy existing order in the polymers. However, it is apparent from subsequent investigations either that this did not occur or that crystallinity was re-introduced on cooling. Corrected densities for quenched samples of PVC 2 and low temperature polymerized PVC were 1389 kg/m³ and 1396 kg/m³, corresponding to calculated crystallinities of 11.35 and 16.26% respectively. X-ray measurements confirmed this conclusion, order factors of 8.7 and 20.1% being obtained in the two cases. Both methods show that the crystallinity remaining in the low temperature PVC is greater.

D.t.a. traces of the quenched polymers can also be explained by this residual crystallinity. The exotherm observed in heating quenched samples is considered to be due to rapid crystallization which occurs when the polymers are heated above T_g ². Approximate areas were obtained for this exotherm and the broad melting endotherm. It was shown that the exotherm was equivalent to 40% of the endotherm for PVC 2 and 15% for the low temperature polymerized PVC.

The smaller value obtained in the latter case is consistent with the relatively high level of crystallinity already present in this material, which limits the amount of material available for further rapid crystallization on heating. The broad melting endotherm observed for both polymers will be due to melting of crystallites introduced during heating, together with those which remain in the sample after pre-treatment and quenching. It would seem likely that residual crystallites will melt at the higher end of the melting range. This range extends to higher temperatures for the low temperature polymerized PVC than for PVC 2.

Effect of annealing below T_g

As reported previously, annealing, or storage below T_g was found to increase the density of samples and also give rise to additional endothermic peaks below or at T_g in the d.t.a. traces. The conditions under which such peaks are obtained have been discussed in considerable detail². Both

sample density and endothermic peak area increase with time and temperature of annealing. Crystallization would not be expected to occur below T_g and this was confirmed by X-ray measurements, no significant changes in order factor being observed for the samples annealed below T_g . Thus the densifying process which occurs does not give rise to three-dimensional order and has been attributed to change in free volume^{1,2,6}. It is of interest that larger enthalpy changes and density increases are observed for PVC 2 than for the low temperature polymerized PVC during annealing or storage below T_g . It seems reasonable to assume that free volume changes occur in amorphous regions, so are observed to a lesser degree in the higher crystallinity polymer.

Effect of annealing above T_g

X-ray results showed that annealing PVC 2 and the low temperature polymerized PVC above T_g caused an increase in crystallinity as shown by order factor (Table 6 and Figure 5). A small amount of crystallinity was present in the copolymer after annealing for 5 h. This was confirmed by d.t.a. results (Table 4).

The accuracy of the X-ray results is at present insufficient to investigate time and temperature dependence of crystallinity in detail, owing to the problem of resolving crystalline and amorphous areas, although the 210 diffraction maximum appeared to increase in height with time of annealing, particularly for the low temperature polymerized PVC. Additional information can be obtained from density measurements and d.t.a. The endotherms observed in d.t.a. traces of annealed samples are considered to be due to the formation of crystallites which melt about 20°C above the annealing temperature. Enthalpy changes corresponding to the fusion of these crystallites are found to pass through a maximum with respect to temperature (Figures 3 and 4) suggesting that crystallization rate passes through a maximum between T_g and the melting temperature T_m in a manner typical of most crystallizing polymers. Density measurements for the low temperature polymerized PVC show a similar trend, but the scattered points observed for PVC 2 did raise the question of degradation, particularly for the samples annealed at 145°C and above for longer periods of time. No voids were detectable by visual or microscopic examination of any of the samples. PVC 2 samples were yellow in colour suggesting that very little degradation had occurred, although low temperature polymerized PVC samples were reddish-brown. As points in Figures 3 and 4 are on reasonably smooth curves it is felt that results are not significantly affected by degradation.

The higher temperature maximum observed for the low temperature polymerized PVC is not unexpected since T_g is higher for this polymer, and T_m is expected to be higher owing to the higher proportion of syndiotacticity. The maximum increase in crystallinity is similar for the two polymers.

Enthalpy changes and density measurements demonstrate an increase of crystallinity with annealing time (e.g. Figure 2). Results show that the increase in crystallinity on annealing occurs fairly rapidly. Even at 100°C half the crystallization has occurred within less than 0.5 h. Further investigation of much shorter annealing times is necessary since it appears that changes will occur in the PVC structure during processing. The exotherm obtained in d.t.a. traces of quenched samples also indicates the rapidity of the crystallization process.

Figure 6 Calculated crystallinity as a function of syndiotacticity for values of ξ_{\min} from 2 to 8. Experimentally determined range of crystallinity from density measurements and X-ray order factors for PVC 2 (X) and low temperature polymerized PVC (O)

Comparison of ordering processes above and below T_g

Density measurements and differential thermal analysis do not show conclusively that different processes are occurring when vinyl chloride polymers are annealed above and below T_g . However, X-ray diffraction shows that crystallization is occurring above T_g while annealing below T_g produces no additional three-dimensional order.

Solvent sorption measurements, reported elsewhere¹⁵, also serve to distinguish between annealing above and below T_g for PVC 2, but show no structural differences for the PVC/PVAC copolymer after quenching, annealing below T_g or annealing above T_g .

Relationship between % crystallinity and syndiotacticity

It is of interest to compare maximum crystallinities obtained for the polymers with the amount of crystallizable material available. Using the relationship of Fordham¹⁶, it is possible to calculate the fraction of the total polymer in syndiotactic sequences from the tacticity.

$$F_{\text{SYNDIO}}^N = N(1 - \alpha)^2 \alpha^N$$

where N is the number of repeat units in a syndiotactic sequence, α is the degree of syndiotacticity.

If PVC is considered as a copolymer in which only the syndiotactic portion is crystallizable Flory's theory of crystallization of copolymers¹⁷ can be applied. This states that on thermodynamic grounds, the crystallites should have a minimum length. Then the parts of the polymer chain which contribute to the crystallite should also have a minimum sequence length, ξ_{\min} .

Using the distribution of syndiotactic sequences obtained from Fordham's relationship it is possible to calculate the degree of crystallinity obtainable, with ξ_{\min} as a variable, by the summation of F_{SYNDIO}^N for $N = 1-20$ (larger N values are neglected as their contribution to the degree of crystallinity becomes very small).

In Figure 6 the calculated crystallinity is plotted against syndiotacticity. Experimental values of crystallinity obtained by the density method, and X-ray order factor are plotted on this graph. These values are consistent with a minimum number of sequences necessary for crystallization of 5-6,

in agreement with Lebedev *et al.*¹⁸ and Talamini and Vidotto¹⁹. However, Kockott²⁰ found a value of 12 for ξ_{\min} , which, according to Lebedev *et al.* is due to the former's low estimation of the degree of crystallinity, for example, a value of zero is quoted for a commercial PVC.

Juijn *et al.*⁸, using values of $\alpha = 0.55$ and $\xi_{\min} = 12$ for commercial PVC obtained a low crystallinity figure of 0.45%. They explained this result by showing how the isotactic portion of the chain could also be incorporated into the crystal lattice. The value of 12 for ξ_{\min} was used as it was 'in agreement with values for other polymers'. However, other evidence suggests that crystallites in PVC are likely to be smaller than those in other crystalline polymers, so that a lower value of ξ_{\min} does not seem unreasonable. The broad d.t.a. melting endotherm indicates that a wide range of crystallite size and/or perfection exists. X-ray diffraction peaks are also broad and ill-defined, and an estimation of crystallite size from diffraction peak width gives a mean value of only about 5.0 nm.

Measurement of crystallinity in PVC

Owing to the low levels of crystallinity in PVC all methods of measurement provide problems.

Thermal analysis is a sensitive method which permits accurate measurement of crystallinity developed in PVC under carefully controlled conditions, so it is a particularly good technique for following small changes in crystallinity. However, it cannot be used to measure total crystallinity in polymers which have not been subjected to a special treatment, since the broad, shallow endotherm produced in these cases cannot be measured accurately.

Density measurements provide some information, but density changes can result from various causes, so the method is unselective. Its accuracy is limited for following the very small changes caused by special treatment of the polymers, and it appears susceptible to minor amounts of degradation.

X-ray diffraction is the only technique used which shows conclusively whether or not crystallinity is present. However, the technique used in this work was not sufficiently accurate to follow changes with time or temperature. There is some scope for improvement here, for example, the step scanning and data averaging techniques discussed by Brunner²¹.

In many respects techniques used are complementary and it is of value to use more than one technique to solve a particular problem.

ACKNOWLEDGEMENTS

We are grateful to the Science Research Council for the award of a Research Studentship to A.G.

Thanks are also due to Mr M. Cudby of ICI Plastics Division who made n.m.r. measurements on the polymers and Mr J. Maisey of the Polymer Supply and Characterization Centre, Rubber and Plastics Research Association for molecular weight determinations.

Effect of molecular weight on the thermal properties of polycarbonates

G. A. Adam, J. N. Hay, I. W. Parsons and R. N. Haward

Department of Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, UK
(Received 26 August 1975)

The relationships between the molecular weight and several thermal properties of 2,2-bis(4-hydroxyphenyl)propane polycarbonate are reported. It is shown that the amount of thermal degradation, measured thermogravimetrically, increases with decrease in molecular weight and is affected by the nature of the end groups present. The heat of fusion at the crystalline melting point has been measured by differential scanning calorimetry and correlated with density and X-ray diffraction estimates of total crystallinity. The heats of melting obtained were 30.4 cal/g and 32.9 cal/g respectively. The effect of molecular weight on specific heat, annealing peaks and glass transition temperature are also reported.

INTRODUCTION

During an earlier programme of research we synthesized a number of polycarbonates from 2,2-bis(4-hydroxyphenyl)propane and compared their properties with commercial materials and with new synthetic copolymers¹. The copolymers made under varying experimental conditions had different molecular weights and it was necessary (for comparison purposes) to make polymers with similar molecular weights. In the course of this programme we observed a number of previously unreported correlations between molecular weight and physical properties.

In this paper results are presented which illustrate both the effects of molecular weight on thermal properties and also the quite significant differences which exist between currently marketed commercial materials and those which may be synthesized by conventional methods^(2,3). Among the subjects studied were: the formation of volatiles by heating at high temperatures, the glass transition temperatures, specific heats, heats of crystallization and annealing peaks as measured by differential scanning calorimetry (d.s.c.). Details of the methods used are given in the experimental section.

EXPERIMENTAL

Polymer preparation

Experimental samples of poly[2,2-propane-bis(4-phenyl carbonate)] used in this study was either prepared by interfacial polycondensation or in a homogeneous (pyridine/methylene chloride) system¹⁻³. Where polymers of different molecular weight were synthesized this was generally achieved by varying the reactant molar ratio but in some cases *p*-cresol was used as a chain terminating reagent. Other samples were obtained from commercial sources.

The polymers used are listed in Table 1.

Acetylation

Polycarbonates, whose molecular weights had been controlled by varying the reactants' ratio, were treated with excess of acetyl chloride in the presence of pyridine and methylene chloride. The latter was used as a solvent for the polymer.

Thermal analyses

Thermogravimetric analysis was carried out on a Perkin-Elmer thermobalance TGS-1 using nitrogen as the carrier gas, and d.s.c. on the Perkin-Elmer DSC.2. Zone refined stearic acid and purified metals (indium, tin, zinc and lead) were used as thermal standards. Heating rate and sample size effects were apparent in measuring T_g but extrapolation to zero weight at constant rate and to zero heating rate at constant weight gave similar values for T_g (± 0.5 K). In specific heat measurements a sample weight of 30 mg was used over a temperature range 350–470 K.

Rate of heating $20^\circ\text{C}/\text{min}$

Molecular weights

Viscosity-average molecular weights (\bar{M}_v) were determined from the limiting viscosity number $[\eta]$ in methylene dichloride solution using the relationship⁴:

$$[\eta] = 1.11 \times 10^{-2} \bar{M}_v^{0.82}$$

The number-average molecular weights (\bar{M}_n) up to 3×10^4 , were measured in chloroform solutions at 32°C with a Hitachi Perkin-Elmer Vapour Pressure Osmometer, model 115. Values above this were estimated from \bar{M}_v (Table 1) using a dispersity (\bar{M}_v/\bar{M}_n) of 2.4 which was checked by gel permeation chromatography for certain of the samples.

Crystallization

Polycarbonates were crystallized by: hot precipitation from 1,2-dichloroethane solutions, treatment with acetone, and melt crystallization in sealed tubes under vacuum at 195°C for 8 and 21 days.

I.r. measurements

Measurements were made on methylene chloride solutions ($40\ \text{g}/\text{dm}^3$) in KBr solution cells of path length 0.3–1.0 cm. Methylene chloride was dried with silica gel immediately before use, and has a limited window region for $3600\text{--}3400\ \text{cm}^{-1}$.

Density measurements

These were carried out on cast films by flotation on aqueous NaNO_3 solutions.

X-ray diffractometer

A Picker Powder Diffractometer was used to measure the degree of crystallinity of finely powdered or film samples. The instrument was used with $\text{CuK}\alpha$ radiation for 2θ values of 4° to 40° at $2^\circ/\text{min}$. The instrument was standardized with α -quartz as a test sample.

RESULTS AND DISCUSSION

Thermogravimetric measurements

This technique measures the weight loss of a polymer sample. The measurement may be carried out either by keeping the polymer at a constant temperature and observing the weight loss, or by raising the temperature at a steady rate until the polymer is substantially decomposed (see Figure 1). These and other similar results showed that the commercial polycarbonates had a better thermal stability than our experimental material and that there was a strong effect of molecular weight which was not just an initial effect but persisted through the main part of the decomposition process. These two factors were investigated separately and for this purpose the constant temperature procedure which gave a linear first order curve suitable for characterizing thermal stability was used.

The results showing the effect of molecular weight on the initial isothermal weight loss at 410°C are given in Figures 2a and 2b. The measurements confirm the observations illustrated in Figure 1 and show that the commercial polymers are significantly superior to the experimental material. With both types of material the amount of decomposition is much greater with low molecular weight

Figure 2a Effect of molecular weight on the thermal decomposition of commercial polycarbonates: \circ , $\bar{M}_v = 78\,000$; \times , $\bar{M}_v = 71\,000$; \bullet , $\bar{M}_v = 25\,500$; where a_0 is the initial weight and X is the weight loss

samples. Polymers terminated by *p*-cresol were not used in these studies.

Nature of the degradation process

Previous work has indicated that the degradation of polycarbonate involves the reaction of end groups^{5,6} (either phenyl or hydroxyl) and this seems to be at least superficially confirmed by our measurements. Also a study of the patent literature⁷ suggested that esterification of the hydroxyl end groups might have a useful stabilizing effect. One of the experimental polymers was therefore acetylated, and so removed $70 \pm 10\%$ of the hydroxyl groups (estimated by i.r. spectroscopy). As shown in Figure 2c the resulting polymer showed a marked increase in thermogravimetric stability although it did not quite reach the level interpolated for a commercial polymer of the same molecular weight. This result points strongly to a catalytic effect on the decomposition process. Indeed, i.r. analysis of the polymers indicated that free and associated hydroxyl groups were present, and that the concentration of free hydroxyl groups measured in methylene chloride solution varied inversely with the square root of the degree of polymerization (Figures 3a, and 3b). This dependence is consistent with association of end groups, as observed previously with polyethylene oxide in benzene⁸, i.e.

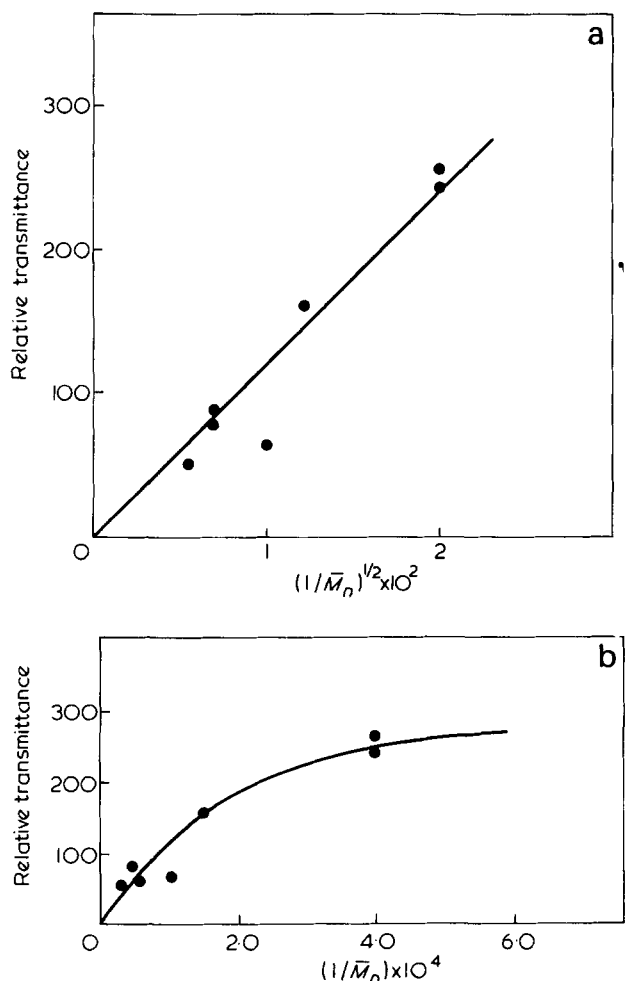

Figure 3 Effect of molecular weight on the i.r. hydroxyl absorption peak (3500 cm^{-1})

Acetylated polymers contained a reduced concentration of hydroxyl groups (reduced by 60–80% as determined from Figure 3b). On the other hand, commercial materials contained an apparently high level of hydroxyl groups which we ascribed to the presence of additives. This is also suggested by the work of Bartosiwiz and Booth⁹ who observed a decrease in polymer stability on purification. Thus the major processes of degradation are different in the two types of polymer and this is further supported by a study of weight loss at increasing temperature as shown in Figure 1. From the instantaneous slopes of these curves at different temperatures it is possible to calculate the energy of activation of the decomposition process over the initial 10% weight loss. The results obtained, which are included in Table 2, show a very significant difference between the commercial and the laboratory materials, which presumably corresponds to the absence of terminal hydroxy groups in the commercial polymers.

It should, however, be appreciated that in this type of measurement an inverse dependence on molecular weights does not itself indicate end group catalysis, since the small molecules which are volatilized in the early stages of decomposition are most likely to be formed from the ends of the polymer molecules and this would therefore give a molecular weight effect even if the degradation process was one of random molecular fracture.

Thermal studies of the glass transition

The glass transition temperature (T_g) may be readily estimated by d.s.c.^{10,11} making use of the marked change in the specific heat which occurs at the glass transition. However, the results directly obtained are dependent both on the rate of heating used (as also occurs with other methods of measurement) and on the sample size. Consistent values of T_g were obtained either by linear extrapolation to zero weight or to zero heating rate (heating rate of 2.5–80 K/min). The results (see Figure 4) followed the conventional type of relationship between T_g and M_n^{-1} ^{12,13} so that:

$$T_g = T_g^\infty - AM_n^{-1}$$

where $T_g = 432 \text{ K}$ and $A = 1.45 \times 10^5 \text{ mol K}$. In this case, it was also found that both commercial and synthetic polymers gave similar results for $T_g: M_n$, (Figure 4).

Another feature which was observed by d.s.c. studies of T_g was the occurrence of annealing peaks^{14–16}. If the polymer is heated at a temperature below T_g , say between T_g and $(T_g - 60) \text{ K}$, a change takes place which leads to an endothermic peak on later heating through T_g . The precise nature of this process is not fully understood but it is probably connected with volume relaxation which has been shown to occur under the same conditions¹⁷, and it may be associated with the formation of nodules reported to be observable under the electron microscope¹⁸. The process is unlikely to be one of nucleation and growth of a new phase since it could be fitted with an Avrami equation:

$$1 - X_t = e^{-Kt^n}$$

Table 2 Activation energies from thermal decomposition curves

Sample	Activation energy (kJ/mol)
Commercial 5705	125 ± 25
Commercial 5730	125 ± 25
Commercial M39	125 ± 25
Experimental polymer 2	65 ± 10
Experimental polymer 5	65 ± 10
Experimental polymer 10	75 ± 15
Experimental polymer 13	80 ± 10
Acetylated polymer	140 ± 30

relating X_t , the extent of development of the new phase, to time t with an n value of 1.0, and with a rate constant K which was dependent on temperature rather than on the under-cooling from the glass transition temperature ΔT . The enthalpic change Q_E increased logarithmically with the annealing time (Figure 5a) and was consistent with a relaxation to the equilibrium glassy state for which at constant temperatures:

$$Q_{E,T_A} - Q_{t,T_A} = A \ln t + A \ln k$$

where A is a constant, k a first order rate constant, Q_{t,T_A} the enthalpy change at time t and annealing temperature T_A , and Q_{E,T_A} the maximum change in energy associated with the transition. This relation is similar to that used by Petrie¹⁹ for polystyrene, though we attach no theoretical significance to the observation of a linear relation over the range studied. However, one would expect Q_E to be equivalent to the specific heat change between liquid and glass multiplied by the temperature interval, i.e.:

$$Q_{E,T_A} = \Delta C_p (T_g - T_A)$$

where $\Delta C_p = C_{p,L} - C_{p,g}$, i.e. the difference in C_p above and below T_g . Times required for relaxation of the enthalpy to the equilibrium glassy state were very long, and annealing was not continued above 100 h. The measured enthalpy changes (0.5 cal/g) were less than Q_{E,T_A} (0.80–2.00 cal/g), and depended on the annealing temperatures. Annealing at 130°C for 48 h established that the enthalpic changes of different molecular weight samples exhibited a similar

dependence on temperature of under cooling (ΔT) (see Figure 5b and Figure 6). It would appear that the enthalpic effects on annealing polycarbonate below the glass transition temperature are sensitive to the degree of undercooling, and perhaps to the free volume of the system. Further studies are required to establish the structure, formation mechanism, size and number of the nodules reported¹⁷ on annealing to see if there is any correlation of these with the enthalpic effect.

Heat of fusion and melting of polycarbonates

Polycarbonate crystallizes only slowly in bulk and samples generally do not have crystallinities in excess of 40%. The heat of fusion was determined by d.s.c. using samples crystallized in different ways, i.e. isothermally in bulk, by precipitation from hot dichloroethane solution and by treatment with acetone. The degree of crystallinity was determined in two ways, by density and by X-ray diffraction.

Density method

For a two phase system, amorphous density ρ_A and crystalline density ρ_C the degree of crystallinity of a sample of density ρ is given by:

$$X_c = \frac{(\rho - \rho_A)}{(\rho_C - \rho_A)}$$

The crystalline density was calculated as $1.30(7) \text{ g/cm}^3$ from the X-ray structure²⁰. However, the probable error in ρ_C obtained in this way (up to 2%) was highly significant in deriving ρ_C and consequently in determining the heat of fusion. The density of the amorphous polymer was not sensibly affected by the rate of cooling but varied from one sample to another. We measured the value of 1.188 for the commercial polymer (\bar{M}_n 19 500) used and 1.204 for the hydroxyl terminated (experimental) material (\bar{M}_n 33 000).

Figure 6 Effect of molecular weight on the endothermic d.s.c. peak: \circ , experimental polycarbonates; \blacktriangle , commercial materials

Figure 7 X-ray diffraction peaks for a partly crystalline polycarbonate. The % crystallinity is obtained from the relative area of the shaded portions

Figure 8 Heat of fusion of polycarbonates with different levels of crystallinity. ○, % crystallinity from density measurements ($\Delta H_f = 30.4 \text{ cal/g} \pm 20\%$); ●, % crystallinity from X-ray diffractometry ($\Delta H_f = 32.9 \text{ cal/g} \pm 4\%$)

X-ray diffraction

Partly crystalline polymers were characterized on an X-ray powder diffractometer, in which scattered intensities were plotted as a function of the Bragg angle 2θ . The amorphous and crystalline contents were measured directly from the areas under the curves shown in Figure 7. With this method it was possible to use polymers prepared by hot precipitation, which had a slightly higher crystallinity than could be reached by isothermal bulk crystallization ($\sim 30\%$ compared with $\sim 25\%$) and this was an advantage

Figure 9 The specific heats of polycarbonates. (a) the effect of molecular weight on the specific heat of amorphous polycarbonate; (b) the effect of crystallinity on the specific heat of polycarbonates. Crystallinity determined from d.s.c. measurements using a heat of fusion of 32 cal/g

Table 3 Specific heat of polycarbonate

Temperature (K)	Specific heat (cal/g)	
	Crystalline	Amorphous
350	0.243	0.327
355	0.247	0.331
360	0.251	0.335

465	0.373	0.457
470	0.378	0.462

of the X-ray method. As is clear from *Figure 7* the limitation of the method lies in the estimation of peak areas from the X-ray diffraction curves.

Measured heats of fusion

The results of the two sets of measurements are given in *Figure 8* where the measured heat of fusion is plotted against the estimated crystallinity. From the slopes of the curves, the heat of fusion for the 100% crystalline material may be estimated. The value obtained from the density method (30.4 cal/g) agrees with that given by Wineman^{21,22}. The value obtained by X-ray diffraction is higher (32.9 cal/g), but in view of the problems concerning the precise determination of crystal density it could well be correct in spite of the disagreement with Wineman's work.

Both values are inconsistent with the value of 13.4 cal/g given by Conix and Jeurissen²³ determined by melting point depression. Analysis of the molecular weight dependence of the melting point of the selected samples gave a very similar low value of the heat of fusion. This would seem to indicate that the assumption of equilibrium in the melting studies cannot be valid. Therefore it is concluded that the two higher figures reported above are a better estimate of the true heat of fusion.

Heat capacity

The specific heats were also measured by extrapolation to zero heating rate and the results obtained varied with the particular material used. Two parameters proved to affect the specific heat significantly, viz, crystallinity and molecular weight.

Samples of amorphous polymer quenched to room temperature showed no endotherm in the melting range so that specific heats could be directly measured and so related to \bar{M}_n as shown in *Figure 9a*. The results may be represented by:

$$C_p(\text{amorphous}) = C_p^\infty + \frac{360}{\bar{M}_n} \text{ cal/g [where } \bar{M}_n = 2.5 \times 10^3 \text{ to } 3.3 \times 10^4]$$

Differences in specific heats for materials of different crystallinities (corrected for differences in molecular weight) are shown in *Figure 9b* from which it may be inferred that

$$C_p(\text{crystalline}) - C_p(\text{amorphous}) = 0.084 \text{ cal/g at } 180^\circ\text{C}$$

The specific heats for crystalline and amorphous polymers are listed in *Table 3* as a function of temperature from which

$$C_p(\text{crystalline}) = 0.243 + (T - 350) \times 9.0 \times 10^{-4} \text{ cal/g}$$

$$C_p(\text{amorphous glass}) = 0.327 + (T - 350) \times 8.0 \times 10^{-4} \text{ cal/g}$$

The change in heat capacity between amorphous glass and liquid at the glass transition temperature was 0.040 cal/g which for our range of annealing temperatures corresponded with $Q_{E,TA}$ values of 0.80–2.00 cal/g.

ACKNOWLEDGEMENTS

We wish to thank Dr J. I. Langford for assistance in carrying out our X-ray diffraction measurements, Dr F. W. Peaker for the g.p.c. measurements and Dr J. K. Brown for i.r. analysis. G.A.A. is indebted to the Iraqi Ministry of Higher Education for financial support.

Effect of phosphine ligand on the activity of palladium/ π -catalysts

Fereidun Hojabri

Department of Chemistry, Arya-Mehr University of Technology, PO Box 3406, Tehran, Iran
(Received 8 May 1975)

Homogeneous palladium/ π -catalysts for olefin polymerization were converted to supported catalysts with styrene-divinylbenzene copolymer as supporting matrix. Phosphine ligand was used for linkage of palladium to the support. The effect of phosphine ligand on the catalytic activity for the polymerization of olefins was studied. A reaction mechanism on the basis of preferred maximum coordination number of Pd(II) is proposed and discussed to explain the reduced activity of phosphinated palladium complexes for olefin polymerization.

INTRODUCTION

Homogeneous catalysts have several advantages over heterogeneous catalysts: (a) they have better defined active sites; (b) usually all of their metal atoms are available to the reactant as catalyst; and (c) they have better mass and heat characteristics. But especially the problem of separation of a homogeneous catalyst from the solution in which it has served as a catalyst has been the major hindrance to the greater employment of homogeneous catalysts in commercial processes. To remove this disadvantage the homogeneous catalysts can be linked to a variety of support materials^{1,2}. Polystyrene-divinylbenzene copolymers have recently been used to chemically bond Rh and Ti to prepare hydrogenation catalysts with interesting selectivity and stability^{3,4}. Phosphine ligand is usually used to link metals to the supports. The same method was applied to this work to bond palladium/ π -allylic complexes to polymer support. The effect of phosphine ligand on the activity of palladium/ π -complex for olefin polymerization is described here.

ATTACHMENT OF PALLADIUM TO POLYMER SUPPORT

The homogeneous palladium catalyst (I) used in these experiments was a palladium/ π -allylic complex⁵. The catalyst was prepared from palladium chloride and β -pinene according to the following scheme:

The supporting matrix was a styrene-divinylbenzene copolymer with a divinylbenzene content of 2% and bead size ranging from 200 to 600 mesh.

The crosslinking with divinylbenzene gives the copolymer a pore-containing structure and increases the ability of substrate to penetrate into the inner parts of the beads.

Since the π -allylic complex of palladium is a bridged compound⁵ and triphenyl phosphine is a well-known bridge-

splitting agent⁶, it was decided to functionalize the polymer with a similar ligand. For the attachment of this ligand, usually, the polymer is first chloromethylated⁷ and then treated with lithiodiphenylphosphide³:

But owing to reported cancer causing properties of chloromethyl ethyl ether, phosphination of the polymer support was carried out through another method:

Phosphinated polymer beads (II) were then equilibrated with an excess of palladium/ π -allylic complex (I) for 20 days.

The polymer-attached palladium complex (3) was deep red in benzene. The catalyst was washed several times with benzene and dried.

CATALYTIC ACTIVITY OF THE SUPPORTED PALLADIUM COMPOUND

To compare the catalytic activity of the supported palladium catalyst with the activity of the homogeneous palladium one, both catalysts were used in polymerization of bicyclohepta-(2, 5)-diene under the same reaction condi-

Figure 1 Polymerization of bicyclohepta-(2,5)-diene at 80°C. ●, Homogeneous Pd catalyst; ■, supported Pd catalyst; ○, supported Pd catalyst refluxed with benzene

Figure 2 Effect of triphenylphosphine on polymerization of bicyclohepta-(2,5)-diene at 80°C with palladium/ π -allylic complex (30 mg)

tions. It was found that the polymerization with the supported catalyst, although slower than with the homogeneous catalyst, was still a fast reaction. But when the supported palladium catalyst was refluxed with benzene for 30 min, prior to its application in polymerization reaction, the catalytic activity was reduced to almost zero. Figure 1 shows the results of polymerization at 80°C, using the same amounts of homogeneous and supported catalyst in respect to palladium content. Apparently residues of uncoordinated palladium/ π -complex were responsible for the remaining catalytic activity. These residues were firmly adsorbed by the polymer support and could be removed only after long treatment with benzene solvent. To determine whether the decline in catalytic activity of the supported palladium was due to coordination of the palladium/

π -complex with phosphine ligand or due to other factors, the homogeneous palladium/ π -complex with different amounts of triphenylphosphine was used in polymerization. As it can be seen from Figure 2, polymerization of bicyclohepta-(2,5)-diene was decreased with increasing amounts of added triphenylphosphine. The activity of the catalyst mixture diminished totally when the ratio Pd:P reached 1:1. Addition of more triphenylphosphine did not change the activity of the catalyst system.

Olefin polymerization by transition metal complexes normally occurs by a π -olefin mechanism, involving an intermediate metal-carbene complex. Such an intermediate might be involved in addition of olefins to palladium/ π -allylic complexes, by olefins acting as bridge-splitting agents (Scheme 1). Rearrangement of π -complex (IV) to (V) and further addition of olefin to these intermediates with vacant coordination site leads to polymerization.

This mechanism is consistent with the experimental results. Palladium remained attached to the produced polymer and it was not possible to separate the applied homogeneous palladium/ π -complexes from the product by solvent extraction. Furthermore, if the polymerization was stopped in the early stages of the reaction, the produced polymer was active and could be used to polymerize more bicyclohepta-(2,5)-diene. The yellow colour of the polymer was another indication that the π -allylic system of the palladium complex was present as part of the produced polymer. More than 90% of palladium present in the original catalyst was also found in the polymer. Dissociation of (VII) and participation of palladium metal occurs at temperatures higher than 140°C.

The mechanism shown in Scheme II best explains the observation on the effect of triphenylphosphine addition. Palladium is in π -allylic complexes, $[\text{PdCl}(\text{allyl})]_2$ in the Pd(II) state and, therefore, has a 8d electronic structure. The maximum coordination number for a 8d configuration is 5 but the tendency for five coordination depends on the ligand and the metal. Palladium, as opposed to Ni or Rh, has little tendency to accept the coordination number 5. Only a few palladium complexes with 5-coordinate structure have so far been determined⁸. Triphenylphosphine adduct (VIII), which is formed by addition of $(\text{C}_6\text{H}_5)_3\text{P}$ to palladium/ π -allylic complex (I), has also the preferred 8d

Scheme 1

Scheme II

structure. However, to add olefin, the complex (VIII) must change to the intermediate (IX) with the coordination number 5. Rearrangement of (IX) to (X) and further addition

of olefin (XI) could lead to final polymerization of bicyclohepta-(2, 5)-diene. Apparently owing to the higher energy of five coordinate structure, the intermediates (IX) and (XI) are not formed and the polymerization does not take place.

The lack of polymerization activity of the supported palladium catalyst may be explained in the same way by a reaction mechanism involving the phosphine ligand as linkage to the support.

Thermal oxidation of poly(1-pentene): 1. Identification of products and mechanisms*

S. M. Gabbay and S. S. Stivala

Department of Chemistry and Chemical Engineering, Stevens Institute of Technology, Hoboken, New Jersey 07030, USA

(Received 18 August 1975)

Isotactic poly(1-pentene) was degraded in the presence of pure oxygen at 115°C. The functional groups present in the non-volatile products were identified using infra-red spectroscopy. The volatile products formed were identified by means of a relatively new technique which combines thermal and mass chromatography. In this study, fourteen volatile products were detected and identified and their relative abundance estimated. The results obtained could readily be reproduced. Various oxidation mechanisms for these products are postulated.

INTRODUCTION

Earlier studies¹⁻⁵ have indicated that isotactic poly(1-pentene) (IPP-1) may crystallize into two modifications: modification 1, having a melting temperature at 130°C, and modification 2, having a melting temperature at 80°C. These melting temperatures are regularly affected by molecular weight but exceptionally dependent on crystallization temperature⁶. Both polymorphous modifications have distinct X-ray crystal structures⁷, (e.g. the chain conformations are 3₁ and 4₁ helix for modification 1 and 2, respectively), and characteristic infra-red spectra, as reported elsewhere⁸.

Since the study of the kinetics and mechanism of thermal oxidative degradation provides a basis from which the most diverse technological phenomena can be controlled, several investigations have been carried out on the mechanism and kinetics of polyolefins, e.g. polyethylene, polypropylene, and poly(1-butene), autoxidation, both in the presence and absence of additives using different methods^{9,10}. However, relatively very little work was reported on the nature and the mechanisms of formation of volatile products (*VP*) evolved during the thermal oxidation of polyolefins^{11,12}.

Recently, a relatively new technique (thermal and mass chromatography) was used to identify the *VP* evolved during the thermal degradation of polyethylene¹³ and polystyrene¹⁴. A modification of this technique was adopted for the detection and identification of *VP* resulting from thermal oxidation of polymers¹⁵. Additionally, a procedure combining thermal chromatography with mass spectrometry was described in an earlier paper for the identification of volatile oxidation products of poly(4-methyl-1-pentene)¹⁶.

The purpose of this paper is to examine the non-volatile products (*NVP*) and the volatile products formed from the oxidation (115°C, 100% O₂) of modification 1 of IPP-1, using the methods of i.r. spectroscopy and thermal/mass chromatography (t.m.c.) respectively.

EXPERIMENTAL

Starting material

The IPP-1 sample used in this study was an unstabilized pure polymer obtained through the courtesy of Dr Gianotti from Montedison, Italy. Its intrinsic viscosity in tetralin at 135°C was 4.7 dl/g. Upon ignition, the sample gave an ash content of 0.01% by wt. A crystalline melting point of 78°C was determined by a Perkin-Elmer Differential Scanning Calorimeter (d.s.c.) using a programmed heating rate of 10°C/min. IPP-1 studied in this work was modification 1.

Apparatus

A Perkin-Elmer spectrophotometer, Model 21, equipped with a sodium chloride prism was used to record the i.r. spectra of oxidized IPP-1 in order to identify the functional groups formed in the *NVP*.

A thermal chromatograph (MP-3) coupled in series with a mass chromatograph (MC-2) (Chromalytics, Division of Spex Industries) were used to identify the *VP* evolved during the thermal oxidation of IPP-1.

Procedure

Clear and uniform films of ~2 to 2.5 mil thickness of modification 2 were prepared when IPP-1 sample was compression moulded in vacuum¹⁷ at 140°C and cooled to room temperature over a 20 min period. These films were converted to modification 1 by refluxing them in absolute ethanol¹⁸ overnight and subsequently dried in a vacuum oven at 50°C for 12 h (thickness not appreciably affected). These films were oxidized at 115°C under 100% oxygen for 75 min in the MP-3. The volatile oxidation products evolved were rapidly swept from the sample chamber for gas chromatographic separation and identification by retention times, mass chromatography (using MC-2 in order to determine the molecular weight of the major *VP*), and peak enhancement. Detailed experimental conditions were described earlier¹⁵. Weight loss of modification 1, owing to formation of *VP*, was 1% at 115°C. Several repeat runs indicated excellent reproducibility.

Figure 1 I.r. spectra of IPP-1 (modification 1) at (a) initial and (b) final stages of oxidation at 115°C

Figure 2 Chromatogram of volatile oxidative degradation products of IPP-1 obtained at 115°C¹⁵. A, CO₂; B, acrolein; C, acetaldehyde; D, propionaldehyde; E, acetone; F, methanol; G, ethanol; H, butyraldehyde; I, water; J, propanol; K, acetic acid; L, propionic acid; M, butyric acid; N, oxalic acid

By means of i.r. spectra, it was ascertained that the oxidized film of IPP-1 was that of modification 1 (see Figure 1) and the *NVP* formation was assessed in terms of hydroxyl, carbonyl, and vinyl groups as described earlier¹⁶.

RESULTS AND DISCUSSION

Figure 1 represents i.r. spectra of modification 1 of IPP-1 at an initial and final stage of oxidation at 115°C. It can be seen that a strong band appeared at 2.85 μm due to the presence of hydroxyl groups. A triplet formation in the carbonyl stretching region (5.70–5.85 μm) indicated the

presence of such functional groups as aldehyde, ketone, ester, and carboxylic acid¹⁹ and a band ingrowth at 11.35 μm indicated the formation of substituted vinylidene bonds²⁰. A representative gas chromatogram of modification 1 oxidized for 75 min is shown in Figure 2. The relative abundance, h_p/h_{CO_2} , of the fourteen volatiles was calculated from the peak heights, h , of an oxidation product, p , to that of CO₂ (the first product appearing in the chromatogram and the most abundant). Values of h_p/h_{CO_2} ratios and their relative percentages are given in Table 1 in an order of decreasing abundance of the *VP* relative to CO₂. The molecular weights of five major *VP* are also given in Table 1. As noted, the molecular weights of some of the *VP* could not be determined owing to their low concentrations. The assessment of the precision and accuracy of the MC-2 over a wide range of molecular weights was previously reported²¹.

Since it has been established that peroxides or hydroperoxides^{22–25} are predominantly formed at the early stages of oxidation, the decomposition of unstable peroxides will give rise to a whole series of secondary compounds, generally containing carbonyl and hydroxyl groups. Based on this observation, various mechanisms for the formation of polar volatile products resulting from the thermal oxidation of poly(4-methyl-1-pentene) were postulated in an earlier publication¹⁶. In a similar manner it is possible to account for the formation of the volatiles of IPP-1 in this work.

In the case of IPP-1, fourteen *VP* were detected (115°C under 100% oxygen for 75 min) whereas in isotactic poly(4-methyl-1-pentene) (IPMP) seventeen *VP* were detected (145°C under 100% oxygen for 10 min). Propionic acid, propionaldehyde, butyraldehyde, butyric acid, and n-propanol were detected in IPP-1 but not in IPMP. The remaining nine *VP* shown in Table 1 were also detected in IPMP and their mechanism of formation was postulated¹⁶. The mechanism of formation of the above five volatile products of IPP-1 is postulated below, including only those *VP* also evolved from IPMP but whose mechanism may differ by virtue of the composition of IPP-1.

The poly(1-pentene) molecule possesses tertiary hydrogens on the main chain. These hydrogens should be more readily abstracted by free radicals and oxygen than the neighbouring secondary hydrogens. Nevertheless, it should be noted that secondary hydrogens would also be expected to participate in reactions along with tertiary hydrogens albeit to a lesser extent.

Table 1 Relative abundance, h_p/h_{CO_2} , of volatile oxidation products of IPP-1 at 115°C¹⁵

Volatiles	h_p/h_{CO_2}	Relative abundance (%)	Calculated MW	Actual MW
Carbon dioxide	1.00	65.3	—	—
Acetic acid	0.125	8.1	61.53	60
Propionic acid	0.116	7.6	74.50	74
Water	0.061	4.0	—	—
Propionaldehyde	0.055	3.6	58.58	58

Butyraldehyde	0.033	2.2	—	—
Acrolein	0.033	2.2	—	—
Ethanol	0.011	0.7	—	—
Methanol	0.008	0.5	—	—
n-Propanol	0.005	0.3	—	—
Acetaldehyde	0.005	0.3	—	—
Oxalic acid	0.003	0.3	—	—

Thus:

or

In these reactions, the IPP-1 moieties II and III are considered to form according to the equations reported earlier¹⁶. The broken lines on structure I indicate bonds which may undergo scission, and also apply to structures II and III.

where RH is the polyolefin chain I

The resulting non-volatile fragment could be ketone which, indeed, was detected by i.r. in the IPP-1 residue following oxidation (see Figure 1). The resulting n-propanol has been identified (Table 1) and may undergo further reaction:

Propionaldehyde may also be derived in the following manner, which involves secondary side chain hydrogen and an isomerization²⁶:

The resulting propionaldehyde can undergo oxidation to the corresponding acid (a major product) while the re-

sulting alkoxide may either liberate H⁺ to form a ketone or may abstract a hydrogen to form the corresponding alcohol (hydroxyl groups have been detected by i.r., see Figure 1).

If two B-scissions are assumed, one of the VP identified, butyraldehyde, may form, thus:

The resulting butyraldehyde may undergo oxidation to yield the corresponding acid, butyric acid (one of the VP identified).

A major product, acetic acid, may be obtained from the oxidation of the corresponding aldehyde (acetaldehyde) which is depicted:

It has been reported in the thermal oxidation of polypropylene²⁷ that acetic acid was an abundant VP formed from further oxidation of an acetyl radical produced by successive scissions as shown:

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to Dr Gianotti from Montedison Company, Italy for the polymer sample.

Model polyurethane networks

G. Allen*, P. L. Egerton and D. J. Walsh

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK

(Received 12 March 1975)

Polyurethane model networks have been prepared in various solvents at different polymer concentrations, in such a way that the topology of the networks could be controlled. The effects of the network defects, i.e. unreacted functionalities, closed loops and entanglements, on the theoretical value of the modulus has been estimated and these theoretical values have been compared with the experimentally determined values of the modulus. The results imply that the front factor A in the equation for the free energy of deformation of the network tends to half rather than unity. In dry networks the effect of physical entanglements on the modulus of the network appears to be comparable in magnitude to that of chemical crosslinking.

INTRODUCTION

The various theories of rubber elasticity lead to a general expression for the free energy of deformation of a network of the form:

$$\Delta F_{eL} = A \left(\frac{\nu}{2} \right) kT(\lambda_x^2 + \lambda_y^2 + \lambda_z^2 - 3) - B\nu kT \ln \lambda_x \lambda_y \lambda_z \quad (1)$$

where ν = no. of elastically effective chains, k = the Boltzmann constant, T = absolute temperature, $\lambda_x, \lambda_y, \lambda_z$ = deformation ratios in the $x, y,$ and z directions and A and B are constants.

The values of A, B differ in the various theories of rubber elasticity. The theories of Flory and Wall¹⁻⁴ sum over all the chains in the network before and after deformation and give a form of equation (1) with $A = 1, B = \frac{1}{2}$. James and Guth⁵⁻⁸ sum over all the crosslink positions and consider the effects of a gradual rather than an instantaneous crosslinking of chains, resulting in $A = \frac{1}{2}, B = 0$. Edwards⁹ considers the network to be an infinitely long polymer molecule, where the entropy of the system is limited by crosslinks which are put in as delta functions. The crosslinks are considered to be random and free to slide along the chains, and then frozen in position. The result obtained here is that $A = \frac{1}{2}, B = 0$. This is in agreement with that obtained by James and Guth although in this latter case no particular crosslinking process is assumed.

The shear modulus, G , of the network is:

$$G = \frac{3}{2} AnkT = AvkT \quad (2)$$

for a network with trifunctional crosslinks where n is the number of crosslinks per unit volume. Thus, if we measure the modulus of a network containing a known number of elastically effective chains it is, in principle, possible to determine the value of A . The value of B can only be determined for network deformations accompanied by changes in volume.

Previous papers^{10,11} have described a procedure for pre-

paring polystyrene networks containing a known number of elastically effective chains at various concentrations in inert solvents. An estimation was made of the commonly considered network defects: (i) unreacted functionalities and free chain ends; (ii) closed loops; (iii) entanglements. The results obtained^{10,11} were consistent with the value of $A = \frac{1}{2}$.

In this paper, simple polyurethane networks have been prepared from propylene oxide polyols which have narrow molecular weight distributions. Thus the crosslinks are distributed more regularly than in the polystyrene gels^{10,11}. Elastic moduli have been measured for gels of different concentrations and crosslink density and the results have been interpreted in a similar manner to that used previously. In general the results support the previous analysis^{10,11}.

EXPERIMENTAL

Preparation of networks

Simple polyurethane networks were prepared by the reaction of long chain poly(propylene oxide) polyols with 4,4'-diphenylmethane diisocyanate (MDI) an aromatic diisocyanate. Two types of polyol were used, one trifunctional (T56) and the other bifunctional (B56); each had an equivalent weight per hydroxyl group of about 1000 and the poly(propylene oxide) chains were terminated by a secondary alcohol group. Both polyols were kindly supplied by ICI Ltd Organics Division.

Prior to use, both T56 and B56 were filtered using a G3 sintered glass filter. The polyols were then dried by passing nitrogen through at reduced pressure and heating for about 1 h at 100–110°C. Once dried, the polyols were stored in an evacuated vessel until required. Polyols used in gel preparation were stored under these conditions for no longer than one week.

MDI was distilled under reduced pressure prior to use. Using a rotary vacuum pump to obtain reduced pressure, the MDI normally distilled in the range 180–188°C depending on precise value of the pressure. The melting point of the MDI was determined to be 42°C. MDI was used on the same day as it had been distilled thus minimising any deterioration of the MDI which would result in inefficient crosslinking.

* Present address: Department of Chemical Engineering and Chemical Technology, Imperial College, London SW7, UK.

Generally, the solvent used in the gel preparation was dibutyl phthalate (DBP). Prior to use it was dried over calcium hydride for at least one week. Immediately before use it was passed through a G3 sintered glass filter. Other solvents used were diethyl phthalate (DEP), dimethyl phthalate (DMP), diheptyl phthalate (DHP), dinonyl phthalate (DNP), tetralin and diglyme. All were dried and filtered in a way similar to that previously described. It was found necessary to distil the tetralin and diglyme before use to remove peroxides; the presence of peroxides resulted in yellow gels, and reduced modulus.

The method of preparation was simple, all the components being mixed in a 250 ml flask. The amount of MDI used was a few per cent less than that required stoichiometrically. Solid MDI ground to a powder was first weighed accurately into the flask, and then the polyol and solvent were added. The mixture was then heated to about 40°C to dissolve the MDI and the flask was then cooled to room temperature. The mixture was then degassed for a few minutes in order to remove dissolved air. Catalyst was then added. The amount of catalyst added depended on the concentration of polymer in the mixture. Generally one small drop was added to the 100% polymer mixtures and more was added to the less concentrated mixtures; typically about 10 drops of catalyst were added to the 15% polymer mixtures. The catalyst generally used was dibutyltin dilaurate (DBTDL) although different catalysts were also used [triethylene diamine (DABCO) and stannous octoate (SnOc)]. After addition of the catalyst the contents of the flask were mixed under vacuum for about 1 min to ensure uniformity of the components and then poured into a mould, which was then placed into a desiccator containing dried silica gel. This prevented any atmospheric water vapour effecting the mixture during gelation. The mould was typically a 3.5 in diameter crystallizing dish. Gelation took place in a period of 1–5 h at room temperature depending on the initial polymer concentration.

Under these conditions any side reactions were kept to a minimum; rate constants of allophanate reactions (i.e. reaction between urethane and isocyanate groups) are much less than the rate constant for the normal urethane forming reaction. We can also assume that the effect of water can be ignored since all reagents were carefully dried. We assume that the main reaction in the formation of the network is:

This is supported by studies on the structure of similar polyurethane elastomers by n.m.r. spectra¹⁷. Sumi *et al.* found that for a polymer made from poly(propylene glycol) and MDI at 85°C for 3 h, only a single NH peak was observed in the n.m.r. spectra, indicating the presence of simple urethane links only in the polymer. Much of the previous work on polyurethanes has been carried out on materials synthesized under conditions where complex crosslinking reactions occur¹⁸ including allophanate and biuret reactions. The results described here should be simpler to interpret since we can assume that reaction (A) is the only one occurring to any appreciable extent.

Networks were prepared at different solvent concentrations (DBP) and at 3 different ratios of T56: B56. These

were 100% T56, 75% T56, 60% T56 by wt. Thus polymer concentration and crosslink density were varied.

Reaction efficiency

The method used in previous work^{10,11} was used to estimate reaction efficiency. The number of unreacted isocyanate groups remaining in the gel was measured using a ¹⁴C labelling technique. After the gel had been used, and mechanically tested, a sample of ~10 g was broken into small pieces and placed in a stoppered vessel. ¹⁴C-methanol (~1 ml of a suitable activity) was added with about 100 ml of tetrahydrofuran to label the residual isocyanate in the gel. The mixture was left to stand for a week to ensure complete reaction. The remaining unreacted ¹⁴C-methanol was then extracted from the gel by standing in excess of solvent. The solvent was changed daily; heptane and methanol were used alternately. After about 10 series of washings a constant value was obtained. Then the gel was dried, swollen in methanol and redried. The activity of the samples was then measured on a Packard Model 3320 liquid scintillation counter, and compared with a dilute solution of the original ¹⁴C-methanol, and a blank. The scintillation 'cocktail' used consisted of 0.30% diphenyl oxazole and 0.03% bis(5 phenyloxazole-2-yl)benzene in xylene.

Modulus measurement

Modulus measurements were determined in the same manner as described in previous papers^{10,11}. This method is based on the indentation of the gel surface with a solid sphere. A modified dial gauge was used to measure the indentations produced by different loads. The equation used to relate modulus (*G*) to applied force (*P*) sphere radius (*r*), and indentation (*d*), is given by Waters¹³:

$$G = \frac{3P}{16d^3/2R^{1/2}} \quad (3)$$

This method was used to compare the moduli of all gels produced. Two sizes of spheres were used on each gel. If the results obtained from both measurements were not consistent, the measurements were repeated until reproducible modulus values were obtained.

In order to test the reliability of the previous method of modulus measurement further tests were carried out on some of the harder samples produced. In these measurements samples were subject to compressive or extensive forces.

For the simple compression tests a mould was made of PTFE of internal height 4 cm and diameter 2 cm. The mould was filled with the reaction mixture. On completion of the reaction the sample was removed by removing the end caps from the mould and pushing the sample through the mould. The sample was then placed on a comparator bench with a flat glass plate placed over it. Loads were then applied on the load platform above the dial gauge and indentations measured on the gauge.

Sheets of polyurethane were prepared for samples to be used in the extension tests. Two glass sheets were cleaned and, using PTFE and silicon sprays, a thin coating of PTFE was applied followed by a thin coating of silicon grease. These coatings aided removal of the sample. A rubber gasket was cut and the plates and gasket held in position with clamps. The reactants were then paired into the slit at the top of the mould and allowed to set. The sample was removed and suitable strips cut for use on a type E, Houns-

Table 1 Agreement between various methods of modulus measurement

Sample	Method of measurement	Modulus $\times 10^{-4}$ (N/m ²)
A	Extension of strip	84
	Indentation of sphere	96
B	Extension of strip	100
	Indentation with sphere	110
C	Compression of block	73
	Indentation with sphere	76
D	Compression of block	22
	Indentation with sphere	26
E	Indentation with sphere	32.0
	Compression of block	27.6
	Extension of strip	28.2
F	Indentation with sphere	17.1
	Compression of block	15.3
	Extension of strip	13.0

Figure 1 Plot of G/nkT versus concentration for 100% T56 networks

field Tensometer. Using this machine the stress applied to the sample was measured automatically by strain gauges and the data were fed to a chart recorder. The extension was measured at various applied stresses by measuring the distance between fiducial marks on the sample using a cathetometer.

Sample dimensions were measured using callipers, and deformations in extension and compression were generally less than 10%. Equation (4) describes the behaviour of the samples approximately under these conditions.

$$f = \frac{E}{3} (\alpha - \alpha^{-2}) \quad (4)$$

where f is the force applied to the sample per unit unstrained cross-section of the sample, E is Young's modulus and α is the extension ratio. Thus a value of E can be obtained if f is plotted against $(\alpha - \alpha^{-2})$. Assuming Poisson's ratio is $\frac{1}{2}$ we can use the relationship, $E = 3G$, and so determine G , the shear modulus of the material. Table 1 shows the agreement obtained in the various samples tested by more than one method. The agreement between the various methods shows that the modulus values obtained by the indentation method are reasonable when compared with other methods of estimating shear modulus.

CALCULATION AND RESULTS

It is necessary to determine the number of chemical crosslinks in the network. In the calculation it has been assumed that the number of T56 units totally incorporated into the network gave the number of crosslinks in the network. Unless all three 'arms' of the T56 molecule are reacted no crosslink is incorporated in the network. This implies that, if we ignore closed loops and entanglements, no continuous network is formed until the reaction is 66.7% complete in the case of T56 networks, 75% complete for 75% T56, 25% B56 networks and 80% complete for 60% T56/40% B56 networks, assuming we have initially equimolar amounts of isocyanate and hydroxyl groups.

On this basis the number of crosslinks in the network (n) has been estimated. Allowance must be made for the fact that exactly equimolar amounts of isocyanate and hydroxyl groups were not used and for the fact that the reaction was never 100% efficient. The number of T56 molecules totally incorporated into the network gives the number of crosslinks in the network. In 100% T56 networks, 3 isocyanate-polyol reactions are required for each T56 molecule to be incorporated completely into the network. In networks of 75% T56 by wt, 2 T56 molecules exist for each B56 molecule. Thus, on average, 4 isocyanate-polyol reactions are required to incorporate each T56 molecule into the network. In networks of 60% T56 by wt, where 1 B56 molecule is present for each T56 molecule, 5 isocyanate-polyol reactions are required to incorporate each T56 molecule into the network. Thus, an $x\%$ inefficiency of reaction reduces the value of n by $3x\%$: for T56 networks, $4x\%$ for 75% networks, and $5x\%$ for 60% networks. Thus n is a sensitive function of the inefficiency of reaction, and the proportions of initial reactants. It can be seen from the table of results that in this experiment the efficiency of reaction is generally close to 100%. This is in agreement with results of Conway *et al.*¹⁹ where a similar value of the efficiency of reaction was found by nitrogen analysis of the urethane network formed by reaction of poly(propylene oxide) with²⁴ toluene di-isocyanate. Using equation (2) an estimate of the modulus excluding effects of defects can be obtained. In the graphs (Figures 1-3) values of G/nkT are shown, where G is the experimental modulus, and $0.75 nkT$ is the theoretical modulus assuming $A = \frac{1}{2}$ and that no closed loops or entanglements are present.

A series of measurements was made at $\sim 50\%$ polymer concentration in a wide range of solvents. These results are shown in Table 2. They suggested that the modulus of the

Figure 2 Plot of G/nkT versus concentration for 75% T56/25% B56 networks

Figure 3 Plot of G/nkT versus concentration for 60% T56/40% B56 networks

gel was independent of the solvent used. Some variation in the value of G/nkT was observed but this was no more than the variation normally observed for any one solvent. The effect of different catalysts was also negligible. Thus we can assume that the results obtained for the system using DBP as solvent and DBDTL as catalyst are not peculiar to this particular system.

Interpretation

If there are no defects in the network we would expect that $G/nkT = 0.75$ for all the series of results. We assume the variation from this result can be explained in terms of network defects. Closed loops result in a loss of elastically effective chain from the network; entanglements result in an increase of effective crosslinks.

Closed loops.

Using the analysis shown in the Appendix, similar to that used previously by Kuhn¹⁴, and Jacobson and Stockmayer¹⁵ we obtain:

$$G/nkT = \frac{3}{2} A \left(1 - \frac{3}{1 + 30C} \right) \left(1 - \frac{3}{1 + 44C} \right) \quad (5)$$

where C = concentration of polymers, and where single closed loops and closed loops involving 2 chains are considered.

For gels with both T56 and B56 present a similar analysis leads equation (A1), to:

$$G/nkT = \frac{3}{2} A \left(1 - \frac{3}{1 + 30C} \right) \left(1 - \frac{3}{1 + K'C} \right) \quad (6)$$

where K' is a constant which can be calculated from the actual ratio of B56 and T56 used. For simplicity, we neglect the effect of larger closed loops which might also be expected to reduce the modulus. Some of the larger loops may also tend to be elastically effective and contribute to the modulus.

Entanglements. Previous results on polystyrene gels^{10,11} have suggested that the effect of entanglements is proportional to C^2 as predicted by Edwards¹⁶. Thus for T56/B56 gels the total variation in G/nkT is described by:

$$\frac{G}{nkT} = \frac{3}{2} A \left(1 - \frac{3}{1 + 30C} \right) \left(1 - \frac{3}{1 + K'C} \right) + 2AR \left(\frac{C}{nkT} \right) C \quad (7)$$

In Figures 1–3 the plots of G/nkT according to equation (7) have been drawn using values of $R = 6 \times 10^5$, 4×10^5 , 3.75×10^5 , where R has been adjusted to give the best fit with experimental results in the high concentration region. These values of R are of the same order as the value of $R = 1 \times 10^5$ determined in the studies of polystyrene gels¹⁰. We might expect that R would be greater for poly(propylene oxide) chains than for polystyrene chains owing to the greater configurational flexibility of the former. The use of different values of R in the three cases might support the view that the effect of entanglements is greater in gels where crosslink density is greater, i.e. the number of entanglement is not only a function of C^2 but also of crosslink density.

A series of measurements have also been obtained of modulus of bulk polymers of varying T56/B56 ratios. Extrapolation of the modulus values to zero T56 concentration allows an estimate to be made of the effect of entanglements in this system at zero chemical crosslink density. The value of R obtained from these results is similar to the value of R used here, for gels with B56 present, i.e. 2×10^5 (Figure 4).

Errors in the experimental value of G/nkT should be small. Values of G/nkT obtained for different gels in similar conditions were within 10% of each other as shown by results in Table 3. This uncertainty arises chiefly from the

Table 2 Effect of solvent and catalyst

Samples 17–24: 60% T56 gels

Figure 4 Modulus of 100% polymer networks of various T56: B56 ratios

modulus measurements which have random errors of about 1.5%.

The curves plotted in Figures 1–3 have been calculated using equation (7). Other theoretical curves have been plotted assuming $A = 1$, and assuming that no entanglements exist in the networks. Of all the curves plotted those predicted by equation (7) give the best agreement with experimental results. Thus our results support the view that the front factor, A , in equation (1) is $\frac{1}{2}$ and that the effect of entanglements is proportional to C^2 .

We see that at lower concentrations theoretical curves predict a higher value of modulus than that experimentally determined. This effect becomes more noticeable as the proportion of B56 in the polymer increases. We might ex-

pect that in the region of low concentration of polymer, where the effect of closed loop formation is greatest, our simple analysis of the fraction of closed loops would underestimate the total number of chains lost in closed loop formation since we consider only two possible types of loop. Hence this could explain our observations at low concentration. Future experiments hope to document this effect more thoroughly.

CONCLUSION

Generally there is a fair agreement between experiment and theory as shown in Figures 1–3. This suggests that the estimate of the network defects, i.e. closed loops and entanglements, in the gels are of the correct order of magnitude. The theoretical curves are plotted with a value of $A = \frac{1}{2}$, supporting the use of this value in theoretical equations. It would be difficult to interpret the results using $A = 1$ in equations (6) and (7). The results of these experiments in poly(propylene oxide) networks, thus support the theoretical conclusions reached in previous work on polystyrene networks^{10,11}. The present results, however, were obtained over a wider range of polymer concentration than was possible for the polystyrene gels used previously. In particular it was possible to study dry rubbers.

APPENDIX

Estimation of the effects of closed loops in polyurethane gels

If we neglect the effect of closed loops:

$$G = \frac{3}{2} AnkT \tag{A1}$$

$$\frac{G}{nkT} = \frac{3}{2} A \tag{A2}$$

Suppose that x is the fraction of wasted crosslinks, in closed loops, then x is also the fraction of -OH groups wasted in closed loops. At least 2/3 of the -OH groups on the trifunctional polyol must be incorporated into the network for a truly infinite network to be formed. If n' is the total number of -OH groups:

$$G = 0.75(n'kT) \left(1 - \frac{2}{3} - x\right) \tag{A3}$$

$$\frac{G}{n'kT} = 0.75 \left(\frac{1}{3} - x\right) \tag{A4}$$

As $n' = 3n$, for a network of T56 molecules:

$$\frac{G}{nkT} = 0.75(1 - 3x) \tag{A5}$$

Thus if we can calculate x , the fraction of wasted crosslinks, we can estimate the effect of closed loops on the modulus.

We assume a Gaussian distribution of ends:

$$W(x, y, z) = \left(\frac{B}{\pi^{1/2}}\right)^3 e^{-B^2(x^2+y^2+z^2)} dx dy dz \tag{A6}$$

Where $W(x, y, z)$ is the probability of one end of the molecule lying in the volume $dx dy dz$ if the other end is at the origin, and $B = (3/2nl^2)^{1/2}$ where $(nl^2)^{1/2}$ is the root mean square end-to-end distance. If the two chain ends are in the same unit volume $dx dy dz$:

$$W(dv) = \left(\frac{3}{2nl^2\pi}\right)^{3/2} \tag{A7}$$

We assume that the reaction probability is proportional to the concentration of groups in its vicinity.

Single closed loops

For a trifunctional polyol there are two possibilities of closed loop formation. Thus:

$$W(dv)_{loop} = 2 \left(\frac{3}{2(99)2.14\pi 5.5}\right)^{3/2} \tag{A8}$$

where we have 99 bonds between crosslinks and the average value of l^2 for the chain is 2.14 \AA^2 , and 5.5 is the characteristic ratio for poly(propylene oxide)²⁰.

Closed loop involving 2 trifunctional chains

There are 4 possibilities of closed loop formation:

$$W(dv)_{loop} = 4 \left(\frac{3}{4(99)2.14\pi 5.5}\right)^{3/2} \tag{A9}$$

$$W(dv)_{loop} = 11.8 \times 10^{-6}$$

We only consider the effects of these two types of loops. Larger loops will become more elastically effective. The choice of two types of loops only is however an approximation.

Effect of closed loops in T56/B56 mixtures

For the case of single closed loops, we need only consider closed loops involving T56 units. The presence or absence of B56 in the gel will not affect the number of crosslinks, and hence the modulus. Thus the first effects of single closed loops will be in equation (A8). However, the value of $W(dv)_{loop}$ for closed loops involving two chains will depend on the ratios of B56 to T56 in the network.

Thus, for a polyol mixture 75% T56 by wt, two T56 molecules exist for each B56 molecule, as shown in the diagram:

Thus in this case:

$$W(dv)_{loop} = 3 \left(\frac{3}{4(99)2.14\pi 5.5}\right) \tag{A10}$$

In a polyol mixture 60% T56 by wt, two T56 molecules exist for two B56 molecules in the mixture. Thus, one T56 molecule has an equal probability of being adjacent to two B56 molecules or one T56 and one B56 molecule.

This gives:

$$W(dv)_{loop} = 2.5 \left(\frac{3}{4(99)2.14\pi 5.5}\right) \tag{A11}$$

Intermolecular chains

Here we must consider the density of end groups per Å, this will again be proportional to the reaction probability:

$$W(d\nu)_{\text{loop}} = \frac{C \times N_0 \times 10^{-24}}{1000} \quad (\text{A12})$$

where C = concentration of polymer in kg/dm^3 ; N_0 = Avogadro's number; 1000 = equivalent weight of T56, B56; $W(d\nu)_{\text{cross}} = 5.3C \times 10^{-4}$.

Effect of modulus

Fraction of closed loops (f) is given by:

$$\begin{aligned} f &= \frac{W(d\nu)_{\text{loop}}}{W(d\nu)_{\text{loop}} + W(d\nu)_{\text{cross}}} \\ &= \frac{1}{1 + 30C} \quad \text{for single loops} \\ &= \frac{1}{1 + 44C} \quad \text{for loops involving 2 chains in 100\% T56} \\ &= \frac{1}{1 + 60C} \quad \text{for loops involving 2 chains in 75\% T56} \\ &= \frac{1}{1 + 72C} \quad \text{for loops involving 2 chains in 60\% T56} \end{aligned} \quad (\text{A13})$$

Substituting these values of f into equation (A5) we obtain the effect of closed loops on the modulus, given by:

$$\frac{G}{nkT} = \frac{3}{2} A \left(1 - \frac{3}{1 + 30C} \right) \left(1 - \frac{3}{1 + K'C} \right) \quad (\text{A14})$$

For T56, B56 networks K' varies as shown in equation (A13).

In equation (A14) the reduction in n due to single and double closed loops formed simultaneously is obtained by multiplying the two separate terms calculated for single and closed loops respectively.

Correlation between physical-mechanical properties and morphological features of cruciform styrene – butadiene block copolymers

Enrico Pedemonte and Giovanni Dondero

Istituto di Chimica Industriale, Università di Genova, 16132 Genova, Italy

and Francesco de Candia and Gennaro Romano

Laboratorio di Ricerche su Tecnologia dei Polimeri e Reologia, CNR, 80072 Arco Felice (Napoli), Italy

(Received 10 June 1975; revised 11 July 1975)

The structural and morphological characterization of a cruciform styrene–butadiene block copolymer of the $(SB)_4Si$ type is reported together with the stress–strain properties of films prepared by compression moulding. The influence of the compression on the morphology (and therefore on the mechanical properties) are considered in detail because the structure of the specimen becomes particularly simple; it consists of polystyrene cylinders arranged perpendicularly to the compression plane. The rods lead to a semi-continuous polystyrene phase, so that the film exhibits the Mullins and hardening effects already observed for linear three block copolymers. Explanations for these phenomena are given, supported by optical observations and by electron microscopical views of sections cut after deformation.

INTRODUCTION

It is well known that ABA type three block copolymers of styrene (monomer A) with butadiene or isoprene (monomer B) give rise to the unusual ‘thermoplastic elastomers’; these can be easily moulded at temperatures higher than 120°C while at room temperature they behave as vulcanized rubbers even though the polymer molecules are perfectly linear and have no chemical crosslinks. These properties are ascribed to the fact that the polystyrene ends aggregate into domains owing to thermodynamic incompatibility of the A and B blocks; at room temperature the domains are glassy and set as rigid network junctions^{1–10}.

Morphology and physical properties of these materials have been widely studied and comprehensively reviewed^{11,12}. The correlation between them is now made sufficiently clear^{12–16}.

In this paper is discussed the relationship between structural characteristics, morphology and mechanical properties of films obtained by compression moulding of a copolymer whose macromolecules are characterized by four polystyrene–polybutadiene blocks coupled to a tetra-functional silicon group: it is a member of a new set of materials having the general formula $(AB)_nX$ which have been recently prepared^{17,18} and studied with regard to the effect of chain geometry on domain morphology¹⁹.

EXPERIMENTAL

Material and molecular characterization

The material used in our experiments has been a laboratory preparation supplied by Anic Company and labelled Europrene T–162. It is a styrene (S)–butadiene (B) block copolymer of the $(SB)_4Si$ type and several of its molecular

and physical characteristics are summarized in *Table 1*.

The techniques employed to obtain the reported data have been extensively described in a previous paper²⁰. The molecular weights have been measured by light scattering and by osmometry in the Anic Laboratories at S. Donato Milanese (Italy). The polystyrene content has been averaged between the values obtained by u.v. analysis at 262 nm^{21,22} (47.5%), and at 269.5 nm (49.5%) and by refractive index increment²³ (49.6%). Infra-red spectroscopy was used to measure the configurational composition of the elastic fraction²⁴ while the length of the elastic chains was obtained by swelling^{25,26}.

The data clearly show that this copolymer has a rather high molecular weight and about the same contents of polystyrene and polybutadiene; hence the lengths of the blocks are similar and owing to the star-structure of the macromolecule, rather short. Only few entanglements are present in the rubber phase, which is mainly in the *cis*–1,4 configuration.

Figure 1 Electron micrograph of an ultra-thin section of Europrene T 162 original copolymer

Compression moulded films preparation and stress-strain measurements

Films of the material were obtained by die casting at 120° – 130° C and under slight pressure (2 – 3 kg/cm²).

Stress-strain measurements were carried out using a tensile tester of the Toyo Measuring Instruments Ltd. The deformation rate was 10 mm/min. The sample length was 2 cm in all the experiments; this gives a strain rate of 0.5 min⁻¹. The stress-strain plots were detected at room temperature (20° C).

The effects of the mechanical history on the sample properties were investigated by resting for 30 min at zero load between two successive deformation cycles.

Morphology

For the morphological analysis by electron microscopy, ultra-thin sections were cut at low temperature²⁷. The

Figure 2 Electron micrograph of ultra-thin sections of compression moulded Europrene T 162 film. Section (a) corresponds to the surface parallel to the compression plane; sections (b) and (c) have been cut along the compression direction and their orientations differ 90°

Figure 3 Stress-strain isotherms of the compression moulded Europrene T 162 films, detected at room temperature. ■, Sample A, first run; □, sample A, second run after 30 min of relaxation at zero load; ●, sample B, first run; ○, sample B, second run (same conditions)

rubbery phase of the specimen was contrasted by exposing the sections to the vapours of an aqueous OsO_4 solution²⁸ at room temperature for several minutes; so that in the electron micrographs the butadiene phase will appear dark and the styrene bright.

The copolymer was studied both as supplied by the manufacturer and as a compression moulded film. In the latter case the effect of the deformation on the morphology has also been investigated.

RESULTS

Figures 1 and 2 show the morphologies of the original material and of the compression moulded film. In the first case morphology is characterized by short rods of polystyrene oriented along a well defined direction, probably as the consequence of an uncontrolled mechanical treatment which follows the polymerization process. In the latter case we can reach some conclusions on the structure of the specimen provided. We were able to look at three sections, cut perpendicularly to each other and corresponding to the planes indicated in Figure 2; it appears that compression arranges the rods almost perpendicularly to the compression plane.

Figure 4 (a) Neck present in a sample deformed at $\alpha = 1.5$. (b) Double neck present in a sample deformed at $\alpha = 4$. The photographs were detected in polarized light, at crossed Nicols

Figure 5 Mullins effect as observed in a sample deformed increasing step by step the maximum strain value

Figure 6 Hysteresis loops detected on a compression moulded film. ●, first run; ■, second run (same conditions of Figure 3)

Figure 3 shows the stress-strain isotherms obtained using compression moulded films. Plots, detected on two different samples, show the effects on the mechanical behaviour when two successive deformation runs are performed, allowing 30 min relaxation at zero load between the first and the second cycle. There is clearly a strong influence of the previous mechanical treatment.

Macroscopic observations give evidence that in the first deformation run the strain increases by neck propagation, while necks are absent in the second run. In Figure 4a the neck which is present in a sample deformed at $\alpha = 1.5$ and in Figure 4b a double neck is present in a sample deformed at $\alpha = 4$. These pictures were obtained with crossed Nicols using light polarized at 45° with respect to the deformation axis.

The effect shown in Figure 3 is stressed in Figure 5, where the mechanical behaviour is studied as function of the previous mechanical history of the specimen, increasing step by step the maximum strain value between two successive deformations. Data of Figure 5 indicate the presence of the well known Mullins effect^{29,30}.

Figure 6 shows the hysteresis loops detected in two successive cycles, observing the same conditions of Figure 3, i.e. 30 min relaxation at zero load between the first and the second cycle.

Figures 7 and 8 show the morphologies of compression moulded films after stretching, at deformation ratios of $\alpha = 3$ and $\alpha = 6$ respectively; the sections have always been cut along the stretching direction.

DISCUSSION

It is evident from Figures 7 and 8 that the deformation of the specimen produces the orientation of the polystyrene rods in the stretching direction. These rods are oriented normally to this direction in the compressed film (Figure 2). Some differences may be observed between Figures 7 and 8, which correspond to different degrees of deformation; in particular the continuity of the polystyrene phase is more pronounced at $\alpha = 3$ than at $\alpha = 6$, where the polystyrene rods are shorter owing to the rods breaking under the strain¹⁵.

On the basis of these morphological features the mechanical behaviour as reported in the previous section can be analysed.

The most important phenomenon observed is the macroscopic deformation mechanism of the sample, i.e. the neck propagation. The presence of a neck is generally due to structural changes induced by the stretching; in the present case the structural change involves orientation of the polystyrene rods. As stated previously, before stretching the rods are perpendicular to the compression plane of the film (and therefore to the strain direction) but they become parallel to it after stretching. The neck formation would

Figure 7 Electron micrograph of ultra-thin section of compression moulded Europrene T 162 film after stretching at $\alpha = 3$. Section cut perpendicular to the compression plane and along the stretching direction

Figure 8 Electron micrograph of ultra-thin sections of compression moulded Europrene T 162 film after stretching at $\alpha = 6$. Section (a) corresponds to the surface of the compression plane; section (b) is perpendicular to it; both have been cut along the stretching direction

correspond to this mechanism. This mechanism is irreversible and necks are present only in the first deformation run; they are not observed in the second one.

The presence of necks gives rise to a plastic deformation which, as far as the mechanical behaviour is concerned, corresponds to the yield region observed in the first stress-strain run of Figure 3. This yield region covers the strain range 1.05–4.5.

The orientation mechanism and rod breaking observed in Figure 8 also explain the stress softening of the second deformation run for the lower values of the strain, generally up to $\alpha = 4$. This phenomenon, clearly shown in Figure 5 where the strain is increased step by step, is due to the irreversibility of the two effects. The mechanical work necessary to orientate and to break some of the rods, is not necessary in the second run and therefore the same values of the strain can be reached with a lower force.

In a previous paper¹⁵ we have shown that when the polystyrene rods are well oriented along the stretching direction, the Mullins effect is due to the breaking of the cylinders. If the rod's axis does not correspond to the stretching direction, it seems reasonable that the organization of the structure needs additional mechanical work which gives its contribution to the irreversible stress-softening effect.

One must seek a different explanation for the stress hardening observed in the second run for the higher values of the strain. As suggested in a previous paper¹⁶, this phenomenon can be due to a kinetic mechanism. The presence of hard polystyrene rods, which behave as fillers, reduces sensitively the conformational freedom of the elastomeric polybuta-

diene chains. The orientation of these chains, owing to the first deformation cycle, is partly irreversible in the time scale of the experiment and therefore, in the second run, we stretch chains that are still stretched, even if partly. Work is in progress to give a more direct evidence of the suggested mechanism.

One may conclude with some considerations about Figure 6. Graphical integration of the two hysteresis loops gives for the first run $\Delta F = 5.26 \text{ cal/cm}^3$ and for the second run $\Delta F = 9.88 \text{ cal/cm}^3$, where ΔF is the free energy dissipated in the hysteresis cycle. The ratio $\Delta F/\Delta F_{\text{tot}}$, where ΔF_{tot} is the energy given to the system on increasing the strain, is the relative amount of dissipated energy; calculation gives 0.58 and 0.64 for the first and second runs, respectively. These results indicate that the absolute value of the dissipated energy is very different in the two runs while the relative values are rather similar. On the basis of the proposed mechanisms, i.e. in the first run a dissipation due mainly to the rods orientation and breaking and in the second one a dissipation due mainly to the low chain mobility, the latter results are surprising. Work is in progress to obtain more experimental data in this field, particularly for specimens whose deformation does not involve any orientation of rods but only breaking.

Creep behaviour of annealed UPVC and PMMA

D. C. Wright

Rubber and Plastics Research Association, Shawbury, Shrewsbury SY4 4NR, UK
(Received 26 March 1975)

The 20°C creep compliance of UPVC is temporarily increased by prior annealing at temperatures above ~45°C and below T_g . This effect increases with decreasing annealing time. Similar behaviour is observed with PMMA which suggests that this may be a general phenomenon shared by polymers in the 'glassy amorphous state'. The temporary, and therefore unstable nature of the annealed state is inappropriate for a test specimen, particularly for tests of long duration. It is suggested that volume relaxation in UPVC below 45°C proceeds by short range separation into regions of molecular order and disorder. This state is rapidly disrupted at temperatures above 45°C.

INTRODUCTION

Thermal conditioning prior to property evaluation is a favoured method of minimizing batch-to-batch variability. A relatively severe and recent thermal conditioning treatment supposedly erases the influence of the (often unknown) previous thermal history. This provides an easily accessible materials reference state which, however, is almost certainly arbitrary. The reference state in addition may be only a transient one and therefore not stable over the period of test. An arbitrary unstable reference state is particularly inappropriate for creep testing, where long test durations are common and creep data are often intended for use in design calculations.

According to classical concepts of the glassy amorphous state, a polymer at any temperature below its glass transition temperature (T_g) undergoes volume relaxation (densification). The rate of this relaxation at temperatures far below T_g is so small that for normal periods of observation the state is apparently stable. At temperatures approaching T_g , the rate of volume relaxation will be increased, resulting in a detectable change in the density and properties of the polymer.

Retting¹ investigated the effect on the tensile modulus of UPVC after annealing for various periods at a temperature of ($T_g - 17$)°C. The modulus (25°C) at low strain rates increased substantially with annealing time. At high strain rates the modulus was not significantly affected. Foltz and McKinney² employed a similar heat treatment on UPVC and attributed the observed increase in the pre-glass transition endotherm to an increase in crystallinity. Illers³ attributed a similar effect to a decrease in free volume. These observations are compatible with classical expectations. Volume relaxation involves an increase in molecular order; this decreases molecular mobility and therefore increases the long term (low strain rate) modulus. The high strain rate modulus is not primarily dependent on molecular mobility and is therefore not sensitive to annealing.

Turner⁴ investigated the effect of pre-conditioning period at 60°C on the creep response of UPVC at 60°C. It was reported that the time dependent creep compliance decreased with increasing pre-conditioning period. Therefore in this respect the response is apparently classical and

indicative of volume relaxation in the direction of equilibrium.

The procedure adopted here involves room temperature creep testing after annealing periods at various temperatures. Although annealing as compared with pre-conditioning introduces an additional interaction (the cooling cycle) it does offer a distinct advantage. The effect of thermal treatment can only be ascertained unambiguously by comparison with the state or response of the untreated material. The creep behaviour with no annealing presents no problem, but the zero pre-conditioning state is unattainable.

EXPERIMENTAL

The following sequence was adopted:

- (1) Calendered sheets of UPVC (Cobex 018 grade supplied by BXL Ltd) were stored for 2 years at 20°C.
- (2) Creep specimens of nominal dimensions 3 × 5 × 140 mm were prepared.
- (3) Creep specimens were stored in ovens at either 60° ± 1°, 50° ± 1°C, or 40° ± 1°C.
- (4) After a specified annealing period covering a range between 1 and 2000 h, specimens were removed and cooled (to 20°C) under controlled forced air convection for 30 min.
- (5) The cross-sectional areas of the cooled specimens were measured and the specimens prepared for tensile creep testing.
- (6) 1 h, 24 h, or 336 h after the removal of the specimen from its oven (termed the delay time) a tensile stress of 25 MN/m² was applied and the creep strain recorded for 10⁴ sec.

A similar sequence but with only one annealing temperature of 60°C, and one delay time of 1 h was applied to PMMA (cast Perspex, ICI Ltd).

The tensile creep machines used in the study have been described previously⁵. A Moiré fringe extensometer, employing crossed diffraction gratings with a ruling pitch of 4 μm provides the means of automatic strain detection. The Moiré fringe image illuminates an assembly of 4 silicon photodiodes. The photodiode signal is amplified and shaped to provide 2 or 4 counter compatible pulses for each 4 μm extension or contraction of the 66.67 mm gauge length.

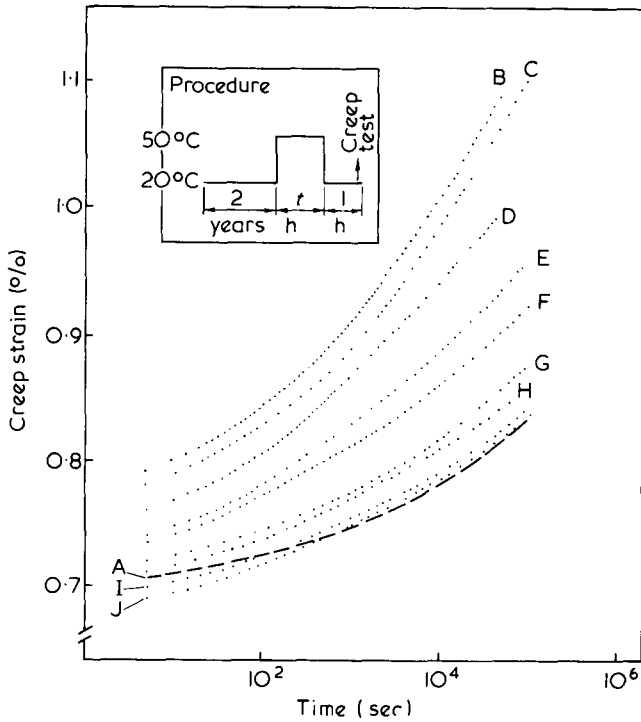

Figure 1 Tensile creep characteristics for UPVC at 20°C and 25MN/m². The parameter is the annealing time in hours. The delay time between cooling and testing is 1 h. Hours (t) stored at 50°C prior to room temperature creep test: A, t = 0; B, t = 1; C, t = 2; D, t = 6; E, t = 14; F, t = 24; G, t = 96; H, t = 600; I, t = 1900; J, t = 2400

Figure 2 Time dependent tensile creep compliance ΔC of UPVC at 20°C vs. annealing time at 60°C. Delay time between annealing and testing: ▲, 1; ○, 24; ▽, 336 h. -----, no annealing

Thus strain increments of 0.0015% can be totalized on a bi-directional counter and/or used to trigger a digital event recorder which essentially records the time coordinate for each positive or negative strain increment for the duration of the creep test.

RESULTS

The family of creep curves shown in Figure 1 are for UPVC with various annealing periods at 50°C with a 1 h delay before testing. The creep characteristic with no thermal treatment is identified by the broken line. Similar data were

generated after longer delay times and at different annealing temperatures. The initial creep response tended to be rather erratic for these annealing treatments, but the time dependent response defined as ΔC , shown in Figure 2, 3, 4 and 5, proved to be smoothly related to annealing and delay time. The time dependent compliance ΔC is defined here:

$$\Delta C = [\epsilon(10^4) - \epsilon(20)] / \sigma$$

Figure 3 Time dependent tensile creep compliance ΔC of UPVC at 20°C vs. annealing time at 50°C. Delay time between annealing and testing: ▲, 1; ○, 24; ▽, 336 h. -----, No annealing

Figure 4 Time dependent tensile creep compliance ΔC of UPVC at 20°C vs. annealing time at 40°C. Delay time between annealing and testing: ▲, 1; ○, 24; ▽, 336 h. -----, No annealing

Figure 5 Time dependent tensile creep compliance ΔC of cast PMMA at 20°C vs. annealing time at 60°C. Delay time between annealing and testing is 1 h. -----, No annealing

where $\epsilon(20)$ and $\epsilon(10^4)$ are the strains recorded 20 sec and 10^4 sec after a stress application of $\sigma = 25 \text{ MN/m}^2$ (UPVC), and $\sigma = 20 \text{ MN/m}^2$ (PMMA). The ΔC versus annealing time format is convenient in that it enables the gross effects of annealing time, delay time, and annealing temperature to be conveniently compared. It is these gross effects rather than detailed changes in the shape of the creep characteristic that are the subject of the discussion.

DISCUSSION

The following features are observed in *Figures 2, 3 and 4*.

- (a) UPVC specimens which have been annealed at 50° and 60°C show a decreased resistance to creep deformation (increase in ΔC compared with unannealed specimens). This effect is enhanced for short annealing and delay periods.
- (b) UPVC specimens which have been annealed for very long periods at 50° or 60°C exhibit similar creep behaviour to those with no heat treatment.
- (c) The severe effect of short annealing periods observed at annealing temperatures of 50° and 60° are not observed after annealing at a temperature of 40°C .
- (d) The effect of increasing the delay time between annealing and testing is to generally reduce the effects of annealing. The material state after short annealing periods is particularly unstable.

The observed increase of the time-dependent compliance after annealing is the reverse of that anticipated for a classical glassy amorphous polymer. *Figure 5* shows that this anomalous behaviour is not peculiar to PVC but also occurs with PMMA. This conclusion is derived from comparison with the non-annealed reference state response. If this response was not known then the data in *Figure 2 and 3* would appear to be classical, i.e. a decrease in compliance with increasing annealing time. This is qualitatively similar to the trend observed by Turner⁴ and discussed in the introduction.

It would be logical in the absence of any other evidence to seek an explanation for this anomalous behaviour by reference to observed morphological differences between UPVC and that of a classical glassy amorphous polymer. Morphological studies have revealed direct evidence of ordered regions in UPVC⁶⁻⁸. These regions might be regarded as small crystallites or regions of molecular orientation with a characteristic cohesive energy and a specific melt temperature, or simply as regions of zero configurational entropy which are stable below a particular temperature. Clearly, both aspects describe the same phenomenon but at this stage it is considered preferable to treat each one separately.

Iobst⁹ has estimated that the smallest stable unit of molecular order in plasticized PVC would be disrupted at temperatures above 50°C . Larger ordered units have a higher melt temperature but their formation is less probable. Stafford¹⁰ has used the argument that the disruption of 'crystallites' is responsible for the phenomenon of 'reversible stiffening in plasticized PVC'. The compliance of plasticized PVC increases dramatically after annealing but slowly returns to its original stiffness with time after annealing. In this respect the response to annealing is similar to that reported here, but Stafford did not observe the transition in short period annealing effects at 45°C . This transition being close to the minimum 'crystal melt' temperature as calculated by Iobst adds considerably to the case for a thermal disruption model. The effect of thermal

history on the creep response of UPVC could be explained by the following sequence:

- (1) Over extended periods (2 years in this case) at 20°C , small crystallites are formed which are stable at this temperature. The low (or zero) free volume within the crystallite structure is responsible for deformation processes with very long retardation times. Hence the presence of crystallites might be considered as delaying the strain response and decreasing the creep compliance after long creep times.
- (2) After short periods of annealing at 50° or 60°C , the crystallites suffer rapid thermal disruption leading to an increase in creep compliance particularly after long periods under load.
- (3) After long periods of annealing above 45°C , the free volume is slowly reduced by the classical process of volume relaxation. As this proceeds the creep compliance will slowly decrease.
- (4) With increasing delay time after annealing, crystallites are slowly reformed with an attendant decrease in compliance.

The second approach is to consider the entropy of the system. Gibbs and Di Marzio¹¹ have proposed that even though the observed T_g is a kinetic phenomenon, there is an underlying thermodynamic transition at a lower temperature T_2 . If the polymer is cooled infinitely slowly, then at T_2 the configurational entropy of the specimen as a whole, would be zero. Adam and Gibbs¹² calculated that a universal expression for T_2 could be:

$$T_2 = (T_g - 53)^\circ\text{C}$$

According to Adam *et al.* the activation volume in the Eyring¹³ viscosity equation is identified as the minimum cooperatively rearranging region. The transition probability, the mobility, and hence the relaxation or creep rate increases as this minimum activation volume decreases. Clearly this cooperative entity must contain free volume for internal rearrangement, or more precisely a unit value of quantized free volume (hole) must be present. The volume of the cooperative entity, and hence the rate of relaxation and creep, might therefore depend significantly on the distribution of free volume or on the size of the quantized unit of free volume. At temperatures below T_2 , close packing is energetically favourable because the equilibrium configurational entropy is zero. This cannot be achieved on a macroscopic scale within a finite time as this involves large diffusion distances and a high degree of molecular cooperation.

It is proposed here, however, that explosion of free volume could be achieved within a finite time at the short range level. The result of such a process would be small regions of aligned molecular segments (crystallites) with zero configurational entropy, bounded by a region with a high free volume content. Pictorially, this is similar to the fringed micellar grain model of the 'glassy' state adopted by Yeh¹⁴. Therefore it could be envisaged that after a finite period of storage at 20°C the quantized unit of free volume would increase in size with a resultant increase in the minimum volume of molecular cooperation and a decrease in creep compliance. On raising the temperature above T_2 the ordered regions are rapidly disrupted with a resultant decrease in the volume of the cooperative entity and increase in compliance.

Both the energy and entropy approach combine strongly to support the hypothesis that the volume relaxation process below $\sim 45^\circ\text{C}$ is quite different from that operating

Figure 6 Density of cast PMMA after a range of annealing periods at 60°C. -----, Density with no annealing

above this temperature. Above 45°C, volume relaxation proceeds classically by a uniform diffusion of free volume. Below ~45°C (T_2) the uniform diffusion process is no longer energetically favourable and is replaced by a short range process which results in the formation of 'small islands' of order in a matrix of disorder. The short range ordered regions are disrupted rapidly on annealing above 45°C and it is proposed that this is responsible for the anomalous creep behaviour reported here for UPVC.

The existence of two different volume relaxation processes could also explain why in some cases (e.g. Retting¹) apparently classical effects are observed after annealing. The period at room temperature prior to annealing determines whether sufficient localized volume relaxation has accumulated to give a non-classical response. Thus a recently processed polymer may be expected to react differently to annealing than one stored below T_2 for a long period prior to annealing.

It is not necessary to predict that on annealing above T_2 the disruption of ordered regions will result in a net decrease in density. The redistribution of free volume can be sufficient to qualitatively account for the effects observed. However, the model would predict a density decrease with further annealing owing to normal volume relaxation. An attempt was made to detect the change in density of UPVC after various annealing treatments but, with the resolution available, this could not be achieved. Density measurements on cast PMMA using a density column gradient of ~0.0005 (g/cm)/cm did, however, reveal a significant decrease in density after annealing for short periods at 60°C, followed by an increase in density with increasing annealing period. These density data are shown in Figure 6. Similar density

changes have been observed by Golden *et al.*¹⁵ for annealed polycarbonate.

CONCLUSION

The materials reference state generated by annealing PVC above ~45°C is not stable at room temperature. The instability is liable to distort the creep characteristics and thereby render this method of specimen conditioning counter-productive. The effect is particularly severe after short (practical) annealing periods.

The effect of annealing UPVC between ~45°C and T_g is to decrease the time dependent creep modulus of the polymer. This phenomenon was also apparent with PMMA at an annealing temperature of 60°C. In the case of PMMA the reduction of creep modulus coincided with a significant decrease in density. The transition temperature, $T_2 = 45^\circ\text{C}$, for UPVC could be associated with either the 'melt' temperature of small crystallites or the equilibrium temperature for zero configurational entropy. It follows from both concepts that the processes of volume relaxation that operate above and below this transition (T_2) are quite different, it is suggested that below T_2 the predominant process is that of local diffusion of free volume to give small but definite regions of molecular order and disorder. Above T_2 the ordered regions are no longer stable and after disruption, volume relaxation proceeds by the operation of a more diffuse or homogeneous contraction of free volume.

Drag reduction effectiveness of macromolecules

B. Hlavacek, L. A. Rollin and H. P. Schreiber*

Department of Chemical Engineering, Ecole Polytechnique, Montreal, P.Q., Canada

(Received 20 July 1975)

A working hypothesis has been developed to account for observed drag reduction properties of dilute polymer solutions. Drag reduction effectiveness of polymer solutes is attributed to their ability to form a deformable network structure which inhibits the formation of microvortices in the solvent and retards their ability to migrate through the fluid, coalesce, and result in fully developed turbulence centres. The size of microvortex precursors is tentatively set in the range of 100 Å, and it is assumed that the damping (drag reduction) effect of macromolecules is due to strong association between solvent molecules and polymer chains, immobilizing many of these active precursors. The hypothesis indicates that drag reduction effectiveness of polymers should depend strongly on polymer/solvent interactions in addition to the recognized variables of molecular weight, concentration and geometry of the flow system. The hypothesis accounts for a number of published anomalous observations and leads to new predictions of drag reduction variations with polymer molecular weight distribution, and temperature. These and related predictions are the focal points of new experimental research studies of the drag reduction phenomenon.

INTRODUCTION

The wide range of potential applications for drag reduction (*DR*) effects of dilute polymer solutions, coupled with the challenge of accounting for *DR* phenomena, have led to numerous studies of the subject. In some¹⁻¹² (only a few of the more recent articles have been noted), successful correlations have been developed for the drag reduction effectiveness (*DRE*) of many polymers over a wide range of shear gradients. However, as noted in recent papers¹³⁻¹⁵, a comprehensive understanding of *DR* mechanisms remains obscure. A pattern is emerging, nevertheless, that accentuates the importance of molecular properties of the drag reducing agent in accounting for *DR* effects. The conceptual basis for our work lies in the molecular characteristics of the *DR* agent and in those characteristics of the solvent which respond to them. In this initial article a working hypothesis which accounts for some apparent conflicts in published studies of *DR* is presented. Important also are experimental consequences which follow from the conceptual approach; tests of these form the goals for our ongoing research, and may motivate a wider research response elsewhere.

Two fundamental prerequisites for the *DR* effect can be postulated:

- (1) The phenomenon reflects an inherent property of the matrix fluid (solvent) to form a microstructure of turbulent eddies under critical gradient conditions.
- (2) *DR* follows from an intervention on the part of macromolecules. Logically, their *DRE* should reflect the influence of those variables which control the size, shape and mobility of the macromolecule under the conditions of observed drag reduction.

In evaluating earlier rationalizations of *DR*, as well as in laying a foundation for the present approach, it is con-

venient to consider turbulence suppression in terms of three kinetic stages:

(a) disturbance initiation. This stage postulates the activation of microeddies from pre-existing microcentres of discontinuity in the solvent.

(b) growth (propagation) stage. In the second stage, one may postulate the growth and diffusion of eddies through the continuum. Growth and mutual interaction of disturbances leads to:

(c) disturbance decay (termination). The decay rate will be a function of energy dissipation as well as of recombination or partial coalescence of eddies. Thus, it does not necessarily follow that the initiation and decay rates must be numerically equal.

A more complete theoretical argument of these concepts is to be published separately¹⁶.

The kinetics of each of the three stages should depend upon the inherent properties of the continuum fluid, on the modifying influence of a macromolecular solute and on the geometry of the flow system. Clearly, stage (a) and, in part, stage (b) are concerned with events of 'incipient disturbance' on a dimensional level much smaller than the events of optically observable macrodisturbance [stages (b) and (c)]. In general, published accounts of *DR* are concerned with the role of polymers as agents for the suppression of macrodisturbances in the late stages of their kinetic development. Thus, Astarita^{7,8} and Fabula⁵ are concerned with the dynamic and relaxation properties of polymers, hence focusing on stages (b) and (c). Others, notably Seyer and Metzner⁹ stress the effect of increased elongational viscosity in polymer solutions and so are concerned with the decay rate of stage (c). Recently, Lacey¹⁴, also focusing on stage (c), has suggested that an eddy-damping effect arises from the migration of macromolecules and thread-like particles to regions of flow disturbance. The approach of Virk and coworkers⁴, to which our concepts relate, introduces specific dimensions in considering the influence of macromolecules on fully developed disturbances, with diameters exceeding 10⁻³ cm. The expectations of Virk's effective

* To whom enquiries should be addressed.

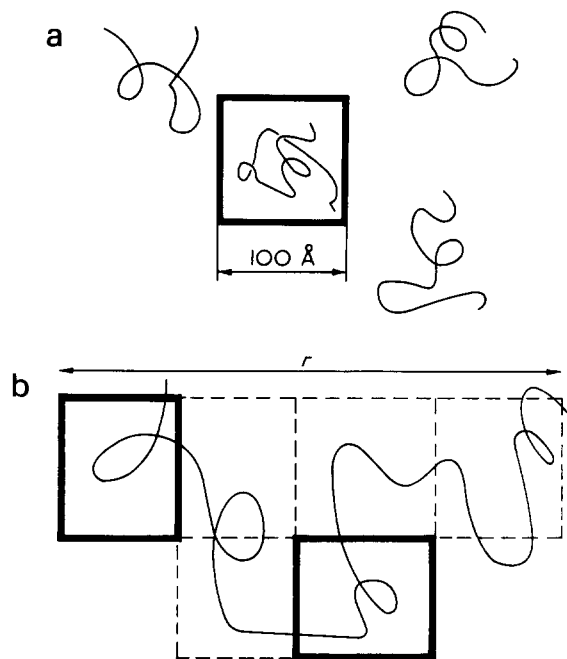

Figure 1 Schematic representation of function in drag reducing polymers. (a) $\langle r_g \rangle \approx d$ microdomains (turbulence precursors); (b) $\langle r_g \rangle \gg d$ microdomains (turbulence precursors)

slip correlations are not universally substantiated. Thus, Peyser and Little¹² reported apparent contradictions to Virk's theory, in that the *DRE* of polystyrene increased with the viscosity of the solvent. It is our opinion that a shortcoming in the Virk approach lies in its attempt to account for the behaviour of fully developed disturbances [in stages (b) and (c)], which are dimensionally inconsistent (much larger) with the average dimensions of the drag reducing macromolecule.

In order to overcome this problem, it would be necessary to consider the properties of macromolecular aggregates or entanglement domains with overall dimensions equal to or greater than the 10^{-3} cm range proposed for the linear dimensions of turbulent eddies⁴. Astarita's treatment^{7,8} of characteristic (bulk) relaxation times can be seen as a step in this direction. The aggregation and entanglement tendencies of polymers in solution are principally dependent on molecular size, flexibility and deformability, under the conditions of relevant stress gradients. These properties will be strongly influenced by the thermodynamics of polymer/solvent interaction, and progress towards the further evolution of *DR* mechanism therefore should be possible from detailed consideration along these lines. Our approach involves the question of molecular structure, and thus resembles the statements of Little and coworkers^{12,13}, of Balakrishnan and Gordon¹⁵ and Kiran¹⁷. An important feature of our approach, however, is its focus on the role of macromolecule as an inhibitor for the initiation stage (a) of micro-disturbance formation.

MOLECULAR MODEL FOR *DR*

To account for the *DRE* of macromolecular solutes, we note that: (1) the concentration of macromolecules needed for *DR* must exceed a minimum¹¹, below which no significant *DR* is noted in any given system; and (2) the molecular size of the solute is important and appreciable *DR* is observed only when the molecular weight exceeds a 'benchmark' parameter, such as the entanglement weight M_c ^{11,18}.

The points suggest that the macromolecule reports on events occurring on a size level comparable with those of the indicating species. In combination, the criteria re-iterate that *DR* is evident only when there is dimensional consistency between turbulence precursors in the solvent and the effective size of the polymer. This size should be related to a critical effective radius of gyration of the macromolecule, $\langle r_g \rangle$. Through changes in polymer molecular weight, concentration and solvent-solute interaction, the right order of $\langle r_g \rangle$ must be attained for any fluid-flow geometry situation, in order for the polymer to act as an effective *DR* agent.

The basis of our argument is represented schematically in Figure 1. The solvent is thought to contain microdisturbances or turbulence precursors, and the macromolecule becomes an effective suppressor only when it is capable of linking, or 'penetrating' two or more of these, thus hindering their free movement and growth. The above criteria for *DR* strongly relate *DR* effectiveness with events which will tend to increase the apparent 'size' of the polymer. Chain entanglement is one such event¹⁸. An important additional effect will be the tendency for multilayers of solvent to form a jacket about the polymer chain, an interfacial effect discussed by Jellinek¹⁹ for polymer/water systems. These stipulations of our model suggest that turbulence precursors will have linear dimensions in the 100 Å range.

Expectedly, *DRE* should increase as $\langle r \rangle$ increases beyond $\langle r_g \rangle$ i.e. as the macromolecule becomes capable of hindering the motion of an increasing mass of discontinuity elements. A limit to the rise in *DRE* is clearly necessary however; at $\langle r \rangle$ much greater than $\langle r_g \rangle$, the energy requirement for transport of the macromolecules through the fluid matrix rises sharply, and significant increases in the friction coefficient of larger units will tend to reduce the relative *DRE* of the macromolecular additive.

Further clarification of the role played by macromolecules in *DR* follows from a consideration of the mechanisms for 'activating' turbulence microdomains. A detailed analysis of the process will be given in a separate publication¹⁶. Here a simple model is adopted which assigns Brownian translation motion to any microdomain:

$$1/2(m\bar{u}^2) = 3/2(kT) \quad (1)$$

Assuming the linear dimension of the domain to be 100 Å and the liquid density $\rho = 1.00$ then:

$$m = \rho D^3 = 10^{-18} \text{g}$$

At 300 K, $(\bar{u}^2)^{1/2} = 3$ m/sec; in a much larger domain, say 1000 Å, $(\bar{u}^2)^{1/2} \approx 0.11$ m/sec. These average values of the Brownian velocity are comparable with the characteristic velocity, ν_0 , of boundary layers in pipe flow as given by^{4,5}:

$$\nu_0 = \left(\frac{\tau\omega}{\rho} \right)^{1/2} \quad (2)$$

According to Levich²⁰, this velocity pertaining to a boundary layer of thickness δ_0 is also characteristic of annihilation of micro-eddies in the continuum fluid.

These concepts are expressed schematically in Figure 2. Here the boundary layer, δ_0 , contains a typical domain, A, populated by N independent hydrodynamic units. Choosing Cartesian coordinates for this system, a Gaussian velocity distribution can be assigned thereto. A similar domain

Figure 2 Schematic representation of velocity distribution in Brownian motion of domains in laminar boundary layer (A) and main stream (B)

B located outside the boundary layer will have velocity distributions related to those in A but shifted, as shown, by a component dimensionally equal to v_0 . The situation is tantamount to the existence of a local entropy gradient ΔS , and a restoring force related to the gradient via:

$$F \propto \Delta S / \delta_0 \quad (3)$$

The magnitude of ΔS will depend on the total number of independent hydrodynamic units involved, as well as on v_0 .^{*} In this context, the role of the macromolecule as drag reducer, rests in its ability to reduce ΔS by reducing the number of independently moving hydrodynamic units. Accordingly, *DRE* will be proportional to D^3 , but in addition, a positive contribution to *DRE* should arise from an increase in δ_0 owing to the presence of polymer. The penetration of microdomains by the macromolecule, its dimensions increased through chain entanglements, and/or the reduction in the degree of translational freedom of microdomains located in a solvent jacket strongly associated with

* We note that with increasing D , both $(\bar{u}^2)^{1/2}$ (equation 1) and v_0 will decrease, the latter variation leading to the empirical statement⁶ $v_0 \propto 1/D$. Thus, the magnitude ΔS will depend most heavily on D , i.e. on the total number of independent hydrodynamic units involved.

the polymer chain¹⁹, are proposed as the major stabilizing effects of the solute. Both routes to a reduction of the local entropy effect must depend on molecular size and on the architecture of the polymer/solvent interface; hence an interdependence is expected between *DRE* and parameters descriptive of thermodynamic interactions in polymer solutions²¹.

Initial tests of the model

The need for the macromolecule to conform in such a way as to immobilize a substantial number of turbulence precursors, indicates a molecular flexibility arising from favourable thermodynamic interactions, and from a molecular weight greater than the critical weight for chain entanglement¹⁸. A rough correlation between *DRE* and M/M_c should be expected and has in fact been reported by several authors. The intrinsic viscosity, $[\eta]$, being a convenient measure of the quality of solvent/solute interaction for a given macromolecule, should also be an acceptable, though approximate normalizing parameter for *DRE*. Thus, we could expect the effective linear dimension of the turbulence-suppressing agent as given by a parameter involving both $[\eta]$ and M/M_c to be particularly useful in accounting for the *DR* performance of a wide range of polymers.

The recent data reported by Liaw *et al.*¹¹ provide a suitable test of this point. These authors tabulate M/M_c , $[\eta]$ and the Mark-Houwink exponent a , for a number of equally effective *DR* systems, and note a qualitative link between *DRE* and $[\eta]$. Expressing the effective dimension of the macromolecule by:

$$\langle r_e \rangle = f[\eta] / (M/M_c)^a \quad (4)$$

it is found that this new parameter correlates with *DRE* more satisfactorily than either $[\eta]$ or M/M_c alone, ($\langle r_e \rangle$ may be thought of as an index of microdomain immobilization on the subchain level). The relevant data are given in Table 1. With one exception the $\langle r_e \rangle$ values are reasonably invariant – a noteworthy fact when considering an inherent error of some 20% in M_c evaluations¹⁸. The exception is ethyl cellulose; the molecular flexibility here may be much more restricted because of the internal bonding capacity of the polymer. The point emphasizes the fact that a given value of $[\eta]$ is not necessarily synonymous with a specific molecular flexibility, i.e. with an equivalent capacity of the macromolecule to immobilize precursor centres by the mechanisms elaborated above. A similar point has been made recently by Frommer and coworkers²².

Some additional progress can be made in rationalizing the *DRE* of macromolecules. If our mechanistic approach is valid, then the following simple considerations should apply. Let (C_s/M) be the number of macromolecules per unit volume, and V_m be the volume of one macromolecule. In the light of our assumptions at any M , the product $(C_s/M) \times V_m$ represents the number of *DR* units necessary to just fill the continuum fluid space. This, however, does not evaluate the efficiency with which the turbulence precursors resident within that space will be immobilized. We therefore introduce the parameter ξ to be proportional to the effective number of turbulence precursors immobilized within V_m . Inherently ξ must be a function again of molecular mass (M) and also of solvent/solute thermodynamic interaction parameters, such as the free energy of mixing value χ_{12} , or the contact energy value X_{12} , drawn from con-

temporary polymer solution theories^{23,24}. This argument indicates that:

$$(C_s/M) \times V_m \cdot \xi = \text{constant} \quad (5)$$

If we assume, for simplicity, that the molecular weight effect predominates, then $\xi \propto M$, and

$$C_s \times V_m = \text{constant} \quad (6)$$

whence $C_s \times D^3 = C_s^{1/3} D = \text{constant} \quad (7)$

Re-introducing the interaction concept, we follow the frequent procedure of using $[\eta]$ as a more convenient measure of solvent/solute interactions. As a first approximation then, $D \propto [\eta]^\kappa$, and at $\kappa = 1.0$,

$$C_s^{1/3} [\eta] = \text{constant} \quad (8)$$

A major problem resides in the fact that $[\eta]$ is defined in the limit $\dot{\gamma} \rightarrow 0$, whilst DR occurs at high rates of shear. Following Subirana²⁵, we note that at high shear rates the $[\eta]$ of all macromolecules corresponds to that of a θ condition, whence a preferred statement is

$$C_s^{1/3} [\eta]_\theta = \text{constant} \quad (9)$$

This development can be tested approximately, again using the data of ref 11. A set of $C_s^{1/3} [\eta]$ values has been calculated from that source, and entered in Table 2. The evidence is strongly in favour of the present argument, for with variations in C_s over a range of 3 decades, the variation in $C_s^{1/3} [\eta]$ is reduced to a fairly narrow range centred on a value of about 1.5. The scatter is random, apparently independent of molecular weight or intrinsic viscosity, and could well reflect the error introduced in using $[\eta]$ instead of the theoretically preferred $[\eta]_\theta$.

A final reminder is made, however, that ideal correlations involving DRE, should include a specific representation of ξ ; we re-iterate that this will be functionally dependent on the free energy of mixing for the polymer/solvent pair, ΔG_M , and consequently on the independent variables of ΔG_M , such as the temperature and concentration.

DISCUSSION

(1) Our molecular approach to DR events bears some similarities to previously reported theories of fluid instability,

in particular the extensive field analysis of fluids due to Denn and Porteous²⁶. These authors concluded that flow instabilities in liquids bear a close similarity to field instabilities in supersonic flow of gases. Our approach is closely analogous, but $(\bar{u}^2)^{1/2}$ of the large flow units in our systems is much less than that in air flow²⁶, hence our flow units can be affected significantly by the velocities v_0 of the relevant boundary layers.

Analogy is also noted to the empirical relationship of Virk⁶

$$K^* \times D = \text{constant} \quad (12)$$

where K^* is the wavenumber and D the particle diameter of vortices. According to Hinze²⁷, K^* is related to the size of energy-dissipating eddies. Thus:

$$K^* \times D \sim \frac{D}{\delta} = \text{constant} \quad (12')$$

and $\frac{D^3}{\delta^3} = \frac{V_m}{\delta^3} = \text{constant} \quad (12'')$

* Codes are fully described in ref 11 from which they are reproduced

This leads to the consistent suggestion that the lower limit of observable turbulence is associated with a constant number of hydrodynamically independent units, regardless of the chemical nature of either solvent or solute.

(2) In a future publication, we will account more formally for the response of *DRE* to independent variables such as *T*, concentration and polymer molecular weight, through analysis of correlation equations derived from the foregoing arguments. Some qualitative experimental expectations are noted at this time, however. We regard these as useful starting points for newer research goals in the *DR* area. (a) The general correlation of molecular weight and *DRE* has been noted frequently, but little concern appears to have been given to the question of which moment of the distribution of a polymer is important. The high molecular weight end of the distribution spectrum will weigh most heavily in immobilizing turbulence centres. Thus, it is suggested that in polydisperse systems, *DRE* will correlate more strongly with *z*-average and weight-average values than with *M_p*, or number-average values of the molecular weight. Further, in the present work, the envisaged role of *DR* agents suggests that a minimum effective number of chain segments must be available before an average molecular unit of the material can produce measurable *DR* results. The existence of a material constant based on a function of the type $F(C_g/M_z)$ is therefore proposed for constant thermodynamic conditions of polymer/solvent interaction. (b) The influence of polymer/solvent interactions on *DRE* is held to be important. The tacit assumption is often made that the intrinsic viscosity can be used as a convenient index of polymer/solvent interactions. As already noted, we regard this choice as too limiting. Among the reasons for this is the fact that $[\eta]$ relates to macromolecular dimensions at vanishing concentration and very low shear rates. In contrast, *DR* occurs at finite concentrations and at very high rates of shear. Although the former problem is likely of little importance, a change to other parameters of interaction, such as the χ or *X* value already referred to earlier should increase the precision of correlations. The difference in shear levels however, would seem to be of great importance²⁵, and it is proposed that more accurate predictions of *DRE* will follow from the inclusion of an index of the shear dependence of solution viscosity in the molecular descriptors of the *DR* agents, or as suggested in equation (9), from the use of experimentally evaluated $[\eta]_\theta$ results. (c) The temperature dependence of *DRE* should reflect the unique temperature dependence patterns of polymer/solvent interaction parameters^{23,24}. In particular, we cite the existence in polymer solutions of both a low and high temperature solubility limit. From these considerations it follows that: a given polymer/solvent system must have an optimum temperature for *DRE*; both positive and negative variations of *DRE* with temperature should exist, depending on which side of the optimum temperature observations are being made.

CONCLUSIONS

We conclude that turbulent eddies in fluids arise from three dynamic processes. Incipient turbulence is associated with microvortex precursors having dimensions in the range of 100 Å, while fully developed turbulence domains are associated with linear dimensions of the order of 10⁻³ cm. *DR* effects of macromolecules are associated with their ability

to form penetrated domains which damp and stabilize the discontinuities of the solvent at the incipient formation stage. By a principle of dimensional consistency this calls for entanglement or penetration domains with linear dimensions of at least 100 Å. It follows that *DRE* will depend on those variables of the system which influence the effective linear dimensions of the macromolecule as well as on the variables which determine the size of microdisturbances in the solvent and the shear gradient at which these first occur.

NOMENCLATURE

Time effects on the thermochemical behaviour of natural rubber

L. Araimo, F. de Candia and V. Vittoria

Laboratorio di Ricerche su Tecnologia dei Polimeri e Reologia, CNR, 80072 Arco Felice (Napoli) Italy
(Received 30 June 1975; revised 30 July 1975)

Some preliminary results, obtained by studying the time effects on the thermomechanical behaviour of a natural rubber network, are reported. Experimental data indicate some thermodynamic features of the relaxation phenomenon under stress. The observed effects are discussed.

INTRODUCTION

At constant pressure and temperature the thermomechanical analysis of the deformation process of a rubberlike material can be carried out using the following state equation¹:

$$\Delta F = \Delta W + \Delta Q - T\Delta S \quad (1)$$

where ΔF is the change in free energy, ΔW is the elastic work and is given by the integral

$$\int_1^\alpha \tau d\alpha$$

where τ is the force on the unit of undeformed cross-sectional area and α is the strain ratio, ΔQ is the heat change and $T\Delta S$ is the entropic term. In equilibrium conditions $\Delta Q = T\Delta S$ and:

$$\Delta F = \int_1^\alpha \tau d\alpha \quad (1a)$$

while in non-equilibrium conditions, taking into account that:

$$T\Delta S = \Delta Q + T\Delta S_{\text{irr}} \quad (2)$$

where ΔS_{irr} is related to the irreversibility of the process, then:

$$\Delta F = \int_1^\alpha \tau d\alpha - T\Delta S_{\text{irr}} \quad (3)$$

and

$$\Delta H = \int_1^\alpha \tau d\alpha + \Delta Q \quad (3a)$$

All the thermodynamic terms of equations (1)–(3) refer to the volume unit.

Therefore, a direct graphical integration of the experimental τ vs. α plots gives the experimental numerical value of ΔW , while, ΔQ can be given by a direct microcalorimetric measurement. In the present paper, using this kind of analysis, time effects on the thermomechanical behaviour of a vulcanized rubber sample have been investigated. In

particular, the thermodynamic functions ΔQ , ΔW , ΔH for increasing and decreasing strain, have been calculated from experimental data, in order to obtain information about the relaxation phenomena at thermodynamic level, for short and long times of relaxation. Moreover, at a qualitative level, information about the entropic term $T\Delta S$ can be obtained.

It is of interest to see if, from the thermomechanical data, it is possible to obtain evidence of chain–chain interactions or aggregation, induced by strain, and some information on the degree of irreversibility of such effects eventually present. This study is related to well known problems of rubber elasticity, where the experimental deviations from the Gaussian theory², suggest connections with intermolecular phenomena such as chain–chain interactions or aggregations^{3–5}.

EXPERIMENTAL

A sample of vulcanized natural rubber was prepared using dicumyl peroxide as initiator; vulcanization was carried out at 145°C for 45 min.

The apparatus used to analyse the thermomechanical behaviour of the sample consists of a Calvet microcalorimeter equipped with a cell previously described³. The microscrew of the deformation cell is connected with a strain gauge that gives the value of the tensile stress. The sample is clamped in part of the cell inside the microcalorimeter which gives the measure of the heat exchanged during the deformation. The use of the microcalorimeter, in this kind of measurement, is based on the Tian equation³. As explained before³, in the present experiment the heat exchanged during the deformation is proportional to the area under the recorded line, and can be easily calculated when the calibration constant is known. A calibration plot (recorded area vs. energy) was obtained using a calibration cell based on the Joule effect. The work temperature was 40°C. The time interval between stretching and relaxing was 20 min. A general view of the apparatus is given in *Figure 1*.

RESULTS

The sample was deformed step by step, relaxing to zero load before stretching to the next strain value. The time interval between stretching and relaxing, and again stretching to the next α value was always 20 min. In this way, for each deformation value, the stress, immediately after stretching and

The arrows indicate increasing (\uparrow) and decreasing (\downarrow) strain

before relaxing the sample, has been detected. Therefore, the calorimeter gives two signals, the first on stretching and the second on relaxing. Using these experimental data, (see Table 1), the curves ΔW vs. α and ΔQ vs. α for increasing and decreasing strain were obtained. Using equation (3a), we have calculated the plot ΔH vs. α for increasing and decreasing strain. Results are reported in Figure 2. Repeating the complete deformation cycle, after a few hours and after two days, the data of Figure 2 are reproducible in the range of experimental errors.

DISCUSSION

In order to give an interpretation of the results obtained, the significance of the measurements as carried out must first be discussed. The difference observed in the thermodynamic functions, between increasing and decreasing strain, takes into account the effects, at thermodynamic

level, of the relaxation phenomenon, occurring when the sample is stretched. Therefore, the comparative analysis of the data of Table 1 and of Figure 2, giving a thermodynamic picture of the mechanical relaxation, provides evidence concerning the relaxation mechanism.

The effect of the relaxation, as is well known, is a dissipation of mechanical energy; this is clearly shown in Table 1, where all the values detected decreasing the strain are smaller than those during increase. From Table 1 it appears that thermal energy also, is dissipated in the deformation process.

Reporting these main results in terms of the cyclic integrals of the two functions ΔW and ΔQ related to cyclic deformation, the data of Table 1 give: $|\oint \Delta Q d\alpha| > |\oint \Delta W d\alpha|$.

The last result indicates that in the overall process, the dissipation of thermal energy is more pronounced and, this gives, as is clear from Figure 2: $\oint \Delta H d\alpha < 0$. As ΔH is a state function this datum is evidence of the irreversibility of the process in the time scale of the experiment.

Moreover, it can be suggested that the negative value of the cyclic integral of the enthalpic term could be related to ordering phenomena. Ordering phenomena, such as the formation or orientation of bundles, or simple chain orientation with interchain aggregation, are consistent with the behaviour observed for the enthalpic term. The suggestion that the relaxation can take place with such a mechanism is supported by results obtained by analysing the infra-red dichroism of stretched natural rubber networks⁶, where it is evident that orientation phenomena take place during the relaxation process. On the other hand, the possibility that aggregation phenomena can occur during the stretching seems to be supported by experimental data obtained analysing the crystallization behaviour of stretched natural rubber^{7,8}. This does not exclude the occurrence of other kind of relaxation mechanisms, e.g. entanglements, or free chains or chain ends slipping.

Figure 2 Enthalpic term as a function of the deformation ratio: ○, increasing the strain; ●, decreasing the strain

Some comment can be made about the entropic term. From equation (2) where $T\Delta S_{irr}$ is always larger than zero, it follows that, even if the entropic term cannot be calculated quantitatively, this term is qualitatively related to the heat term. Thus *Table 1* shows that the difference in entropy between the strained and unstrained state is greater on stretching than on relaxing.

This observation is valid in the hypothesis that ΔS_{irr} on stretching and ΔS_{irr} on relaxing are not drastically different, can be in agreement with the occurrence of ordering phenomena such as chain orientation and aggregation which are irreversible in the time scale of the experiment. Ordering phenomena also seem to be suggested by the residual creep after the relaxing.

In addition, the evidence regarding the reversibility of the data of *Table 1* and *Figure 2* on repeating the deformation cycle after a few hours and a few days, indicate that the phenomena responsible for the observed effects that take place during relaxation under stress, are reversible after a moderate time of relaxation at zero load. In conclusion, at this stage, we cannot prove without doubt, from the time effects on the thermomechanical behaviour the existence of ordering phenomena. However, we have no results that disagree with this hypothesis, which is so important for the understanding of the mechanical behaviour

of the rubber-like materials. On the other hand, the hypothesis seems to be directly supported by other kinds of experimental observations⁶⁻⁸

ACKNOWLEDGEMENT

We wish to thank Mr G. Permicola for the technical assistance in the realization of the apparatus of *Figure 1*.

A new approach in permeation chromatography calibration

Paweł Szewczyk

Polish Academy of Sciences, Institute of Polymer Chemistry 41-800 Zabrze, Poland
(Received 22 May 1975)

The first step in the determination of molecular weight distribution (*MWD*) of polymers using the gel permeation chromatography (g.p.c.) technique is to calibrate a given set of columns with a series of reference solutes. True molecular weight averages may be calculated from a g.p.c. chromatogram when a complete form of the calibration curve is known and corrections for imperfect resolution are made¹.

A large variety of calibration methods have been proposed²⁻⁶, involving narrow or broad *MWD* standards or using the hydrodynamic volume concept. Among the existing calibration procedures incorporating both of the above mentioned conditions, only the effective linear calibration method proposed by Balke *et al.*⁷ is relatively simple and has potential general utility. However, the linearity of this effective calibration becomes questionable when the calibration line is to be extrapolated to interstitial volume on one end and elution volume for monomers on the other.

In this paper a new concept in the effective g.p.c. calibration approach is presented. It is assumed that for a given type of polymer and fixed experimental conditions the molecular weight calibration curve in the elution volume range of practical importance may be accurately represented by a polynomial of degree n , i.e.:

$$\log M = a_0 + a_1 V + a_2 V^2 + \dots + a_n V^n = f(V) \quad (1)$$

where M , V , a_0 , a_1 , ..., a_n are the molecular weight of a hypothetically monodisperse fraction, the peak elution volume and polynomial coefficients, respectively. If equation (1) holds for monodisperse fractions, the coefficients a_0 , a_1 , ..., a_n are evaluated from an identical equation (2) by means of the least squares method⁸:

$$\log \bar{M}_r = a_0 + a_1 \bar{V}_p + a_2 \bar{V}_p^2 + \dots + a_n \bar{V}_p^n = f(\bar{V}_p) \quad (2)$$

in which \bar{M}_r denotes any type of polymer average molecular weight (e.g. number-, viscosity-, weight-average molecular weight, etc.) and \bar{V}_p represents a suitably averaged value of its elution volume. From the definition of the reciprocal function the following relation for \bar{V}_p is obtained from equation (2):

$$\bar{V}_p = f^{-1}(\log \bar{M}_r) = b_0 + b_1 (\log \bar{M}_r) + \dots + b_n (\log \bar{M}_r)^n \quad (3)$$

where b_0 , b_1 , ..., b_n are coefficients of the reciprocal polynomial.

Equations (2) and (3) are the basis of the proposed calibration procedure. In order to calculate $(n + 1)$ values of the a_i and b_i ($i = 0, 1, 2, \dots, n$), polynomial coefficients at

least $(n + 2)$ values of average molecular weights \bar{M}_r , and the chromatograms of samples of which the \bar{M}_r are measured, have to be known.

Starting values of the a_i and b_i coefficients are evaluated from the $\log \bar{M}_r$ versus V_{peak} , and V_{peak} versus $\log \bar{M}_r$ relations using the known $(n + 2)$ values of average molecular weights \bar{M}_r and peak elution volumes V_{peak} of samples chosen as standards for the polymer investigated. Values of the average elution volumes \bar{V}_p are then calculated for each of the standards. If the number-average molecular weight \bar{M}_n of a standard is known, $\bar{V}_p \equiv \bar{V}_1$, is calculated according to a formula derived from equations (3) and (2) and the definition of \bar{M}_n :

$$\begin{aligned} \bar{V}_1 &= f^{-1}(\log \bar{M}_n) = f^{-1} \left[\log \left(\sum_i w_i M_i^{-1} \right) - 1 \right] \\ &= f^{-1} \left[-\log \left(\sum_i w_i 10^{-f(V_i)} \right) \right] \end{aligned} \quad (4)$$

In the case when viscosity-average \bar{M}_v or weight-average \bar{M}_w molecular weights of the chosen standards are known, equations from which the corresponding \bar{V}_2 or \bar{V}_3 average elution volumes may be evaluated are as follows:

$$\bar{V}_2 = f^{-1}(\log \bar{M}_v) = f^{-1} \left[\alpha^{-1} \log \left(\sum_i w_i 10^{\alpha f(V_i)} \right) \right] \quad (5)$$

$$\bar{V}_3 = f^{-1}(\log \bar{M}_w) = f^{-1} \left[\log \left(\sum_i w_i 10^{f(V_i)} \right) \right] \quad (6)$$

In equations (4)–(6) f and f^{-1} denote the polynomials defined in equations (2) and (3), w_i are the established from the chromatogram weight fractions of polymer with molecular weight M_i and α is the corresponding Mark–Houwink equation exponent.

In this way $(n + 2)$ values of average elution volumes \bar{V}_p are obtained and the least squares evaluation of the a_i and b_i coefficients repeated. An iteration procedure is then performed on the successive a_i and b_i coefficients until a minimum value of the average percentage accuracy of the calculated from the corresponding chromatograms average molecular weights $\bar{M}_r(\text{calc.})$ using the latest calibration polynomial is obtained, i.e.:

$$1/(n + 2) \sum_{i=1}^{n=2} 100(\bar{M}_r^i - \bar{M}_r^i(\text{calc.}))/\bar{M}_r^i \quad (7)$$

In analogy to the ultracentrifugation method of establishing the sedimentation coefficient—molecular weight relation, using averaged values of sedimentation coefficients^{9,10}, the concept of averaging the experimental g.p.c. elution volumes was used in the above presented calibration procedure. Peak elution volumes almost exclusively applied in calibrating the g.p.c. columns are known not to correspond to any of the experimentally measurable average molecular weights¹¹. This may lead to serious errors in the case of generally encountered polydisperse polymer samples. In the presented method polymer samples of any polydispersity may be used as standards, yet their molecular weights should cover as broad a molecular weight range as possible.

This new calibration method is presently being tested to establish whether it does in fact correct for the g.p.c. instrumental spreading, and how its accuracy is influenced by experimental errors in average molecular weights and polydispersity of standards.

Spin-labelling of hydroxyl groups in polysaccharides

Michael C. Cafe, Norman G. Pryce and Ian D. Robb

Unilever Research Laboratory, Port Sunlight, Wirral, Merseyside L62 4XN, UK

(Received 21 August 1975; revised 29 September 1975)

INTRODUCTION

Spin labelled polymers have been used to study both the solution properties of polymers^{1,2} and their behaviour when adsorbed at the solid/liquid interface^{3,4}. Various methods for labelling polymers have been used, though one of the more difficult problems has been the labelling of hydroxyl groups on polymers such as polysaccharides that are soluble only in water or other hydroxylic solvents. Serine-OH groups on proteins have been labelled⁵, though the toxicity of the label requires great caution with the experiment. Labelling hydroxyl groups in proteins or polysaccharides by other methods such as using water soluble carbodiimides⁶, Woodward's reagent K⁷ or cyanuric chloride⁸ has been briefly reviewed^{9,10}. These methods however can sometimes lead to crosslinking.

The method of spin-labelling polysaccharides outlined in this note involves modifying the hydroxyl group with cyanogen bromide. This method has been used to attach proteins and polypeptides to cellulose or Sephadex gels¹¹⁻¹³. Although the pH in this work was 11, the reaction can be carried out in more moderately alkaline conditions (9.5-10). At pH 11, degradation of the polymer which occasionally occurs in acid conditions is avoided and a high efficiency of labelling can be achieved. Provided the polymer is completely dissolved, labels will be attached to OH groups and be randomly distributed along the chain. The polysaccharide to be labelled was sodium carboxymethylcellulose (SCMC) and the spin-label was 4-amino-2,2,6,6-tetramethylpiperidine-*N*-oxyl (I), (as supplied by Aldrich Chem. Co. Ltd).

EXPERIMENTAL AND RESULTS

A 2% solution of the SCMC (F4 grade from British Celanese Products, degree of substitution, 0.6) was filtered through a No. 4 sintered glass filter and then dialysed against distilled water for 2 weeks. Its molecular weight determined by viscosity¹⁴ in 0.1 M NaCl was 32 500. Purified SCMC (2 g) was dissolved in 40 ml H₂O and the pH adjusted to 11 with 1.0 M NaOH. Cyanogen bromide, (0.1 g, supplied by BDH) in 2 ml H₂O, was added and the mixture stirred for 4 h at room temperature, while keeping the pH constant at 11, using an automatic titrator. Spin label (I) (0.1 g) was added and the solution left a further 18 h at room temperature and at pH 11. The SCMC solution was then dialysed against distilled water until no further spin label (I) could be detected in the external solution by e.p.r. methods and then freeze-dried. Spectra were recorded on a Varian E-4 X-band spectrometer.

The molecular weight of the labelled SCMC¹¹, again determined by viscosity in 0.1 M NaCl was 34 000, indicating a minimum degree of crosslinking. The ¹H and ¹³C spectra measured on a Bruker WH90, showed no difference in the linewidths or chemical shifts of the labelled or unlabelled samples, again indicating that no significant crosslinking had taken place. Solutions of the labelled polymer were optically clear. The e.p.r. intensity of a 2% solution of the labelled polymer was compared with that of a known concentration of spin label (I). From this comparison it was calculated that there was 1 label per 24 glucose units. The spectrum from the labelled polymer is shown in *Figure 1*.

In analogy to the ultracentrifugation method of establishing the sedimentation coefficient—molecular weight relation, using averaged values of sedimentation coefficients^{9,10}, the concept of averaging the experimental g.p.c. elution volumes was used in the above presented calibration procedure. Peak elution volumes almost exclusively applied in calibrating the g.p.c. columns are known not to correspond to any of the experimentally measurable average molecular weights¹¹. This may lead to serious errors in the case of generally encountered polydisperse polymer samples. In the presented method polymer samples of any polydispersity may be used as standards, yet their molecular weights should cover as broad a molecular weight range as possible.

This new calibration method is presently being tested to establish whether it does in fact correct for the g.p.c. instrumental spreading, and how its accuracy is influenced by experimental errors in average molecular weights and polydispersity of standards.

(Received 21 August 1975; revised 29 September 1975)

INTRODUCTION

Spin labelled polymers have been used to study both the solution properties of polymers^{1,2} and their behaviour when adsorbed at the solid/liquid interface^{3,4}. Various methods for labelling polymers have been used, though one of the more difficult problems has been the labelling of hydroxyl groups on polymers such as polysaccharides that are soluble only in water or other hydroxylic solvents. Serine-OH groups on proteins have been labelled⁵, though the toxicity of the label requires great caution with the experiment. Labelling hydroxyl groups in proteins or polysaccharides by other methods such as using water soluble carbodiimides⁶, Woodward's reagent K⁷ or cyanuric chloride⁸ has been briefly reviewed^{9,10}. These methods however can sometimes lead to crosslinking.

The method of spin-labelling polysaccharides outlined in this note involves modifying the hydroxyl group with cyanogen bromide. This method has been used to attach proteins and polypeptides to cellulose or Sephadex gels¹¹⁻¹³. Although the pH in this work was 11, the reaction can be carried out in more moderately alkaline conditions (9.5-10). At pH 11, degradation of the polymer which occasionally occurs in acid conditions is avoided and a high efficiency of labelling can be achieved. Provided the polymer is completely dissolved, labels will be attached to OH groups and be randomly distributed along the chain. The polysaccharide to be labelled was sodium carboxymethylcellulose (SCMC) and the spin-label was 4-amino-2,2,6,6-tetramethylpiperidine-*N*-oxyl (I), (as supplied by Aldrich Chem. Co. Ltd).

EXPERIMENTAL AND RESULTS

A 2% solution of the SCMC (F4 grade from British Celanese Products, degree of substitution, 0.6) was filtered through a No. 4 sintered glass filter and then dialysed against distilled water for 2 weeks. Its molecular weight determined by viscosity¹⁴ in 0.1 M NaCl was 32 500. Purified SCMC (2 g) was dissolved in 40 ml H₂O and the pH adjusted to 11 with 1.0 M NaOH. Cyanogen bromide, (0.1 g, supplied by BDH) in 2 ml H₂O, was added and the mixture stirred for 4 h at room temperature, while keeping the pH constant at 11, using an automatic titrator. Spin label (I) (0.1 g) was added and the solution left a further 18 h at room temperature and at pH 11. The SCMC solution was then dialysed against distilled water until no further spin label (I) could be detected in the external solution by e.p.r. methods and then freeze-dried. Spectra were recorded on a Varian E-4 X-band spectrometer.

The molecular weight of the labelled SCMC¹¹, again determined by viscosity in 0.1 M NaCl was 34 000, indicating a minimum degree of crosslinking. The ¹H and ¹³C spectra measured on a Bruker WH90, showed no difference in the linewidths or chemical shifts of the labelled or unlabelled samples, again indicating that no significant crosslinking had taken place. Solutions of the labelled polymer were optically clear. The e.p.r. intensity of a 2% solution of the labelled polymer was compared with that of a known concentration of spin label (I). From this comparison it was calculated that there was 1 label per 24 glucose units. The spectrum from the labelled polymer is shown in *Figure 1*.

Figure 1 Spectrum of 3% polymer solution, pH 7

The correlation time was calculated to be about 5×10^{-10} sec, indicating slower tumbling of the label on the polymer, than when free in solution.

Thus it is possible to spin-label polysaccharides under alkaline conditions, causing a minimal change in the solubility, crosslinking or degradation.

Small-angle X-ray scattering from ultrathin films of cellulose acetate

Thin films (300–4000 Å) of cellulose acetate can be used to make composite reverse osmosis membranes¹. Since the mechanism of reverse osmosis separation is not fully understood, the structure of these films is of interest. Schultz and Asunmaa² obtained electron micrographs of shadowed films of cellulose acetate which they interpreted as showing an irregular close-packed array of roughly spherical particles, about 188 Å in diameter.

In the present study, thin films of cellulose 2.5 acetate (Eastman Kodak E-398-3) were made from a 2% w/w solution in acetone by the Carnell–Cassidy^{3,4} method. Assuming a film density of 1.3 g/cm³, the film thickness (determined by weighing) was 1900 ± 100 Å. The true film density may be considerably less than 1.3 g/cm³ in view of the structural model discussed below. A stack of the films (not heat-treated) was examined using a Kratky camera and a version of the Franks camera with the X-ray beam (CuKα) perpendicular to the plane of the films. A range of s down to $s = 0.0012 \text{ \AA}^{-1}$ was studied with the Franks camera (photographic detection) and down to $s = 0.00044 \text{ \AA}^{-1}$ with the Kratky (counter detection) where $s = 2 \sin \theta / \lambda$. Kratky data were desmeared by the method of Glatter⁵.

From $s = 0.00044$ to 0.025 \AA^{-1} the scattered intensity decreases monotonically apart from two 'shoulders' at $s = 0.0043$ and 0.0084 \AA^{-1} (Figure 1). If the films consist of a paracrystalline array of particles then the shoulder at $s = 0.0084 \text{ \AA}^{-1}$ could be due to the structure factor of individual particles. The first subsidiary maximum in the structure factor of a sphere radius R , occurs at $sR = 0.92$, and the (110) reflection of spheres in an hexagonal close packed (h.c.p.) lattice occurs at $sR = 1.00$. Spherical particles would then have a radius of 110–120 Å. The $s = 0.0043 \text{ \AA}^{-1}$ reflection is probably due to interparticle interference. The (002) reflection for an infinite h.c.p. lattice of spheres occurs at $sR = 0.613$. However, the structure factor of a sphere is changing rapidly at this value of sR and if a crystalite contained only 3 lattice repeats in the z direction then the (002) peak would be displaced⁷ to about $sR = 0.571$, i.e. to $s = 0.0050 \text{ \AA}^{-1}$ for $R = 115 \text{ \AA}$. The shoulder at $s =$

Figure 1 Scattering from cellulose acetate films. Desmeared Kratky camera data (small angle region)

Figure 2 Scattering from cellulose acetate films. Desmeared Kratky camera data (higher angle region)

0.0043 \AA^{-1} thus seems consistent with rather irregular packing, with some gaps between the spheres.

The above results are in reasonable agreement with those of Schultz and Asunmaa². Contrary to the assertion of Kesting⁸, the results confirm that the postulated paracrystalline structure of these films can be detected by X-ray scattering.

The minimum scattered intensity occurs at $s = 0.0256 \text{ \AA}^{-1}$. At higher angles there are several broad subsidiary maxima, notably at $s = 0.0324$ and 0.0422 \AA^{-1} (Figure 2). A very small percentage of material present in the CTA II crystal structure⁹ would produce a (100) reflection at $s = 0.0408 \text{ \AA}^{-1}$ which might account for the latter peak, but not for the former. Alternatively, if the $s = 0.0422 \text{ \AA}^{-1}$ peak were due to the first subsidiary maximum in the structure factor of a sphere, then this would correspond to a sphere radius of 21.9 Å and (assuming a density of 1.3 g/cm³) a mass of about 34 000 amu. The stated mean molecular weight of the polymer is 27 000 amu which suggests that the 115 Å radius particles are made up of globular sub-units, each consisting of one molecule. If the 21.9 Å subunits were close packed on an f.c.c. lattice they would give (200) type reflections at $s = 0.0323 \text{ \AA}^{-1}$ in good agreement with the observed peak at $s = 0.0324$. No (111) reflection was observed. However, if the paracrystalline regions were small then the (111) reflection would be displaced to smaller angles in the same way as the (002) reflection of the h.c.p. lattice of 115 Å particles. The peak would then be inseparable from the start of the small angle scattering.

SAXS studies of these cellulose acetate films are continuing.

New thermal initiators of free-radical polymerization and block copolymerization

Much information is available about the initiation of free-radical polymerization by organo-transition metal complexes in the presence of reactive organic halides^{1,2}. We now report two types of thermally initiating systems based on transition metal carbonyls which either contain no abstractable halide atoms or are free from halides.

Systems containing transition metal carbonyls (I)

In addition to a transition metal carbonyl, notably manganese or rhenium carbonyl ($Mn_2(CO)_{10}$, $Re_2(CO)_{10}$, respectively), these systems contain a low concentration of an additive such as tetrafluoroethylene or other ethylenic derivative carrying electron-withdrawing groups or an acetylenic derivative. *Figure 1* illustrates the characteristics of initiators of this type based on $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$. Rates of polymerization of methyl methacrylate at 100°C, ω , are shown as a function of the concentration of additive, either tetrafluoroethylene or acetylene dicarboxylic acid dimethyl ester (ADCADME). The curves are highly reminiscent of the 'halide' curves in initiating systems containing reactive halides, showing a plateau value at high additive concentrations^{1,2}. For comparison, the dependence of ω on $[CCl_4]$ for initiation by $Mn_2(CO)_{10}/CCl_4$ at 100°C is also illustrated in *Figure 1*; evidently C_2F_4 and ADCADME

Figure 1 Thermal initiation by systems of type I. Methyl methacrylate (bulk), 100°C. ■, $Mn_2(CO)_{10}$ (4.77×10^{-4} mol/l) + ADCADME; ▲, $Mn_2(CO)_{10}$ (4.77×10^{-4} mol/l) + C_2F_4 ; ●, $Mn_2(CO)_{10}$ (4.77×10^{-4} mol/l) + CCl_4 ; ○, $Re_2(CO)_{10}$ (5.48×10^{-4} mol/l) + ADCADME; △, $Re_2(CO)_{10}$ (5.48×10^{-4} mol/l) + C_2F_4 . The concentrations of C_2F_4 given are nominal values only, being calculated on the assumption that all the gas is dissolved in the methyl methacrylate. When [additive] = 0, $\omega = 1.02 \times 10^{-5}$ mol $l^{-1} s^{-1}$

are less effective than CCl_4 in producing high rates of initiation in association with $Mn_2(CO)_{10}$.

Under suitable conditions, polymers prepared with the new initiators show absorption in the infra-red near 2000 cm^{-1} similar to that of $(CO)_5MnA-$ or $(CO)_5ReA-$ end-groups³⁻⁵, where A represents a ligand derived from the additive, e.g. $-CF_2CF_2-$ or $-C(COOMe)=C(COOMe)-$. Thus the primary radicals probably have structures such as $(CO)_5MnCF_2\dot{C}F_2$ or $(CO)_5MnC(COOMe)=\dot{C}(COOMe)$, which may conveniently be abbreviated to $(CO)_5Mn\dot{A}$, although more complex variants cannot be excluded. The final polymers contain covalently bound atoms of manganese or rhenium.

Macromolecular initiators: block copolymerization (II)

In earlier papers³⁻⁷ we have shown that some transition metal carbonyls, particularly $Mn_2(CO)_{10}$, $Re(CO)_{10}$, in the presence of an additive of the types described above can photoinitiate the polymerization of common vinyl monomers at ambient temperatures. The resulting polymers have end-groups of structure $(CO)_5MnA-$ or $(CO)_5ReA-$. In the examples described below the additives were C_2F_4 and $MeOOC\equiv CCOOMe$, so that the corresponding end-groups [from $Mn_2(CO)_{10}$] were $(CO)_5MnCF_2CF_2-$ and $(CO)_5MnC(COOMe)=C(COOMe)-$, respectively. These polymers are active thermal initiators at higher temperatures (e.g. 100°C); we believe that initiation results from a homolytic process of the type:

in which $\sim M_1 \sim$ represents a polymer chain derived from monomer M_1 . The polymeric product obtained from a monomer M_2 is, therefore, in the simplest case, (when termination in M_2 is 100% disproportionation) a block copolymer:

When an additive of the type described is present the species $Mn(CO)_5$ also initiates, giving rise to primary radicals such as $(CO)_5Mn\dot{A}$; the rate of polymerization is therefore increased.

Preparative details and molecular weights of typical macroinitiators are given in *Table 1*. The experimental arrangements have been described in earlier papers^{3,5-7}.

Figure 2 presents conversion-time data for the polymerization of methyl methacrylate at 100°C in the presence of the macroinitiators 1 and 2 (*Table 1*). Some corresponding data for the rhenium macroinitiators are given in *Table 2*. These experiments also show that the presence

New thermal initiators of free-radical polymerization and block copolymerization

Much information is available about the initiation of free-radical polymerization by organo-transition metal complexes in the presence of reactive organic halides^{1,2}. We now report two types of thermally initiating systems based on transition metal carbonyls which either contain no abstractable halide atoms or are free from halides.

Systems containing transition metal carbonyls (I)

In addition to a transition metal carbonyl, notably manganese or rhenium carbonyl ($Mn_2(CO)_{10}$, $Re_2(CO)_{10}$, respectively), these systems contain a low concentration of an additive such as tetrafluoroethylene or other ethylenic derivative carrying electron-withdrawing groups or an acetylenic derivative. *Figure 1* illustrates the characteristics of initiators of this type based on $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$. Rates of polymerization of methyl methacrylate at 100°C, ω , are shown as a function of the concentration of additive, either tetrafluoroethylene or acetylene dicarboxylic acid dimethyl ester (ADCADME). The curves are highly reminiscent of the 'halide' curves in initiating systems containing reactive halides, showing a plateau value at high additive concentrations^{1,2}. For comparison, the dependence of ω on $[CCl_4]$ for initiation by $Mn_2(CO)_{10}/CCl_4$ at 100°C is also illustrated in *Figure 1*; evidently C_2F_4 and ADCADME

Figure 1 Thermal initiation by systems of type I. Methyl methacrylate (bulk), 100°C. ■, $Mn_2(CO)_{10}$ (4.77×10^{-4} mol/l) + ADCADME; ▲, $Mn_2(CO)_{10}$ (4.77×10^{-4} mol/l) + C_2F_4 ; ●, $Mn_2(CO)_{10}$ (4.77×10^{-4} mol/l) + CCl_4 ; ○, $Re_2(CO)_{10}$ (5.48×10^{-4} mol/l) + ADCADME; △, $Re_2(CO)_{10}$ (5.48×10^{-4} mol/l) + C_2F_4 . The concentrations of C_2F_4 given are nominal values only, being calculated on the assumption that all the gas is dissolved in the methyl methacrylate. When [additive] = 0, $\omega = 1.02 \times 10^{-5}$ mol $l^{-1} s^{-1}$

are less effective than CCl_4 in producing high rates of initiation in association with $Mn_2(CO)_{10}$.

Under suitable conditions, polymers prepared with the new initiators show absorption in the infra-red near 2000 cm^{-1} similar to that of $(CO)_5MnA-$ or $(CO)_5ReA-$ end-groups³⁻⁵, where A represents a ligand derived from the additive, e.g. $-CF_2CF_2-$ or $-C(COOMe)=C(COOMe)-$. Thus the primary radicals probably have structures such as $(CO)_5MnCF_2\dot{C}F_2$ or $(CO)_5MnC(COOMe)=\dot{C}(COOMe)$, which may conveniently be abbreviated to $(CO)_5Mn\dot{A}$, although more complex variants cannot be excluded. The final polymers contain covalently bound atoms of manganese or rhenium.

Macromolecular initiators: block copolymerization (II)

In earlier papers³⁻⁷ we have shown that some transition metal carbonyls, particularly $Mn_2(CO)_{10}$, $Re(CO)_{10}$, in the presence of an additive of the types described above can photoinitiate the polymerization of common vinyl monomers at ambient temperatures. The resulting polymers have end-groups of structure $(CO)_5MnA-$ or $(CO)_5ReA-$. In the examples described below the additives were C_2F_4 and $MeOOC\equiv CCOOMe$, so that the corresponding end-groups [from $Mn_2(CO)_{10}$] were $(CO)_5MnCF_2CF_2-$ and $(CO)_5MnC(COOMe)=C(COOMe)-$, respectively. These polymers are active thermal initiators at higher temperatures (e.g. 100°C); we believe that initiation results from a homolytic process of the type:

in which $\sim M_1 \sim$ represents a polymer chain derived from monomer M_1 . The polymeric product obtained from a monomer M_2 is, therefore, in the simplest case, (when termination in M_2 is 100% disproportionation) a block copolymer:

When an additive of the type described is present the species $Mn(CO)_5$ also initiates, giving rise to primary radicals such as $(CO)_5Mn\dot{A}$; the rate of polymerization is therefore increased.

Preparative details and molecular weights of typical macroinitiators are given in *Table 1*. The experimental arrangements have been described in earlier papers^{3,5-7}.

Figure 2 presents conversion-time data for the polymerization of methyl methacrylate at 100°C in the presence of the macroinitiators 1 and 2 (*Table 1*). Some corresponding data for the rhenium macroinitiators are given in *Table 2*. These experiments also show that the presence

5	C ₂ F ₄ , 153	65	—

In each experiment 10 mg macroinitiator in 10 ml methyl methacrylate were used and the mixture was heated at 100°C

of the additive increases the rate of polymerization, as already mentioned. The dependence of the rate of polymerization initiated by polymers 1 and 2 (Table 1) on the concentration of ADCADME is presented in Figure 3. The results with polymer 2, showing a plateau value with increasing [ADCADME], are as would be expected, but polymer 1 behaves in a more complicated fashion which at present is being studied in detail.

Block copolymer formation has been demonstrated in the polymerization of acrylonitrile (AN) initiated by the polymers 1 and 2 (Table 1) and in the polymerization of methyl methacrylate (MMA) initiated by polymer 3 (Table 1). Details are given in Table 3. In three cases the products were separated into fractions soluble and insoluble in chloroform as indicated in Table 3. Infra-red spectra of the polymeric products from macroinitiators 1 and 2 (Table 3) showed that in the chloroform-insoluble fractions both AN and MMA units were present, while in the chloroform-soluble portions no AN could be detected. The latter fractions therefore contained mainly the unreacted macroinitiator together perhaps with reacted material with very short AN chains. Both fractions of the polymer from experiment 3 (Table 3) contained tetrafluoroethylene and methyl meth-

acrylate units, but the former predominated in the insoluble fractions.

It seems clear that these macroinitiators are of considerable potential value in the synthesis of block copolymers.

Book Reviews

Peptides, polypeptides and proteins

Edited by E. R. Blout, F. A. Bovey, M. Goodman and N. Lotan

John Wiley, New York, 1975. 656 pp. £12.25

This volume contains forty-six papers given at a symposium held in Israel in May 1974. They are grouped under six main headings: Conformational calculations, Polypeptide and protein conformations, Cyclic and linear oligopeptides, Optical spectroscopy, Intermolecular interactions and Biological properties. While these papers might have been published in the usual journals, together they give a spectrum of current experimental and theoretical work for research workers in these areas. The discussions that followed the papers are not reported, but the authors had the opportunity to revise their papers following the meeting, and the substantial revision and editing of the preprint versions (which weighed 5 kilos!) is evident and beneficial.

While it may be, as Traub suggests, that the usefulness of X-ray studies of poly(amino acids) as models in relation to proteins has now largely been exhausted, undoubtedly the relative simplicity of these polymers is still of great value in providing a sound experimental and theoretical basis for n.m.r., optical and conformational studies of proteins, as is shown by many papers. Similarly, work on the cyclic peptides, which are of considerable intrinsic interest, may be relevant to the turns in protein structures. Undoubtedly the hope of predicting (successfully) the full conformation of a protein is a strong motivating factor here, but a spin-off from this extensive work is a better understanding of polymeric systems in general, and workers in other fields could find this book stimulating.

The accounts of the use of linear and branched chain polypeptides as synthetic antigens to study the immune response will be of particular interest to biologists.

Many will find the volume a valuable compilation at a not unrealistic price, and all concerned are to be congratulated on its speedy publication.

Progress in polymer science, Japan, Volume 7

Edited by T. Otsu and M. Takayanagi

Kodansha, Tokyo and John Wiley, New York, 1974, 380 pp. £14.50

Much Japanese work in polymer science is published in English, but there is still a large amount which is published in Japanese and hence not readily available internationally. This series is aimed at publicising fundamental studies currently in hand in Japanese laboratories by an annual selection of areas of work of topical interest and importance.

The present volume is divided between the synthesis of polymers and selected aspects of the study of physical properties.

Three articles on synthetic chemistry deal with photoresponsive polymers, polymers containing nucleic acid bases and their derivatives, and the polymerization of diallyl dicarboxylates. Current interest in photoresponsive polymers deal with all aspects of properties influenced by light such as colour, conduction, fluorescence and redox catalysis. The incorporation of nucleic acid bases in a variety of synthetic backbones is of obvious biochemical and biological interest and the article includes some comments on possible uses for these special molecules. The polymerization of diallyl dicarboxylates leads ultimately to the formation of extensive gel structures and in addition to further studies of the kinetics of reaction, attention has been given to gelation and copolymerization mechanisms together with the compilation of much quantitative information.

The structural articles are three in number and deal with solid state polymerization products, properties of crystalline polymers under high pressure and the structure of polypeptides and protein molecules. In the solid state work a variety of mechanisms is described and the morphology of the polymer studied in relation to the structure of the monomer in the solid state. The effect of pressure on polymers has also been extensively reviewed and includes instrumentation to measure a variety of properties including transitions and mechanical relaxation. Several vinyl and condensation polymers have been examined in this respect. The structure of the polypeptides section includes studies of model compounds for polypeptide chains and of vibrational spectra for poly(α -amino acids).

All the articles are well documented and provided with much quantitative information. For those interested in these fields this work must be a valuable review and even for those with more general interests, the clear presentation is conducive to browsing. The price is not low but the book represents good value by present day standards.

J. C. Robb

Conference Announcement

IVth European Symposium on Polymer Spectroscopy

Strasbourg, France, 22–24 March 1976

This conference is organized on behalf of the European Physical Society (Section of Macromolecular Physics of the Condensed Matter Division), the European Group on Polymer Spectroscopy, the French Physical Society and the French Polymer Group and will take place at Louis Pasteur University in Strasbourg from 22 to 24 March 1976. There will be five scientific sessions, each introduced by an invited lecture and followed by short contributed communications in the following fields: infra-red and Raman spectroscopy, inelastic neutron scattering, n.m.r., e.p.r., e.s.c.a., optical spectroscopy and fluorescence. The number of participants will be limited to 120. The second circular and registration form are now available from Professor G. Weill, Symposium Européen de Spectroscopie des Polymères, Centre de Recherches sur les Macromolécules, CNRS, 6 Rue Boussingault, 67083 Strasbourg, France and to whom completed registration forms should be sent by 31 January 1976.

Conference Announcement

Second Symposium on Poly(vinyl chloride)

Lyon, France, 5–9 July 1976

Following the first symposium held in Prague in 1970, a second symposium on poly(vinyl chloride), sponsored by IUPAC, CNRS and GRP will be organized in Lyon from 5 to 9 July 1976. It will cover eight topics: polymerization, chemical modifications, characterization, rheology, processing, properties, degradation and stabilization, and combustion and toxicity. Each topic will include a main lecture, short communications and a panel discussion. Further information may be obtained from the Symposium Secretary: Dr A. Michel, LA 199—CNRS, 39 Bd du 11 novembre 1918, 69626 Villeurbanne, France.

Crystallization of dilute polyethylene solutions: influence of molecular weight

E. Riande and J. M. G. Fatou

Sección de Fisicoquímica y Física de polímeros, Instituto de Plásticos y Caucho, Juan de la Cierva 3, Madrid-6, Spain

(Received 30 June 1975)

The crystallization kinetics of linear polyethylene over the molecular weight range 14 000–1 200 000 was studied in dilute solutions of α -chloronaphthalene by dilatometric techniques. The experimental results could be quantitatively described by the Avrami and Göler–Sachs theories for a significant part of the transformation. The influence of molecular weight on the time necessary for 10% of crystallinity to develop was also analysed and the obtained curves follow the same pattern as in the bulk. The temperature coefficient of crystallization was studied by using the two-dimensional nucleation theory and it was found that the basic interfacial free energy is about four times lower than the value reported previously for the pure polymer.

INTRODUCTION

The nucleation process plays an important role in the crystallization of polymers. Nucleation theories for finite molecular weight were developed in the past¹ and significant departures from monomer theory have been observed in the molecular weight range of interest. Accordingly, the crystallization kinetics of polymers strongly depends on the crystallization temperature, molecular weight and diluent concentration. Earlier work² has re-investigated the nucleation theory for fractionated polymer diluent systems (polyethylene in α -chloronaphthalene) over a composition range extending from pure polymer to 0.30 polymer fraction solutions and we have shown that the crystallization process in polymer/diluent mixtures is governed by the nucleation of the system and that the phase transformation is described by a function of the free energy required for nucleation. In the present paper this analysis is extended to very dilute solutions ($v_2 = 0.0030$) in the system polyethylene/ α -chloronaphthalene over a wide range of molecular weights.

EXPERIMENTAL

Materials

The linear polyethylene fractions were obtained from unfractionated Marlex 50 using the column fractionation technique that has been described elsewhere³. The solvent/non-solvent system used was tetralin/*n*-butyl glycol. The polyethylene fractionation was carried out at 128.0°C under a nitrogen atmosphere to prevent oxidation. The highest molecular fraction used in this work was obtained from a NBS linear high molecular weight polyethylene sample using a liquid–liquid phase separation technique which has been described previously⁴.

The α -chloronaphthalene (Fluka, AG) used in this work was of high purity.

Viscosity measurements

The determination of the intrinsic viscosities of the polyethylene fractions has been described elsewhere³. Viscosity-average molecular weights, M_η , were obtained from the rela-

tion given by Chiang⁵ for decalin at 135°C. The viscosity-average molecular weights for polyethylene fractions studied in this work were: 14 000; 20 000; 47 000; 190 000 and 1 200 000.

Crystallization

The sample and solvent were introduced into the bulb of the dilatometer and the sample was dissolved under a nitrogen atmosphere. Then the dilatometer was sealed. Filling the dilatometer with mercury was carried out according to the procedure described by Mandelkern *et al.*⁶. The crystallization was conducted in a silicone oil thermostat bath and the column of the mercury in the dilatometer was recorded as a function of time and could be measured to within ± 0.1 mm. The total change in the mercury height to completion of the crystallization was about 4 cm. Prior to the initiation of the crystallization the polymer sample in the dilatometer was dissolved by heating and the dilatometer was quickly transferred to a thermostat at a pre-assigned temperature. Thermal equilibrium was reached in about 10 min.

RESULTS AND DISCUSSION

At very high dilutions, comparative large undercoolings are necessary to obtain kinetic data in a reasonable time period. The data could be obtained in the temperature range from 96° to 102°C. The total crystallization time involved in the results reported here range from 1400 minutes to 10 000 min depending on the crystallization temperature. The lower crystallization temperature used in these experiments was that one with which a slight transformation (0.4%) was obtained in about 40 min.

It was found that the crystallization rates depend on the thermal history of the solution. Reproducible isotherms were obtained for low molecular weights when the dilatometer was kept in a bath for 60 min at a temperature of 150.0°C. As the molecular weight increases longer times and higher solution temperatures were necessary to achieve complete solubility. With the two higher molecular weight fractions, reproducible isotherms were obtained once the

Figure 1 Plot of degree of crystallinity as function of log t for fraction $M = 190\,000$. Solution temperatures: \circ , 180° ; Δ , 190° ; \square , 210°C

Figure 2 Double logarithmic plot of degree of crystallinity against t at different crystallization temperatures, for fraction $M_\eta = 14\,000$. $+$, 98° ; \circ , 98.9° ; Δ , 100.1° ; \bullet , 100.9° ; \square , 101.9°C

dilatometers were kept in a bath at 220°C for 12 h as is shown in Figure 1.

The prior thermal history strongly influences the crystallization kinetics. As an example, the first stages of the crystallization isotherms as a function of the thermal history will be analysed for the molecular weight fraction of 190 000. The experiments were carried out one after another in which the sample was crystallized at 99.0°C . As indicated in Figure 1 the crystallization rates are higher the lower the solution temperatures and the induction time increases as long as the solution temperature increases. It would appear that a very high solution temperature is necessary to get the polymer chains completely at random in solution and completely homogenized solutions. The same behaviour concerning the irreproducibility of the isotherms

was found by Ergoz *et al.*⁷ with undilute high molecular weight fractions ($\bar{M}_\eta = 1.2 \times 10^6$). However, these authors reported that if the sample was never cooled below the crystallization temperature, then on the third and subsequent melting and crystallization the results were reproducible.

Kinetic analysis

The kinetic data were analysed using the G6ler-Sachs or free growth approximation⁸. Accordingly, for the initial portion of the transformation it is found that:

$$1 - \lambda(t) = (k_3 t)^4 / 4$$

$$1 - \lambda(t) = (k_2 t)^3 / 6 \tag{1}$$

$$1 - \lambda(t) = (k_1 t)^2 / 2$$

depending on the respective growth geometries, i.e. the exponent in equation (1) defines, respectively, three, two or one-dimensional growth. The experimental results, concerning the complete molecular weight range studied, are plotted in Figures 2-6 according to equation (1). For a given molecular weight fraction a linear relation is obtained for a significant part of the total transformation and the slope of these portions is found to be independent of crystallization temperature. However, the slope of the linear portion of the double logarithmic plot $1 - \lambda(t)$ vs. t , is dependent on molecular weight. For the two lowest molecular weights analysed here, the slope is four. As the molecular weight increases up to and including $M = 1.2 \times 10^6$, the slope is three. Similar results were obtained in previous work⁷ for undiluted fractionated polyethylene covering the same molecular weight range. The slopes have the exact integral value and the close adherence of these straight lines to the experimental data is quite clear.

Figure 3 Double logarithmic plot of degree of crystallinity against t at different crystallization temperatures for fraction $M_\eta = 20\,000$. \circ , 98° ; Δ , 99° ; \square , 99.9° ; $+$, 100.9°C

Figure 4 Double logarithmic plot of degree of crystallinity against t at different crystallization temperatures for fraction $M_n = 47\,000$. \circ , 98.25° ; \triangle , 99.2° ; \square , 100.1° ; $+$, 100.9° ; \bullet , 101.8° C

Figure 5 Double logarithmic plot of degree of crystallinity against t at different crystallization temperatures for fraction $M_n = 190\,000$. \circ , 98.1° ; \blacktriangle , 98.9° ; \square , 100° ; \triangle , 100.9° ; $+$, 102° C

The fact that integral values of 3 for the slope are obtained is very important. As will be seen below, the magnitude of the slope corresponds to the exponent in the Avrami equation.

As occurs with the crystallization in bulk, after deviations from linearity develop, the experimental results for each temperature and for a given molecular weight form a common straight line of very small slope.

The G6ler-Sachs approximation assumes a free growth over the complete range of the transformation, i.e. it neglects the impingement. On the contrary, the Avrami equation takes into account the mutual impingement of growing centres upon each other. The assumption is made that upon impingement, further crystal growth ceases. The Avrami equation⁹ can be written as:

$$\ln(1 - X) = kt^n \quad (2)$$

It is very easy to show that equation (2) reduces to equation (1) for small extents of the transformation.

The agreement of the experimental data with the Avrami theory is about the same as with the G6ler-Sachs theory so that deviation from either of the theories occurs at about the same level of crystallinity. Then, the introduction of impingement does not improve the agreement between theory and experiment for crystallization of long chains from solutions. This conclusion is analogous to that obtained in the crystallization of long chains in bulk.⁷

Therefore in the first stages of the transformation the curves $1 - \lambda(t)$ vs. $\log t$ show, for a given molecular weight, good agreement with the theoretical equations and the superposition principle holds. However, in the final stages, deviations occur so that the same time-temperature reduce variable is no longer maintained throughout the transformation. In the analysis of the crystallization kinetics of fractionated polyethylene carried out by Ergoz *et al.*⁷, it is shown that for a given molecular weight and below a critical undercooling the superposition principle holds over the complete extent of the transformation. Deviations occur at lower undercoolings. Our data were obtained at relatively low undercoolings and we do not have sufficient experimental evidence to reach any reliable conclusion relative to this point.

It should be stressed that our data seem to indicate that in comparison with the crystallization in bulk higher crystallinity levels are obtained in solution.

Crystallinity slightly depends on molecular weight and reaches an asymptotic value for infinite time, independent of crystallization temperature. In the lower molecular weight range, from 14 000 to 190 000, the total crystallinity after two decades in the time scale, varies from 90 to 85%. The highest molecular weight develops 75% crystallinity, relatively higher than the crystallinity levels obtained for this fraction crystallized from the bulk, which corresponds to 40%.⁷

Figure 6 Double logarithmic plot of degree of crystallinity against t at different crystallization temperatures for fraction $M_n = 1.2 \times 10^6$. \square , 96.4° ; \triangle , 98.4° ; \circ , 99.4° ; $+$, 100.4° C

Figure 7 Double logarithmic plot of $\tau_{0.1}$ against molecular weight for different crystallization temperatures. \blacktriangle , 368.2; \bullet , 369.2; \circ , 371.2; \triangle , 372.2; \square , 373.2; \times , 374.2K

These results indicate that in comparison with the crystallization in bulk, higher crystallinity levels are obtained in solution with the higher molecular weight and about the same in the lowest molecular weight range.

Finally, it is of interest to investigate the influence of molecular weight on the time scale of the crystallization process. The time required for 10% of the absolute amount of crystallinity to develop as a function of the molecular weight is plotted in Figure 7. The obtained curves follow the same pattern as in the bulk. Thus, the crystallization time decreases as the molecular weight increases, reaching a minimum within the molecular weight interval 10 000–20 000. For molecular weights higher than 20 000 the crystallization times increase as the molecular weight increases. Again the polyethylene in solution behaves as the polymer in bulk as far as the relation crystallization time–molecular weight, is concerned. This is a very important conclusion.

Temperature coefficient of the crystallization

In order to analyse the temperature coefficient of the crystallization, it is important to consider the nucleation act. The crystallization process is governed by the nucleation of the system, and the phase transformation is described by the free energy required to form a stable critical nucleus^{10,11}. Nucleation theory has been developed for finite molecular weights in diluent–polymer systems² and the importance of molecular weight and concentration in analysing the temperature coefficient in high and moderate concentrations has been shown.

The free energy change involved in forming a cylindrically arranged crystalline array of ξ units long and ρ sequen-

ces in cross-section for a diluted system containing N polymer molecules each comprised of x repeating units in which the volume fraction of diluent is v_2 , is given by^{2,12,13}:

$$\Delta F_d = 2\pi^{1/2}\rho^{1/2}\sigma_u\xi - 2\rho\sigma_e\ln v_2 - \xi\rho\Delta f'_u + \xi\rho\frac{RT}{x}v_2 - \rho RT \ln \frac{x - \xi + 1}{x} \quad (3)$$

where σ_u is the lateral interfacial free energy, σ_e is the excess interfacial free energy per repeating unit as it emerges from the crystal face normal to the chain direction. The first two terms in equation (3) represent the positive contribution to the total free energy of interfaces present. The third term of equation (3) represents the depressed energy of fusion for the $\xi\rho$ units involved in the transformation and is given by:

$$\Delta f'_u = \Delta f_u - RT \left\{ \frac{V_u}{V_l} (1 - v_2) - \mu(1 - v_2)^2 \right\} \quad (4)$$

where Δf_u is the energy of fusion per repeating unit for a chain of infinite molecular weight, V_u is the volume per repeating unit of the polymer and V_l is the molar volume of the diluent, μ is a parameter depending of the interaction polymer–diluent.

The last two terms result from the finite length of the chains. The first of these terms expresses the entropy gain which results from the increased volume available to the ends of the molecule after melting. The last term represents the entropy gain that arises from the number of different ways a sequence of ξ units can be located in a chain x units long with the terminal unit being excluded from the sequence in question. The surface described by equation (3) contains a saddle point and the coordinates of this point prescribe the dimensions of a nucleus of critical size. These dimensions are given by the relations²:

$$\rho^{1/2} = \frac{2\pi^{1/2}\sigma_u}{\Delta f'_u - (RT/x)v_2 - RT/(x - \xi + 1)} \quad (5)$$

$$\frac{\xi}{2} \left(\Delta f'_u - \frac{RT}{x}v_2 + \frac{RT}{x - \xi + 1} \right) = 2\sigma_e - RT \ln v_2 - RT \ln \frac{x - \xi + 1}{x}$$

Accordingly, the free energy change, ΔF^* , involved in forming the critical nucleus is given by²:

$$\Delta F^* = \pi^{1/2}\xi\rho^{1/2}\sigma_u \quad (6)$$

If a two-dimensional nucleation is assumed and we use the concepts and notation of the previous analysis, the change in free energy that accompanies the formation of a monomolecular nucleus, ξ units long and ρ sequences breadth is given by²:

$$\Delta F^* = 2\sigma_u\xi \quad (7)$$

Figure 8 Plot of σ_e against volume fraction v_2^2 . 1, $M = 250\,000$; 2, $M = 10\,000$; 3, $M = 4\,000$

where ξ is expressed by the transcendent equation:

$$\xi = \frac{2\sigma_e - RT \ln \left(\frac{x - \xi + 1}{x} \right) - RT \ln v_2}{\Delta f_u' - \frac{RT}{x} v_2} \quad (8)$$

These theories rest heavily on the Flory-Huggins theory which, as is well known, only holds for high and moderate concentrations in which the excluded volume effects are not important. Basically, in dilute solutions, the free energy of mixing departs drastically from that predicted by the Flory-Huggins theory because of the lack of homogeneity in the solution. Therefore, from a rigorous point of view, the nucleation theories described above are only applicable to concentrated solutions and to those dilute solutions in which the excluded volume effects are negligible.

With these reservations in mind we will apply the nucleation theories to analyse the coefficient temperature of the kinetic data. Owing to the fact that n equals three, we have used two-dimensional theory. The results and conclusions do not depend on this assumption. Consequently, no unique conclusions can be made with regard to the molecular nature of the nucleus because the experimental data fit the form for either of the two major types of nucleation.

In order to analyse the temperature coefficient of the crystallization process it is convenient to take $\tau_{0.1}$ the time required for 10% of the transformation to occur, as a measure of the rate constant. Then the data can be analysed by the equation:

$$\ln \tau_{0.1}^{-1} = \ln(\tau_{0.1})_0 - \frac{\Delta F^*}{RT} \quad (9)$$

By introducing equation (7) into equation (9) one obtains:

$$\ln \tau_{0.1}^{-1} = \ln(\tau_{0.1})_0 - \sigma_u \frac{\xi}{T} \quad (10)$$

It is quite clear from equation (10) that by plotting $\ln \tau_{0.1}^{-1}$ against ξ/T a straight line should be obtained whose slope should be the interfacial lateral free energy.

It is clear that this analysis does not involve the independent establishment of values for T_s , the equilibrium melting temperature (or dissolution temperature) of the dilute solution as has been done previously⁶. However, in order to proceed with the present treatment the basic interfacial free energy σ_e needs to be specified.

Recent work² has established that for undiluted polyethylene σ_e ranges from 4600 cal/mol to 4000 cal/mol for the molecular weight range 4000–250 000 if σ_u has a constant value of 25 cal/mol. Furthermore, it has been stated that in the system polyethylene/ α -chloronaphthalene for high and moderate concentrations, σ_e decreases sharply with dilution at very high concentrations and slowly at moderate concentrations if σ_u remains constant.

For very dilute systems, a lower value of σ_e of about 1000 cal/mol can be extrapolated although this extrapolation is very risky since the lowest experimental concentration corresponds to $v_2 = 0.30$ (Figure 8).

Figure 9 Plot of $\ln \tau_{0.1}^{-1}$ against ξ/T for various molecular weights. $\sigma_e = 1000$ cal/mol for 14 000 and 20 000 molecular weight fractions; $\sigma_e = 1.200$ cal/mol for 47 000 and 190 000; $\sigma_e = 1.400$ cal/mol M : \square , 14 000; \circ , 20 000; \blacksquare , 47 000; \triangle , 190 000; \bullet , 1 200 000

Taking into account these earlier findings the temperature coefficient of our data has been analysed by equation (9). By plotting $\ln \tau_0^{-1}$ against ξ/T a set of non-parallel straight lines is obtained if a unique value of σ_e is considered for all molecular weights. This result means that σ_u changes with molecular weight, a conclusion which is very difficult to accept.

Assuming that σ_u does not change with dilution a unique straight line is obtained independent of molecular weight and parallel to that of undiluted polymer if the basic interfacial free energy is allowed to change slightly from 1000 cal/mol ($M = 14\,000$) to 1400 cal/mol ($M = 1.2 \times 10^6$) as can be seen in Figure 9.

The conclusion is very important. The values of σ_e are, in this concentration range, slightly dependent on molecular weight in the range analysed in this work and about four times lower than the values reported earlier for pure polymer.²

The theory presents limitations when it is applied to very dilute solutions, because the tacit assumption of a uniform distribution of polymer segments through the amorphous regions is made. The inaccuracy should become serious at the lowest chain length. However, in spite of the limitation of equations (4) and (7), the general conclusion

stated above may be reached if small excluded volume effects are present in this system. Further investigation is in progress using other polymer-diluent systems to assess the reliability of this approach.

Melting of ethylene oxide – propylene oxide type P(EP)_n block copolymers

P. C. Ashman and C. Booth

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK
(Received 30 May 1975)

Multiblock copolymers of poly(ethylene oxide) and poly(propylene oxide), type P(EP)_n, have been prepared by condensation of hydroxy- and chlorocarboxy-ended polymers. Small-angle X-ray scattering and dilatometry have been used to determine lamella spacings and melting points of the copolymers. The melting points of the multiblock copolymers can be predicted from the melting points of corresponding triblock (PEP) copolymers.

INTRODUCTION

It is possible to avoid undue complexity in the molecular interpretation of the thermodynamic properties of crystallizable block copolymers provided that the polymeric components are compatible in the melt and that only one component is crystallizable. These criteria are fulfilled by poly(ethylene oxide)–poly(propylene oxide) block copolymers with fairly short block lengths. We have reported elsewhere the melting behaviour of model block copolymers of type PE¹, PEP^{2,3} and EPE⁴. Here we present results for multiblock copolymers of type P(EP)_n where $n = 1-7$.

EXPERIMENTAL AND RESULTS

Preparation

P(EP)_n block copolymers were prepared by the condensation of α , ω -hydroxy-poly(ethylene oxide) with α , ω -chlorocarboxy-poly(propylene oxide) for $n > 1$ or with α -methoxy, ω -chlorocarboxy-poly(propylene oxide) for $n = 1$. Reagents and solvents were purified as described earlier¹.

Samples of α , ω -hydroxy-poly(ethylene oxide) were prepared using potassium hydroxide as catalyst and ethylene glycol as initiator as described previously³ (samples 48 and 75) or were commercial samples (Hoechst Chemicals Ltd, samples 45 and 136). Samples of α , ω -hydroxy-poly(propylene oxide) were similarly prepared, but with 1,2-propanediol (dried over anhydrous sodium sulphate and distilled, 104°C and 32 mmHg, before use) as initiator.

Samples of α -methoxy, ω -hydroxy-poly(propylene oxide) were prepared using a sodium methanol mixture as catalyst/initiator. The polymerizations were carried out in dry evacuated sealed ampoules kept in the dark at room temperature for 3 months. Polymers were neutralized with a solution of dilute hydrochloric acid in methanol (50% v/v). Water and methanol were removed by rotary evaporation, and sodium chloride by centrifugation (15 000 \times g for 1 h). In a typical experiment sodium (0.29 g), methanol (1.65 g) and propylene oxide (10.30 g) gave polymer with $\bar{M}_n = 220$ (calculated 200).

The hydroxy-ended poly(propylene oxide) samples were reacted with phosgene (ICI Ltd) to form the chloroformate intermediates. The polymer was dried by evacuation (<1 N/m², 50°C, 1 h) and dissolved (10 g) in dry benzene

(75 cm³). Phosgene was bubbled slowly through the stirred solution at 20°C for 1 h. Thereafter dry nitrogen was bubbled slowly through the solution to remove excess phosgene. Benzene and remaining traces of phosgene were removed by distillation under reduced pressure, and finally by evacuation (<1 N/m², 24 h). The polymers were stored under dry nitrogen in order to avoid hydrolysis. The infra-red spectra of the polymers prepared in this way were consistent with complete conversion of hydroxy- to chlorocarboxy-end groups⁵. Gel permeation chromatography served to show that the molecular weight distributions (*MWD*) of the polymers were unchanged during the phosgenation.

The α , ω -hydroxy-poly(ethylene oxide) was dried by evacuation (<1 N/m², 2 h, $T > T_m$) and dissolved (5 g) in pyridine* (20 cm³, dried over and distilled from calcium hydride). To this solution blanketed with dry nitrogen and stirred at 60°C under reflux, was added, using a syringe, a solution of the chlorocarboxy-ended poly(propylene oxide) in dry benzene (10 cm³). Preliminary experiments (*Table 1*)

Table 1 Effect of mole ratio on the degree of condensation (n) in the formation of 12(136–12)_n copolymers

Mole ratio (P:E)	Degree of condensation
0.86	1.3
1.00	2.1
1.08	2.9
1.19	3.7
1.34	5.9
1.42	4.0
1.83	3.2

* In preliminary experiments we found that a chlorocarboxy-group reacts more readily with a hydroxy-group in solution in pyridine than with an alkoxy-group in the melt. This is attributable to the formation of a complex which is particularly susceptible to nucleophilic attack by an alcohol:

This reaction is favoured by primary hydroxy-groups, such as the end groups of poly(ethylene oxide), rather than by secondary hydroxy-groups, such as the end groups of poly(propylene oxide)⁶.

^a Predicted from preparative conditions

^b Data mainly from Refs 1, 2 and 10

served to define a mole ratio (P:E) of 1.3:1 as optimum for obtaining a high degree of condensation when using α, ω -chlorocarboxy-poly(propylene oxide) in the preparation of multiblock copolymers. A mole ratio of 4:1 was used for α -methoxy, ω -hydroxy-poly(propylene oxide) in the preparation of triblock copolymers. Reaction was complete in 15 min (prolonged heating at 60°C led to chain scission, detectable by gel permeation chromatography). Termination of P(EP)_n chains by poly(propylene oxide) blocks was ensured at this stage by the addition of further α, ω -chlorocarboxy-poly(propylene oxide) to bring the overall mole ratio to 1.6:1.

The condensation was terminated by adding methanol (10 cm³). Pyridine and methanol were removed by rotary evaporation followed by evacuation of the melt (<1 N/m², 50°C, 24 h). Pyridinium hydrochloride was removed by dissolving the dry polymer in dry benzene and centrifuging the mixture (15 000 × g for 15 min). The copolymer was separated from poly(propylene oxide) homopolymer by adding excess iso-octane to the benzene solution at 0°C, followed by repeated washing with iso-octane at room temperature.

Notation

We refer to samples by their number-average block lengths (expressed in monomer units) and their degree of condensation as established by their preparation and subsequent characterization. For example, sample 5(45–5)₇ denotes an alternating block copolymer composed of 8 poly(propylene oxide) blocks of length 5 units and 7 poly(ethylene oxide) blocks of length 45 chain units.

Characterization

Vapour pressure osmometry (v.p.o.) (Mechrolab, benzene at 25°C) and end group analysis (e.g.a.) (phthaloylation of hydroxy-groups^{7–9}) were used to characterize the homopolymers, as indicated in Table 2. Gel permeation chromatography (g.p.c.) was used to determine *MWD* of the poly(ethylene oxide) homopolymers; details are given elsewhere^{3,10}. Results are listed in Table 2.

G.p.c. was used to check that the PEP copolymers were free from polymeric impurities. Five Styragel columns (Waters Associates) with nominal pore sizes in the range 150

to 1500 nm were used with tetrahydrofuran solvent (25°C, flow rate 1 cm³/min). Chromatograms showed a complete absence of multiblock copolymer or excess homopolymer. (Chromatograms of the poly(propylene oxide) homopolymers under the same conditions were resolved into individual oligomers). In addition proton magnetic resonance spectroscopy¹¹ (p.m.r.) was used to check that the composition of the PEP copolymers was as expected; the results are given in Table 3.

G.p.c. was also used to check the degree of condensation of the multiblock copolymers, and to investigate their *MWD*. Four Styragel columns with nominal pore sizes in the range 70 to 5 × 10⁵ nm were used with *N,N*-dimethylacetamide as solvent (80°C, flow rate 1 cm³/min). Calibration was by fractions of poly(ethylene oxide) and poly(propylene oxide), which gave coincident plots. The results are summarized in Table 4. Number-average values of *n* were in the range 2 to 7; weight- to number-average molecular weight ratios were generally greater than 2. For a condensation, the distribution should be most probable with $\bar{M}_w/\bar{M}_n = (2n + 1)/(n + 1)$ varying from 1.7 (*n* = 2) to 1.9 (*n* = 7)¹². The generally higher values of \bar{M}_w/\bar{M}_n observed are attributable in part to instrumental spreading and in part to adventitious termination by hydrolysis during the condensation.

Dilatometry and X-ray scattering

The methods used to determine melting points by dilatometry and lamella spacings by small-angle X-ray scattering have been described earlier¹.

All polymers were crystallized as completely as possible. The degree of crystallinity attained with the multiblock copolymers was lower than that attained with triblock (PEP) copolymers, e.g. the dilatometric contractions observed for the multiblock samples were only about 60% of those observed for comparable PEP copolymers. A similar effect has been noted with segmented poly(ethylene oxide) samples¹³.

Melting points are listed in Table 5. Multiple melting points were observed only for the P(45–P)_n type copoly-

mers, as indicated in Table 5 (lower melting points in parentheses). Melting ranges were similar for both tri- and multi-block copolymers, and were from 3 to 4 K. The melting points were more dependent on crystallization temperature T_c than hitherto observed¹⁻⁴ with poly(ethylene oxide)/poly(propylene oxide) block copolymers, especially those of the multiblock copolymers.

The small-angle X-ray scattering patterns of the PEP copolymers were similar to those observed for homopolymers^{10,14} and copolymers¹⁻³ and consisted of several sharp peaks. By contrast the peaks derived from the multiblock copolymers were broad. Sharp peaks could be obtained for samples annealed for several days at temperatures 5 K below T_m . The annealing did not change the peak position. Lamella spacings¹ obtained from small-angle X-ray measurements are listed in Table 5. Comparison of the results of Table 5 with those obtained earlier for ether linked PEP block copolymers (e.g. sample 5-48-5 crystallized at 29°C had² $l = 10.9$ nm, 3-75-3 crystallized at 37°C had³ $l = 12.6$ nm) is sufficient to identify the PEP polycrystals as predominantly once-folded chain type. Similar comparison of the lamella spacings of the multiblock copolymers is complicated by their relatively low degree of crystallinity

(with the possibility that the amorphous material is located in the amorphous lamellae of the polycrystal). With this in mind we identify the 45 and 75 series of multiblock copolymers as forming predominantly once-folded chain polycrystals, and the 136 series as forming predominantly twice-folded chain polycrystals. We assign the lower melting points observed for samples 7(45-7) $_2$, 9(45-9) $_5$ and 12(45-12) $_5$ to predominantly twice-folded chain polycrystals.

DISCUSSION

Compared to the melting points of poly(ethylene oxide) homopolymers of corresponding (block) length, the melting points of the copolymers are substantially reduced, e.g. compare the results of Table 5 with^{10,15} $T_m = 53.8^\circ\text{C}$ for poly(ethylene oxide) 2000 ($\bar{x}_n = 45$); $T_m = 60.2^\circ\text{C}$ for poly(ethylene oxide) 3300 ($\bar{x}_n = 75$); and $T_m = 64.1^\circ\text{C}$ for poly(ethylene oxide) 6000 ($\bar{x}_n = 136$). The melting point depression is due in part to chain folding in the crystalline lamellae [compare $T_m = 60.1^\circ\text{C}$ for once-folded chain poly(ethylene oxide) 6000] and in part to the inclusion of the poly(propylene oxide) blocks in the amorphous lamellae of the polycrystal^{1,2}.

We have shown elsewhere^{1,2} that successful quantitative interpretation of the melting of homopolymers and block polymers is possible only when information is available concerning the polycrystalline structure. In terms of the stacked lamella model we have used^{1,2}, this information is the thickness of the crystalline and amorphous lamellae. Nevertheless it is possible to qualitatively interpret the results of Table 5 in the light of the Flory-Vrij¹⁶ model of melting of short polymer chains, the use of which is justified elsewhere¹. Here it is sufficient to consider the simplified case of an alternating block copolymer, P(EP) $_n$, having monodisperse E- and P-blocks. The feature of this model is that the E block ends are paired at the surface of the crystalline lamella. We envisage two extreme cases.

Long P blocks. The E blocks are haphazardly placed in the crystalline lamellae (Figure 1a). Assuming random placement of the E blocks in the lamellae, the free energy of fusion per chain (ΔG) is given by^{1,16,17}:

$$\Delta G = n(x\Delta g - 4\sigma_e - RT\ln x + RT\ln\phi_e) \quad (1)$$

where n is the number of E blocks (length x) in the copolymer chain, ΔG is the free energy of fusion per chain unit of perfectly crystalline poly(ethylene oxide), σ_e is the free

energy of formation from the melt of the crystal/amorphous interface and the amorphous lamella, and ϕ_e is the segment fractions of E in the copolymer melt (one segment has the volume of one poly(ethylene oxide) unit). The term $RT\ln\phi_e$ arises from the necessity that the first segment of a chosen sequence (which must be paired at the interface) is a poly(ethylene oxide) unit; the term $RT\ln x$ from the necessity that the sequence is *x* E units long. The factor 4 in the interfacial free energy term is introduced because our data pertain to once-folded chain polycrystals in which the E block occupies 4 interfacial sites. This equation is identical to that for *n* independent PEP copolymers and leads directly to the melting point expression*:

$$T_m = T_m^0 [1 - 4\sigma_e/x\Delta h] / [1 - (RT_m^0/x\Delta h)\ln(\phi_e/x)] \quad (2)$$

where T_m^0 and Δh are, respectively, the melting point and the enthalpy of fusion per chain unit of perfectly crystalline poly(ethylene oxide). The melting point T_m is independent of *n*.

Short P blocks. The -EPEPEPE- chain forms a regularly folded lamella (Figure 1b) in which the E blocks are sequentially placed and in which the inner P blocks form identical folds. In this case proper location of the end unit of the -EPEPEPE- chain uniquely locates the rest. For this restrictive case the free energy of fusion per chain, in a once-folded chain polycrystal is:

$$\Delta G = nx\Delta g + 4n\sigma_e' - RT\ln z + RT\ln\phi_e \quad (3)$$

where σ_e' is the free energy of formation from the melt of the interface and *z* is the chain length in segments of the -EPEPEPE- chain (i.e. the chain length excluding the two end P blocks). This equation leads to the melting point expression:

$$T_m = T_m^0 [1 - (4\sigma_e'/x\Delta h)] / [1 - (RT_m^0/nx\Delta h)\ln(\phi_e/z)] \quad (4)$$

The melting point T_m depends upon *n*.

* We use the condition $\Delta G = 0$ when $T = T_m$ and the relationship $\Delta g = \Delta h [1 - (T_m/T_m^0)]$

Values of T_m calculated from equation (4) for a typical copolymer series, 5(45-5)_n are listed in Table 6. We use $T_m^0 = 349^{18-20}$ and $\Delta h = 8.4$ kJ/mol²¹ and choose σ_e' to be 8.0 kJ/mol in order to bring the calculated melting points into approximate agreement with those observed. Parameters ϕ_e and *z* are calculated assuming that the specific volumes of supercooled poly(ethylene oxide) and poly(propylene oxide) melts at 40°C are, respectively, 0.901 cm³/g and 1.012 cm³/g¹.

A comparison of the experimental and the predicted variation of T_m with *n* is made in Table 7. Experimental results fall between those predicted from the extreme models. This is in keeping with our finding a low degree of crystallinity in the multiblock copolymers; presumably, although the P blocks are short in our systems, a random structure of type (a) (Figure 1) is approached by the incorporation of E blocks in the amorphous layer.

The fact that the experimental values of ΔT in Table 7 are fairly small means that the melting point of a copolymer with alternating blocks of crystallizable (E) and non-crystallizable (P) polymers can be predicted with success, say to within a degree, from the melting point of the corresponding triblock (PEP) copolymer.

ACKNOWLEDGEMENTS

We thank Dr R. Mobbs for practical assistance in the preparation of the copolymers and Messrs D. J. Roy and D. Rowlinson for help with their characterization. P.C.A. acknowledges receipt of a Science Research Council Student ship.

Effect of chain structure on the melting of low molecular weight poly(ethylene oxide)

J. O. G. Maclaine, P. C. Ashman and C. Booth

Department of Chemistry, University of Manchester, Manchester, M13 9PL, UK

(Received 30 May 1975)

Linked poly(ethylene oxide) samples have been prepared by the condensation of α -methoxy- ω -chlorocarboxy-poly(ethylene oxide) with alcohols of various functionalities. Melting points (by dilatometry) and lamella spacings (by small-angle X-ray scattering) have been determined. The linked polymers have higher melting points than their unlinked precursors. The increased melting point is interpreted in the light of the model of Flory and Vrij.

INTRODUCTION

Investigations have been made of the crystalline structure¹⁻⁵ and the melting⁴⁻⁶ of linear low molecular weight α , ω -hydroxy-poly(ethylene oxide), of poly(ethylene oxide) samples with other end groups^{7,8} or with segmented structure⁹, and of block copolymers of poly(ethylene oxide) with poly(propylene oxide)¹⁰⁻¹⁴, polystyrene^{15,16} or poly(ϵ -caprolactam)¹⁷. In the absence of effects attributable to incompatibility in the melt^{15,16} or crystallization of the copolymerized component¹⁷ the experimental results can be broadly interpreted in terms of a polycrystalline structure of alternating crystalline and amorphous lamellae^{12,13}. In this paper we report an extension of the range of investigations to include branched poly(ethylene oxide) samples.

EXPERIMENTAL AND RESULTS

Preparation

Poly(ethylene oxide) samples were prepared by the condensation of α -methoxy- ω -chlorocarboxy-poly(ethylene oxide) with alcohols of various functionalities.

Samples of α -methoxy- ω -hydroxy-poly(ethylene oxide) were prepared by use of a sodium methoxide/methanol mixture as catalyst/initiator. These polymers were reacted with phosgene to form the α -methoxy- ω -chlorocarboxy-polymer intermediates for the condensation. The preparative methods have been described elsewhere¹⁴.

The chloroformate intermediates were reacted with either methanol (distilled from magnesium activated by iodine), ethylene glycol (distilled from calcium sulphate), glycerol (dried under high vacuum for 4 days at 40°C), or penta-erythritol (Hopkins and Williams Ltd, m.p. 260.5°C, used as received). The liquid alcohols were stored over type 4A molecular sieves and were degassed before use. Reactions were carried out in pyridine which had been distilled from calcium hydride. The α -methoxy- ω -chlorocarboxy-poly(ethylene oxide) was melted at 60°C under vacuum (<1 N/m², 2 h). The system was then blanketed with dry nitrogen and a solution of the appropriate alcohol in pyridine (~0.1 g/cm³ in sufficient quantity to ensure a 20% molar excess of chlorocarboxy- over hydroxy-groups in the linking reactions and *vice versa* in the reaction with methanol) was added using a syringe. The mixture was held under reflux at 60°C for 1 h. The condensation was terminated by atmospheric moisture. Volatiles were removed by rotary evacuation. Pyridinium hydrochloride was re-

moved by dissolving the dry polymer in dry benzene and centrifuging the mixture (15 000 \times g for 15 min). The polymer was recovered by freeze-drying.

Nomenclature

Starting from α -methoxy- ω -hydroxy-poly(ethylene oxide) samples of molecular weight $\bar{M}_n = 1600$ or 2700 we prepared two series of polymers. We refer to these by their chain lengths (36 or 61 chain units respectively); by their end groups (M = methoxy-, H = hydroxy-, C = carboxy-methoxy-); by the alcohol used in the condensation (O = hydroxy-ended polymer, E = ethylene glycol, G = glycerol and P = penta-erythritol); and by the number of poly(ethylene oxide) blocks. This is illustrated, for the 36 series, in Table 1.

Fractionation

The preparative conditions for the α -methoxy- ω -hydroxy-poly(ethylene oxide) samples lead to the formation of a small proportion of α , ω -hydroxy-poly(ethylene oxide) initiated by adventitious water. This polymer will form α , ω -chlorocarboxy-poly(ethylene oxide) at the second stage of the preparation and so may undergo chain extension by reactions with the polyfunctional alcohols. Moreover, because of the excess of chloroformate in the reaction mixture, condensation with a polyfunctional alcohol gives both linked and unlinked polymers. Consequently the molecular weight distributions of the linked polymers may be wide. Accordingly the polymers were all fractionated before use. Fractionation was from a dilute solution of toluene (<5 g/dm³) by addition of isoctane in the manner described elsewhere¹⁸. Generally 3 or 4 fractionations were needed to reduce the width of the molecular weight distribution to an acceptable figure (see Table 2).

Characterization

Vapour pressure osmometry (v.p.o.) (Mechrolab Model 301A, benzene at 25°C), end group analysis (e.g.a.) (phthaloylation of hydroxy end-groups^{19,20}), dilute solution viscometry (d.s.v.) (tetrahydrofuran at 25°C) and gel permeation chromatography (g.p.c.) (tetrahydrofuran at 25°C) were used to characterize the polymers with respect to molecular weight. Results are given in Table 2. Infra-red spectroscopy and reaction with phthalic anhydride served to demonstrate an absence of hydroxy end-groups in all samples but MH36 and MH61.

D.s.v. was carried out with modified Desreux–Bischoff viscometers. Kinetic energy and shear corrections were negligible. A density correction was applied²¹.

G.p.c. was carried out with 5 Styragel columns of nominal pore sizes in the range 15 to 1500 nm. Calibration was with narrow fractions of known molecular weight⁴; the calibration curve was adjusted to reproduce the values of \bar{M}_n for the calibrants. Values of \bar{M}_n for the branched samples were based upon a 'universal' calibration²² i.e. a plot of $\log_{10}[\eta]M$ against elution volume. Corrections for instrumental spreading were not made.

Values for \bar{M}_n obtained by end group analysis are low compared with those obtained by the other methods; this is as expected if the samples (MH36 and MH61) contain a fraction of α , ω -hydroxy-poly(ethylene oxide).

Values of \bar{M}_n , based on those established for samples MH36 (1600) and MH61 (2700) taking into account the structure of the polymers, are listed in the last column of Table 2. The agreement between the predicted and the experimental values is satisfactory.

Small-angle X-ray scattering

The methods used for small-angle X-ray scattering have been described earlier¹². The scattering patterns were similar to those observed for other poly(ethylene oxide) homopolymers^{1,4} and copolymers¹². Lamella spacings were calculated directly from Bragg's Law, slit smearing effects being unimportant.

Lamella spacings are listed in Table 3. Polymers were crystallized at several temperatures (T_c); scattering was at

20°C. The chain length of poly(ethylene oxide) homopolymer of length 36 chain units is 10.1 nm and that of length 61 chain units is 17.1 nm. (Calculated assuming 0.28 nm per chain unit, in keeping with a repeat distance of 1.95 nm for the 7–2 helix of crystalline poly(ethylene oxide)²³. The spacings indicate that the polymers form predominantly extended chain lamellae, as is found for other poly(ethylene oxide) homopolymers of comparable chain (block) length^{1,4,5}. The increase in lamella spacing with degree of branching is possibly due to rejection of the shorter branches from the crystalline lamellae; the temperature dependence of lamella spacing is also consistent with a fractionation mechanism of this kind.

Dilatometry

The methods used for dilatometry have been described elsewhere^{12,24}. Contractions on crystallization (Δv , cm³/g) are listed in Table 4. These may be compared (see Table 4) with those for the process*:

melt → perfect crystal

The volume contractions must be considered in conjunction with the melting temperatures of the samples (Table 5) since, due to fractionation during the crystallization process^{1,26}, Δv can vary considerably with undercooling. The

* We use the following specific volumes to calculate Δv for the perfect crystallization^{2,23,25}:
Melt $v = 0.891$ cm³/g at 25°C $\alpha = 0.00069$ cm³/g K
Crystal $v = 0.813$ cm³/g at 25°C $\alpha = 0.00015$ cm³/g K.

Table 4 Contraction on crystallization ($10^2 \times \text{cm}^3/\text{g}$) for poly(ethylene oxide) fractions

Sample	T_c (°C)		
	36.1	40.0	43.2
MH36	6.1	5.5	—
MC36	—	5.6	—
(M36) ₂ O	—	6.4	—
(M36) ₂ E	6.5	5.5	—
(M36) ₃ G	—	5.5	—
(M36) ₄ P	4.8	4.7	—
MH61	—	7.3	5.1
(M61) ₂ E	—	5.7	6.3
(M61) ₃ G	—	6.1	6.5
Perfect crystallization	8.4	8.6	8.8

evidence we have is that Δv is not greatly affected by branching (with the possible exception of sample (M36)₄P).

Melting points (Table 5) are defined by the point of disappearance of the last trace of crystallinity¹². Within the temperature range $T_m \pm 5$ K we found only one melting point in any fraction; this is in keeping with other results on poly(ethylene oxide) homopolymers of molecular length⁶⁻⁸ less than 70 chain units. Melting points of the branched samples are slightly dependent on T_c ; those of the linear samples are independent of T_c .

DISCUSSION

Replacement of the hydroxy-end groups of samples MH36 and MH61 by methoxycarbonyl-end groups in samples MC36 and MC61 changes the melting point very little (<0.5 K, see Table 5). This is in keeping with a recent²⁷ comparison of hydroxy- and methoxy-ended poly(ethylene oxide) fractions which revealed a similarly small divergence in melting behaviour. We take these results to mean that the contribution of the free energy of mixing of end- and chain-groups to the free energy of formation from the melt of the amorphous lamellae of the polycrystal is small¹². Consequently we are able, in these systems, to ascribe changes in melting point between single and linked chains mainly to changes in structure. We note that this is not so for poly(ethylene oxide) linked with 2,4-toluene di-isocyanate⁹ because the introduction of aryl groups is known to depress the melting point of low molecular weight poly(ethylene oxide)⁷. (In fact melting point depressions were found by Galin *et al*⁹ for the 2,4-toluene di-isocyanate linked polymers.)

Effect of chain structure on melting

For simplicity we consider firstly the melting of polymers composed of p branches each of equal length (x chain units) which form crystalline lamellae of thickness x chain units. The case of single chains ($p = 1$) has been treated by Flory and Vrij²⁸ who write the free energy of fusion per chain:

$$\Delta G = x\Delta g - 2\sigma_0 - RT\ln x \quad (1)$$

where Δg is the free energy of fusion per chain unit of perfectly crystalline poly(ethylene oxide) and σ_0 is the free energy of formation from the melt of the crystal/melt interface (i.e. the layer of end groups). This equation leads to the melting point expression*:

* We use the condition $\Delta G = 0$ when $T = T_m$ and the relationship $\Delta g = \Delta h[1 - (T_m/T_m^0)]$.

$$T_m = T_m^0 [1 - (2\sigma_0/x\Delta h)] / [1 + (RT_m^0/x\Delta h)\ln x] \quad (2)$$

where T_m^0 and Δh are, respectively, the melting point and the enthalpy of fusion per chain unit of perfectly crystalline poly(ethylene oxide).

For the case $p \geq 1$, the free energy of fusion per chain can be written:

$$\Delta G = px\Delta g - 2p\sigma_0 - RT\ln z \quad (3)$$

where z is the total chain length. In formulating the term $RT\ln z$ we note that all p branches of length x enter the crystal and so the pairing of a chain end, in a crystal of thickness x units, is sufficient to ensure that all other ends are paired. The melting point expression corresponding to equation (3) is:

$$T_m = T_m^0 [1 - (2\sigma_0/x\Delta h)] / [1 + (RT_m^0/px\Delta h)\ln z] \quad (4)$$

The Flory-Vrij model can be extended²⁸ to take account of a crystalline lamella of thickness $l_c < x$, i.e. the case of partial melting²⁸. The free energy of fusion per chain can be written:

$$\Delta G = pl_c\Delta g - 2p\sigma_e - RT\ln z + pRT\ln(x - l_c + 1) \quad (5)$$

where σ_e is the free energy of formation from the melt of the crystal/amorphous interface and the amorphous layer of uncrystallized chain ends. The term $RT\ln(x - l_c + 1)$ originates in the additional combinatorial entropy of the partly melted crystal. We assume here an identical contribution of $RT\ln(x - l_c + 1)$ from each branch. (This is for an idealized model in which the constraints of one branch on another are ignored.) The melting point expression corresponding to equation (5) is:

$$T_m = T_m^0 [1 - (2\sigma_e/l_c\Delta h)] / [1 - (RT_m^0/pl_c\Delta h)\ln I] \quad (6)$$

where:

$$I = (x - l_c + 1)^p/z \quad (7)$$

We have shown elsewhere^{6,12} how these equations can be recast to take account of polydispersity of chain length, provided that simple assumptions are made concerning the nature of chain folding of the longer chains in the distributions. In fact we can demonstrate the important effects of chain structure without recourse to more complex equations than those above.

(M61) ₂ E	58.4	60.1	61.4	9.7
(M61) ₃ G	58.5	61.3	63.2	10.6

^a Calculated assuming that for the 36 series of copolymers $\sigma_0 = 6.8$ kJ/mol and $\sigma_e = 6.6$ kJ/mol, and that for the 61 series $\sigma_0 = \sigma_e = 8.2$ kJ/mol

Comparison of theory and experiment

Values of T_m calculated according to equations (4) and (6) are listed in Table 6. We use $T_m = 349K^{29-31}$ and $\Delta h = 8.4$ kJ/mol³². The lamella thickness l_c is assumed to be $0.7x$, in keeping with the values of l_c found¹² for extended chain polycrystals. The values of σ_0 and σ_e (indicated in Table 6) were chosen so as to bring measured and calculated melting points into agreement for the single chains MC36 and MC61.

At constant end interfacial free energy the theoretical prediction is that T_m is increased as p is increased. The predicted increase varies somewhat with the model used. However the end-paired model is for chains with zero combinatorial entropy in the polycrystal so that we might expect to observe increases in T_m at least as large as those predicted by equation (4). In fact we do not observe a constant increase in T_m with p ; moreover the observed increases in T_m are markedly lower than those predicted. We interpret this to mean that the interfacial free energy is increased as p is increased.

For the more realistic partly melted model, represented by equation (6), we have determined the values of σ_e required to bring theory and experiment into agreement. These values are listed in Table 6. An increase in σ_e of up to 2.5 kJ/mol is sufficient to explain the observed melting points. Such an increase in σ_e would be consistent^{12,13} with conformational distortions of the poly(ethylene oxide) chains in the amorphous layer (as a consequence of accommodating linking points in the amorphous layer whilst maintaining a high extent of crystallinity), or with an increase in thickness of the amorphous lamellae (as might be the case with sample (M36)₄P, see Table 4).

ACKNOWLEDGEMENTS

We thank Dr R. Mobbs for help with the preparation of the linked polymers and Messrs D. J. Roy and D. Rowlinson for assistance with their characterization. P.C.A. and J.Q.G.M. acknowledge receipt of Science Research Council Studentships.

Sequence distribution of *cis*-1,4- and *trans*-1,4-units in polyisoprenes

Yasuyuki Tanaka and Hisaya Sato

Department of Textiles and Polymer Science, Faculty of Technology, Tokyo University of Agriculture and Technology, Tokyo, Japan

(Received 9 June 1975)

The ^{13}C n.m.r. spectra of chicle polyisoprene and *cis*-*trans* isomerized 1,4-polyisoprenes were studied. The splittings of signals were observed in the C_1 , C_2 , and C_4 carbon signals of the isomerized polyisoprenes. The newly appearing signals were assigned to the carbon atoms in *cis*-*trans* linkages. The fractions of the diad sequences (*trans*-*trans*, *trans*-*cis*, *cis*-*trans*, and *cis*-*cis*) were determined by using the four signals of C_1 carbon. It was found that the *cis*-1,4- and *trans*-1,4-units were randomly distributed in the isomerized polyisoprenes and it was confirmed that the chicle polyisoprene was a mixture of *cis*-1,4- and *trans*-1,4-polyisoprenes.

INTRODUCTION

Recently ^{13}C n.m.r. spectroscopy has been successfully applied to investigate the sequence distribution of 1,2- and 1,4-units or *cis*-1,4- and *trans*-1,4-units in polybutadienes¹⁻⁴. As for polyisoprenes, however, few investigations have been made on the sequence distribution of isomeric structures using this technique, although Duch and Grant have assigned the ^{13}C n.m.r. signals of *cis*-1,4- and *trans*-1,4-homopolyisoprenes⁵.

In previous work we have found new signals attributed to *cis*-*trans* linkages in the ^{13}C n.m.r. spectra of *cis*-*trans* isomerized polyisoprenes and assigned the signals using diad sequences of *cis*-1,4- and *trans*-1,4-units⁶. We have also studied the ^{13}C n.m.r. spectra of hydrogenated polyisoprenes containing various amounts of 1,4- and 3,4-units and the sequence distribution of 1,4- and 3,4-units were discussed for *n*-BuLi catalysed polyisoprenes⁷. In this work we have investigated the sequence distribution of chicle polyisoprene and *cis*-*trans* isomerized 1,4-polyisoprenes containing various ratios of *cis*-1,4- and *trans*-1,4-units.

EXPERIMENTAL

Materials

Chicle polyisoprene was obtained by the extraction of crude chicle with benzene after removing the acetone-soluble compounds. This polyisoprene was purified by repeated reprecipitation from a benzene solution into acetone. The purified chicle polyisoprene consisted of exclusively 1,4-polyisoprene, which was confirmed by ^1H n.m.r. and infra-red spectroscopies.

Gutta percha (*trans*-1,4-: 100%) and synthetic *cis*-1,4-polyisoprene (*cis*-1,4-: 97.1%, *trans*-1,4-: 1.9%, 3,4-: 1.0%) were used for the starting polymer of *cis*-*trans* isomerization without further purification. The benzene solution of the polymer (2 or 3 % w/v) was irradiated with a high pressure mercury lamp in the presence of thiobenzoic acid (1-8% w/w of the polymer) stirring with a magnetic stirrer at 20°C under nitrogen atmosphere. The isomerized polymer was purified by repeated reprecipitation

from a benzene solution into acetone. The ratio of *cis*-1,4- and *trans*-1,4-units of the polymer was determined by ^1H n.m.r. spectroscopy.

Measurement

The ^{13}C n.m.r. spectra were obtained at 25.1 or 15.0 MHz using respectively a JEOL JNM-PS 100 or a Varian CFT-20 spectrometer equipped with a Fourier transfer accessory. Measurements were made at room temperature or 60°C in CDCl_3 (about 25% w/v). Chemical shifts were referred to tetramethylsilane added as an internal standard. All the spectra were proton noise decoupled and obtained with multiple scans at a pulse repetition time of 2.0 or 2.2 sec.

RESULT AND DISCUSSION

Assignments of ^{13}C n.m.r. signals

The ^{13}C n.m.r. spectrum of chicle polyisoprene was identical to that of a mixture of *cis*-1,4- and *trans*-1,4-polyisoprenes showing five signals due to *cis* polymer at 134.85, 124.65, 32.25, 26.36, and 23.25 ppm and also five signals due to *trans* polymer at 134.38, 123.87, 39.67, 26.67, and 15.87 ppm (Figure 1). These signals were assigned to the C_2 , C_3 , C_1 , C_4 , and C_5 carbons in the order of increasing magnetic field for both *cis*-1,4- and *trans*-1,4-polymers⁵. The symbols of carbon atoms are denoted as follows:

The observation that chicle contains both *cis*-1,4- and *trans*-1,4-polyisoprenes is in accord with the finding obtained by Schlesinger and Leeper using fractionation⁸.

Polyisoprenes containing various ratios of *cis*-1,4- and *trans*-1,4-units were obtained by *cis*-*trans* isomerization of 1,4-polyisoprenes. Figure 2 shows the differences between the ^{13}C n.m.r. spectra of chicle and isomerized polyisoprenes. In the spectra of isomerized polyisoprenes signals due to C_1 carbon split into two peaks for both *cis* and *trans* resonances. Similar splittings were observed in

Figure 1 ^{13}C n.m.r. spectrum of chicle polyisoprene (25.1 MHz)

Figure 2 ^{13}C n.m.r. spectra of 1,4-polyisoprenes (25.1 MHz). (a) Chicle polyisoprene; (b) isomerized gutta percha (*trans*-1,4-: 64%); (c) isomerized *cis*-1,4-polyisoprene (*trans*-1,4-: 50%)

the signals due to C_2 and C_4 carbons of isomerized polymers, though new signals appeared between the original *cis* and *trans* peaks and overlapped with one another. These new signals were not observed for chicle polyisoprene, gutta percha, and synthetic *cis*-1,4-polyisoprene.

The structures of the isomerized polyisoprenes were also investigated by X-ray diffraction. The crystallinity of gutta percha drastically decreased by the isomerization as shown in Figure 3. On the other hand, the isomerized *cis*-1,4-polyisoprene displayed no peaks due to the crystallinity of long sequences of *trans*-1,4-unit, even though it had

more than 50% of *trans*-1,4-unit (Figure 3c). This finding shows that the long sequences of the *trans*-1,4-unit disappeared by the isomerization of the *trans* polymer and was not produced by the isomerization of the *cis* polymer. Hence, it is concluded that *cis*-*trans* linkages were produced by the isomerization of both *cis* and *trans* polymers. It was confirmed that side reactions such as main chain scission reaction and cyclization were negligible in the course of *cis*-*trans* isomerization as discussed later. Consequently, the newly appearing signals were attributed to the carbon atoms in the *cis*-*trans* or *trans*-*cis* linkages. The signals due to C_1 , C_2 , and C_4 carbon atoms were assigned to the carbon atoms in diad sequences of *cis*-1,4- and *trans*-1,4-units as shown in Table 1.

Sequence distribution of *cis*-1,4 and *trans*-1,4 units

The fractions of diad sequences of *cis*-1,4- and *trans*-1,4-units, i.e., *trans*-*cis*, *trans*-*trans*, *cis*-*cis*, and *cis*-*trans* were determined from the relative intensities of the four signals of C_1 carbon atom. These diad fractions are plotted against the fraction of *trans*-1,4-unit for the isomerized polyisoprenes as shown in Figure 4. The observed values of

Figure 3 X-ray diffraction patterns of 1,4-polyisoprenes. A, gutta percha; B, isomerized gutta percha (*trans*-1,4-: 87%); C, isomerized *cis*-1,4 polyisoprene (*trans*-1,4-: 50%)

Table 1 Assignment of ^{13}C n.m.r. signals

Carbon	Chemical shift (ppm from TMS)			
	<i>trans</i> - <i>trans</i>	<i>trans</i> - <i>cis</i>	<i>cis</i> - <i>trans</i>	<i>cis</i> - <i>cis</i>
C_1	39.67	39.91	32.01	32.25
C_2	134.38	134.55	134.68	134.85
C_4	26.69	~26.55	~26.45	26.36

Figure 4 Diad sequence fraction of *cis*-1,4- and *trans*-1,4-units. Points show experimental points, and curves the theoretical dependence assuming Bernoullian distribution; \circ , *cis*-*cis*; \square , *cis*-*trans*; \times , *trans*-*cis*; \bullet , *trans*-*trans* fraction

each diad sequence lay on the theoretical curves assumed for a random distribution of *cis*-1,4- and *trans*-1,4-units. Therefore it is concluded that the *cis*-*trans* isomerization proceeded randomly regardless of the ultraviolet irradiation time, the concentration of thiobenzoic acid, and the microstructure of the starting polymer. It is noteworthy that the fractions of *cis*-*trans* and *trans*-*cis* linkages were almost equal for all polymers, which indicates the validity of the signal assignments. The fractions of *trans*-1,4-unit determined from relative intensities between C_1 -*cis* and C_1 -*trans* signals were in good agreement with those obtained by ^1H n.m.r. spectroscopy. This indicates that the differences of the nuclear Overhauser enhancement factor and the effect of spin-lattice relaxation time among these C_1 carbon atoms were negligible in these measurements. However, the fractions of *trans*-1,4-unit determined from the signals of C_5 carbon atom were lower than those obtained by ^1H n.m.r. spectroscopy up to 8%.

The chicle polyisoprene did not exhibit definite signals characteristic of the *cis*-*trans* or *trans*-*cis* linkages, which indicates that this polymer is a mixture of *cis*-1,4- and *trans*-1,4-polyisoprenes or a block copolymer consisting of long sequences of *cis*-1,4- and *trans*-1,4-units. The fractionation of the chicle polyisoprene was carried out according to the method of Schlesinger and Leeper⁸. The polymer was separated into a pure *trans*-1,4-polymer and *cis*-1,4-polymer containing 10% of *trans*-1,4-unit. Characteristic signals due to *cis*-*trans* linkages were not observed in either fraction. Therefore it is confirmed that the chicle polyisoprene is a mixture of *cis*-1,4- and *trans*-1,4-homopolymers, although a pure *cis* polymer was not obtained by the fractionation.

cis-*trans* Isomerization by ultra-violet irradiation

The *trans*-1,4-fractions of the isomerized polymers were plotted as a function of ultra-violet irradiation time in Figure 4. The isomerization proceeded as the irradiation

time increased and the isomerization rate increased with the concentration of thiobenzoic acid. Both *cis* and *trans* polymers were isomerized to a common equilibrium structure containing 50 to 65% of *trans*-1,4-unit. This equilibrium composition is almost in agreement with one obtained by Cunneen *et al.*⁹.

Golub *et al.* reported that 3,4-, 1,2-, and cyclic-units were produced resulting from the side reactions of *cis*-*trans* isomerization of 1,4-polyisoprenes by the u.v. irradiation in the absence of sensitizer¹⁰. The microstructure of the isomerized polymers was examined according to the method of Golub *et al.* using ^1H n.m.r. and i.r. spectroscopies. Under the present experimental conditions the isomerized polymers contained 3,4-, 1,2- and cyclic-units less than 3, 1, and 1%, respectively. This result indicates that thiobenzoic acid accelerated exclusively *cis*-*trans* isomerization. In the course of *cis*-*trans* isomerization process only a slight amount of side reactions was also confirmed by the analysis of hydrogenated polyisoprenes⁷. Only four signals corresponding to four types of carbon atoms linked by head-to-tail 1,4 structure were observed in the ^{13}C n.m.r. spectra of hydrogenated polyisoprenes prepared by the hydrogenation of isomerized polymers using *p*-toluenesulphonylhydrazide.

^{13}C n.m.r. spectra of polyisoprenes containing only *cis*-1,4- and *trans*-1,4-units were rather simple. The sequence distributions of these units were determined for chicle polyisoprene and *cis*-*trans* isomerized 1,4-polyisoprenes. It was found that *cis*-1,4- and *trans*-1,4-units were distributed randomly along the *cis*-*trans* isomerized polyisoprenes. A similar random distribution of *cis*-1,4- and *trans*-1,4-units was also observed for *cis*-*trans* isomerized polybutadienes³. The sequence distribution of 3,4- and 1,4-units were also determined by ^{13}C n.m.r. measurement of hydrogenated polyisoprenes as described in a previous paper⁷. On the other hand, polyisoprenes containing *cis*-1,4-, *trans*-1,4 and 3,4-units exhibited quite complicated ^{13}C n.m.r. signals due to various types of carbon atoms in different sequences. These complicated resonances can be analysed by referring to the results obtained

Figure 5 Isomerization of 1,4-polyisoprenes. \square Thiobenzoic acid; \circ , 1; \times , 3; \bullet , 8% w/w polymer

hitherto and the sequence distribution of *cis*-1, 4-, *trans*-1, 4 and 3, 4-units will be discussed in a subsequent paper.

ACKNOWLEDGEMENTS

The authors are very grateful to Mr Ichiro Nagoya of Asahi Chemical Industry Co. and Mr Kiyoshi Aoki of Nippon Electric Varian Co. for the measurement of ^{13}C n.m.r. spectra.

Diimide reduction of *cis*-1,4-polyisoprene with *p*-toluenesulphonylhydrazide

Tran Dai Nang*, Yasuo Katabe and Yuji Minoura

Department of Chemistry, Research Institute for Atomic Energy, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka, Japan

(Received 29 August 1975)

The hydrogenation of *cis*-1,4-polyisoprene with diimide generated *in situ* from *p*-toluenesulphonylhydrazide (TSH), was investigated under various conditions. In aromatic solvents at 100–140°C, the rate of hydrogenation was increased with increase in concentration of polyisoprene and of TSH. Part of the polymer was depolymerized and cyclized during the reaction. Increasing the hydrogenation tended to decrease the rate of sulphur vulcanization, of the compounded rubber and the physical properties of vulcanizates were poor. The reaction of polyisoprene rubber with TSH, was also carried out in a solid state at 140°C for 20–60 min. It was found that by using a large amount of TSH hydrogenation and cyclization of rubber occurred. The quantity of TSH used as a blowing agent, for rubber in the manufacture of sponge rubber, i.e. 5–10 phr, did not cause hydrogenation.

INTRODUCTION

The hydrogenation of unsaturated polymers, especially polydienes, has been studied for many years, in order to derive polymers exhibiting substantially altered physical properties and generally improved resistance to oxidative and thermal degradation.

Previously, hydrogenation techniques usually required the use of highly reactive chemicals or heterogeneous catalysts, which generally resulted in appreciable degradation to the polymer chain.

Recently, the transitory species diimide, $N_2H_2^{1,2}$, has been extensively studied as a general hydrogenation reagent for low molecular weight olefins^{3,4}. The use of diimide with polymeric substrates was first reported by Okawara and coworkers⁵, who employed it to remove residual unsaturation from polyvinylchloride.

Lenz *et al.*^{6,7} and Harwood *et al.*⁸ have investigated the hydrogenation of polydienes (i.e. *cis*- and *trans*-1,4-polybutadiene, *cis*-1,4-polyisoprene, random and block SBR, poly(2,3-dimethylbutadiene), polycyclohexadiene, etc.) with diimide generated *in situ* from *p*-toluenesulphonylhydrazide.

In the present work, the reduction of *cis*-1,4-polyisoprene with diimide, has been studied in order to clarify the effect of reaction conditions on the hydrogenation and of polymer composition on the physical properties of the product.

EXPERIMENT

Commercial *cis*-1,4-polyisoprene (Natsyn 2200) as provided by the Goodyear Tyre and Rubber Company, and of composition 96.9% *cis* and 3.1% 3,4-bond content, was purified by dissolving it in benzene, followed by filtration and precipitation in methanol. The precipitated polymer was washed with alcohol and dried at room temperature *in vacuo*. Commercial *p*-toluenesulphonylhydrazide (TSH) was purified by recrystallization from ethanol and dried *in vacuo*. (TSH has decomposition point 107°C). Solvents used were purified by distillation.

* Present address: Chemical Engineering School, National Technical Institute, Saigon, South Vietnam.

Reduction

Polymer samples (10 g) and 500 ml of solvent (xylene, dichlorobenzene, pyridine etc.) were heated under nitrogen with stirring until the polymer dissolved. The solution was kept at a suitable temperature (100°–135°C) and the *p*-toluenesulphonylhydrazide (TSH) was added. Aliquots of 30 ml were removed from the reaction mixture at suitable times and the polymers were isolated by precipitation from methanol. After washing with methanol, water and more methanol, the hydrogenated polymers were purified by reprecipitation from benzene solution by methanol and dried at room temperature *in vacuo* to constant weight.

Physical measurements and analysis

Polymer characterizations were carried out by elemental analysis, infra-red spectroscopy, the determination of the unsaturation of rubber by Wij's method⁹ and n.m.r. spectroscopy.

Infra-red analyses were carried out using a Jasco IR type spectrometer of Japan Spectroscopic Co. Ltd. Films suitable for infra-red measurements were prepared on a NaCl plate by casting from the benzene solution. N.m.r. measurements were carried out using Hitachi–Perkin Elmer Corp. R-2018 instrument at 60 MHz.

The intrinsic viscosities of polyisoprene and the reaction products, were measured by means of Ubbelohde viscometer in toluene at 30°C. The molecular weights of polyisoprene were calculated using the equation, $[\eta] = 5 \times 10^{-4} M^{0.67}$.

Physical properties of vulcanizates

The hydrogenated rubbers that had been kept in methanol, plus 0.2% phenyl β -naphthylamine, were washed with methanol then dried *in vacuo*. The original rubber, was dissolved in xylene, precipitated in methanol, and treated as above.

All the rubbers were compounded with curing agents, according to the following method; rubber (10 g), zinc stearate (0.2 g), zinc oxide (0.6 g), zinc dimethyl dithiocarbamate (0.06 g) and sulphur (0.2 g). The rubber and ingredients were compounded on a Micro 'RAPRA–Shawbury' mill at a temperature of 40°C for about 15 min.

Figure 1 Effect of TSH on hydrogenation of polyisoprene (Natsyn) at 100°C. Concentration of polyisoprene: 0.29 mol/l, i.e. polyisoprene (10 g)/xylene (400 ml) + pyridine (100 ml). Concentration of TSH (mol/l); A, 0.88, B, 0.59; C, 0.29

Using the 'Wallace Shawbury MK V', curometer a cure chart of each compound was recorded at 130°C. The vulcanization of each sample was carried out at 130°C and for T_{90} min.

The physical properties of vulcanizates i.e. tensile strength, modulus, elongation and hardness, were measured according to the JIS K 6301 method. The heat ageing test was carried out simultaneously for each sample at 70°C for 24 h.

RESULTS AND DISCUSSION

Determination of suitable conditions

The diimide reductions of polyisoprene were carried out in various solvents. In *o*-dichlorobenzene, the reaction system turned brown after about 3 h and black after 5 h at 135°C, whilst, in xylene, the reaction mixture turned brown and then black at 135°C after about 5 h, owing to decomposition of the polymer. *p*-Toluenesulphonic acid produced from TSH, was partly converted to *p*-toluenesulphonic acid which caused the cyclization of polyisoprene and the acceleration of the thermal decomposition of the polymer. The effect of the *p*-toluenesulphonic acid was prevented by use of a basic solvent, i.e. pyridine. The diimide reduction carried out at 125°C in the mixed solvent, (i.e. xylene/pyridine = 4:1), gave a dark brown product after 8 h but at a lower temperature, (100°C), the decomposition was avoided and a clear product was produced.

Effect of concentration of TSH

At constant concentration of polyisoprene (10 g/500 ml), the rate of hydrogenation increased at a rate directly proportional to concentration of TSH (Figure 1).

Table 1 Effect of concentration of *p*-toluenesulphonylhydrazide on degree of hydrogenation. Natsyn (10 g); solvent [xylene (400 ml), pyridine (100 ml)] at 100°C for 8 h

Natsyn/TSH (mol ratio)	C (%)	H (%)	$[\eta]$	$M_w \times 10^{-3}$	Hydrogenation (%)
1:0	87.72 (88.23)	12.35 11.77 calc. for C_5H_8	2.38	308	0
1:1	85.91	12.82	1.14	103	11.7
1:2	85.90	13.64	1.19	110	20.2
1:3	86.01	14.04	1.18	109	26.5

The partly hydrogenated *cis*-polyisoprene and natural rubber were soluble in aromatic and chlorinated hydrocarbon solvents at room temperature and were analysed for residual unsaturation by i.r. and n.m.r. spectroscopy.

The n.m.r. spectrum of the original polyisoprene compared with that of the partly hydrogenated sample, show that the resonance of $-C=CH-$ units (5.1 ppm) is decreased and the resonance at 1.3–1.2 and 0.9–0.8 ppm due to hydrogenated isoprene units appeared in the spectrum.

The results of elemental analysis of products (Table 1), show H% clearly increased and C% decreased compared with the original polyisoprene. The results were not satisfactory for the calculation of degree of hydrogenation, and this was determined by Wij's method.

Intrinsic viscosity measurements (Table 1) show that polyisoprene degrades under the reaction conditions required to generate diimide. The i.r. spectrum of the hydrogenated *cis*-polyisoprene (Figure 2) showed a decrease in percentage absorption of the C=C peaks at 570, 835 and 1665 cm^{-1} proving that the hydrogenation had occurred. The slight shifts of the CH_3 deformation vibration at 1450 cm^{-1} of the hydrogenated polymer, also showed the occurrence of cyclization¹⁰.

Effect of concentration of polyisoprene

The diimide reductions of polyisoprene, carried out at 100°C for varying concentrations of rubber and at constant concentration of TSH, are shown in Figure 3. The degrees of hydrogenation and the rate of hydrogenation increased with increase in the concentration of rubber, and in each case reached a saturation value at almost the same reaction time. Therefore, the rate of hydrogenation of polyisoprene by diimide obeys the equation:

$$\text{rate of hydrogenation} = K [\text{polymer}] [\text{TSH}]$$

where K is the rate constant.

Figure 2 Infra-red spectrum of *cis*-1,4-polyisoprene (A) and hydrogenated *cis*-1,4-polyisoprene (26.5%) (B)

Effect of solvents

General reaction conditions of constant polyisoprene concentration (0.441 mol/l), TSH concentration (0.882 mol/l) and reaction temperature (100°C–102°C), were applied to four reactions using different solvent mixtures of 100:0, 80:20, 40:60 and 0:100 v/v of *m*-xylene and pyridine.

Iodine titrations on the samples taken at determined reaction times, were used to measure the degree of hydrogenation. The results (Figure 4) show that the rate of hydrogenation was decreased with increasing amounts of pyridine in the reaction solvent.

The infra-red spectra of reaction products showed that the hydrogenation occurred with all the samples and that the degree of hydrogenation decreased continuously from *m*-xylene to pyridine.

The shifts of the peak at 1450 cm⁻¹ were observed in *m*-xylene, and in *m*-xylene and pyridine mixtures, but not in pure pyridine, showing that the cyclization could be avoided in the pyridine solution. These results were summarized in Table 2.

Physical properties of hydrogenated rubber

All the hydrogenated rubbers obtained as described above, were compounded to observe their vulcanizing characteristics and to measure the physical properties of vulcanizates. *T*₉₀ was chosen as the cure time for each compound. After curing, the physical properties (Table 3) were measured on dumb bell specimens of the vulcanizates.

In general, the physical properties of vulcanizates from the hydrogenated rubbers were poor, owing to the depolymerization during the hydrogenation reaction. It was found that increase of the hydrogenation tended to decrease the rate of vulcanization.

Table 2 Effect of *m*-xylene/pyridine mixture on hydrogenation reaction at 100°C. Natsyn 15 g (0.441 mol/l); TSH 82.2 g (0.882 mol/l), mole ratio = ½; solvent 500 ml

Solid reaction of TSH with polyisoprene

p-Toluenesulphonylhydrazide (TSH) is usually used as a blowing agent in the rubber sponge industry. The reaction of TSH with rubber was carried out in a solid state by mixing various amounts of TSH and rubber, on rolls heated to 140°C for 20 and 60 min. After heating, the rubber was dissolved in benzene and the unreacted TSH was removed by filtration. The filtrate was concentrated, poured in methanol, and the rubber was recovered as a precipitate. The degree of hydrogenation was measured by n.m.r., and the results are shown in Table 4.

The results of n.m.r. and i.r., show that, the use of large amounts of TSH led to the hydrogenation and cyclization of rubber. The amount of TSH used for rubber in the actual

sponge manufacture is generally up to 5–10 phr, and under these conditions the hydrogenation of rubber would be negligible.

ACKNOWLEDGEMENTS

The authors thank Dr K. Yamaguchi and Mr H. Ishikawa of the Industrial Research Institute of Hyogo Prefecture for their collaboration in the measurements of n.m.r. and physical properties of vulcanizates.

Infra-red study of poly(1-pentene) and poly(4-methyl-1-pentene)*

S. M. Gabbay and S. S. Stivala

Department of Chemistry and Chemical Engineering, Stevens Institute of Technology, Hoboken, New Jersey 07030, USA

(Received 14 April 1975; revised 13 October 1975)

The infra-red (i.r.) spectra of the two polymorphous forms (modification 1 and 2) of isotactic poly(1-pentene) are reported. Several absorption bands characteristic of the two modifications have been detected and attributed to the helical conformation of the polymer chains. The differences between the two modifications are reproducible, thus enabling their identification from i.r. spectroscopy. The infra-red spectra of isotactic poly(4-methyl-1-pentene) is also reported, and compared with that of the atactic polymer. General assignment of absorption bands is presented.

INTRODUCTION

The i.r. spectra of several hydrocarbons and polymers have been studied extensively. Much of this work has been concerned with establishing and determining the origin of characteristic group frequencies. These data have been summarized and critically reviewed by several investigators¹⁻⁵.

In previous publications on the i.r. spectra of polyolefins, e.g. polyethylene⁶⁻⁷, isotactic polypropylene (IPP)⁸⁻¹², syndiotactic polypropylene^{13,14}, and isotactic poly(1-butene) (IPB)¹⁵⁻¹⁹, assignments for the principal vibrations were reported. The correlations of the i.r. spectra with crystallinity and stereoregularity of IPB, were studied by Nishioka and Yanagisawa²⁰. Their studies showed that certain absorption bands are related to the crystallinity, while others were not assigned because of the complexity of the molecule. In the case of isotactic and atactic polypropylene, Luongo²¹ obtained an analytical curve for determining atactic or isotactic content in a polypropylene sample from i.r.

The present investigation considers a general assignment of the i.r. absorption bands of isotactic poly(1-pentene) (IPP-1), isotactic poly(4-methyl-1-pentene) (IPMP), and atactic poly(4-methyl-1-pentene) (APMP), including the correlation of certain bands to crystallinity and tacticity, which depend upon the thermal history and stereoregularity of the samples.

EXPERIMENTAL

The samples selected for this study were: (a) a highly isotactic poly(1-pentene) obtained from Montedison Company, Italy through the courtesy of Dr G. Gianotti; (b) a highly isotactic poly(4-methyl-1-pentene) obtained from Imperial Chemical Industries Ltd, England; (c) atactic poly(4-methyl-1-pentene), extracted from a commercial sample from Poly-science, and (d) mixtures of 100/0, 75/25, 50/50, 25/75, 0/100, by wt of IPMP/APMP, prepared by dissolution in cyclohexane at 60°C with subsequent recovery by freeze-drying.

Films of modification 1 of IPP-1 were obtained by refluxing films of modification 2 in absolute ethanol overnight and subsequently dried in a vacuum oven at 50°C for 12 h²².

* From the thesis submitted by S. M. Gabbay in partial fulfillment of the requirements for the degree of Doctor of Philosophy, Stevens Institute of Technology, 1975.

Figure 1 (a) i.r. spectrum of IPP-1 modification 1; (b) i.r. spectrum of IPP-1 modification 2

The identity of these samples (modification 1 and 2), was established by reference to their crystalline melting temperature¹⁵. Uniform and clear films of the above samples of approximately 2–2.5 mils thickness were prepared following the procedure described in an earlier publication²².

All spectra were recorded on a Perkin Elmer Model 21 infra-red spectrophotometer equipped with NaCl prism.

RESULTS AND DISCUSSION

Poly(1-pentene)

Significant differences in the characteristic i.r. spectra were detected between 7.0 to 14.0 μm of the two polymorphous forms (modification 1 and 2), in Figure 1. Of particular note in Figure 1a, the bands at 7.73, 8.40, 9.65, 11.15 μm appear to be specific to modification 1. The modification 2 spectra shown in Figure 1b does not contain these bands, but does show others, e.g. 7.37 (shoulder), 7.42 (shoulder), 7.52, 7.80, 7.85, 8.02, 9.80, 10.07, 10.60, 11.32, and 13.55 μm (shoulder), which distinguishes it from modification 1. The appearance of these characteristic bands confirms the reproducibility of the method of preparation of modification 1, and it is possible to identify which modification of IPP-1 is present from the i.r. spectra of the sample. These spectral differences reflect variation in helical chain conformation between the two modifications and not their isotacticity nor any new chemical groups. In fact, Turner-Jones and Aizlewood²³ reported that both polymorphous forms have

distinct X-ray crystal structure and the chain conformations are 3, and 4, helix for modification 1 and 2, respectively.

Grant and Ward¹⁴, used a simplified approach in assigning absorption bands in isotactic and syndiotactic polypropylene. Their work was examined in this study, in light of the applicability of their simplified approach in assigning absorption bands for the case of poly(1-pentene) and to search for a trend among polyolefins existing in two modifications. The close agreement that they obtained between the ratios of the calculated and observed number of modes of vibrations in the i.r. spectra would seem to render their method acceptable. Briefly, the number of fundamental vibrations for a repeat unit of a polymer helix, is calculated from the selection rules ($3N - 4$) where N is the number of atoms in one complete turn of the helix. These selection rules, which yields the maximum number of calculated fundamental absorption bands, were derived from a simplified model of a single polymer molecule by Liang *et al.*²⁴.

In modification 1 and 2 of IPP-1 there are three and four monomer units respectively, in one complete turn of the

helix²³. Thus, by applying the same selection rules and comparing the ratios of the calculated and observed number of modes of vibrations in the i.r. spectra, a satisfactory agreement was obtained. Additionally, by examining the i.r. spectra of the two polymorphous forms of IPB reported by Calpitt and Hughes¹⁷ and by applying the same selection rules, we also found a satisfactory agreement. These results are presented in *Table 1*. It is reasonable to presume therefore that there is a certain trend among polyolefins assuming different helical chain conformations in two polymorphous forms. Finally, by following these selection rules together with band assignments from the literature of similar polymers it was possible to make a tentative assignment of most of the absorption bands of IPP-1, listed in *Table 2*. No practical assignment of bands was given to modification 2 since they closely correspond to the bands in modification 1.

Poly(4-methyl-1-pentene)

Natta *et al.*²⁵ indicated that, the 'isotactic' synthesis ensures that the side groups in a polymer are sterically all in

the same orientation, i.e. they are either all in a right-handed or all in a left-handed position with respect to the carbon atom in the chain. Because of this regularity of the side groups, an isotactic polymer can be obtained in crystalline

form in contrast to the so-called atactic polymer where the steric positions of the side groups are in an irregular sequence and thus is completely amorphous. Therefore, IPMP has been assumed to be fully crystalline whereas the APMP is considered to be fully amorphous. In fact, its amorphicity was established by X-ray diffraction. Significant differences in the characteristics of the i.r. spectra were noted between 10.0 to 14.50 μm of isotactic and atactic poly(4-methyl-1-pentene), in Figure 2. The wavelengths of the absorption bands with indications of their intensity and tentative assignment are listed in Table 3. As can be seen in Figure 2a, the absorption bands in the IPMP spectrum at 10.55 (shoulder), 11.85, and 12.35 μm, either are extremely weak or eliminated in the spectrum of APMP. The 10.70 μm band with a shoulder at 10.55 μm in IPMP becomes a broad band at 10.70 μm in APMP. The 11.55 μm strong band in IPMP is shifted to 11.60 μm in APMP with a shoulder at 11.30 μm. The sharp band at 12.00 μm, in APMP becomes a shoulder in IPMP and the band 13.95 μm, in APMP is completely absent in IPMP. This indicates that these bands are sensitive to tacticity, however, the 11.85 μm and 12.35 μm bands in IPMP were also found to be sensitive to crystallinity. This conclusion was based on the fact that, in the i.r. spectra of molten IPMP (recorded at 245°C under nitrogen) only these two bands disappeared completely (see Figure 3) and reappeared when the polymer was brought back to room temperature. Film samples containing 100, 75, 25, and 0% (w/w) APMP, were subjected to i.r. analysis. The 11.85 μm absorbance band gradually diminishes from the 0 to 100% atactic sample, while the 13.95 μm absorbance band gradually increases from 100 to 0% atactic sample. Since the 11.85 μm band has disappeared in the molten state (see Figure 3) of IPMP and significantly diminished in APMP at 25°C, it would thus appear that this band shows that isotactic content and crystallinity are closely related. An 11.85 μm band in the case of polypropylene was also correlated to crystallinity by Heinen²⁶.

Interpretation of broad line nuclear magnetic resonance in oriented poly(ethylene terephthalate)

A. Cunningham*, A. J. Manuel and I. M. Ward

Department of Physics, University of Leeds, Leeds LS2 9JT, UK

(Received 23 July 1975; revised 15 September 1975)

Broad line nuclear magnetic resonance measurements on oriented poly(ethylene terephthalate) sheets have been reconsidered, in the light of recent infra-red data on similar materials. It is shown that the n.m.r. anisotropy is consistent with a model for the molecular orientation, in which the fraction of the polymer in the *trans* conformation is highly oriented, whereas the *gauche* fraction is sensibly isotropic.

INTRODUCTION

In a recent publication¹, polarized infra-red spectroscopy was used to study the changes in molecular orientation and conformation which occur in drawing poly(ethylene terephthalate) (PET) sheets. Detailed information was obtained, concerning both the development of overall orientation and the changes in molecular conformation in the glycol residue; the *trans/gauche* conformations. It was found that drawing decreased the proportion of *gauche* conformations at the expense of *trans*, and moreover, that the remaining *gauche* conformations remained sensibly unoriented, as overall molecular orientation increased with drawing.

In a previous publication we have attempted to use broad line nuclear magnetic resonance (n.m.r.) measurements and optical anisotropy to characterize the molecular orientation in PET². This investigation remained incomplete, however, partly because of the intrinsic difficulties in using the n.m.r. method to deal with orthorhombic symmetry, and partly because the *trans/gauche* content of the sheets was not known. In the present paper, we will now examine these earlier n.m.r. results and show that they provide excellent support for the conclusions made on the basis of the infra-red data, regarding the development of molecular orientation in drawn PET films.

NUCLEAR MAGNETIC RESONANCE

In the study of anisotropic materials by nuclear magnetic resonance (n.m.r.), the second moment $\langle \Delta H^2 \rangle$ of the absorption line, is measured for different orientations of the applied magnetic field with respect to the symmetry axes of the specimen. In PET film², we take a set of orthogonal axes with the *z* axis in the draw direction, the *x* axis in the plane of the film and the *y* axis normal to the plane of the film. The direction of the magnetic field *H*, may then be specified by the polar angle γ , between the direction of *H* and the *z* axis, and the azimuthal angle ϕ_γ between the *x* axis and the plane containing *H* and the *z* axis (Figure 1). The value of $\langle \Delta H^2 \rangle$ for a given direction of *H*, depends on a combination of a set of numbers S_{lm} (the lattice sums), characteristic of the structural units, and an orientation

distribution function for the structural units. For an anisotropic structural unit, a set of orthogonal axes *uvw* may be defined and their orientation with respect to the specimen axes (*x, y, z*) may be related through the Euler angles (ϕ, θ, ψ), as shown in Figure 1. The orientation distribution of the structural units may then be represented by a function $\rho(\phi, \theta, \psi)$, where $\rho(\phi, \theta, \psi)d\phi d\theta d\psi$ represents the volume fraction of structural units with Euler angles in the range ϕ to $\phi + d\phi, \theta$ to $\theta + d\theta$ and ψ to $\psi + d\psi$. Knowledge of the lattice sums for the structural units and the orientation functions $\rho(\phi, \theta, \psi)$ permits the calculation of $\langle \Delta H^2 \rangle$ as a function of γ and ϕ_γ . To carry out the inverse procedure and obtain information about the orientation distribution of the structural units from the measured variation of $\langle \Delta H^2 \rangle$ with γ and ϕ_γ and the calculated lattice sums, it is necessary to expand $\rho(\phi, \theta, \psi)$ in a suitable set of orthogonal functions and solve the relevant equations for the coefficients of the expansion. This can only be done for certain symmetry conditions or simplifying assumptions. These are discussed in ref. 2, where for PET films of low draw ratio (2:1 and 2.5:1) and for drawn rods, the structural units are taken as small aggregates of crystalline and amorphous material, with the chain axes (crystalline *c* axis), in both the crystalline and amorphous regions, lying along the *w* axis of Figure 1, but with no preferred orientation.

Figure 1 The relationship of the axes (*u, v, w*) of a structural unit to the symmetry axes *x, y, z* of a specimen of drawn material through the Euler angles (ϕ, θ, ψ) and the definitions of the angles γ and ϕ_γ specifying the direction of the magnetic field *H* with respect to the specimen axes

* Present address: ICI Corporate Laboratory, Runcorn, Cheshire WA7 4QE

Figure 2 The vector r_{jk} and the angles θ_{jk} and ϕ_{jk} for the protons j and k of a structural unit for the calculation of the lattice sums

tation of the u and v axes about w . This means that for the low draw ratio films it is permissible to take the orientation distribution function $\rho(\phi, \theta, \psi)$ as independent of ψ , and it can be reduced to the form $\rho(\theta, \phi)$, where θ and ϕ are the polar and azimuthal angles specifying the w (crystalline) axis of the transversely isotropic aggregate, with respect to the specimen axis. This situation corresponds to case (ii) a ref. 2, for which the following equations are valid:

$$\rho(\theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=0}^l 2\pi \left(\frac{4\pi}{2l+1} \right)^{1/2} \rho_{lm0} Y_{lm}^e(\theta, \phi) \quad (1)$$

$$B_{lm} = 4G \frac{4\pi a_l}{2l+1} \frac{8\pi^2}{2l+1} S_{l0} \rho_{lm0} \quad (2)$$

$$\langle \Delta H^2 \rangle = \sum_{l=0, 2, 4} \sum_{m=0}^l B_{lm} Y_{lm}^e(\gamma, \phi_\gamma) \quad (3)$$

$G = 3/2 [I(I+1)g^2\mu_n^2]$ where I is the nuclear spin quantum number, g the nuclear g factor and μ_n the nuclear magneton and $a_0 = 1/5$, $a_2 = 2/7$ and $a_4 = 18/35$. These equations correspond to equations (18)–(20) of ref. 2 but are written here with the real form of spherical harmonics. The factor of 2π appearing in equation (1) should also be present in equation (18) of ref. 2. It arises, because in going from $\rho(\theta, \phi, \psi)$ to $\rho(\theta, \phi)$, there is an effective integration over ψ . For a similar reason the right hand side of equation (15) of ref. 2 should be multiplied by $4\pi^2$. The lattice sums S_{l0} are determined from the general form S_{lm} given by:

$$S_{lm} = \frac{1}{N} \sum_{j>k} r_{jk}^{-6} Y_{lm}^e(\theta_{jk}, \phi_{jk}) \quad (4)$$

corresponding to equation (8) of ref. 2.

$$S_{l0} = \frac{1}{N} \sum_{j>k} r_{jk}^{-6} \left[\frac{2l+1}{4\pi} \right]^{1/2} P_l(\cos \theta_{jk}) \quad (5)$$

r_{jk} is the internuclear vector between protons j and k of a structural unit and θ_{jk} the angle between r_{jk} and the w axis of the structural unit. This is illustrated in Figure 2. For the case of a drawn rod having transverse isotropy, the dependence of $\langle \Delta H^2 \rangle$ on ϕ_γ vanishes and equations (1)–(3) are simplified.

The six coefficients B_{lm} for $l = 0, 2, 4$, are determined from the experimental measurements of $\langle \Delta H^2 \rangle$ for various γ and ϕ_γ , through equation (3), by a least squares fitting procedure. Values for ρ_{lm} for $l = 0, 2, 4$ may then be obtained from equation (2), using calculated values for S_{l0} . The lattice sums are intrinsic properties of the structural units and were calculated, in ref. 2, for the *trans* conformation which exists in the crystalline regions of PET. They are reproduced in Table 1. The calculations are based on the crystal structure determination of Daubeny, Bunn and Brown³. The intramolecular contributions to the lattice sums which are shown separately in Table 1, can be seen to be of major importance, and for S_{20} and S_{40} , which determine the anisotropic n.m.r. behaviour, they are dominant. It can therefore be inferred that for molecules in an amorphous environment, the lattice sums will also be dominated by the intramolecular interactions. We must in this case, however, also consider the effect of the *gauche* conformations.

It is now generally accepted that the *gauche* conformation arises from a rotation within the glycol group^{4,5}. Figure 3 shows a projection of the glycol group along the methylene C–C bond, in both the *trans* and in a hypothetical *gauche* conformation which is produced from the *trans* conformation by a rotation about the C1–C1' methylene bond; with the further assumption that the C1–O2 bond length remains constant (i.e. C1'–O2' bond length = C1–O2 bond length). The coordinates of this molecule are listed in Table 2, and the projections of the molecular positions on the xz plane are shown in Figure 4.

Although these coordinates are not expected to be very accurate numerically, it is reasonable to assume that the qualitative anisotropy of the resultant intramolecular *gauche* lattice sums, is correct. The values for these lattice sums are given in Table 1, together with the differences between the intramolecular contributions to S_{00} , S_{20} and S_{40} for the *trans* and *gauche* conformations. There is little difference between the values of S_{00} but S_{20} and S_{40} are of opposite sign for the two conformations. This difference is not dependent on the exact form of the *gauche* molecule as can be seen by comparing the contributions to S_{00} , S_{20} and S_{40} of the four protons in the glycol group in the *trans* and *gauche* conformations, which are also given in Table 1.

OPTICAL ANISOTROPY

The principal refractive indices n_q for an oriented sample can be related to the average molecular polarizabilities $\langle\alpha_{qq}\rangle$ by the Lorentz-Lorenz equation:

$$\frac{n_q^2 - 1}{n_q^2 + 2} = \frac{4\pi}{3} N \langle\alpha_{qq}\rangle \quad (6)$$

where, N is the number of polarizable units per unit volume. If, for a transversely isotropic structural unit, the principal polarizabilities are represented by α_{33} , along the axis of a symmetry and α_{tt} , in the transverse directions, then it has been shown² that for a transversely isotropic distribution of the structural units:

$$\begin{aligned} \langle\alpha_{11}\rangle &= \langle\sin^2\theta \cos^2\phi\rangle (\alpha_{33} - \alpha_{tt}) + \alpha_{tt} \\ \langle\alpha_{22}\rangle &= \langle\sin^2\theta \sin^2\phi\rangle (\alpha_{33} - \alpha_{tt}) + \alpha_{tt} \\ \langle\alpha_{33}\rangle &= \frac{2}{3} \langle P_2(\cos\theta)\rangle (\alpha_{33} - \alpha_{tt}) + \frac{1}{3} (\alpha_{33} + 2\alpha_{tt}) \end{aligned} \quad (7)$$

These equations correspond to equation (30) of ref. 2, reduced to the case of a transversely isotropic distribution of structural units. The α_{33} and α_{tt} are seen to depend only on the intrinsic molecular state and not on the overall orientation, and for the optical measurements have the same significance as the lattice sums in n.m.r.

The values of the principal polarizabilities, α_{11} , α_{22} and α_{33} for the *trans* and *gauche* configurations of molecules, are now calculated by the addition of bond polarizabilities as discussed in ref. 2. They yield the values shown in Table 3 from which $\alpha_{tt} = \frac{1}{2}(\alpha_{11} + \alpha_{22})$ can be calculated. The results in Table 3 show that the values of α_{33} and α_{tt} for the *trans* and *gauche* conformations, are essentially identical and hence the overall optical anisotropy cannot be sensitive to the *trans/gauche* ratio or to changes in that ratio.

It is therefore to be expected, that the optical anisotropy of PET should be primarily a function of the overall chain axis orientation. This conclusion was confirmed directly by the infra-red spectroscopic studies¹, where it was shown that there is an excellent correlation between the orientation function derived from birefringence and from absorption assigned to benzene ring mode vibrations. For these calculations of $\langle P_2(\cos\theta)\rangle^{\text{overall}}$, the procedure followed has been described in the previous publications^{1,2}. It is recognised that the calculated values for bond polarizabilities can be in error by a small amount ($\sim 2-3\%$). The value of α_{33} was therefore adjusted to a value of $2.3 \times 10^{-23} \text{ cm}^3$ to be consistent with values obtained from birefringence measurements on drawn samples of PET. No alteration was required in the values of α_{tt} , but an average value of $1.70 \times 10^{-23} \text{ cm}^3$ was assumed. These values of α_{33} and α_{tt} lead to the value of 0.105 for $\Delta\alpha/3\alpha_0$ used in ref. 1.

In contrast to the optical situation, the n.m.r. lattice sums S_{20} and S_{40} , are extremely sensitive to the conformation of the molecule, being of opposite signs for the *trans* and *gauche* cases and their contributions to the second mo-

ment anisotropy act in opposition to each other. Because of this, although the wide line n.m.r. technique cannot on its own determine the *trans/gauche* ratio or the orientation distribution, the extreme sensitivity of S_{20} and S_{40} to the configuration can be used to examine the validity of the model for the structure of oriented PET films put forward in ref. 2.

If we consider a model comprising a fraction f of *trans* molecules with orientation characterized by coefficients ρ_{100}^t and $(1-f)$ of *gauche* molecules with orientation coefficients ρ_{100}^g , and we assume that the contributions to the overall second moment are additive we should find:

$$\rho_{100}(\text{experimental}) = f\rho_{100}^t + (1-f)\rho_{100}^g \quad (8)$$

for ρ_{200} this leads, using equation (2), to:

$$\frac{B_{20}}{a_2} = 4G \left(\frac{4\pi}{5}\right) \left(\frac{8\pi^2}{5}\right) [fS_{20}^t\rho_{200}^t + (1-f)S_{20}^g\rho_{200}^g] \quad (9)$$

where S_{20}^t and S_{20}^g are the relevant lattice sums for the *trans* and *gauche* materials.

A value of B_{20} for the proposed model² specifying f , ρ_{200}^t and ρ_{200}^g can thus be calculated and compared with the value obtained from n.m.r. measurements through equation (1).

The detailed analysis of the infra-red spectra described in ref. 1, resulted in considerable information on the molecular state of oriented PET. It was shown that to a good approximation, the *gauche* molecular distribution could be taken as isotropic over the range of molecular orientations and drawing conditions investigated.

This result will now be used to predict the overall n.m.r. response (as reflected through B_{20}) for such oriented polymers.

For isotropic *gauche* material we have $\rho_{200}^g = 0$. Equation (8) now becomes:

$$\frac{B_{20}}{a_2} (\text{proposed}) = 4G \left(\frac{4\pi}{5}\right) \left(\frac{8\pi^2}{5}\right) fS_{20}^t\rho_{200}^t \quad (10)$$

Let the average value of the coefficient of $P_2(\cos\theta)$ for the molecular orientation function of the *trans* material be $\langle P_2(\cos\theta) \rangle^t$. Then $\langle P_2(\cos\theta) \rangle^{\text{overall}} = f\langle P_2(\cos\theta) \rangle^t$

$$= f\rho_{200}^t \left(\frac{8\pi^2}{5}\right)$$

Substitution into equation (9) gives:

$$\frac{B_{20}}{a_2} (\text{proposed}) = 4G \left(\frac{4\pi}{5}\right) S_{20}^t \langle P_2(\cos\theta) \rangle^{\text{overall}} \quad (11)$$

This equation is valid for films with orthorhombic specimen symmetry, as well as for cylindrically symmetrical rod specimens. It is to be noted that equation (11) is independent of f . If therefore the model is correct, the value of B_{20} determined experimentally from n.m.r. measurements, should be a linear function of the $\langle P_2(\cos\theta) \rangle^{\text{overall}}$ values obtained from refractive index measurements.

For the other extreme situation of isotropic *trans* and oriented *gauche* material, equation (11) would require the use of S_{20}^g instead of S_{20}^t . Remembering that these values are nearly equal in magnitude and opposite in sign this equation becomes a very sensitive test of the proposed model, particularly as the infra-red investigation showed that on average at least 50% of the monomers were in their *gauche* conformation.

RESULTS AND DISCUSSION

The experimental work on the three drawn films of orthorhombic symmetry (draw ratios 2:1, 2.5:1 and 5:1) and the cylindrically symmetrical rod (draw ratio 3.25:1) is described in detail in ref. 2. The results are summarized in Table 4 together with values of $\langle P_2(\cos\theta) \rangle^{\text{overall}}$ and the equivalent isotropic refractive indices \bar{n} calculated from the experimental values of n_1 , n_2 and n_3 . The values of \bar{n} lie close to the experimentally determined refractive index of 1.583 for an isotropic sample of density $\rho = 1.338$. This reflects the insensitivity of the average principal polarizabilities of the monomer units in the transversely isotropic

Figure 5 B_{20}/a_2 plotted against $\langle P_2(\cos \theta) \rangle_{\text{overall}}$ from Table 4 together with the theoretical boundaries (A) for wholly *gauche* oriented material. (B) for wholly *trans* oriented material. Draw ratios (a) 2:1; (b) 2.5:1; (c) 5:1 for two way drawn film; (d) 3.25:1 uniaxial drawn rod

structural unit to the conformation, as shown in Table 3. A similar situation, is shown by the experimental value of B_{00}/a_0 of Table 4 which reflects the insensitivity of S_{00} to the conformation (Table 1).

However B_{20}/a_0 in Table 4 shows a behaviour which correlates with $P_2(\cos \theta)_{\text{overall}}$. Figure 5 shows these two quantities plotted against each other, together with the boundaries between which they should lie for the two extreme cases in which the oriented material is wholly *trans* or wholly *gauche*.

The experimental results for the 2:1, 2.5:1 draw ratio film and 3.25:1 draw ratio rod do, in fact, lie close to the line predicted on the assumption of isotropic distribution of *gauche* conformer material, the oriented parts of the specimens being those with the *trans* conformation.

The point in Figure 5 for the 5:1 draw ratio film, shows less good agreement with the points for the other material. This is not surprising since as was shown in ref. 3, there is a distinct preferred orientation distribution of the molecules with respect to the plane of the film. The position of the point in Figure 5 for this specimen does suggest, however, that here also the *gauche* material is sensibly isotropic in molecular orientation distribution.

Ziegler–Natta catalysis: 7. The settling period

D. R. Burfield,* I. D. McKenzie† and P. J. T. Tait

Department of Chemistry, University of Manchester Institute of Science and Technology, Manchester M60 1QD, UK

(Received 24 July 1975; revised 17 October 1975)

Factors affecting the duration of the settling period in the polymerization of 4-methylpentene-1 by the catalyst system $\text{VCl}_3/\text{AlR}_3$ in benzene have been systematically investigated. Plots of $\log_{10}(100 - \%R_p)$ versus time show that the so-called settling period can be divided into two distinct regions; an initial region which is not time dependent and a steady state region in which the formation of C_0 follows a strictly first order time dependence. The initial region is believed to arise from the removal of adsorbed AlR_2Cl species, while the steady state region can be interpreted as describing a rearrangement reaction involving the production of initiated chains.

INTRODUCTION

One of the puzzling features of many Ziegler–Natta polymerization systems, when using catalysts derived from solid transition metal halides and aluminium alkyls, is the initial period during which the rate of polymerization gradually increases to reach either a maximum or a steady state value. This so-called ‘settling period’ has been observed in a large number of systems^{1–5} and is a characteristic feature of these polymerization systems⁶. Typical kinetic curves for these systems are shown in *Figure 1* and can be seen to be divided into either three [as in (a)] or two [as in (b)] parts. Curve (a) shows a settling period I, during which the rate of polymerization increases rapidly to a maximum followed by a decay period, II, when the rate decreases gradually to reach that of the steady state, III. In the case of Curve (b) there is a gradual increase in the rate of polymerization during the settling period, I until the steady state, III is reached directly.

The duration of the settling period appears to be influenced by the majority of the variable parameters in these complex polymerization systems, e.g. monomer and alkyl concentrations, and its cause has been variously interpreted as arising from a number of factors. These factors include the breakdown of catalyst crystals to expose additional active centres², slow initiation by monomer^{4,7}, and the presence of impurities⁸. It is now generally believed, however, that its origin may be more complex.

The present study is concerned with an investigation of the settling period, as observed in the polymerization of 4-methylpentene-1 by the catalyst system $\text{VCl}_3/\text{AlR}_3$ in benzene, and forms part of a detailed study⁷ of the kinetics of Ziegler–Natta polymerization systems, by this highly pure and stable catalyst system.

EXPERIMENTAL

Materials

Details of catalysts have already been published⁷.

† Present address: Imperial Chemical Industries Ltd., Plastics Division Welwyn Garden City, Herts, UK

Procedure

All polymerization runs were carried out under high vacuum in specially constructed dilatometers. However, two distinct procedures were employed for the preparation of the catalyst systems.

Method A. The vanadium trichloride addition was followed by the desired amounts of benzene and then alumin-

Figure 1 Plots of rate versus time (a) showing decay characteristics; (b) showing steady state characteristics

Figure 2 Plot of $R_p/[VCl_3]$ versus time. $[VCl_3] = 18.5$ mmol/l; $[Al(iBu)_3] = 37.0$ mmol/l; $[4-MP-1] = 2.0$ mol/l; solvent = benzene; temperature = $30^\circ C$

ium alkyl in benzene by means of graduated syringes. The dilatometer filler or reaction vessel was then quickly stoppered, removed from the dry box, and attached to the high vacuum system. The contents were degassed twice, and the catalyst 'aged' for 10 and 15 min respectively at $30^\circ C$, before the required amount of degassed monomer was distilled in from a graduated tube.

Method B. In this method the vanadium trichloride addition was followed by addition of the required quantities of monomer, benzene and aluminium alkyl in benzene in that order. The reaction mixture was then degassed on the vacuum line as in Method A, but without ageing.

RESULTS

All polymerization runs were characterized by an initial settling period during which the overall rate of polymerization increased. This period was followed by a much longer period of decreasing rate owing to depletion in monomer concentration. It can be shown^{5,7}, that if correction is made for the decrease in the monomer concentration, the rate of polymerization has now reached a steady value during this latter period. A typical plot of steady rate versus time is shown in Figure 2, and this rate plot is analogous to Curve (b) in Figure 1. The duration of the settling period can be determined, either by extrapolation of the steady state portion of the percentage conversion versus time plot to zero conversion and measuring the intercept on the time axis, or by extrapolation of the linear portion of the $\log(100 - \% \text{ conversion})$ versus time plot to zero conversion (Figure 3). This latter procedure is considered to be the more satisfactory, and was usually adopted in this work.

The effect of ageing of catalyst on catalyst activity and duration of settling period

The effect of ageing the catalyst is shown in Table 1. It is apparent that the steady state rate of polymerization is not greatly affected by the ageing process. However, the observed settling period is increased when the catalyst is aged. In addition it was found that the rates of polymerization were less reproducible when aged catalysts were used; in general the measured rates showed a spread of $\pm 7\%$ for Method A, but only a spread of $\pm 4\%$ for Method B. Furthermore, the duration of the settling period was very much more reproducible when Method B was used. It was found that polymerization runs carried out under identical conditions using Method A, could have settling periods that differed by twenty or more minutes.

The observation that the settling period is shorter when the catalyst is unaged suggests that in the absence of monomer, VCl_3 reacts with $Al(iBu)_3$ to form a strong complex which has to be broken up subsequently when monomer is added. It also indicates that the settling period is not due to a slow alkylation process, and is consistent with other evidence⁹ that the alkylation reaction is rapid.

Effect of concentration of components of polymerization system on duration of settling period

The effect of the monomer concentration on the duration of the settling period was investigated at 30° and $40^\circ C$, and the results are shown in Table 2. A marked decrease in the duration of the settling period with increase in monomer concentration, is observed at both temperatures.

Variation in the concentration of vanadium trichloride had a complex effect on the duration of the settling period. Provided that the ratio of $[\text{Al}] : [\text{V}]$ remained constant, an increase in the concentration of vanadium trichloride caused a decrease in the length of the settling period, as is evident from *Table 3*. However, if the concentration of aluminium alkyl remained constant, i.e. when using constant $[\text{M}] : [\text{Al}]$ ratios, the initial region of increasing rate is unaffected by change in the vanadium trichloride concentration (*Table 4*).

Table 5 shows that, the concentration of the aluminium alkyl compound has little or no effect on the duration of the settling period, except at low $[\text{Al}] : [\text{V}]$ ratios where the settling period tends to be longer, especially at 30°C .

Effect of different aluminium alkyl compounds on the duration of the settling period

The durations of the settling period observed for a number of different aluminium alkyl compounds are listed in *Table 6*. It can be seen that the ability of these alkyls to reduce the settling period is in the following order:

This order is similar to that already established for overall rates of polymerization⁷, except that $\text{Al}(\text{iBu})_3$ is much lower in the above series. If the alkylation of the surface is a rapid reaction, the above order may correspond to the rate of initiation, i.e. the rate of addition of the first monomer unit to the metal-carbon bond in the newly formed transition metal alkyl. Initiation with the branched chain alkyl, $\text{Al}(\text{iBu})_3$, may be slower than that with its unbranched isomer, $\text{Al}(\text{nBu})_3$, because of steric effects.

Effect of ball-milling on the duration of the settling period

The polymerizations listed in *Table 7*, were carried out using a sample of vanadium trichloride which had been ball-milled, and whose surface area, as determined by a BET method was $5.3 \text{ m}^2/\text{g}$ as compared to a value of $2.3 \text{ m}^2/\text{g}$ for the unground vanadium trichloride.

* Ball-milled sample

Comparison with the values listed in Table 3 shows, that the duration of the settling period, when a ball-milled sample of vanadium trichloride is used, is considerably reduced. These results are broadly in agreement with the findings of Natta¹.

Effect of polymerization media and temperature on the duration of the settling period

In Table 8, the effect of temperature on the duration of the settling period is shown for polymerizations carried out in benzene and in n-heptane.

The polymerizations in n-heptane were carried out using a ball-milled sample of vanadium trichloride. If the results of these polymerizations at 30°C are compared with those obtained using the ball-milled catalyst in benzene at 30°C (Table 7), it is evident that the settling period is considerably longer when n-heptane is used as the polymerization media. These results may suggest that the duration of the settling period is affected by the presence of a good solvent for the polymer, or that these partially ionic reactions occur faster in the slightly more polar benzene.

DISCUSSION

Natta² has explained the settling period by assuming that large crystals and crystal aggregates, present in these solid transition metal halides, were cleaved during the settling period by the mechanical action of the growing polymer chains, and that this process exposed more lattice defects for the formation of further numbers of active centres. Factors which increased the polymerization rate, such as high monomer concentration and temperature, were considered to shorten the settling period by increasing the rate of disruption of metal halide crystals by the growing polymer chains.

The above model does not, however, explain all the dependencies of the settling period observed for the present system, when using the particular variety of highly pure vanadium trichloride employed as the transition metal halide compound. Thus the model does not explain the reduction in the duration of the settling period observed as the catalyst concentration is increased, for although the rate is increased, the rate per unit catalyst concentration remains constant over a fairly wide range⁷. Further, the model does not explain, the variation in the settling period observed with different metal alkyls as in this work, nor the

dependence of the rate of polymerization on the initial surface area of the metal halide observed by several authors¹⁰⁻¹³

It is possible, however, to obtain additional information concerning the nature of the initial settling period by means of a detailed examination of the change in polymerization rate with time. Thus Keii¹⁴ has shown that Natta's data² on the acceleration period, are consistent with a first order rate law for the change in polymerization rate with time. A similar first order relationship is found in this work.

If it is supposed that the formation of active centres follows the general scheme:

where C_i is the number of potentially active centres on the VCl₃ surfaces, either formed by the fast interaction of catalyst components and monomer (equation 1), or already formed before monomer is added. Equations (2) and (3) thus describe slow processes which give rise to actual active centres, either in the absence (equation 2), or in the presence (equation 3) of monomer.

Now if C_0 is the total number of centres which can become active (at this stage the overall rate of polymerization will reach a maximum value and will be time independent), and if $C_{0(t)}$ is the number of active centres which have been converted from potential to actual active centres at time t , then under these circumstances the rate of formation of C_0 will be given by:

$$\frac{dC_{0(t)}}{dt} = k_i C_i \quad (4a)$$

or

$$\frac{dC_{0(t)}}{dt} = k_i \theta_M C_i \quad (4b)$$

where θ_M is the fraction of surface covered by adsorbed monomer^{7,15,16}.

In either case, if the monomer concentration is constant, the relationship will be:

$$\frac{dC_{0(t)}}{dt} = k'_i C_i \quad (5)$$

where $k'_i = k_i$ or $k_i \theta_M$ depending on the validity of the above expressions. Since $C_i = C_0 - C_{0(t)}$, integration of equation (5) gives rise to the result:

$$\ln \left(\frac{C_0}{C_0 - C_{0(t)}} \right) = k'_i t \quad (6)$$

Since it has already been established that during the steady state period the overall rate of polymerization, R_p , is given by the equation^{7,15,16}:

$$R_p = k_p \theta_M C_0 \quad (7)$$

Figure 4 Plot of $\log_{10}(100 - \%R_p)$ versus time. \circ , Al(nDec)₃; \bullet , Al(iBu)₃. Experimental conditions as for Figure 2

then the overall rate of polymerization at time t , $R_{p(t)}$, corrected for decrease in monomer concentration, will be directly proportional to the number of propagating active centres at time t , $C_{0(t)}$. Thus the variation of propagating active centres with time can be followed by an examination of the polymerization rate, since at constant $k_p\theta_M$, equation (6) becomes:

$$\ln \left(\frac{R_p}{R_p - R_{p(t)}} \right) = k'_i t \quad (8)$$

which rearranges to give:

$$-\ln \left(1 - \frac{R_{p(t)}}{R_p} \right) = k'_i t \quad (9)$$

Now if this expression holds for the acceleration period, a plot of $\ln(1 - R_{p(t)}/R_p)$ versus t should be linear. In practice plots of $\log_{10}(100 - \%R_p)$, where $\%R_p = 100R_{p(t)}/R_p$, were more often made. Typical plots for the alkyls Al(iBu)₃ and Al(nDec)₃ are shown in Figure 4.

It is apparent that when the results are plotted in this way that the acceleration period can be seen to be characterized by two regions:

- (i) an initial region where the rate of formation of C_0 is increasing, followed by
- (ii) a steady region, where the formation of C_0 follows a strictly first order dependence.

That the initial region is not due to extraneous impurities, is shown by the observation that it is dependent on the nature of the aluminium alkyl. Also, since the initial region is shortest for Al(nDec)₃, the least reactive alkyl, it cannot be associated with slow alkylation. It could, however, conceivably involve the removal of some adsorbed AlR_2Cl species, the concentration of which, would be expected to be higher for the more reactive alkyls. The exceptionally long initial region in the case of Al(iBu)₃, may then reflect difficulty in the removal of Al(iBu)₂Cl because of the limited dimerisation of this sterically hindered alkyl¹⁷.

The variation of the slope of the first order plot (k'_i) with variation in polymerization component concentrations and conditions will now be discussed.

Variation of k'_i with monomer concentration

The effect of the initial monomer concentration on k'_i is shown in Table 9. It can be seen that k'_i is virtually inde-

pendent of the monomer concentration over a twelvefold range. This strongly suggests that the monomer is not involved in the slow step of active site formation; i.e. this reaction may be formulated:

This is not to say that monomer is not involved in the formation of a precursor of the active sites, e.g. in the formation of C_i . Earlier work has shown, that the concentration¹⁶ and order of addition¹⁷ of monomer does significantly affect the final C_0 value, presumably by affecting the concentration of C_i .

Interestingly, the value of the initial region is affected by the monomer concentration, being much longer at low monomer concentrations, presumably due to the slower formation of C_i . Thus the longer initial region, rather than a lower k'_i value is the reason for the observed variation of the settling period with monomer concentration.

Variation of k'_i with the nature of the aluminium alkyl

The effect of the alkyl group on k'_i is shown in Table 10. The rate of formation of C_0 is seen to be very dependent on the nature of the alkyl group. This is irreconcilable with the view that the acceleration region is due to breakdown of the catalyst particles to a limiting size. It suggests that the intermediate (C_i) is a species such as VCl_2RM whose rate of rearrangement to form C_0 is dependent on the nature of R .

Variation of k'_i with catalyst component concentration

Inspection of Tables 11 and 12 shows that k'_i is independent of the concentration of VCl_3 and Al(iBu)₃ over a five-fold range. This again fits the picture of a fairly rapid formation of a reactive intermediate, whose decomposition is not affected by the concentration of the polymerization components.

Effect of donor addition

Addition of triethylamine does not affect the value of k'_i but does considerably shorten the initial region. This is

Table 9 Effect of monomer concentration on k'_i at 30°C

18.5	0.018
	0.020
8.61	0.022
5.44	0.021
3.54	0.023

consistent with earlier proposals¹⁷ that donors primarily activate the polymerization by removal of AlR₂Cl species rather than by interaction with the active centre.

Effect of temperature

The value of k'_i is increased by increase in temperature as would be expected (Table 13). The value of the activation energy for this process is found to be about 68.6 kJ/mol (16.4 kcal/mol) for Al(iBu)₃. It should be emphasized that this is only an approximate figure since appreciable catalyst deactivation occurs at 50°C which makes derivation of an accurate k'_i value impossible.

The present study does not unfortunately shed much information on the basic chemical steps which give rise to chain initiation. It does, nevertheless, clearly establish the complexity of these processes and shows that the so-called settling period is itself composed of at least two phases, the first of which has been ascribed to the removal by complexation of adsorbed chloroalkyl, and the second of which is believed to describe a rearrangement reaction producing an initiated chain.

The catalyst forming reactions have been formulated in a previous paper⁷ as:

These equations are in qualitative agreement with the experimental findings detailed in the results section of this paper. Increase in monomer concentration should lead to an increase in the rate of initiation according to equations (12) and (13). Equations (12) and (14) would explain the complex effect of increase in vanadium trichloride concentration. The relatively slight effect of increase in tri-isobutylaluminium concentration arises because reactions (11) and (14) tend to cancel each other out.

The fact that an 'initial region' can be observed in the induction period is believed to arise because the establishment of reaction (11) is so much slower than reaction (10). In this respect the results of the analyses presented in this paper are in agreement with the catalyst forming reactions proposed in previous papers. The major difficulty lies in

identifying the nature of C_i and C_0 . It might seem reasonable to suppose that C_i is some monomer containing complex (formulated VCl₂R · M in equation 12), which rearranges by means of a slow reaction to give an entity of the type VCl₂MR, i.e. the first monomer molecule is inserted into the metal–carbon bond.

The observed dependence of k'_i on the nature of R is in keeping with such a hypothesis. However, this raises the problem as why the first monomer unit should be more difficult to insert than subsequent monomer units. Therefore, it might seem more reasonable to believe that the slow rearrangement step occurs before complexation with monomer. However, this is at variance with the observation that C_0 (and hence R_p) decreases sharply at low monomer concentrations¹⁶. There is also the possibility that reaction (2) is connected with a slow production of vacant sites owing to some surface decomposition reaction, or that it arises from some structural rearrangement on the catalyst surface. The present study does not allow an unequivocal decision to be reached on this matter.

It can nevertheless be concluded that the apparent dependence of the settling period on the monomer concentration, arises because of the slow formation of C_i , a reaction involving the monomer, together with a dependence of the 'initial region' on the monomer concentration, in spite of the fact that k'_i is independent of the monomer concentration.

One of the largest areas of uncertainty in the literature is doubtless the effect of ball-milling on the settling period. Keii⁶ has demonstrated quite thoroughly that the steady state rate is dependent, and quite likely proportional, to the initial surface area of the catalyst, i.e. that in these polymerization systems there is little change in the surface area as the polymerization proceeds. Also, it seems quite clear that when using pure vanadium trichloride catalysts of the type employed in the present study, there is little breakdown of the catalyst particles during the polymerization process. However, the situation with more complex catalysts, e.g. those based on TiCl₃·0.3AlCl₃ may be very different.

One possible reason for the reduced settling periods on ball-milling could be the production of extremely small particles, perhaps by 'chipping off' corners from the main crystal lattice of large particles. These very small species

Table 12 Effect of aluminium alkyl concentration on k'_i at 30°C

Temperature (°C)	k'_i (min ⁻¹)
30	0.019
50	0.104

might then be solubilized by the reaction media (containing monomer), and behave somewhat akin to soluble systems, i.e. having a very high but decaying initial rate. This behaviour superimposed on the conventional polymerization would result in an apparently shortened settling period. This hypothesis is consistent with the observation that, finely ball-milled catalysts often show an initial decaying rate which can be eliminated by washing or by prolonged storage.

Finally, it is not considered that impurities play any role in the settling periods which are observed in this polymerization system. Impurities can, nevertheless, affect the duration of the settling period as has been demonstrated by Vesely¹⁰ in the case of H₂O and by McKenzie¹⁸ in the case of impurities in 4-methylpentene-1. Certainly some of the confusion found in the literature may well arise from the presence of impurities of one kind or another.

Kinetics of the thermal oxidation of poly(4-methyl-1-pentene)*

S. M. Gabbay and S. S. Stivala

Department of Chemistry and Chemical Engineering, Stevens Institute of Technology, Hoboken, New Jersey 07030, USA

(Received 30 June 1975; revised 30 September 1975)

The kinetics of the thermal oxidation of isotactic and atactic poly(4-methyl-1-pentene) were studied in the bulk phase using infra-red (i.r.) spectroscopy. The rates of formation of the non-volatile products were assessed from the i.r. bands of the carbonyl groups at different temperatures and various oxygen concentrations. Reaction temperature varied from 120° to 185°C and oxygen concentrations from 10 to 100%, by volume. A general kinetic scheme and mathematical expressions, previously reported for the thermal oxidation of polyolefins, satisfactorily explained the experimental results. Single activation energies for the major oxidation stages in the scheme, were estimated from various Arrhenius plots.

INTRODUCTION

The thermal oxidation of poly(4-methyl-1-pentene) (PMP) was first examined by Winslow and coworkers¹ using oxygen uptake methods. These investigators found that isotactic poly(4-methyl-1-pentene) (IPMP), was more susceptible to oxidation, than polyethylene and polypropylene. They attributed this observation to the presence of ordered and disordered regions of nearly identical densities at 100°C, as reported by Griffith and Ranby². Recently, the authors³ identified the main volatile products evolved during the thermal oxidation of IPMP and atactic poly(4-methyl-1-pentene) (APMP), using thermal and mass spectroscopy. In an earlier paper⁴, the kinetics of the thermal oxidation of isotactic poly(1-pentene) (IPP-1) was reported and compared to atactic and isotactic polypropylene and poly(1-butene). The purpose of this paper, is to examine the kinetics of the thermal oxidation of PMP and to compare the IPMP to the APMP under similar experimental conditions, particularly since the former has been reported to be less resistant to oxidation than the latter^{1,9}. The interesting aspect of the tertiary carbon in the pendant group of PMP, lacking in the pendant groups of polypropylene and its higher homologues, may present some differences, particularly at higher temperatures of oxidation.

EXPERIMENTAL

Starting Material

(a) The IPMP used in this study, was an unstabilized pure homopolymer obtained from Imperial Chemical Industries. Upon ignition, the sample gave an ash content of 0.004%. A number average molecular weight of 108 000 was determined from osmotic pressure in cyclohexane at 35°C using a Mechrolab automatic membrane osmometer. A crystalline melting point of 235°C was determined on a Perkin Elmer differential scanning calorimeter (d.s.c.), using a programmed heating rate of 10°C/min.

(b) The APMP sample was obtained from a double extraction with boiling ether, of a commercial poly(4-methyl-1-pentene) from Polysciences. After extraction (1% yield), the APMP was purified several times by standard precipitation procedures using cyclohexane-methanol as solvent-nonsolvent. Its amorphicity was established by X-ray diffraction (powder technique using a cylindrical camera). Upon ignition the APMP gave an ash of 0.03%, by weight. A number average molecular weight of 88 000 was obtained from osmotic pressure measurements in cyclohexane at 35°C using a Mechrolab membrane osmometer. Weight loss, due to formation of volatile products, was ~3% at 145°C and 100% oxygen.

Apparatus

(a) A Perkin Elmer Recording Spectrophotometer, Model 21, was used, to which was attached an oxidation cell similar to that previously described⁴.

(b) A Dupont Thermogravimetric Analyzer Model 950 was used to record the weight losses of IPMP films as a function of time at different temperatures above 150°C and under various oxygen concentrations. The rate of flow of O₂/N₂ mixtures was 30 cm³/min, using isothermal mode.

Procedure

Clear and uniform films of IPMP and APMP of 2–2.5 mils thickness were prepared by compression moulding and solution casting, respectively, as described elsewhere^{4–6}. The films were then placed on sodium chloride discs, which were assembled in the oxidation cell mounted onto the infra-red spectrophotometer. By means of i.r. spectra, it was ascertained that no pre-oxidation of the sample occurred, during film preparation or when the sample was heated to the desired reaction temperature, under a blanket of nitrogen, as noted by the absence of any carbonyl bands. Known mixtures of purified oxygen and nitrogen were passed into the oxidation cell at a constant rate of 30 cm³/min, after the desired reaction temperature had been reached. The concentrations of oxygen in nitrogen varied between 10 to 100%, by volume. Reaction temperatures ranged from 120° to 135°C for the APMP, and 125° to 185°C for the IPMP. Infra-red spectra of the carbonyl

(5.50–6.00 μm) region were recorded, at various temperatures and oxygen concentrations, as a function of exposure time. The carbonyl absorbance areas for a given film, were computed in terms of the total absorbance area (cm²) and normalized to unit thickness as described earlier⁴. Diffusion control was found to be absent for the mil thickness of the films used in this study, pursuant to procedure described elsewhere^{5,6}.

RESULTS

As in the case of IPP-1⁴ and other polyolefins^{6,7}, it was observed that for IPMP and APMP, at all oxygen concentrations employed, the reaction rate increased while the induction period decreased with increasing reaction temperature. Further, as the oxygen concentration was increased, the rate of formation of total carbonyl increased while the induction time decreased, at any one given temperature. Maximum rates of formation of total carbonyl (ρ_m) were determined from plots of carbonyl absorbance area versus time, for various temperatures and oxygen concentrations. These plots were similar in nature to those described for IPP-1⁴. Values of observed ρ_m for APMP and IPMP are listed in Tables 1 and 2, respectively.

DISCUSSION

The general kinetic scheme for the thermal oxidation of polyolefins^{6,7}, including the mathematical expressions derived therefrom, were reproduced for convenience in a recent paper⁴ on IPP-1. Accordingly, all kinetic parameters and equation numbers designated in this paper, refer to those of the paper on the IPP-1. Values of $A, A',$ and k' calculated from equation (4) are shown in Tables 3 and 4. The observed maximum rates of formation of nonvolatile (NVP) carbonyl products, (ρ_m)_{obs.} for APMP, were found

to satisfactorily agree to those calculated, (ρ_m)_{calc.} (see Table 1), in the temperature range examined (120°–135°C). However, in the case of the IPMP, where the oxidation was conducted in the range of 125°–185°C, the (ρ_m)_{obs.} was found to agree within $\pm 3\%$ to the (ρ_m)_{calc.} for the oxidation conducted between 125° to 145°C (see Table 2). It should be noted that PMP contains a tertiary carbon on each pendant group, in addition to the tertiary carbons contained on the main chain. Since it was noted from the i.r. bands of the isopropyl moiety of the pendant group (7.25 μm), that there was no perceptible decrease in the maximum absorbance band, it is reasonable to assume that the oxidation occurred primarily on the main chain. Accordingly, one can assert that this pendant group, effectively behaved as if it contained no reactive site. However, the use of the derived mathematical expressions for the IPMP oxidation above 150°C, showed deviations between observed and calculated ρ_m , which increased with increasing reaction tem-

perature, e.g. about 25% deviation at 175°C. It should be mentioned that in prior work reported by Stivala and co-workers on the thermal oxidation of the polypropylenes⁶, poly(1-butenes)⁶, and poly(1-pentene)⁴, the weight loss following any oxidation was less than 1%. A low weight loss was also observed for APMP, and for IPMP below 150°C (3% at 145°C under 100% oxygen). This is consistent with the assumptions made by Stivala and Reich^{6,7}, that the scheme is applicable for conditions where volatile losses are low. On the other hand, in the case of IPMP oxidation conducted above 150°C, the weight loss following oxidation was as high as 16%. Therefore, it would not have been expected that one would obtain good agreement between calculated and observed ρ_m . The higher weight loss in the case of IPMP oxidized above 150°C, compared to IPMP oxidized below 150°C and the polyolefins studied earlier^{6,7}, is due to increased volatile formation resulting from attack by oxygen on the tertiary carbons of the pendant groups in IPMP. This was confirmed by the observed decrease in the maximum absorbance band of the isopropyl moiety in the pendant group with reaction time. Further, % relative abundance of volatile products, e.g. acetone, was higher at 175°C compared to oxidation at 145°C³. It is interesting to note that in isotactic polypropylene (IPP), where the pendant group contains no tertiary carbon, only a 4% weight loss was observed by the authors when this polymer was oxidized in pure oxygen at 165°C (m.p. ~171°C) for 3 h.

The question that one has to consider is whether the general kinetic scheme for the thermal oxidation of polyolefins, might not be still applicable to IPMP oxidized above 150°C. Therefore, in considering this question it was believed that the poor agreement between calculated and observed ρ_m , may have been due to the lower magnitude of maximum absorption of the carbonyl groups (assessed from the absorbance area), by virtue of the high losses of the volatile carbonyl containing products. Therefore, a correction to the observed area was deemed necessary to account for the high volatile losses. The observed carbonyl absorbance areas were corrected as follows:

$$A_c = \frac{A_m \times 100}{(100 - x)}$$

where: A_c = corrected carbonyl absorbance area; A_m = measured carbonyl absorbance area; x = percentage weight loss.

In the above correction, it was assumed that the weight of carbonyl per unit weight of solid film approximately equals the weight of carbonyl per unit weight of volatiles. The weight losses, at a given temperature and oxygen concentration as a function of time, were obtained from thermal gravimetric analysis (t.g.a.).

When the areas were corrected in this manner for all oxidations conducted at 155°, 165°, 175°, and 185°C, satisfactory agreement between observed and calculated ρ_m within an experimental error of ±4%, was obtained (see Table 2). On the basis of the satisfactory agreement between observed and calculated ρ_m , following the correction, it may appear that the general kinetic scheme also holds for the thermal oxidation of IPMP above 150°C.

Arrhenius plots of $-\ln \rho_m A / [O_2]$, $\ln K_2 / K_1 K_3$, $\ln K_3$, and $-\ln k' K_2 / K_3$ versus $1/T$, as in the previous paper⁴ on IPP-1, afforded values of energies of activation of $E_1 + E_6$, $E_1 + E_6 - E_5$, $E_8 - E_9$, and E_5 , respectively. It was noted in the case of IPMP, that each plot yielded two linear relationships of different slopes (e.g. see Figure 1), depending on the temperature range of oxidation. Hence, two values of energies of activation were obtained for any given stage (or combined stages of oxidation), see Table 5. In this context it is noteworthy to mention the work of Grieverson *et al.*⁸, who investigated the effect of temperature on the rate of oxidation of Zeigler polyethylene. They found that at temperatures between 140° and 170°C, the activation energy of the reaction was constant at 31 kcal/mol but that above 170°C, it decreased progressively until at 200°C the value was about 15 kcal/mol. Between 80° and 125°C an

Figure 1 Arrhenius plot of $\log K_2/K_1K_3$ versus reciprocal temperature for IPMP

activation energy of 21 kcal/mol was found. They ascribed their results to phase changes and to diffusional factors. Thus, the temperature range of 140° to 170°C is above the crystalline melting point of linear polyethylene, and it was postulated that above 170°C , the rate of oxygen diffusion into the polymer could no longer keep pace with the chemical reaction rate between the oxygen and the polymer. In the case of IPMP, it is unlikely that the lower activation energies obtained above 150°C is attributed to diffusional factors, since no diffusion barrier for film thickness 2.5 mil exists. It would appear, therefore, that in the case of the thermal oxidation of IPMP above 150°C , attack on the tertiary carbons on the pendant groups should be considered. This would require a knowledge of the energy of activation of each step in the kinetic scheme, particularly that of step 6, i.e. the decomposition of RO_2R into non-volatile carbonyl products. It was possible, as described below, to estimate E_6 , from which E_1 is then obtained from the value of $E_1 + E_6$.

Thus, in the Arrhenius plot of $-\ln k'K_2/K_3$ versus $1/T$ (from which E_5 is obtained) the intercept yields $\ln Z_5$, where Z_5 is the frequency (pre-exponential) factor for step 5; from which k_5 is obtained from $k = Ze^{-E/RT}$. In this manner values of k_5 were calculated at different temperatures. In the kinetic scheme, k' represents $k_5 + k_6$ (see equation 3a) calculated from the ratio of A/A' . Values of k' , A , and A' at different temperatures are shown in Table 3. From the above, values of k_6 were obtained at the different temperatures and Arrhenius plots of $\ln k_6$ versus $1/T$ afforded E_6 for oxidations conducted above and below 150°C . E_1 was found to be constant over the temperature range of 125° to 185°C , whereas, E_6 decreased in the range above 150°C (Table 5 summarizes the estimated activation energies). It may well be that the rate constant k_6 for that step (formation of *NVP*, above 150°C becomes a complicated function of rate constants which could be represented in the following way:

where the subscripts m and p represent the main chain and pendant group, respectively. Thus:

$$k_6[\text{RO}_2\text{R}] = k'_6[\text{RO}_2\text{R}]_m + k''_6[\text{RO}_2\text{R}]_p$$

Table 5 Activation energies of APMP, IPMP, isotactic polypropylene (IPP) and atactic polypropylene (APP) for various oxidation stages

Polyolefin	Activation energies (kcal/mol)				
	$E_8 - E_9$	$E_1 + E_6 - E_5$	$E_1 + E_6$	E_5	E_6
APMP	16	17	43	27	30
IPMP, below 150°C	19	16	33	17	23
IPMP, above 150°C	4	7	28	19	18
IPP ¹¹	6	18	51	33	24
APP ¹¹	9	17	48	31	30

Below 150°C , the tertiary carbons on the main chain are the major reactive sites, thus $k_6 = k'_6$. Above 150°C , the tertiary carbons on the pendant groups become reactive. This may be due to morphological changes, where the chains become more mobile exposing the hidden tertiary carbons from the pendant group to the surface, and/or chain fold enhancement (see below). Indeed, the relative abundance of acetone formation at 175°C , was much greater than at 145°C ⁷ and this observation may account for side chain tertiary carbon oxidation. As stated earlier, the isopropyl i.r. band ($7.25 \mu\text{m}$), diminished significantly during the oxidation above 150°C whereas below 150°C no perceptible change was noted.

It would thus appear that the general kinetic scheme reported by Stivala and coworkers^{6,7} for the thermal oxidation of polyolefins, has not been violated in the case of IPMP above 150°C , where side chain oxidation occurs along with main chain attack. This is supported by a subsequent study on the kinetics of IPMP oxidation above 150°C from volatile product formation from t.g.a. data (to be published).

Examination of the energies of activation, for the various steps of the thermal oxidation of IPMP and APMP, indicate that IPMP is more susceptible to oxidation than APMP. This observation is consistent with those made by the authors reported in an earlier publication³ and by Bassett⁹. Bassett explained his observation by suggesting that in aggregated IPMP crystals, oxidation preferentially selects chain folds as reaction sites, since the strained backbone configuration would reduce the energy of activation for reaction. The suggestion was based on low angle X-ray scattering of oxidized films of IPMP. The observed lower energies of activation for the oxidation of IPMP conducted above 150°C (see Table 5) may indicate chain fold enhancement at the high temperatures. It is noteworthy to mention that, in the case of poly(1-butene), the isotactic form had a lower energy of activation than the atactic polymer for oxidation⁶, and in the case of polystyrene the isotactic form was more susceptible to oxidation than the atactic form, reported by Jellinek¹⁰.

Table 5 also contains energies of activation for the various steps of PMP in the kinetic scheme compared to IPP and APP. It is noted from these values, for example, E_5 that PMP is more susceptible to oxidation than polypropylene. This is consistent with the observation made by Winslow *et al.*¹.

ACKNOWLEDGEMENTS

The authors are most grateful to Imperial Chemical Industries, England, and to Polysciences for supplying the polymers, to Mr R. F. Westover and Bell Telephone Labora-

ories for the preparation of the preliminary compression moulded films and to Dr T. Dougherty and Dr R. Jones for useful discussions.

Swelling of bonded-rubber cylinders

L. R. G. Treloar

Department of Polymer and Fibre Science, University of Manchester Institute of Science and Technology, PO Box 88, Manchester M60 1QD, UK

(Received 18 July 1975; revised 14 August 1975)

The equations governing the equilibrium of the stresses, and the equilibrium between the stresses and the degree of swelling at any point, for a rubber cylinder bonded to a rigid cylindrical core and immersed in a swelling liquid are derived. These equations may be solved numerically, for given values of the parameters defining the system, assuming the Flory–Huggins equation for the free energy of swelling to apply. A typical example of the resultant stress and swelling distribution is included.

STATEMENT OF PROBLEM

The objective of the paper is to calculate the equilibrium degree of swelling of an infinitely long rubber cylinder containing a cylindrical metal core to which it is rigidly bonded, when immersed in a swelling liquid. This system approximates closely to the practical problem of the swelling of an ‘O-ring’, consisting of a rubber toroid bonded to a toroidal metal core, provided that the radius of the cross-section of the toroid is small compared with the radius of the axis of the ring.

The presence of the metal core, which is considered to be perfectly rigid, imposes restraints on the swelling of the rubber which give rise to a distribution of stress throughout the system. As a result, an inhomogeneous state of swelling is brought about. The problem is to determine the relations between the local stresses and the corresponding equilibrium degree of swelling at any point, and hence by integration to obtain the total amount of liquid absorbed in the final equilibrium state. The equations derived to represent this equilibrium do not yield an explicit solution in general terms, but may be solved numerically for specific values of the geometrical and physical parameters defining the system. An example of the type of solution obtained is included by way of illustration.

NATURE OF SOLUTION

Before proceeding with the detailed analysis, it may be helpful to consider in a general way the nature of the solution ultimately obtained. In this, and in the later full treatment, the following symbols will be used:

v_2	volume fraction of rubber in swollen state
l_1, l_2, l_3	principal extension ratios, referred to unstrained, unswollen state
t_1, t_2, t_3	principal (tensile) stresses
a_0	radius of cylinder in unswollen state
a	radius of cylinder in swollen state
b_0	radius of core
r_0	radial position of element in unswollen state
r	radial position of element in swollen state
ρ	density of unswollen rubber
M_c	mean molecular weight of network chains
V_0	molar volume of swelling liquid
A_{0m}	molar free energy of dilution

The geometry of the system is indicated in *Figure 1*. Since the system possesses axial symmetry, any given element of the rubber at a distance r_0 from the axis is displaced radially outwards, on swelling to a new position r , without change of its angular coordinate. Also, the presence of the inextensible core requires that there shall be no strain in the axial direction, i.e. no change in the axial coordinate. The problem is thus a two-dimensional one, and by symmetry the principal axes of the strain ellipsoid in any plane normal to the axis must be along and perpendicular to the radial direction. Denoting the circumferential, radial and axial extension ratios by l_1, l_2 , and l_3 respectively we have then $l_3 = 1$. If we consider an element of unit volume in the unswollen state, its volume in the swollen state is $1/v_2$, where v_2 is the volume fraction of rubber corresponding to the radial position r . Assuming additivity of volumes it follows that:

$$1/v_2 = l_1 l_2 l_3 = l_1 l_2 \quad (1)$$

i.e. that the state of swelling at any point is determined by the two strain parameters l_1 and l_2 .

As will be shown later, particular significance is attached to the state existing at the inner and outer boundaries. At the inner boundary ($r = b_0$), it is clear that $l_1 = 1$. Since also $l_3 = 1$, it follows that the swelling in the immediate vicinity of this boundary is associated solely with an increase in the radial dimension l_2 . This generates a lateral *compressive* stress, represented by a negative value of t_1 , together with a radial *tensile* stress, t_2 . On proceeding outwards, the restraining influence of the core diminishes, per-

Figure 1 Strain geometry and principal stresses in cylindrical system: (a) unswollen; (b) swollen

Figure 2 Typical variation of circumferential (l_1) and radial (l_2) extension ratios, and of volume swelling ratio ($1/v_2$) with radial position referred to core radius b_0 (lower scale) or to external radius b of swollen cylinder (upper scale): A, $l_1 l_2 = 1/v_2$; B, l_2 ; C, l_1

mitting an increase both in l_1 and in the degree of swelling $1/v_2$. Correspondingly, the numerical values of both t_1 and t_2 progressively diminish, until at the surface ($r = a$), the radial stress t_2 falls to zero, though t_1 (and also t_3) remain finite, (see Figures 5 and 6).

The changes in the geometrical parameters l_1 and l_2 are illustrated in Figure 2. This refers to the particular case $b_0/a_0 = 0.4601$, and is taken from the data presented in Figures 3 and 4, the scale of abscissae being converted to r/b_0 . It is seen that as r increases the two lateral strains tend to converge; at the same time the volume swelling ratio $l_1 l_2$ increases, becoming a maximum at the outer boundary ($r = a$).

DERIVATION OF EQUATIONS

The quantitative treatment of the problem involves four types of equations. These are concerned with the following considerations: (a) Compatibility of strains; (b) relations between stresses and strains; (c) equilibrium of stresses; (d) relations between swelling equilibrium and stresses. These will be dealt with in succession.

Compatibility of strains

The radial variation of l_1 and l_2 is not entirely arbitrary, but is subject to certain geometrical conditions of compat-

ibility. From Figure 1 we see that the initial radius r_0 of a circular arc is changed on swelling to the value r ; the circumferential extension ratio is therefore r/r_0 . Also, the thickness of a cylindrical shell is correspondingly changed from dr_0 to dr , giving the radial extension ratio dr/dr_0 .

Figure 3 Radial variation of v_2 (volume fraction of rubber) for values of b_0/a_0 : A, 0.1634; B, 0.4601; C, 0.5695; D, 0.7249; E, 0.8354; F, 0.9201; G, 0.9880; H, 1.000; O, 0

Figure 4 Radial variation of principal extension ratios l_1 and l_2 (referred to unswollen unstrained dimensions). b_0/a_0 values: A A', 0.1634; B B', 0.4601; C C', 0.5695; D D', 0.7249; E E', 0.8354; F F', 0.9201; G G', 0.9880; H, 1.0000

Remembering that $l_3 = 1$, the three principal extension ratios are therefore:

$$l_1 = \frac{r}{r_0}; \quad l_2 = \frac{dr}{dr_0}; \quad l_3 = 1 \quad (2)$$

From these equations we have:

$$l_2 = \frac{dr}{dr_0} = \frac{d(l_1 r_0)}{dr_0} = l_1 + r_0 \frac{dl_1}{dr_0}$$

whence:

$$\frac{dl_1}{dr_0} = \frac{l_2 - l_1}{r_0}$$

We thus obtain:

$$\frac{dl_1}{dr} = \frac{dl_1}{dr_0} \times \frac{dr_0}{dr} = \frac{l_2 - l_1}{r_0} \times \frac{dr_0}{dr}$$

Substituting for r_0 and dr_0/dr from equation (2) this gives:

$$\frac{dl_1}{dr} = \frac{1}{r} \left(l_1 - \frac{l_1^2}{l_2} \right) \quad (3)$$

Equation (3) implies that, if the values of the principal extension ratios at any point r are known, the rate of change of l_1 with respect to r is determined.

Relations between stresses and strains

The relations between the principal stress differences ($t_1 - t_2$), ($t_2 - t_3$), ($t_3 - t_1$) and the principal extension ratios, in a pure homogeneous deformation, are given by the Gaussian network theory of rubber elasticity in the form¹:

$$t_1 - t_2 = \frac{\rho RT}{M_c} v_2 (l_1^2 - l_2^2) \text{ etc.} \quad (4)$$

where t_1, t_2, t_3 are the respective forces per unit area, measured in the strained swollen state.

Equilibrium of stresses

It may easily be shown² that the conditions for internal equilibrium of the stresses in a cylindrical system lead to the differential equation:

$$\frac{dt_2}{dr} = \frac{t_1 - t_2}{r} \quad (5)$$

By virtue of equation (4), this may be put in the alternative form:

$$\frac{dt_2}{dr} = \frac{\rho RT}{M_c} \times \frac{l_1^2 - l_2^2}{r} \times v_2 \quad (5a)$$

Relation between swelling equilibrium and stresses

The relations between the equilibrium swelling and the principal stresses, in a pure homogeneous strain, have been

given by the author¹. For the present purpose the relevant relation is of the form:

$$t_2 = \frac{A_{0m}}{V_0} + \frac{\rho RT}{M_c} v_2 l_2^2 \quad (6)$$

in which A_{0m} is the free energy of dilution of the polymer (in the non-crosslinked state) by the swelling liquid. In the present numerical analysis this will be assumed to be given by the Flory-Huggins relation³:

$$A_{0m} = RT \left(\ln(1 - v_2) + v_2 + \chi v_2^2 \right) \quad (7)$$

where χ is an interaction parameter which is specific to the particular polymer-liquid system considered. The method of analysis is, however, not restricted to any particular form of A_{0m} .

RADIAL VARIATION OF v_2

Equations (1) to (7) provide the essential basis for the solution of the present problem. For the purpose of computation, however, it is convenient to derive a further relation expressing the radial variation of the degree of swelling, as represented by the parameter v_2 . (This avoids the necessity of having to work directly with the cumbersome equation 7.)

Putting $l_2 = 1/l_1 v_2$ in equation (6) and differentiating with respect to r , we obtain:

$$\begin{aligned} \frac{dt_2}{dr} &= \frac{1}{V_0} \frac{dA_{0m}}{dr} + \frac{\rho RT}{M_c} \times \frac{d}{dr} \left(\frac{1}{v_2 l_1^2} \right) \\ &= \frac{RT}{V_0} \left[-\frac{1}{(1-v_2)} + 1 + 2\chi v_2 \right] \frac{dv_2}{dr} \\ &\quad + \frac{\rho RT}{M_c} \left[-\left(\frac{1}{v_2^2 l_1^2} \times \frac{dv_2}{dr} \right) - \left(\frac{2}{v_2 l_1^3} \times \frac{dl_1}{dr} \right) \right] \end{aligned}$$

or

$$\begin{aligned} \frac{dt_2}{dr} &= \frac{RT}{V_0} \left\{ \left[2\chi - \frac{1}{(1-v_2)} \right] v_2 - \frac{\rho V_0}{M_c} l_2^2 \right\} \frac{dv_2}{dr} \\ &\quad - \left(\frac{\rho RT}{M_c} \times \frac{2l_2}{l_1^2} \frac{dl_1}{dr} \right) \end{aligned} \quad (8)$$

Introducing dt_2/dr from equation (5) and dl_1/dr from equation (3):

$$\begin{aligned} \frac{t_1 - t_2}{r} &= \frac{RT}{V_0} \left\{ \left[2\chi - \frac{1}{(1-v_2)} \right] v_2 - \frac{\rho V_0}{M_c} l_2^2 \right\} \frac{dv_2}{dr} \\ &\quad - \left[\frac{\rho RT}{M_c} \times \frac{2l_2}{l_1^2} r \left(l_1 - \frac{l_1^2}{l_2} \right) \right] \end{aligned}$$

or

$$\frac{dv_2}{dr} = \frac{(M_c/\rho RT) (t_1 - t_2) + 2(l_2/l_1 - 1)}{\left\{ \frac{M_c}{\rho V_0} \left[2\chi - \frac{1}{(1-v_2)} \right] v_2 - l_2^2 \right\} r} \quad (9)$$

Figure 5 Variation of tensile stress (t_2) in radial direction. b_0/a_0 values: A, 0.1634; B, 0.4601; C, 0.5695; D, 0.7249; E, 0.8354; F, 0.9201; G, 0.9880

NUMERICAL ANALYSIS

Procedure

The problem cannot be solved directly, given the values of a_0 , b_0 , and the parameters defining the material properties. The boundary conditions are: (1) at $r = a$, $t_2 = 0$ and (2) at $r = b_0$, $l_1 = 1$. Neither of these gives a unique solution for the remaining variables at the respective boundary. The problem may, however, be solved indirectly by choosing an arbitrary value of one of the variables at either the inner or the outer boundary, solving for the remaining variables at this boundary, and then applying the above equations to obtain the values at a neighbouring point. The latter process is then repeated in a stepwise manner until a value of r is reached at which the required condition at the other boundary is satisfied; this then defines the second boundary.

In the present case, the calculation was started from the outer boundary, $r = a$. Assuming an arbitrary value of v_2 , and inserting the condition $t_2 = 0$, equation (6) was solved for l_2 . Knowing l_2 and v_2 , l_1 was then obtained from equation (1), following which t_1 was obtained from equation (4). The values of v_2 and t_2 at a neighbouring point ($r - \delta r$) were then obtained, using the gradients dt_2/dr and dv_2/dr as given by equations (5a) and (9) respectively; using these values the solution for l_2 and t_1 was then obtained as before. The process was repeated until the condition $l_1 = 1$ was attained; this corresponds to the inner boundary ($r = b_0$), and hence determines the value of b_0 .

Numerical values

To obtain a typical numerical solution, values of the parameters were chosen to correspond to a vulcanized natural rubber swollen with benzene, as used in a preceding study of swelling under compression⁴. These values were as follows:

$$\rho = 950 \text{ kg/m}^3; V_0 = 8.94 \times 10^{-5} \text{ m}^3/\text{mol}; \chi = 0.41.$$

Taking $M_c = 8.490 \text{ kg/mol}$ we then have $\rho V_0/M_c = 1/100$. For a temperature of 298 K this yields the value of shear modulus for the unswollen rubber $\rho RT/M_c = 0.2772 \text{ MN/m}^2$

The accuracy of the calculations depends on the interval δr between successive radial positions. Two values of this interval were used, i.e. $\delta r/r = 0.005$ and $\delta r/r = 0.001$. The resulting figures differed only slightly (i.e. in the 4th significant digit in l_1 and v_2), indicating that the smaller interval gives reasonably accurate results. For any chosen value of v_2 at the surface, there is a corresponding value of b_0 ; this, as already noted, is the value of r at which $l_1 = 1$, which was obtained by interpolation.

Figure 3 shows the radial variation of v_2 , for 7 values of b_0/a_0 , obtained in this way. The circumferential and radial strains are shown in Figure 4. Figure 5 gives the variation of the radial (tensile) stress t_2 and Figure 6 the circumferential (compressive) stress, $-t_1$, and the (compressive) stress parallel to the axis, $-t_3$. All the stresses are given relative to the shear modulus $\rho RT/M_c$.

Overall degree of swelling

The effect of the solid core on the overall swelling ratio of the rubber component is obtained from the formula:

$$Q = \frac{a^2 - b_0^2}{a_0^2 - b_0^2} \quad (10)$$

This quantity is shown in Figure 7, as a function of b_0/a_0 .

LIMITING CASES

Two limiting cases may be treated generally. These are: (a) infinitesimal thickness of rubber ($b_0/a_0 \rightarrow 1$) and (b) infinitesimal core radius ($b_0/a_0 \rightarrow 0$).

Figure 6 Radial variation of compressive stresses in circumferential direction ($-t_1$) and in axial direction ($-t_3$). —, $-t_1/(\rho RT/M_c)$; ---, $-t_3/(\rho RT/M_c)$. b_0/a_0 values: A, 0.1634; B, 0.4601; C, 0.5695; D, 0.7249; E, 0.8354; F, 0.9201; G, 0.9880; H, 1.0000

Figure 7 Dependence of overall swelling ratio Q on ratio of internal to external radii of unswollen cylinder. X, calculated from equations (10) and (11)

(a) For this case $l_1 = l_3 = 1$, $\nu_2 = 1/l_2$, $t_2 = 0$. Substituting these values in equation (6), we obtain an equation for ν_2 , namely:

$$\frac{A_0 m}{RT} + \frac{\rho V_0}{M_c} \nu_2^{-1} = 0 \tag{11}$$

The remaining variables are then obtained directly.

(b) For this case it may be assumed that the region of non-uniform strain is restricted to an infinitesimal distance from the axis. Except for this infinitesimal region the swelling and strain will be homogeneous, the effect of the core being merely to restrict the axial extension. The only stress present will be the axial compressive stress $-t_3$. Hence $l_1^2 = l_2^2 = 1/\nu_2$; $t_1 = t_2 = 0$; and equation (6) becomes:

$$\frac{A_0 m}{RT} + \frac{\rho V_0}{M_c} = 0 \tag{12}$$

The solutions for ν_2 corresponding to these two limiting cases are represented in Figure 3 by the point for $b_0/a_0 = 1$ and the horizontal line for $b_0/a_0 = 0$. Corresponding values for case (a) are shown also in Figures 4 and 6.

DISCUSSION

Origin of swelling stresses

The origin of the stresses developed on swelling, already briefly referred to earlier, can easily be understood in a qualitative way. If the core were removed, leaving a hollow cylinder of rubber, this would swell isotropically. Such a swollen cylinder would have a greater axial length, and a greater internal radius, than the core to which it was originally attached in the unswollen state. In order to fit the internal surface of the swollen cylinder to the core, it is necessary to apply forces to the boundary surfaces so as to reduce the internal radius and the axial length to their original values. Given that the outer surface is stress-free, the necessary forces are obviously: (1) a radial tensile force on the inner surface, and (2) an axial compressive force on the end surfaces. These forces correspond to the radial tensile stress t_2 and the axial compressive stress $-t_3$ derived from the above calculations. The circumferential compressive stress $-t_1$ is a result of the radial tensile stress t_2 .

ACKNOWLEDGEMENTS

The author is indebted to Dr M. D. Heaton for carrying out the necessary computational work, and to Dr W. F. Watson of the Rubber and Plastics Research Association for discussions related to the problem considered.

Comparison of bound rubber and swelling in silicone rubber/silica mixes and in silicone rubber vulcanizates

David W. Southwart

Dunlop Limited, Precision Rubbers Division, Shepshed, Loughborough, Leics. LE12 9 EQ, UK

(Received 8 January 1975; revised 5 August 1975)

Unextracted polymer and liquid absorption values have been determined on unvulcanized silicone rubber/silica mixes and on unfilled silicone rubber vulcanizates, for comparison of the two different types of three-dimensional structure which must exist. In both types, the amount of rubber extracted on immersion in liquid is dependent on the expansion of the respective network but only in the former is the amount dependent on the method of extraction; this is attributed to interaction between filler and rubber continuing as a result of immersion. Even at equilibrium, the amount of unextracted polymer can be greater than that of bound rubber. In some mixes, liquid absorption is substantially constant during extraction of considerable amounts of soluble rubber. This is attributed, in the presence of filler, to a dependence of the absorption on the previously postulated interparticular rubber which, in turn, is dependent on the mean distance between filler particles. Although unextracted polymer is also dependent on that mean distance, it is proposed that this is a secondary effect of network expansion by the absorbed liquid. As some published values of bound rubber have undoubtedly been of unextracted polymer, these results help to explain published differences of opinion on the value of bound rubber for investigation of filler reinforcement phenomena.

INTRODUCTION

In previous work, the author has attempted to correlate various changes occurring in mixtures of silicone rubber and fine particle fume silica, on storage. The well known increase in bound rubber was shown to be more complex than previously realized, e.g. immersion times in excess of six months¹ were sometimes required to reach an equilibrium (constant) value; furthermore, the increase in bound rubber on storage, accompanied by a decrease in swelling, was shown not to correlate directly with processability, the latter sometimes passing through a minimum as the bound rubber continued to increase. Similarly, heat of melting was shown to pass through a minimum on storage².

Comparison of unvulcanized and vulcanized mixes was restricted to modulus measurements³. Vulcanization was found to decrease the rate, but not the extent, of increase of (low strain) Young's modulus on storage. Sometimes the maximum Young's modulus of the unvulcanized mix was greater than that of the corresponding vulcanizate.

To account for these results, the author⁴ proposed that silicone rubber and silica interact to produce two different structures in the unvulcanized state; one giving an effective three-dimensional structure but both immobilizing some of the rubber. These were described as:

(a) adsorbed rubber: polymer segments immobilized in the immediate vicinity of filler particles, whether by orientation on the filler surface or by entrapment in filler agglomerates;

(b) interparticular rubber: polymer segments joining filler particles to give effective crosslinkages, and (interlocking) polymer loops attached to filler particles.

The two terms are synonymous with the 'shell of rubber' and 'rubber bridgehead chains' respectively described by Gessler⁵. The polymer free of interaction with filler was termed matrix rubber.

In this paper further experiments are reported on the comparison of the behaviour in liquids of (unvulcanized) silicone rubber/silica mixes, with that of (pure gum) silicone rubber, lightly vulcanized with peroxide so that up to 30% of the rubber remained soluble (i.e. bound rubber ~70%). Interesting observations have been made, which help to demonstrate the differences in structure between silicone rubber conventionally crosslinked by peroxide, and silicone rubber 'effectively crosslinked' by interaction with a fine particle reinforcing filler.

MATERIALS

The silicone rubber was a commercial methyl vinyl polysiloxane obtained from Imperial Chemical Industries Limited. It was used in its original form, E302, and in its devolatilized form, E303; the latter having reduced loss during high temperature post curing of its vulcanizates, for normal commercial applications. The fine particle fume silica was Aerosil 300, produced by Degussa and supplied by Bush Beach and Segner Bayley Ltd. It has a nominal specific surface area of 300 m²/g. The peroxide was a commercial form of 2,4-dichlorobenzoyl peroxide in an equal weight of unspecified silicone oil, obtained from Novadel Limited as Perkadox PDS-50. The liquids used were generally of analar or similar high purity grades.

BOUND RUBBER

Time to equilibrium

Bound rubber is generally reported as % original rubber, remaining in a sample after immersion in a good solvent for a time considered sufficient to reach an equilibrium condition, i.e. a state where there is no further change in composition of the swollen gel during continued immersion.

Such values of bound rubber include any soluble rubber remaining in the swollen gel. A better term, which can also be used for values obtained under non-equilibrium conditions, is 'unextracted polymer'. It will generally be greater than the bound rubber, if that term is reserved for the sum of the adsorbed rubber and interparticular rubber as defined above.

In the case of a silicone rubber/fume silica mix, the rate of extraction of soluble rubber is dependent on the storage time of that mix and on the type and concentration of filler. In addition the rate and amount of extraction are affected by repeatedly replacing the solvent containing extracted rubber by fresh solvent. If the solvent contains soluble rubber there is an effect on the swelling of the gel and on the amount of soluble rubber remaining in the gel. This arises from a back pressure effect⁶ which has been confirmed by others^{7,8} and recently analysed by Blow⁹, using the concept of a partition coefficient, for the distribution of soluble rubber between the solvent present in the gel and that in which the gel is immersed. It was claimed that the bound rubber, as defined in the previous paragraph, can be calculated from values of extracted rubber, obtained from the immersion of samples of the mix in a range of silicone rubber solutions instead of in the pure solvent; it is, however, necessary to ensure equilibrium¹⁰.

Several samples (~0.4 g) of silicone rubber (E302) containing 26 parts by weight per hundred of rubber (phr) of fume silica were immersed in toluene for varying periods up to 4 years, with occasional transfer of the swollen jelly to fresh solvent. Unextracted polymer was found to be linearly related to the square root of the immersion time. Extrapolation of the line indicated that all the rubber would be extracted in approximately 20 years.

It is possible that the slow and continuing fall in the unextracted polymer value in the case of the above experimental procedure is due not to a low rate of diffusion of soluble polymer but to solubilization of bound rubber by hydrolysis, or by some other mechanism.

To study the rate of extraction of soluble rubber in the absence of filler, lightly crosslinked unfilled silicone rubber

has been used as a model system. Although variation of peroxide concentration would have provided the desired variation in liquid absorption through crosslink density effects, it would also have varied the soluble rubber concentration. To provide variation of liquid absorption, at constant soluble rubber concentration, the vulcanizate was swollen in several liquids covering a wide range of solubility parameters.

Effect of liquid composition

Silicone rubber (E303) containing 0.5 phr of peroxide was moulded for 10 min at 110°C into nominally 175 × 175 × 2.5 mm sheets. Test pieces (~0.4 g) were immersed in various liquids, then dried at room temperature to determine the unextracted polymer. Some test pieces were subjected to successive determinations, by being reswollen and extracted for longer periods until equilibrium was attained, as shown by a horizontal portion of the line obtained when unextracted polymer was plotted against the square root of immersion time. Other test pieces were immersed concurrently and continuously until equilibrium had been attained by the method of successive determinations. In all cases the liquid was replaced frequently so that final values were not subject to any significant back pressure effect. As no correction was made for residual peroxide etc. values are subject to a small error not exceeding 0.5%.

The data in *Table 1* show that, with one exception, there was a small, but probably significant, increase in unextracted polymer with increase of solubility parameter of the extracting liquid, when values were obtained by successive determinations. Similarly, with the exception of the values obtained in toluene, unextracted polymer determined by continuous immersion, also increased with increases of solubility parameter. Although the differences in values are small there appears to be no significant effect of test method, i.e. unextracted polymer is the same whether or not immersion is interrupted by drying down and reswelling. When test pieces dried after successive determinations for 5 weeks were transferred to hexane they gave values identical within likely experimental error.

			Continuous immersion		
8 weeks	93.3	75.5	74.0	67.3	64.8

ND = not determined

The data in Table 2 show that, in a similar series of determinations on unvulcanized portions of silicone rubber (E303) containing 32 phr of fume silica, unextracted polymer on successive determinations was similarly, but considerably more, dependent on the liquid. On the other hand: (a) no more soluble rubber was extracted on subsequent immersion in hexane (except in the case of samples originally immersed in acetone); (b) more (sometimes considerably more) rubber was extracted by continuous immersion than by repeated immersion and drying (again with the exception of the samples immersed in acetone).

Comparison of the two sets of data reveals several differences between vulcanized (unfilled) silicone rubber and unvulcanized silicone rubber containing silica, but also some similarities. These can be summarized as follows.

(1) In both systems unextracted polymer is liquid dependent.

(2) In the case of a filled unvulcanized mix, unextracted polymer is greater when determined by successive determinations to equilibrium than by continuous immersion whereas a gum vulcanizate shows little, if any, dependence on the test method.

(3) Gum vulcanizate samples, previously extracted in the various liquids (successive drying and reswelling) undergo further extraction on immersion in hexane to give the same value as a sample not previously extracted. Filled unvulcanized samples, on the other hand, undergo no further extraction when immersed in hexane.

The dependence of unextracted polymer on the solubility parameter of the liquid, could be due to the differing solubility of the polymer in the various liquids and/or to the variation in the amount of network expansion produced by the liquids. In the case of the filled unvulcanized mix, it is particularly significant that the higher values of unextracted polymer obtained by successive determinations (rather than by continuous immersion) in the various liquids, were not reduced by subsequent immersion in the most powerful solvent, i.e. hexane, except for a small reduction when the first liquid had been acetone.

The effects of acetone and hexane were also compared at higher soluble rubber concentration by using separate

portions of silicone rubber (E303) vulcanized with only 0.2 phr of peroxide. Acetone, in which the rubber is only partly soluble, extracted only 5.5% of the polymer at equilibrium in approximately 5 days, by which time hexane has extracted 25%. The extract in hexane continued to increase and had attained 34% in 132 days. In a further sample, the 4 and 12 day acetone extracts were both found to have a molecular weight of 0.35×10^6 as determined by intrinsic viscosity in toluene after drying down, whereas the first extract after transfer to hexane for 1 day had a molecular weight of 0.48×10^6 ; (original polymer 0.64×10^6). This provides some limited evidence for a belief that the amount of polymer extracted and its molecular weight are dependent upon the degree of expansion of the network, possibly through some fractionation or molecular 'window' effect, similar to that proposed by Cooper and Smith for natural rubber¹¹.

RELATIONSHIP BETWEEN LIQUID ABSORPTION AND UNEXTRACTED POLYMER

The swelling of a 'bound rubber gel', expressed as the weight of liquid per 100 parts by weight of unextracted polymer, can be linearly related to the 'bound rubber', or more correctly to the unextracted polymer. This has been established both for unvulcanized silicone rubber containing silica, in toluene with variation of storage and immersion times and, from the data of J. W. Watson¹², for unvulcanized natural rubber containing carbon black, in benzene¹; also for unvulcanized nitrile rubber containing silica, in acetone, methyl isobutyl ketone and toluene¹³.

In the experiments reported in this paper the weight of the test piece increased rapidly on immersion and attained a near constant value within one day. Thereafter there were generally further small but comparatively insignificant weight changes over several weeks while rubber continued to be extracted. In Figure 1, the unextracted polymer values from Tables 1 and 2 for the various liquids, taking those at 3 weeks and 8 weeks (continuous immersion) respectively as representing equilibrium, are plotted against the liquid absorption, expressed as the volume of liquid

Figure 1 Relationship between unextracted polymer and volume swelling (V_B) for a silicone rubber vulcanizate (○) and an unvulcanized silicone rubber/silica mix (●)

(V_B) per 100 volumes of unextracted polymer. Both plots show the same decrease of unextracted polymer with increase of swelling.

There is an alternative way of expressing liquid absorption, i.e. as the parts by weight of liquid absorbed per 100 parts of original mix (S_M). This value is substantially independent of storage time before immersion¹⁰; it is also substantially independent of immersion time as the following experiment demonstrates.

Eight portions of five silicone rubber (E302) mixes containing various proportions (8–48 phr) of fume silica were immersed in toluene (which was renewed frequently), and removed successively during 100 days. In Figure 2, unextracted polymer versus S_M is plotted for the five mixes after the varying immersion times. The slope of the linear portions of these plots varies slightly and is a maximum for the mix with 24 phr of filler, which had substantially constant toluene absorption.

A similar series of mixes was extracted, with weekly changes of toluene, until there was no residue on drying down the replaced solvent on three successive weeks. Excluding the lowest filler concentration, there was an approximately linear relationship between the unextracted polymer and the liquid absorption expressed (in this instance to take account of varying silica content) as parts by weight of toluene (S_P) per 100 parts of E302 originally present in the mix (Figure 3).

DISCUSSION

Unextracted polymer is believed to comprise three different types: (1) bound rubber, as interparticular rubber and/or adsorbed rubber; (2) soluble rubber which cannot be

Figure 2 Relationship between unextracted polymer and liquid absorption (S_M) with increase of immersion time as arrowed; filler concentration (phr): ○, 48; □, 32; ■, 24; △, 16; ▽, 8

extracted through available 'windows' in the network because of its molecular size, or for other reasons; (3) soluble rubber which will be extracted if immersion is sufficiently prolonged, with sufficiently frequent replacement of the extracting liquid by fresh solvent.

Changes may well occur during determinations of unextracted polymer because bound rubber is desorbed, or because networks have expanded under the influence of liquid pressure — the well known swelling increment. One of the most significant observations is that, equilibrium values of unextracted polymer obtained by successive determinations of unvulcanized silicone rubber containing fine particle fume silica, are higher than values obtained by continuous immersion. This is attributed to an increase in bound rubber, particularly on drying after an increase in the mobility of the reactive species in the swollen expanded network. On the other hand, vulcanized but unfilled silicone rubber, whose network structure should not be changed by the liquid, gives values of unextracted polymer which are little, if at all, affected by the method of determination.

At equilibrium the amount of soluble rubber extracted from a three-dimensional silicone rubber network is related to the amount of expansion of that network imposed by the extracting liquid; whether the network consists of rubber molecules joined by peroxide-induced linkages or by adsorption to filler particles (Figure 1). In lightly vulcanized silicone rubber it seems unlikely that the amount of soluble rubber present depends on the solvent used; the increase in the amount of soluble rubber extracted with increase in solvent absorption is therefore attributed to the increase there must be in network expansion. In unvul-

canized silicone rubber containing silica, liquid might desorb rubber adsorbed on the filler surface, thus effectively increasing the soluble rubber content. However, hexane was apparently unable to desorb the rubber bound during the successive determinations in all but acetone (Table 2). The similarity between the two curves in Figure 1 is therefore attributed to a dependence of the amount of rubber extracted on the degree of expansion of the two types of three-dimensional network.

Another significant observation is the tendency for the amount of liquid absorbed to be substantially independent of storage time and immersion time, for a given mix and liquid, even when further rubber is adsorbed (by the filler) during the determination. It is proposed that the liquid absorption is largely determined by the length of the interparticular rubber chains in a silicone rubber/silica mix, rather than by their number and thus related to the mean distance between filler particles in the unswollen mix.

It is in the effect of additional linkages that the two three-dimensional structures are believed to differ most. In a gum vulcanizate the effect is well known, and characterized by the Flory-Rehner relationship¹⁴; generally each additional crosslink reduces the mean distance between crosslinks, and thus the extent of swelling. It is postulated that in a uniform three-dimensional network in a filled unvulcanized mix, filler particles are joined by rubber chains of constant length (interparticular rubber). The addition of a further chain will reduce the degree of swelling in a liquid but this reduction will be less than that of an additional crosslink in a vulcanizate. Additional linkages introduced during drying after immersion will however tend to be of greater chain length than the original ones and thus have even less subsequent effect. In other words, if, during the determination of unextracted polymer, additional linkages form and insolubilize some previously soluble rubber, the liquid absorption will not be appreciably altered.

The data in Figure 2, obtained by continuous immersion, show that liquid absorption is dependent on filler concentration. At high filler concentrations liquid absorption increases with increase of immersion time; probably owing to the swelling increment mentioned earlier. At low filler concentrations immersion time has the opposite effect on liquid absorption, probably owing to greater absorption of liquid by the soluble rubber before its extraction. At the median filler concentration liquid absorption is remarkably constant. The deviation of the first one or two values from the straight lines drawn, particularly for the mix with the highest liquid absorption, is attributed to a normal diffusion rate effect on the liquid.

The relationship between unextracted polymer and filler concentration is considered next. Vondráček and Schätz have recently proposed¹⁵ that bound rubber is directly proportional to filler contact area, up to a limiting volume concentration of approximately 0.08 with a lower specific area fume silica. This is equivalent to direct proportionality of bound rubber to filler volume concentration, as found in an earlier stage of the present work when only four filler concentrations were used. However the data obtained from near-equilibrium conditions (Figure 3) did not fit that relationship but instead indicated that unextracted polymer is proportional to the logarithm of filler volume concentration as shown in Figure 4. Similarly the data of Vondráček and Schätz were found to agree with that relationship, up to a high unextracted polymer value.

It is interesting finally to examine the relationship between unextracted polymer and mean interparticle distance.

Figure 5 Relationship between unextracted polymer and the calculated mean distance between filler particles before immersion. Data from Figure 3

Again using the data from near-equilibrium conditions (Figure 3), there is found to be a linear relationship (Figure 5), with the line indicating complete insolubility when the filler particles are touching, i.e. at a volume concentration of 0.52, this is equivalent to nearly 250 phr of Aerosil 300, far in excess of practical concentrations.

CONCLUSIONS

It appears that both the liquid absorption and the unextracted polymer of a three-dimensional silicone rubber/

fume silica network, are dependent upon the mean distance between filler particles. However, the work with different liquids indicated that unextracted polymer often included unextracted, or unextractable, matrix rubber as well as true bound rubber i.e. adsorbed rubber and interparticular rubber. It is therefore concluded that liquid absorption is the primary parameter, dependent on the interparticular rubber and the mean distance between filler particles, while unextracted polymer is largely a secondary parameter, dependent on the liquid absorption.

In the mathematical model recently called for by Blow⁹, the importance of filler particle diameter was emphasized, it is now suggested that this is because of its effect upon the mean distance between the filler particles at any given loading.

(Received 7 July 1975; revised 15 August 1975)

The three strong sharp lines in the 50 cm^{-1} region of the infra-red spectrum of polytetrafluoroethylene (PTFE) at liquid nitrogen temperature, have been shown to be strongly polarized, with the transition moments lying perpendicular to the molecular axes. This result is interpreted in terms of the lattice-mode theory and in terms of possible symmetries for the unit cell.

INTRODUCTION

Recently there has been considerable interest in the far infra-red spectrum of polytetrafluoroethylene (PTFE). The absorption bands observed, have been interpreted in terms of specific models for the dependence of the crystal structure on temperature¹. Further information may be obtained, by observing the spectra of specimens in which some degree of molecular alignment has been introduced e.g. by stretching in a tensile testing machine²⁻⁴. The polarization of the absorption bands may be predicted from the models and compared with experiment.

EXPERIMENTAL

Samples cut from a commercial sheet were stretched at 250°C in air, to a draw ratio of 2.3 at a rate of 100 mm/min and cooled slowly (3-4 h) at constant extension. Spectra were recorded between 30 and 100 cm^{-1} , both at room and liquid nitrogen temperatures using an NPL - Grubb Parsons modular Michelson interferometer, with a wire grid polarizer in the beam.

RESULTS AND DISCUSSION

The room temperature spectra showed the presence of the weak broad feature at 50 cm^{-1} and this was clearly, polarized strongly with the transition moment perpendicular to the draw direction. This result is exactly what would be expected if, as has been postulated, this band arises from the z-axis rotational lattice mode. On cooling to low temperature, the set of absorption bands in the $30-90\text{ cm}^{-1}$ region appears. This phenomenon is well known for unstretched PTFE and has been attributed to the onset of a two segment unit cell¹. Its persistence in the stretched material must mean that on stretching there is an orientation of crystallites, each of which is still able to undergo the phase transitions. A model for this would be a set of randomly oriented crystallites connected by disordered chains. On stretching, the disordered regions take the strain and pull the crystallites into alignment.

The nature of the 19°C transition in PTFE is still a matter for controversy, but the infra-red results are consistent with a model, in which rotational disorder leads essentially to there being one segment per unit cell above 19°C , i.e. a hexagonal form. Then there is a progressively closer

approach to a perfect two segment per unit cell structure (the monoclinic form) as the temperature continues to fall below the 19°C transition. This fact does not mean of course that this model is established, since i.r. studies are not the most sensitive way of establishing phase transitions, but nevertheless we will use the model to interpret our present results.

For an isolated chain molecule, there are four modes of vibration which have zero frequency for $k = 0$, these are the three translations T_x, T_y, T_z , and the rotation about the chain axis R_z . Because of the strong covalent bonding between repeat units, the two other rotations R_x and R_y take on the form of bond stretching or angle deformation modes and have finite and in fact quite high frequencies. When the chain-molecule forms part of a crystal lattice, the z-axis rotation has likewise a finite frequency, as the molecule does not have cylindrical symmetry nor is it moving in a cylindrically symmetric force field. The three translations are still of zero frequency, for one segment per unit cell, since they correspond to overall translation of the crystal. When there are two segments per unit cell, the in- and out-of phase coupling splits the z-axis rotation into a doublet and produces a finite frequency for each of the out of phase translational modes. One would then expect five lattice modes, but their spectral activity will depend on the cell symmetry. It is natural to compare results with the well known case^{5,6} of polyethylene but this has to be done with care because of the much higher symmetry (V_h) of the polyethylene unit cell. For PE* one has two i.r. active modes (T_x and T_y belonging to the irreducible representations B_{2u} and B_{3u} respectively), two Raman active modes (the split R_z in A_g and B_{1g} respectively) and an inactive mode in class A_u . For PTFE, where the current model postulates no higher than C_2 symmetry for the two segment unit cell, all five modes would be active in both i.r. and Raman scattering. In the i.r. case, the two translations T_x and T_y and both components of the split R_z would be polarized perpendicular to the draw direction and the fifth mode, now corresponding to z-axis translation, would be polarized parallel to the draw direction. In our previous assignment, we assumed that the line at 45 cm^{-1} was the analogue of the

* The point group $V_h(D_{2h})$ has an unavoidable ambiguity of axis labelling and consequently one may see one and the same vibration referred to as B_{1u} or B_{2u} ; this confusing situation is especially prevalent for the 73 cm^{-1} lattice mode.

Figure 1 Polarized far infra-red spectra of a stretched sample of PTFE at room temperature. Resolution 4 cm^{-1} . A, Electric field perpendicular to draw axis; B, Electric field parallel to draw axis

B_{2u}^* (73 cm^{-1}) lattice mode of PE and that, the lines at 53.5 and 56.7 cm^{-1} were the components of the R_z doublet. This assumption is strongly confirmed by our present results. The location of the two other lattice bands is however much more problematical. In Figure 2 there will be seen weak lines at 70 , 76 and 86 cm^{-1} all of which are polarized perpendicularly and are therefore candidates for the B_{3u} mode. However, by analogy with PE, one would expect the B_{3u} (often referred to as the B_{2u} !) line to lie at higher frequency and to be much weaker than the B_{2u} (45 cm^{-1}) line; so perhaps the 70 or 76 cm^{-1} line can be identified with the B_{3u} mode. The 86 cm^{-1} line is probably at too high a frequency for consideration. There are no parallel polarized lines evident in Figure 2, so we have not yet succeeded in identifying the T_z lattice mode. Again by analogy with PE where calculations have placed the A_u mode below the B_{2u} mode, one would expect the T_z mode for PTFE to be below 45 cm^{-1} . It will however almost certainly be extremely weak, for it is only active in principle because of the slight helical distortion away from the planar zig zag. The perpendicularly polarized line at 34 cm^{-1} has previously¹ been assigned to the E_1 intersection of B_8 , and since this mode should give a perpendicularly polarized line, our present results confirm the assignment. We have as yet no clear explanation for the line at 86 cm^{-1} or for whichever of the 76 , 70 cm^{-1} pair is not the second perpendicular lattice mode. However the polarization evidence shown in Figures 1 and 2 provides further strong evidence in support of the two segment unit cell theory for the structure below 19°C .

Non-Newtonian viscosity and non-linear flow birefringence of cellulose tricarbaniolate

J. W. M. Noordermeer, R. Daryanani and H. Janeschitz-Kriegl

Laboratory of Physical Chemistry, Delft University of Technology, Delft 8, The Netherlands
(Received 30 June 1975; revised 21 August 1975)

The shear rate dependence of the intrinsic viscosity and of the intrinsic property, which can be derived from the extinction angle, was investigated for a sample of cellulose tricarbaniolate. Its number-average molecular weight was 4.4×10^5 ; the solvents used were dioxane at 25°C and phenyl benzoate at 75°C , the latter being known to break most intramolecular hydrogen bonds. The onset of non-Newtonian viscosity was found at a reduced shear rate of about 0.1, whereas non-linear behaviour in the extinction angle was noticed already at 0.02. The obtained data were compared with the theory by Noda and Hearst¹⁰, which deals with the influence of chain stiffness on the viscoelastic properties of polymer solutions. The qualitative outcome of this theory agrees fairly well with the experimental results. However, the onset of non-linear behaviour, especially in the extinction angle, occurs at lower values of the reduced shear rate than predicted. The stress-optical law remains surprisingly valid for this stiff polymer throughout almost the whole accessible range of reduced shear rates. However, some experiments with the highly viscous solvent tri-*o*-cresyl phosphate at 30°C show appreciable deviations at reduced shear rates larger than 1.0.

INTRODUCTION

At the present time the shear rate dependence of the hydrodynamic properties of macromolecules is the subject of intensive study, both theoretical and experimental. The theory for the non-Newtonian viscosity of solutions of rigid ellipsoidal particles is satisfactorily developed¹ and is reasonably well confirmed by experiments^{2,3}. On the other hand, for solutions of flexible linear macromolecules the theoretical and experimental situations are still rather obscure. In a previous work⁴ we described the linear viscosity and flow birefringence behaviour of cellulose tricarbaniolate. We showed that the chain stiffness of this polymer depends on the temperature and the type of solvent. In etheric solvents this polymer has a stiffer conformation than in an ester or ketone.

The purpose of this paper is to report upon the non-linear behaviour of the viscosity and flow birefringence of this cellulose tricarbaniolate. Because of the great chain stiffness of cellulose derivatives, these polymers usually have too low a degree of polymerization to behave in solution as Gaussian coils⁵. This results in a hydrodynamic behaviour, which may differ appreciably from that of flexible Gaussian polymers such as polyethylene, polystyrene etc. The possibility of influencing the chain stiffness, in the case of cellulose tricarbaniolate, by a particular choice of solvent provides us with an additional parameter in the study of non-linear effects.

The general theories on the dynamics of dilute solutions of flexible macromolecules do not account for non-linear effects^{6,7}. This is due essentially to the linear character of the models underlying these theories. The results of these theories with respect to the polymer contributions to the stress tensor of a flowing solution, may be conveniently summarized as follows:

$$\Delta p \cos 2\chi' = p_{11} - p_{22} = \theta q^2 \quad (1)$$

$$\Delta p \sin 2\chi' = 2p_{12} = 2(\eta - \eta_s)q \quad (2)$$

where $\Delta p = p_{11} - p_{22}$ is the difference of the two principal stresses in the plane of flow, χ' , the orientation angle of the polymer contribution to the stress tensor in the plane of flow (defined as the smallest angle between the direction of one of the principal stresses and the direction of the flow), $p_{11} - p_{22}$, the so-called primary normal stress difference (related to the shear rate q by the primary normal stress coefficient, θ), p_{12} , the contribution of the polymer molecules to the shear stress, η the viscosity of the solution and η_s the solvent viscosity.

According to these theories θ and η should be independent of shear rate. In particular, the intrinsic viscosity $[\eta]$, defined as:

$$[\eta] = \lim_{c \rightarrow 0} \frac{p_{12}}{q\eta_s c} = [\eta]_0 \quad (3)$$

is independent of shear rate. In equation (3) c is the concentration (g/ml) and the subscript 0 indicates the value of $[\eta]$ at zero shear rate. Further:

$$\cot 2\chi' = \frac{p_{11} - p_{22}}{2p_{12}} = \frac{\theta q}{2(\eta - \eta_s)} \quad (4)$$

should be a linear function of shear rate.

Equation (4) can be presented in another form:

$$\cot 2\chi' = J_{eR} \beta_N \quad (5)$$

where J_{eR} is reduced steady-state shear compliance⁸, for which numerical values for flexible coil molecules^{6,7} and stiff rods^{9,10} were given earlier⁴. The reduced shear rate β_N is defined as¹¹:

$$\beta_N = \frac{Mq(\eta - \eta_s)}{cRT} \quad (6)$$

Table 1 Data of the solvents

Solvent	Temp. (°C)	Density (g/cm ³)	Viscosity × 10 ² (P)	$\Delta n_s \times 10^7$ at $q = 10^4$ (sec ⁻¹)
1, 4-Dioxane	25	1.0283	1.193	-----
Phenyl benzoate	75	1.0893	2.699	1.137
Tri- <i>o</i> -cresyl phosphate	30	1.1523	60.208	10.1

where M is the molecular weight of the polymer, R the gas constant and T the absolute temperature. The subscript N is used to indicate that the Newtonian 'zero shear' viscosity of the solution must be inserted*.

From an experimental point of view, however, it is well known that the ratios p_{12}/q and $(p_{11} - p_{22})/q^2$ both decrease with increasing q , in some cases even by several orders of magnitude. The first of both non-linear effects is usually referred to as the non-Newtonian viscosity.

Various attempts have been made to give a theoretical description of these non-linear phenomena. The reasons, usually quoted as responsible for non-linear effects are¹²: (i) changes in the excluded volume of the chain when the chain becomes extended at high shear rates¹³; (ii) an anisotropy of the hydrodynamic interaction at high shear rates^{14,15} (this is not accounted for in most molecular theories because of the necessity to preaverage the hydrodynamic interaction in order to facilitate further calculations); (iii) deviations from a perfect flexibility of the chain due to constraints imposed on the mobility of chain elements by fixed bond lengths and bond angles^{10,16}.

For the comparison with experimental results we have chosen the theory by Noda and Hearst¹⁰, as this theory seems to predict the most pronounced deviations from linearity. Moreover, it uses the parameters which were determined earlier⁴.

From a fundamental point of view it should be noted that, insofar as the mentioned theories make use of modifications of the linearized diffusion equation, this diffusion equation itself only holds for small deviations from equilibrium¹⁷. From such a linearized diffusion equation only a linear viscoelastic behaviour may be derived, in principle. Applying this equation to large deviations from equilibrium, where non-linearity appears, would seem to be incompatible with the linearization procedures needed to obtain the diffusion equation itself¹⁸. It should be mentioned as well that this doubt also holds for the basis of the theories described in refs. 1 and 24.

In terms of the stress-optical law¹⁹ there exists a direct relation between the contributions of coiled macromolecules to the stress tensor and the the flow birefringence of a streaming solution. According to this law:

$$\chi' = \chi \quad (7)$$

and

$$\Delta n \sin 2\chi = 2Cq(\eta - \eta_s) \quad (8)$$

where χ is the extinction angle, Δn the birefringence, both measured at shear rate q , and C is the so called stress-optical coefficient. The validity of the stress-optical law

* In principle, one can interpret the quantity β (without subscript N) also as a reduced shear stress. In that case, however, one has to insert the non-Newtonian viscosity of the solution, as measured at shear rate q .

is not necessarily linked to all peculiarities of the linear theories describing the hydrodynamic properties of polymers. Therefore, the non-linearity in η can tentatively be taken into account in equation (8) by inserting the non-Newtonian solution viscosity η , as measured at the finite shear rate q at which also the birefringence is measured.

Theoretically the constancy of the stress-optical coefficient can be made acceptable for polymers with Gaussian distributions of their end-to-end distances¹⁹⁻²³. For rigid ellipsoidal particles the stress-optical coefficient was predicted to decrease in value with increasing shear rate²⁴. For non-Gaussian polymers, like the cellulose tricarbanilate sample under investigation in this paper, an intermediate behaviour may be found.

EXPERIMENTAL

For the present investigation a sample of cellulose tricarbanilate (CCIV) was used. Its number-average molecular weight (M_n) was 4.4×10^5 and its polydispersity index (M_w/M_n) was about 1.5.

As solvents 1, 4-dioxane, phenyl benzoate and tri-*o*-cresyl phosphate were used. Dioxane (UCB) was dried over $MgSO_4$ and distilled afterwards. Phenyl benzoate (Fluka AG) was recrystallized from ethanol and thoroughly dried in vacuum. Tri-*o*-cresyl phosphate (K & K Laboratories) was dried over $MgSO_4$ and distilled under vacuum. Colourless products were obtained.

Solutions in dioxane were prepared by weighing dried cellulose tricarbanilate and freshly prepared solvent. In dioxane the polymer dissolved within one day at room temperature. The solutions in phenyl benzoate and in tri-*o*-cresyl phosphate were prepared by gently shaking at 75°C over several hours in a nitrogen atmosphere.

Table 1 contains data of the pure solvents for the temperatures at which measurements were carried out. The pure solvents phenyl benzoate and tri-*o*-cresyl phosphate show a measurable flow birefringence by themselves. It means that flow birefringence measurements, made in these solvents, have to be corrected for the solvent contribution Δn_s to the total birefringence Δn of the solution. Appropriate correction formulae were given by Sadron²⁵. Values of Δn_s are given as measured at a shear rate $q = 10^4$ sec⁻¹. Since, for low molecular weight fluids the dependence of Δn_s on shear rate is always linear, Table 1 contains all the information needed for these corrections.

Newtonian viscosities at low shear rates were measured with the aid of ordinary Ubbelohde viscometers. Shear rate dependent viscosities at higher rates of shear were measured with the aid of a special capillary viscometer at the Central Laboratory TNO, Delft, described by Daum and Janeschitz-Kriegl²⁶. The flow birefringence measurements were carried out in the equipment previously described by Janeschitz-Kriegl and Nauta²⁷.

RESULTS

Figure 1 gives an example for the non-Newtonian viscosity of cellulose tricarbanilate solutions. In this Figure the contributions of the solute to the viscosity are represented for solutions in dioxane at 25°C. The concentrations of the solutions range from 0.3×10^{-2} to 0.8×10^{-2} g/ml. In this Figure also a number of measurements is given, carried out with Ubbelohde viscometers. The shear rates in the

Ubbelohde viscometers were estimated from the dimensions of the apparatus. All viscosities measured with these Ubbelohde viscometers are in fair agreement with the Newtonian viscosities at low shear rates.

Figures 2 and 3 show the reduced viscosities of cellulose tricarbaniolate in dioxane at 25°C and in phenyl benzoate at 75°C as functions of the reduced shear rate $\langle\beta_N\rangle_n$. In the latter quantity $\langle \rangle_n$ signifies that the number-average molecular weight $\langle M \rangle_n$ is inserted in equation (6) for β_N .

From both Figures it is evident that the decrease of the reduced viscosity with increasing $\langle\beta_N\rangle_n$ is more pronounced for higher concentrations. An extrapolation of the reduced viscosities to zero concentration can be made with a reasonable accuracy. There are discussions^{28,29} on whether the extrapolations should be carried out at constant shear rate or at constant shear stress. Considering that in almost all theoretical works non-linear effects are basically expressed in terms of the reduced shear rate β_N , we chose to make the extrapolations at constant $\langle\beta_N\rangle_n$. The results, the intrinsic viscosities as functions of $\langle\beta_N\rangle_n$, are given by broken lines.

If one plots the reduced viscosity against reduced 'shear stress' $\langle\beta_n\rangle$, where the latter quantity is defined in exactly the same manner as $\langle\beta_N\rangle_n$, equation (6), except that the non-Newtonian solution viscosity is inserted, one obtains more pronounced non-Newtonian effects. All curves in Figures 2 and 3 converge in a stronger way. In extrapolat-

ing at constant $\langle\beta_n\rangle$ the Huggins constant approaches zero with increasing $\langle\beta_n\rangle$, so that the reduced viscosity seems to become more and more independent of concentration. This agrees with the observations of Munk and Peterlin³⁰ on solutions of polystyrene in Aroclor 1248.

In both solvents the non-Newtonian effects become perceptible at $\langle\beta_N\rangle_n$ values of about 10^{-1} . Further, in none of the solvents sufficiently large values of $\langle\beta_N\rangle_n$ are attained to reach a new constant value of the intrinsic viscosity (second Newtonian region).

Figures 4 and 5 show the non-linear behaviour of the extinction angle for cellulose tricarbaniolate in both solvents. Data are plotted as $\cot 2\chi/\langle\beta_N\rangle_n$ against $\langle\beta_N\rangle_n$. While according to linear theories $\cot 2\chi/\beta_N$ should be independent of β_N (equations (4) and (7)), a strong decrease is observed with increasing $\langle\beta_N\rangle_n$. A linear region is hardly found. For the solutions in dioxane the value of $\cot 2\chi/\langle\beta_N\rangle_n$ seems to level off at $\langle\beta_N\rangle_n$ values around 2×10^{-2} . The larger scatter which is observed at the lowest $\langle\beta_N\rangle_n$ values is caused by the relative inaccuracy in measuring extinction angles close to 45°. For the solutions in phenyl benzoate the measurements could not be extended to low enough shear rates to approach the linear region.

Figure 3 Shear rate dependence of the reduced viscosity for solutions of cellulose tricarbaniolate in phenyl benzoate at 75°C. Symbols as in Figure 1. ---, curve extrapolated to zero concentration

Figure 4 Shear rate dependence of the extinction angle for solutions of cellulose tricarbaniolate in dioxane at 25°C. Data plotted as $\cot 2\chi/\langle\beta_N\rangle_n$ against $\langle\beta_N\rangle_n$. Symbols as in Figure 1. ---, curve extrapolated to zero concentration

Figure 5 Shear rate dependence of the extinction angle for solutions of cellulose tricarbanilate in phenyl benzoate at 75°C. Data plotted as $\cot 2\chi/(\beta_N)_n$ against $(\beta_N)_n$. Symbols as in Figure 1. —, curve extrapolated to zero concentration

In view of the observable concentration dependence of $\cot 2\chi/(\beta_N)_n$ an extrapolation to infinite dilution was carried out, again at constant $(\beta_N)_n$. The resulting curves are given by broken lines. As to the kind of solvent no influence on the general shape of the curves can be observed, except that the curve for cellulose tricarbanilate in phenyl benzoate is lying slightly lower than the one for cellulose tricarbanilate in dioxane.

As a last type of non-linear behaviour deviations from the stress-optical law may be considered. In Figure 6 data are shown, chosen out of a variety of experimental data gathered on this subject. The given results were obtained on solutions of cellulose tricarbanilate in dioxane at 25°C (0.8×10^{-2} g/ml), in phenyl benzoate at 75°C (0.8×10^{-2} g/ml) and in the highly viscous solvent tri-*o*-cresyl phosphate at 30°C (0.564×10^{-2} g/ml). All values of the stress-optical coefficient were calculated according to equation (8), using the non-Newtonian solution viscosities. In all three solvents the stress-optical coefficient appears to be nearly independent of shear rate up to a $(\beta_N)_n$ value of about 1.0. Only the viscosity of the solution in tri-*o*-cresyl phosphate was high enough to enable measurements at sufficiently high reduced shear rates, where a significant decrease of the value of the stress-optical coefficient could be observed.

DISCUSSION

The experimental results show the occurrence of strong non-linear effects for cellulose tricarbanilate. The viscosity shows the first deviations from linear behaviour at $(\beta_N)_n$ values of about 10^{-1} . The ratio of $\cot 2\chi$ to $(\beta_N)_n$ shows a non-linear behaviour even at lower values of $(\beta_N)_n$.

A number of polystyrene samples of narrow *MWD* investigated by Janeschitz-Kriegl³¹, showed a linear relationship between $\cot 2\chi$ and $(\beta_N)_n$ up to $\beta_N = 0.5$. Also Munk and Peterlin³⁰ found similar results for polystyrene in Aroclor 1248, both on the intrinsic viscosity and on the ratio of $\cot 2\chi$ to $(\beta_N)_n$. It means that for this cellulose tricarbanilate the onset of non-linear behaviour is shifted to lower values of $(\beta_N)_n$.

It is of interest to compare the present data with the results of the theory of Noda and Hearst¹⁰. For that purpose, in Figure 7 the intrinsic viscosity of cellulose tricarbanilate in both solvents, as obtained from Figures 2 and 3, is replotted

as $[\eta]_{rel} \equiv [\eta]/[\eta]_0$ against $(\beta_N)_n$. The curves according to Noda and Hearst correspond to chains with various degrees of chain stiffness and a dominant hydrodynamic interaction. The numbers λL at the curves are the measures of chain stiffness; they correspond to the ratio of the contour length L of the chain to the length of a statistical random link l/λ . With increasing chain stiffness (smaller λL) the Noda and Hearst theory predicts that the onset of non-Newtonian viscosity shifts along the logarithmic $(\beta_N)_n$ scale to lower values of $(\beta_N)_n$. From the investigation⁴, values of λL can be derived for our sample of cellulose tricarbanilate in the solvents under consideration: $\lambda L = 17$ in dioxane at 25°C and $\lambda L = 28$ in phenyl benzoate at 75°C. The difference between these two values of λL seems to show up correctly in Figure 7. However, this difference is perhaps too small for a discrimination of the points where the solutions start to show non-Newtonian behaviour. Values of λL which apply to flexible polystyrene samples, as those investigated by Janeschitz-Kriegl, Munk and Peterlin, are at least an order of magnitude larger than those for cellulose tricarbanilate. The much greater chain stiffness of the latter may explain the shift of the onset of non-Newtonian effects to lower values of $(\beta_N)_n$. However, according to observa-

tions on other polymers²⁹ the different slopes between the curves for dioxane and phenyl benzoate should be attributed to differences in solvent power. This implies that dioxane should be considered as a better solvent for cellulose tricarbaniolate than phenyl benzoate. This is noticeable, since phenyl benzoate breaks intramolecular hydrogen bonds⁴ in contrast to dioxane. The explanation may lie in the fact that cellulose tricarbaniolate has a hybrid nature with respect to solvents³⁶.

The theory predicts the total non-Newtonian behaviour of a polymer solution, i.e. the change from constant $[\eta]_0$ to a new constant $[\eta]_\infty$, to occur within about 3 decades of $\langle \beta_N \rangle_n$. This is found experimentally for solutions of monodisperse polymer samples^{3,32}. For the investigated sample of cellulose tricarbaniolate, the non-Newtonian viscosity range covers a broader region of shear rates: the whole transition seems to comprise at least 4 decades in $\langle \beta_N \rangle_n$. This broadening of the transition range is a well known polydispersity effect. The fact that the first deviations from Newtonian behaviour are observed at $\langle \beta_N \rangle_n$ values which are slightly smaller than those predicted by theory may therefore be due to the polydispersity of our sample.

The influence of the polydispersity on the behaviour of the extinction angle is appreciably more pronounced. Within the linear region (where $\cot 2\chi / \langle \beta_N \rangle_n$ is still independent of $\langle \beta_N \rangle_n$) the polydispersity raises $\cot 2\chi / \langle \beta_N \rangle_n$ to a value far outside the theoretical range for $J_e R$ ³³. Within the linear region the effect of polydispersity on the extinction angle can be calculated, if detailed information on the molecular weight distribution of the polymer and the molecular weight dependence of the intrinsic viscosity is available³⁴ and this was done previously⁴. Concerning the influence of polydispersity outside the linear region no detailed theoretical predictions are available yet.

Noda and Hearst have calculated the shear rate dependence of $[\cot 2\chi / \langle \beta_N \rangle_n]$ for monodisperse polymers with various degrees of chain stiffness. The large influence of polydispersity prohibits a quantitative comparison of the experimental data with their theory. On the other hand, a qualitative comparison can be tried by plotting $[\cot 2\chi / \langle \beta_N \rangle_n]_{\text{rel}} = [\cot 2\chi / \langle \beta_N \rangle_n] / [\cot 2\chi / \langle \beta_N \rangle_n]_0$ against $\langle \beta_N \rangle_n$. The subscript 0 refers to an extrapolation to zero shear rate. The infinite dilution curves in Figures 4 and 5 are replotted in this form in Figure 8. For the data obtained on cellulose tricarbaniolate in phenyl benzoate some arbitrariness is involved, because the value of $[\cot 2\chi / \langle \beta_N \rangle_n]_0$ had to be guessed. Besides these curves of experimental origin

Figure 8 also contains a theoretical curves for dominant hydrodynamic interaction and the same degrees of chain stiffness as in Figure 7. The shapes of the theoretical and experimental curves agree remarkably well. Furthermore, no difference in slope can be observed between the two experimental curves. This seems to indicate that polydispersity and solvent power do not influence the shape of the shear rate dependence of $[\cot 2\chi / \langle \beta_N \rangle_n]_{\text{rel}}$ to a large extent. However, the actual position of the experimental curves is shifted with respect to the theoretical curves by about one decade to lower values of $\langle \beta_N \rangle_n$.

The flexible polystyrene samples, mentioned before, start to behave non-linearly at $\langle \beta_N \rangle_n$ values of about 0.5, which is still small compared to what the Noda–Hearst theory predicts for the appropriate values of λL . It indicates that the Noda–Hearst theory underestimates the effect of non-linearity in the ratio $[\cot 2\chi / \langle \beta_N \rangle_n]$. Unfortunately, the other non-linear theories mentioned in the introduction, underestimate the non-linear effects even more.

As pointed out in Fig.8 of our previous paper⁴, the molecular weight of the sample under investigation is sufficiently high, so that any influences of polydispersity on the values of the stress–optical coefficient in Figure 6 can be neglected. By comparing the results in Figure 6 with those on the viscosity and the extinction angle, one observes quite clearly that the stress–optical law remains valid until far in the non-linear range of the former two. In this region cellulose tricarbaniolate still shows the same behaviour as Gaussian polymers, although the number of random links in dioxane, for example, amounts to only 17. At $\langle \beta_N \rangle_n$ values above 1.0, however, appreciable deviations from the stress–optical law are observed. For very flexible polymers many examples are known of a validity up to much higher values of $\langle \beta_N \rangle_n$ ^{30,33,35}. Therefore, the conclusion must be drawn that, although the stress–optical law still holds in a limited range of shear rates, it loses much of its general validity in the case of non-Gaussian polymers.

ACKNOWLEDGEMENTS

The authors wish to express their thanks to U. Daum at the Central Laboratory TNO, Delft, for giving the opportunity to measure non-Newtonian viscosities and to Professor W. Burchard, University of Freiburg, for many valuable discussions.

Influence of the molecular weight of poly(methyl methacrylate) on fracture surface energy in notched tension

R. P. Kusy and D. T. Turner

Dental Research Center, School of Dentistry, University of North Carolina at Chapel Hill, NC 27514, USA

(Received 11 August 1975)

Specimens of poly(methyl methacrylate) (PMMA) were prepared by the radiolysis of a polymer from an initial viscosity average molecular weight of $\bar{M}_v = 1.1 \times 10^6$ down to 1.5×10^4 . Corresponding values of fracture surface energy, ranging from 3.5×10^5 erg/cm² to 4.5×10^2 erg/cm², were calculated from tensile data using Griffith's equation. A theoretical dependence of fracture energy on molecular weight was derived on the assumption that only molecules exceeding a critical molecular weight can contribute to the work of plastic deformation. Comparison with experimental data indicates this molecular weight to be about 1×10^5 . Limitations of the theoretical treatment are discussed.

INTRODUCTION

The concepts of fracture surface energy (γ) and inherent flaw size have become more important as an understanding of their associated fracture mechanisms (e.g. crazing) has led to better materials. Starting with Griffith¹, investigators have tested many materials by different techniques, to compare experimental results with theory²⁻¹⁰. Today however, little experimental data exists describing the effect which molecular weight has on the fracture surface energy of glassy polymers (see Figure 1).

Berry¹¹, measured the fracture energy of PMMA for M in the range $(0.9-60) \times 10^5$. By an equation of the form $\gamma = A - BM^{-1}$, where A and B are arbitrary constants, he considered that γ should equal zero for $M = 2.5 \times 10^4$. He qualified this conclusion 'in view of the uncertain validity of that extrapolation', stating further that 'it would clearly be desirable to determine directly the fracture surface energy and other ultimate properties of samples with molecular weights extending down to the critical value'. In 1974, Kusy and Turner¹² carried out preliminary work in this direction, by the controlled radiation degradation of high molecular weight PMMA. While their results agreed with Berry's general statement that γ 'should become zero for a polymer of molecular weight 25 000', the functional dependence in the region of decreasing γ was not linear, but rather concave upward (see Figure 2 of ref 12). This trend was similar to data found, between the flexural strength and the reciprocal of number average molecular weight for PMMA at -196°C and ambient temperature, respectively^{13,14}. Moreover, work by Robertson¹⁵ on narrow molecular weight fractions of polystyrene, yielded a concave upward relationship for the molecular weight range below 10^5 . He also stated that, 'one deduces from this that the fracture energy vs. log (molecular weight) over the entire molecular weight range should be S-shaped with the maximum slope occurring around 10^5 '.

In general, information of this nature is hard to obtain because of inherent difficulties in preparing specimens of brittle, low molecular weight polymers. However, PMMA is an exception in that its molecular weight can be decreased in a controlled manner by exposure of specimens, conveniently machined at high molecular weight, to high

energy radiation. The objective of the present paper, is to make use of this property to document the dependence of fracture energy over a wide range of molecular weight.

EXPERIMENTAL

Material preparation

An unplasticized PMMA homopolymer, Plexiglas G (Rohm and Haas Co.), was cut at random into two sets of specimens: A, $12.7 \times 2.5 \times 0.32$ cm; B, $12.7 \times 3.2 \times 0.32$ cm. Slots were cut in the A specimens with a 0.015 cm thick circular saw, from 0.025 to 0.25 cm in depth, either before or after irradiation. Cracks were made in unirradiated B specimens using a method similar to that described by Berry¹⁶, in which a wedge was driven into a slot 0.7 cm deep. Subsequently, 0.7 cm was milled off to reduce the B specimens to the same dimensions as the A specimens. Residual stresses were relieved by heat treating at one of three equivalent time-temperature schemes: 5 h at 90°C , $10\frac{1}{2}$ h at 80°C , or 24 h at 70°C . A few specimens were not annealed for purposes of comparison.

Figure 2 Preparation of notched tensile bars: (a), machined and notched; (b), with PMMA flats bonded for direct gripping; (c), with PMMA lap joints bonded for indirect gripping. Hatched regions represent gripping areas while shaded zones are epoxy fillets

Irradiation

Specimens were exposed in air at an ambient temperature of 30°–40°C to gamma rays from either a ^{137}Cs or ^{60}Co source. Nominal dose rates were 0.90 and 2.1 Mrad/h, respectively. Irradiation resulted in the formation of gaseous products, which were removed by degassing over periods ranging up to six months. Degassing was considered to be complete when gas bubbles no longer formed when specimens were heated above the glass transition temperature, i.e. above 105°C¹⁷. As reported by Charlesby¹⁸, heating immediately after irradiation resulted in such extensive outgassing, that an expanded foam was formed. In order to evaluate any influence owing to trapped gas, some specimens were tested without degassing, shortly after irradiation.

Testing procedures

The flexural modulus, E , was calculated from the deflection, δ , produced by a force, P , in a three point bending test using equation (1), in which l , b , and d are the length, width, and thickness of the unnotched specimen, respectively¹⁹:

$$E = \frac{Pl^3}{4bd^3\delta} \quad (1)$$

The engineering stress at fracture, σ_f , was determined in tension using an Instron machine at a crosshead separation of 0.1 cm/min. Specimens given high doses were extremely brittle so that lap joints were bonded to the grip areas to prevent premature fracture (Figure 2).

Limiting viscosity numbers $[\eta]$ were determined in benzene at 25°C. Viscosity molecular weights, \bar{M}_v , were calculated from the Mark–Houwink equation (2) in which $K = 5.5 \times 10^{-5}$ dl/g and $\alpha = 0.76$ ²⁰:

$$[\eta] = K\bar{M}_v^\alpha \quad (2)$$

RESULTS AND DISCUSSION

Controlled degradation by radiolysis

The PMMA made as commercially cast sheets, is a linear polymer with a Schulz-type molecular weight distribution (equation 3):

$$W(r) = \left(\frac{k}{\bar{x}_n}\right)^{k+1} \left(\frac{r^k}{k!}\right) \exp\left(\frac{-kr}{\bar{x}_n}\right); 1 \leq k \leq 2 \quad (3)$$

in which $W(r)$ is the weight fraction of r -mers and \bar{x}_n is the number average degree of polymerization²¹. On exposure to high energy radiation, PMMA molecules are fractured at random at a rate of 1.7 fractures per 100 eV of absorbed energy, i.e. $G(\text{fractures}) \equiv G(F) \approx 1.7$ ²². This controlled degradation by radiolysis is both convenient and reproducible, since the fracture reaction is insensitive to wide variations in radiation source-type (X , γ or e^-), dose rates (0.1–100 Mrad/h), atmosphere (air or *in vacuo*), or ambient source temperature (20°–40°C)²³. Furthermore, the G -value remains relatively constant up to doses of at least 40 Mrad (1 Mrad = 6×10^{19} eV/g)²⁴. A dose of a few Mrad transforms the initial distribution to a ‘most probable distribution’, for which $k = 1$ ²⁵. In such cases the number average molecular weight, \bar{M}_n , can be calculated from the value prior to irradiation, $\bar{M}_{n,0}$, (equation 4) in which R is the dose in Mrad:

$$\frac{1}{\bar{M}_n} = \frac{1}{\bar{M}_{n,0}} + \left[\frac{R \times G(F)}{9.6}\right] \times 10^{-5} \quad (4)$$

In a first approach it would suffice to calculate molecular weights from equation (4), but in the present work reliance was placed on experimentally determined limiting viscosity numbers, $[\eta]$. This allows the calculation of a viscosity molecular weight, \bar{M}_v , (equation 2) and derivation of a number average, \bar{M}_n , from equation (5):

$$\bar{M}_v = \frac{\bar{M}_n}{k} \left[\frac{\Gamma(1+k+\alpha)}{\Gamma(1+k)}\right]^{1/\alpha} \quad (5)$$

i.e.

$$\bar{M}_v = 1.89\bar{M}_n \text{ for } k = 1 \quad (6a)$$

and

$$\bar{M}_v = 1.45\bar{M}_n \text{ for } k = 2 \quad (6b)$$

Equation (6a) was used since the ‘most probable distribution’ is generated by random fracture^{25,26}.

The above considerations are the result of the simple fracture of PMMA molecules by irradiation. In polymers, however, fracture is usually accompanied by crosslinking reactions. PMMA is unusual in that it is degraded ‘without appreciable crosslinking’. Definitive evidence has been reported by Shultz *et al.*²⁷ for doses up to 11 Mrad. In the present work it is assumed provisionally that it is valid to even higher doses.

Radiolysis of PMMA is also known to cause other chemical reactions which are normally considered to be of secondary importance because they do not influence molecular size. Nevertheless, attention should be given to factors which might influence the measurements of fracture energy.

Figure 3 Influence of crack length (c) on tensile strength (σ_f) as a function of molecular weight (\bar{M}_v): A, $\gamma = 2.4 \times 10^5$ erg/cm², $\bar{M}_v = 1\,120\,000$, ● degassed specimens; B, $\gamma = 4.7 \times 10^4$ erg/cm², $\bar{M}_v = 52\,600$, ▲ degassed, △ not degassed specimens; C, $\gamma = 1.3 \times 10^4$ erg/cm², $\bar{M}_v = 29\,200$, ■ degassed, □ not degassed; D, $\gamma = 3.4 \times 10^3$ erg/cm²; $\bar{M}_v = 15\,000$, ▼ degassed, ▽ not degassed

By far the most important of these reactions is the G -value of gas formation. This subject will be pursued in a subsequent section.

Estimation of fracture energy

Values for γ , can be calculated from Griffith's equation (7) (plane strain)¹ in which σ_f is the tensile stress at fracture, c , the crack length, E , Young's modulus, and ν , Poisson's ratio:

$$\sigma_f = \left[\frac{2E\gamma}{\pi c(1-\nu^2)} \right]^{1/2} \quad (7)$$

This expression may be used since the ratio of the crack length to specimen width (c/w) is small (<0.1), which minimizes the interaction of the strain energy field near the crack tip with the specimen edge²⁸. The functional dependence of σ_f on c has been demonstrated previously for high molecular weight PMMA¹⁶ and is now shown for low molecular weights (Figure 3). Theoretically, Griffith's equation is only applicable to brittle materials but its use has been extended to other materials, e.g. PMMA, which conform empirically but which, nevertheless, are known to undergo localized plastic deformation in the vicinity of the crack tip. In such cases Griffith's equation may be used but the physical significance of γ is a matter of conjecture. In the case of metals, Orowan³ and Irwin⁵ independently suggested that γ be regarded as the sum of an elastic and plastic component. In the present work, γ comprises a contribution from the energy expended in generating surfaces by cleavage, γ_1 , and in causing localized plastic deformation, γ_2 , i.e.

$$\gamma = \gamma_1 + \gamma_2 \quad (8)$$

Values of γ were calculated from the slopes of Figure 3 in which $\nu = 0.32$ and $E = 3.8 \times 10^{10}$ dyn/cm². The value of E was measured as a flexural modulus which was found to be independent of molecular weight (Figure 4). Sisman

and Bopp²⁹ found that Young's modulus was unaffected when specimens of PMMA were exposed to radiation from an atomic pile ($E = 3.2 \times 10^{10}$ dyn/cm²). Furthermore from a plot of $\log P/\delta$ vs. $\log l$ on irradiated double cantilever beams, the intercept and slope, both of which are related to the elastic properties of the material, were insensitive to molecular weight change¹⁴. These observations are in contrast to Berry's report that E increases from 2.30×10^{10} to 3.06×10^{10} dyn/cm² as \bar{M}_v increases from 0.98×10^5 to 3.0×10^6 ¹¹. The present data is preferred, because, in principle, there is no reason why E should be dependent on the molecular weight range studied.

A number of factors might influence estimates of fracture energy. First, it is known that gases are formed on irradiation of PMMA with initial G -values (up to a dose of 6.5 Mrad) as follows: $G(\text{CH}_4) = 0.55$; $G(\text{CO}) = 0.44$; $G(\text{CO}_2) = 0.32$; $G(\text{H}_2) = 0.21$ and $G(\text{HCO}_2\text{H}) = 0.09$ ³⁰. This would correspond to a total gas formation of ~ 3 cm³ (STP)/cm³ polymer/Mrad. From the foaming phenomenon associated with heating the irradiated polymer, it is apparent that some of this gas remains trapped immediately after irradiation. This does not result in the formation of any flaws detectable to the naked eye; e.g. there is no turbidity. However, since cavitation is an important phenomenon in crazing, which occurs immediately ahead of the crack tip, there is some possibility that gas might influence fracture energy. A comparison of specimens which were degassed with those tested immediately after irradiation, shows that gas formation is unimportant (Table 1). This suggests that, similar to experiments describing the yielding in metals, moderate hydrostatic stresses do not, in the first approximation, affect the failure criterion of PMMA^{31,32}.

The second factor, which Griffith found important in his study of silicate glasses, was the influence of initial stress on fracture energy. For PMMA no significant effect was detected throughout the range of molecular weights

Figure 4 Influence of molecular weight (\bar{M}_v) on modulus of elasticity (E) in transverse bending

Table 1 Dependence of fracture energy (γ) on residual gas

Nominal dose R (Mrad)	\bar{M}_v	γ (erg/cm ²)*	
		degassed	not degassed
0	1 120 000	$2.5 (\pm 18) \times 10^5$	
		$2.4 (\pm 15) \times 10^5$	
5	193 000	$1.7 (\pm 16) \times 10^5$	$1.6 (\pm 25) \times 10^5$
10	112 000	$1.7 (\pm 20) \times 10^5$	$1.6 (\pm 17) \times 10^5$
17	75 000	$1.4 (\pm 30) \times 10^5$	$9.7 (\pm 29) \times 10^4$
25	52 600	$4.9 (\pm 30) \times 10^4$	$4.5 (\pm 7) \times 10^4$

40	33 500	$1.7 (\pm 31) \times 10^4$	$1.8 (\pm 20) \times 10^4$
50	29 200	$1.1 (\pm 38) \times 10^4$	$1.4 (\pm 20) \times 10^4$
65	21 700	$6.1 (\pm 38) \times 10^3$	$5.3 (\pm 34) \times 10^3$
80	15 000	$2.3 (\pm 41) \times 10^3$	$4.5 (\pm 49) \times 10^3$

* Mean (\pm SD) of ten specimens which were tested with saw notches (pre-irradiation notched) after annealing ($\dot{R} = 0.90$ Mrad/h). SD expressed as % of mean.

Table 2 Dependence of fracture energy (γ) on residual stress

Dose R(Mrad)	\bar{M}_v	γ (erg/cm ²)*	
		annealed	unannealed
0	1 160 000	2.4 (± 20) $\times 10^5$ (35)**	1.9 (± 15) $\times 10^5$ (15)
30.9 (\dot{R} = 0.90 Mrad/ h)	37 100	6.6 (± 15) $\times 10^3$ (5)	6.8 (± 28) $\times 10^3$ (5)
30.9 (\dot{R} = 2.1 Mrad/ h)	28 900	6.3 (± 32) $\times 10^3$ (5)	4.2 (± 18) $\times 10^3$ (5)

* Mean (\pm SD) of indicated number of specimens (***) which were tested with saw notches (pre-irradiation notched) after degassing. SD expressed as % of mean.

Figure 5 Comparison of fracture energy (γ) versus molecular weight (\bar{M}_v): x, saw notches; •, natural notches formed by driving in wedge. Specimens were pre-irradiation notched and tested in annealed and degassed condition

studied (Table 2). While it might be argued that PMMA tested at room temperature is sufficiently close to its glass transition temperature to relieve the residual stresses introduced from specimen preparation, it is more plausible that the residual stress is relieved in the vicinity of the crack tip by the applied stress field during testing. Andrews and Kazama³³ have suggested in unplasticized PVC that, with increasing stress, localized yielding occurs as the glass transition is reduced to the test temperature. Similarly, stress-induced annealing could occur in the proximity of the initial notch long before unstable fracture initiated. It is worthwhile to note that the glass transition temperature (105°C) does decrease as a function of molecular weight^{26,34}.

A third factor of concern in measuring fracture energy is the influence of crack tip geometry. For high molecular weight specimens, similar results were obtained whether a crude slot was introduced directly with a saw or whether a crack-craze combination was created by driving in a wedge (Figure 5). Apparently the time consumed in the buildup of stress prior to fracture, is sufficient to result in some typical crack-craze combination, which makes the initial notch geometry immaterial. In contrast the surface energy of more brittle specimens, of lower molecular weight, in which modification of the crack tip by crazing is expected to be less important, are influenced by the sharpness of the crack tip (Figure 5). For studying the influence of molecu-

lar weight on fracture energy, crack formation by driving in a wedge is preferred.

In order to put the present results in perspective, a comparison of surface energy of PMMA with previous work is shown (Figure 6). Comparisons are only possible for high molecular weight specimens. In agreement with Marshall *et al.*²⁸, a scatter of some $\pm 15\%$ is observed for the original (0 Mrad) material (Table 1 and 2) compared with $\pm 9\%$ for parallel cleavage bars. Also for a given molecular weight, cleavage tests give lower values of γ than do notched tensile bars. This is consistent with energy *versus* crack velocity data (the test method was immaterial), in which the high crack velocities of notched tensile specimens yield greater values of γ than do the slower crack velocities done in cleavage. Present experiments do not account for large variations in crack velocity which might perturb the results with respect to variations in molecular weight. Experiments on irradiated parallel cleavage specimens are in progress to investigate this factor.

A theoretical relationship for the dependence of fracture energy on molecular weight

Berry noted from his data that a marked decrease in γ did not occur until $\bar{M}_v < 4 \times 10^5$ ¹¹. He suggested that only molecules long enough to pass through the craze region immediately ahead of the crack tip, could act as stress bearing members between the two adjacent uncrazed boundaries. In his words, 'The contribution which any particular molecule makes to the surface energy will be determined by the length that is contained within this region. A sufficiently long molecule will start in the unyielded region, pass through the yielded region, and terminate once again in the unyielded region. Under these conditions, the contribution made by the molecule to the surface energy will be independent of its length. Correspondingly this energy should tend to a limiting value at high molecular weights, ...'¹¹. Berry's views may be expressed in quantitative terms by making the additional assumption, that the molecules above

Figure 7 Influence of x and k on the theoretical relationship for fracture energy (γ). [Present experimental results, (●) are shown versus ———, $k = 1$; ———, $k = 2$]. A, $x = 2.5 \times 10^2$; B, $x = 1 \times 10^3$; C, $x = 5 \times 10^3$

a critical length contribute to the γ_2 term in proportion to their volume fraction. This procedure approximates to the 'rule of mixtures', a familiar empirical relationship. However, as a variation to this rule, it is physically more significant to assume that the γ_1 term is constant rather than proportional to the volume fraction of molecules below the critical length. In practice this variation is unimportant at higher average molecular weights since the γ_1 contribution is negligible.

On the assumption that only molecules with more than a critical number of monomer units (x) contribute to the work of plastic deformation, i.e. to the γ_2 term, and that γ_2 is equal to the product of the volume fraction of such molecules, v_2 , and a constant energy term, γ_c , equation 9 results:

$$\gamma = \gamma_1 + \gamma_2 = \gamma_1 + v_2 \gamma_c \quad (9)$$

For convenience equation (9) can be expressed in terms of the volume fraction of molecules with numbers of units (i.e. degree of polymerization) $\leq x$, v_1 , and by replacing volume fractions with corresponding weight fractions, i.e. w_1 for v_1 (equation 10). This last approximation is permissible as the density of PMMA is virtually independent of molecular weight.

$$\gamma \approx \gamma_1 + (1 - w_1) \gamma_c \quad (10)$$

The weight fraction of all molecules with up to x monomer units (equation 11) can be evaluated for the case of the 'most probable distribution' ($k = 1$) from the expression for $W(r)$ (see equation 3 and equation 12). Substitution of w_1 in equation (10) yields equation (13).

$$w_1 = \int_0^x W(r) dr \quad (11)$$

$$W(r) = \frac{r}{x_n^2} e^{-r/x_n} \quad (12)$$

$$\gamma \approx \gamma_1 + \gamma_c e^{-x/x_n} \left(1 + \frac{x}{x_n} \right) \quad (13)$$

Similar expressions can be evaluated for other molecular weight distributions, e.g. when $k = 2$ (see equation 3):

$$\gamma \approx \gamma_1 + \gamma_c e^{-\frac{2x}{x_n}} \left(1 + \frac{2x}{x_n} + \frac{2x^2}{x_n^2} \right) \quad (14)$$

Comparison of theory and experiment

The theory, as expressed by equation (13), agrees with experiment (Figure 6) by giving a sigmoidal dependence of γ on number average molecular weight, i.e. on $\bar{M}_n = x_n M_0$ or, equivalently, on $\bar{M}_v = 1.89 \bar{M}_n$ (M_0 is the molecular weight of the monomer unit, which equals 100 for PMMA). The limiting values for the sigmoid are as follows:

$$\lim_{x_n \rightarrow 0} \gamma = \gamma_1$$

$$\lim_{x_n \rightarrow \infty} \gamma = \gamma_1 + \gamma_c \approx \gamma_c, (\gamma_c \gg \gamma_1)$$

A theoretical value of $\gamma_1 = 450 \text{ erg/cm}^2$ has been calculated by Berry¹⁶ on the assumption that cleavage of a monolayer of covalent bonds occurs. The experimental value of $\gamma_1 = 450 \pm 250 \text{ erg/cm}^2$ is in agreement with this calculation, but the experimental data are too erratic to warrant further comment. No theoretical estimate is available for γ_c , although values fluctuate from $1.1\text{--}4.9 \times 10^5 \text{ erg/cm}^2$,^{15,16,28,35-37} the former considered to be the best at slow crack velocities²⁸, i.e. the isothermal state. However, a precise value is not a critical consideration at this stage and an empirical value was selected which best represented the present data (Figure 6), of $\gamma_c = 3.5 \times 10^5 \text{ erg/cm}^2$.

With values for γ_1 and γ_c determined, the dependence of γ on average molecular weight can be calculated from equation (13) for any selected critical degree of polymerization, x . Calculated curves for $x = 2.5 \times 10^2$, 1×10^3 , and 5×10^3 are shown in Figure 7, in which \bar{M}_v is expressed instead of \bar{M}_n to facilitate comparison with experimental data. In order to test the sensitivity of such plots to the extremes of molecular weight distribution, the foregoing procedure was applied for the case when $k = 2$ using equation (14). This factor is small in relation to changes caused by the selection of values of x . From the theoretical curves and experimental data in Figure 7, the critical value of x is near 1×10^3 , i.e. to a molecular weight of 1×10^5 .

A test of the theory would be to check whether the dependence of fracture energy on average molecular weight could be predicted for other distributions. A particularly challenging test would be to check whether or not, as theory would predict, a step function dependence of γ on molecular weight for monodisperse fractions (i.e. $\bar{M}_n = \bar{M}_v$) would result with $\gamma = \gamma_1$ for $M < 1 \times 10^5$ and $\gamma = \gamma_c$ for $M > 1 \times 10^5$. Information of this kind is not available for PMMA, but has been determined for approximately monodisperse specimens of polystyrene¹⁵. Robertson's data (Figure 1), point to an obvious inadequacy of the theory. The assumption that there is an unique boundary molecular chain length which determines an all or nothing contribution to the energy of plastic deformation, is an over simplification. In fact, the physical significance of this assumption is not entirely clear. According to Berry¹¹, a critical molecular chain length is required to bridge the craze layer immediately ahead of the crack tip (i.e. the 'crack opening displacement' in the Dugdale model). Direct observations on high molecular weight PMMA, however, indicate that this dimension is about $1 \times 10^4 \text{ \AA}$ ³⁸, whereas a fully extended molecule of molecular weight 10^5 is smaller by a factor of three. It would be more realistic to regard the craze as an extended network of polymer molecules held together by physical entanglements³⁹. Then the upturn in γ_1 at $\log \bar{M}_v \approx 4.3$ (Figure 7), could be interpreted as the molecular weight required for incipient net-

work formation due to entanglements. Bueche⁴⁰ has reported a range of values ($\log \bar{M}_v \approx 4.30-4.56$), for the molecular weight at which entanglements cause a sudden increase in bulk viscosity measurements of PMMA, plasticized with 75% diethyl phthalate (at 60°C). Naturally, the conditions are not strictly comparable since the craze is 'plasticized' not by solvent but by about 40% holes, 100 Å in diameter⁴¹. Despite the considerable attention given to entanglements with respect to viscosity measurements, no quantitative treatment for γ could be developed in these terms. For the moment then, the role which entanglements have must be limited to some form of negative skewing of the sigmoid.

CONCLUSIONS

(1) γ may be conveniently determined as a function of molecular weight by the radiolysis of PMMA.

(2) The Griffith theory is valid over the entire range of molecular weights studied from the straight line relationship of σ_f vs. $c^{-1/2}$.

(3) While the formation of gas and the presence of residual stresses have no significant effect on γ , notch geometry is critical with decreasing molecular weight ($\bar{M}_v \lesssim 10^5$).

(4) For notched tensile specimens varying from $\bar{M}_v = 1.5 \times 10^4 - 1.1 \times 10^6$, γ ranged from $4.5 \times 10^2 - 3.5 \times 10^5$.

(5) The dependence of γ on molecular weight was shown by partitioning γ into an elastic (γ_1) and plastic (γ_2) component and by assuming that only molecules greater than x , contribute to γ_2 . (a) Both theoretical and experimental data indicate that γ has a sigmoidal dependence on molecular weight. (b) Varying x greatly influences the sigmoid, while k has little effect. (c) The critical molecular chain length (x) corresponds to $\approx 1 \times 10^3$. (d) The crazed layer may be best described as a network of extended chains containing periodic entanglements. (e) The upturn of γ_1 at $\log \bar{M}_v \approx 4.3$ may be interpreted as the onset of entanglement networks.

ACKNOWLEDGEMENT

We are grateful to the Applied Radiation Division of NBS and the Physics Department at UNC for use of the ⁶⁰Co and ¹³⁷Cs facilities. We thank Mrs Beverly Lytwyn and Mr Gerald Thalken for assistance with the experimental work. This investigation was supported by NIH research grant number DE 02668 from the National Institute of Dental Research and by NIH grant number RR 05333 from the Division of Research Facilities and Resources.

Notes to the Editor

Optical anisotropy and orientation of structural units

P. Zoller

Kunststofflabor, Neu-Technikum Buchs, CH-9470 Buchs, Switzerland

(Received 11 July 1975; revised 21 August 1975)

A situation is considered, where the optical anisotropy of a polymer is caused exclusively by a non-random distribution of anisotropic structural units. A structural unit is thought to be some structure in the polymer which does not change its internal structure during orientation. Electrically it is characterized by the principal values α_{ii} ($i = 1, 2, 3$) of its polarizability tensor. The associated principal axes attached to the structural unit are designated by x'_i ($i = 1, 2, 3$). The optical anisotropy of the sample is specified by the three principal refractive indices n_i ($i = 1, 2, 3$) and the associated principal axes of the sample x_i ($i = 1, 2, 3$)¹.

The polarizability tensor b_{ij} of the sample, is diagonal ($b_{ij} = 0$, if $i \neq j$) when its components are referred to the x_i set of axes, and the diagonal components of b_{ij} can be related to the principal refractive indices in a good approximation by the Lorentz-Lorenz equations¹:

$$b_{ii} = \frac{3}{4\pi N} \times \frac{n_i^2 - 1}{n_i^2 + 2} \quad i = 1, 2, 3 \quad (1)$$

in which N is the number of structural units per unit volume. Therefore, $N = \delta N_0/M$, where δ is the density of the sample, N_0 is Avogadro's number ($6.02 \times 10^{-23} \text{ mol}^{-1}$) and M is the molecular weight of the structural unit.

Another way of expressing b_{ij} , is by transforming the polarizability tensor α_{ij} of each structural unit from the sets of axes x'_i , attached to the structural units, to the set of axes x_i , attached to the sample (in which its components are designated by α''_{ij}). Assuming additivity of the contributions from all structural units we obtain:

$$\begin{aligned} b_{11} &= \langle \alpha''_{11} \rangle = \langle t_{11}^2 \rangle \alpha_{11} + \langle t_{12}^2 \rangle \alpha_{22} + \langle t_{13}^2 \rangle \alpha_{33} \\ b_{22} &= \langle \alpha''_{22} \rangle = \langle t_{21}^2 \rangle \alpha_{11} + \langle t_{22}^2 \rangle \alpha_{22} + \langle t_{23}^2 \rangle \alpha_{33} \\ b_{33} &= \langle \alpha''_{33} \rangle = \langle t_{31}^2 \rangle \alpha_{11} + \langle t_{32}^2 \rangle \alpha_{22} + \langle t_{33}^2 \rangle \alpha_{33} \end{aligned} \quad (2)$$

The t_{nm} are the components of the transformation matrix between the x'_i and the x_i sets of axes:

$$\alpha''_{kl} = t_{k'l} \alpha_{ij} \quad k, l = 1, 2, 3 \quad (3)$$

and the brackets $\langle \rangle$ denote averaging over the distribution of structural units. Since the transformation is between sets of orthogonal coordinate systems the coefficients t_{nm} obey the orthonormality relations:

$$t_{im} t_{in} = \delta_{mn} = \begin{cases} 0 & \text{if } m \neq n \\ 1 & \text{if } m = n \end{cases} \quad (4)$$

From these equations the following relations can be deduced by taking averages:

$$\begin{aligned} \langle t_{11}^2 \rangle + \langle t_{12}^2 \rangle + \langle t_{13}^2 \rangle &= 1 & \langle t_{11}^2 \rangle + \langle t_{21}^2 \rangle + \langle t_{31}^2 \rangle &= 1 \\ \langle t_{21}^2 \rangle + \langle t_{22}^2 \rangle + \langle t_{23}^2 \rangle &= 1 & \langle t_{12}^2 \rangle + \langle t_{22}^2 \rangle + \langle t_{32}^2 \rangle &= 1 \\ \langle t_{31}^2 \rangle + \langle t_{32}^2 \rangle + \langle t_{33}^2 \rangle &= 1 & \langle t_{13}^2 \rangle + \langle t_{23}^2 \rangle + \langle t_{33}^2 \rangle &= 1 \end{aligned} \quad (5)$$

Note, that only five of these six equations are independent. Because of the orthonormality conditions, it is possible to express the t_{nm} through trigonometric functions of three angles (called the Euler angles, see e.g. Kashiwagi *et al.*²), such that the orthonormality relations are automatically met. We feel, however, that it is clearer to proceed with the usual meaning of the t_{nm} as direction cosines

$$t_{nm} = \cos(X_n, X'_m) \quad n, m = 1, 2, 3 \quad (6)$$

and keeping equations (5) as a set of auxiliary equations. Equations (2) and (5) form a set of nine linear, inhomogeneous equations for the quantities $\langle t_{nm}^2 \rangle$. Since only seven of the nine equations of the associated homogeneous system are linearly independent, the $\langle t_{nm}^2 \rangle$ can in general not be determined uniquely. Note also that the inhomogeneous system only has a solution if:

$$b_{11} + b_{22} + b_{33} = \alpha_{11} + \alpha_{22} + \alpha_{33} \quad (7)$$

We will proceed to investigate in a formal mathematical way, information about the $\langle t_{nm}^2 \rangle$ that can be obtained from equations (2) and (5). This will depend on the degree of optical symmetry that either the sample or the structural unit possesses. The following cases are possible:

The sample possesses orthorhombic optical symmetry

In this case, $b_{11} \neq b_{22} \neq b_{33} \neq b_{11}$ (or $n_1 \neq n_2 \neq n_3 \neq n_1$); this is the most general case for the optical anisotropy of the sample. The directions of the principal axes of the sample are completely determined.

The structural unit possesses orthorhombic optical symmetry

In this case, $\alpha_{11} \neq \alpha_{22} \neq \alpha_{33} \neq \alpha_{11}$; this is the most general case for the anisotropy of the polarizability of the structural unit. The directions of the principal axes of the polarizability tensor in the structural unit are completely determined.

Notes to the Editor

The sample is optically transversally isotropic

In this case, $b_{11} \neq b_{22} = b_{33} = b_T$ (or $n_1 \neq n_2 = n_3 = n_T$); the direction of only one principal axis in the sample is determined (x_1); the other two (x_2 and x_3) can be chosen at will, provided they form an orthogonal system of axes with x_1 .

The structural unit is transversally isotropic

In this case, $\alpha_{11} \neq \alpha_{22} = \alpha_{33} = \alpha_T$. The direction of only one principal axis of the polarizability tensor of the structural unit is determined (x'_1); the other two (x'_2 and x'_3) can be chosen at will, provided they form an orthogonal system of axes with x'_1 .

The sample is optically isotropic

In this case, $b_{11} = b_{22} = b_{33} = b$ (or $n_1 = n_2 = n_3 = n$). Any system of orthogonal axes in the sample is a system of principal axes.

The structural unit is isotropic

In this case, $\alpha_{11} = \alpha_{22} = \alpha_{33}$. Since an isotropic structural unit can only lead to an isotropic sample this case is pursued no further.

The solution derived below for different combinations of these cases could be written in somewhat different forms by making use of equation (7) to replace one of the three α_{ii} or one of the three b_{ii} , by the remaining α_{ii} and b_{ii} .

Transversally isotropic structural unit

The choice in the directions of x'_2 and x'_3 in each structural unit can clearly be used to make:

$$\langle t_{12}^2 \rangle = \langle t_{13}^2 \rangle, \langle t_{22}^2 \rangle = \langle t_{23}^2 \rangle, \langle t_{32}^2 \rangle = \langle t_{33}^2 \rangle \quad (8)$$

The only $\langle t_{nm}^2 \rangle$ with physical significance are the ones with the second index equal to one.

For a sample with orthorhombic optical symmetry we obtain from equations (2) and (5):

$$\begin{aligned} \langle t_{11}^2 \rangle &= \frac{b_{11} - \alpha_T}{\alpha_{11} - \alpha_T} \\ \langle t_{21}^2 \rangle &= \frac{b_{22} - \alpha_T}{\alpha_{11} - \alpha_T}, \quad \langle t_{31}^2 \rangle = \frac{b_{33} - \alpha_T}{\alpha_{11} - \alpha_T} \end{aligned} \quad (9)$$

If the sample is transversally isotropic the result is (for any choice of the x_2 and x_3 axes):

$$\begin{aligned} \langle t_{11}^2 \rangle &= \frac{b_{11} - \alpha_T}{\alpha_{11} - \alpha_T} \\ \langle t_{21}^2 \rangle = \langle t_{31}^2 \rangle &= \frac{b_T - \alpha_T}{\alpha_{11} - \alpha_T} \end{aligned} \quad (10)$$

If the sample is isotropic we immediately obtain:

$$\langle t_{11}^2 \rangle = \langle t_{21}^2 \rangle = \langle t_{31}^2 \rangle = 1/3 \quad (11)$$

for any choice of the x_1, x_2 and x_3 axes in the sample.

The cases of a transversally isotropic structural unit and either an orthorhombic or a transversally isotropic sample have been worked out by Kashiwagi *et al.*² using Euler angles to specify the orientation.

OPTICALLY ORTHORHOMBIC STRUCTURAL UNIT AND ORTHORHOMBIC OPTICAL SYMMETRY OF THE SAMPLE

The general solution for the $\langle t_{nm}^2 \rangle$ of our basic equations (2) and (5) contain two parameters λ_1 and λ_2 . One way of writing the solution is:

$$\begin{aligned} \langle t_{11}^2 \rangle &= \frac{\alpha_{22} - b_{11}}{\alpha_{22} - \alpha_{11}} + (\lambda_1 - \lambda_2) \frac{\alpha_{33} - \alpha_{22}}{\alpha_{22} - \alpha_{11}} \\ \langle t_{12}^2 \rangle &= \frac{b_{11} - \alpha_{11}}{\alpha_{22} - \alpha_{11}} - (\lambda_1 - \lambda_2) \frac{\alpha_{33} - \alpha_{11}}{\alpha_{22} - \alpha_{11}} \\ \langle t_{13}^2 \rangle &= \lambda_1 - \lambda_2 \\ \langle t_{21}^2 \rangle &= \frac{\alpha_{22} - b_{22}}{\alpha_{22} - \alpha_{11}} + \lambda_2 \frac{\alpha_{33} - \alpha_{22}}{\alpha_{22} - \alpha_{11}} \\ \langle t_{22}^2 \rangle &= \frac{b_{22} - \alpha_{11}}{\alpha_{22} - \alpha_{11}} - \lambda_2 \frac{\alpha_{33} - \alpha_{11}}{\alpha_{22} - \alpha_{11}} \\ \langle t_{23}^2 \rangle &= \lambda_2 \\ \langle t_{31}^2 \rangle &= \frac{\alpha_{33} - b_{33}}{\alpha_{22} - \alpha_{11}} - \lambda_1 \frac{\alpha_{33} - \alpha_{22}}{\alpha_{22} - \alpha_{11}} \\ \langle t_{32}^2 \rangle &= \frac{b_{33} - \alpha_{33}}{\alpha_{22} - \alpha_{11}} + \lambda_1 \frac{\alpha_{33} - \alpha_{11}}{\alpha_{22} - \alpha_{11}} \\ \langle t_{33}^2 \rangle &= 1 - \lambda_1 \end{aligned} \quad (12)$$

Any choice of the parameters λ_1 and λ_2 will give a solution to the system, and all possible solutions are obtained by varying λ_1 and λ_2 . However, only certain choices of λ_1 and λ_2 will give physically meaningful results, since, from the meaning of the $\langle t_{nm}^2 \rangle$ as averages of the squares of direction cosines, we must require:

$$0 \leq \langle t_{nm}^2 \rangle \leq 1 \quad n, m = 1, 2, 3 \quad (13)$$

This immediately puts the following conditions on λ_1 and λ_2 :

$$0 \leq \lambda_1 \leq 1, 0 \leq \lambda_2 \leq 1, \lambda_1 \geq \lambda_2 \quad (14)$$

In general the range of the allowed λ_1 and λ_2 , will be even more restricted by equation (13), but a certain finite range will remain for λ_1 and λ_2 and with it, through equations (12), a certain range for the $\langle t_{nm}^2 \rangle$. This calculation of the allowed ranges for the $\langle t_{nm}^2 \rangle$ is the maximum information which can be extracted from the optical anisotropy without additional assumptions. If this range is small for one or more of the $\langle t_{nm}^2 \rangle$ this knowledge constitutes valuable information.

An additional assumption which can be made to reach a complete solution, is that of random orientation of the x'_3 and x'_2 axes around the x'_1 axis in different structural units. Mathematically this implies:

$$\langle t_{12}^2 \rangle = \langle t_{13}^2 \rangle, \langle t_{22}^2 \rangle = \langle t_{23}^2 \rangle, \langle t_{32}^2 \rangle = \langle t_{33}^2 \rangle \quad (15)$$

These equations fix the values of λ_1 and λ_2 exactly, yielding the following solution for the $\langle t_{nm}^2 \rangle$:

$$\begin{aligned}
 \langle t_{11}^2 \rangle &= \frac{\alpha_{22} + \alpha_{33} - 2b_{11}}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}} \\
 \langle t_{12}^2 \rangle = \langle t_{13}^2 \rangle &= \frac{b_{11} - \alpha_{11}}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}} \\
 \langle t_{21}^2 \rangle &= \frac{\alpha_{22} + \alpha_{33} - 2b_{22}}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}} \\
 \langle t_{22}^2 \rangle = \langle t_{23}^2 \rangle &= \frac{b_{22} - \alpha_{11}}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}} \\
 \langle t_{31}^2 \rangle &= \frac{\alpha_{22} + \alpha_{33} - 2b_{33}}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}} \\
 \langle t_{32}^2 \rangle = \langle t_{33}^2 \rangle &= \frac{b_{33} - \alpha_{11}}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}}
 \end{aligned} \tag{16}$$

OPTICALLY ORTHORHOMBIC STRUCTURAL UNIT AND TRANSVERSALLY ISOTROPIC SAMPLE

For any choice of the x_2 and x_3 axes:

$$\langle t_{21}^2 \rangle = \langle t_{31}^2 \rangle, \langle t_{22}^2 \rangle = \langle t_{32}^2 \rangle, \langle t_{23}^2 \rangle = \langle t_{33}^2 \rangle \tag{17}$$

These equations put the additional condition $\lambda_1 + \lambda_2 = 1$ on our two parameters. Eliminating λ_2 yields:

$$\begin{aligned}
 \langle t_{11}^2 \rangle &= \frac{2\alpha_{22} - \alpha_{33} - b_{11}}{\alpha_{22} - \alpha_{11}} + 2\lambda_1 \frac{\alpha_{33} - \alpha_{22}}{\alpha_{22} - \alpha_{11}} \\
 \langle t_{12}^2 \rangle &= \frac{\alpha_{33} - 2\alpha_{22} + b_{11}}{\alpha_{22} - \alpha_{11}} - 2\lambda_1 \frac{\alpha_{33} - \alpha_{11}}{\alpha_{22} - \alpha_{11}} \\
 \langle t_{13}^2 \rangle &= 2\lambda_1 - 1 \\
 \langle t_{21}^2 \rangle = \langle t_{31}^2 \rangle &= \frac{\alpha_{33} - b_T}{\alpha_{22} - \alpha_{11}} - \lambda_1 \frac{\alpha_{33} - \alpha_{22}}{\alpha_{22} - \alpha_{11}} \\
 \langle t_{22}^2 \rangle = \langle t_{32}^2 \rangle &= \frac{b_T - \alpha_{33}}{\alpha_{22} - \alpha_{11}} + \lambda_1 \frac{\alpha_{33} - \alpha_{11}}{\alpha_{22} - \alpha_{11}} \\
 \langle t_{23}^2 \rangle = \langle t_{33}^2 \rangle &= 1 - \lambda_1
 \end{aligned} \tag{18}$$

Equation (13) again limits the range of λ_1 . From the third of equations (18) we get at once:

$$0.5 \leq \lambda_1 \leq 1 \tag{19}$$

but, as before, in general the range of λ_1 will be even more restricted. The resulting ranges in the $\langle t_{nm}^2 \rangle$ are again the maximum information obtainable from the optical anisotropy without further assumptions.

If we again make the assumption of random orientation of the x'_2 and x'_3 axes around the x'_1 axis, i.e. if we again require equations (15) to hold, we get the following unique solutions:

$$\begin{aligned}
 \langle t_{11}^2 \rangle &= \frac{\alpha_{22} + \alpha_{33} - 2b_{11}}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}} \\
 \langle t_{12}^2 \rangle = \langle t_{13}^2 \rangle &= \frac{b_{11} - \alpha_{11}}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}} \\
 \langle t_{21}^2 \rangle = \langle t_{31}^2 \rangle &= \frac{\alpha_{22} + \alpha_{33} - 2b_T}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}} \\
 \langle t_{22}^2 \rangle = \langle t_{32}^2 \rangle = \langle t_{23}^2 \rangle = \langle t_{33}^2 \rangle &= \frac{b_T - \alpha_{11}}{\alpha_{22} + \alpha_{33} - 2\alpha_{11}}
 \end{aligned} \tag{20}$$

OPTICALLY ORTHORHOMBIC STRUCTURAL UNIT AND ISOTROPIC SAMPLE

We obtain at once the result that all $\langle t_{nm}^2 \rangle$ are equal for any choice of the x_1, x_2 and x_3 axes, which means:

$$\langle t_{nm}^2 \rangle = 1/3 \quad n, m = 1, 2, 3 \tag{21}$$

Simple and direct assignment of the methylene and methine ^{13}C resonances in polystyrene

J. R. Ebdon and T. N. Huckerby

Department of Chemistry, University of Lancaster, Lancaster LA1 4YA, UK
(Received 29 September 1975)

There is considerable confusion in the recent literature concerning the assignment of ^{13}C resonances to the methylene and methine carbons in polystyrenes. In the original study¹ only the aromatic carbons were discussed, but in several subsequent papers it has been assumed that for the aliphatic signals the 'normal' order, i.e. $\delta\text{CH} > \delta\text{CH}_2$ was obeyed^{2,3}.

There is however, some indirect evidence⁴⁻⁶ not described in detail which would suggest that this intuitive assignment is incorrect. The importance of making a correct assignment is obvious, since past and future studies on homo- and co-polymers of styrene together with parallel work on α -methyl styrenes and similar compounds will all be affected.

Figure 1 illustrates 20 MHz proton noise decoupled carbon spectra, for 10% w/v solutions of atactic polystyrene and the corresponding β,β -dideutero derivative (with a degree of deuteration exceeding 95%). It is seen that the relatively sharp upfield signal remains almost unaffected in appearance upon deuteration apart from a small upfield isotope shift while the downfield resonance, which now bears C-D couplings and no longer benefits from the nuclear Overhauser effect, has almost disappeared. This therefore constitutes direct evidence for the assignment of the high field ($\delta \approx 40.5$ ppm) aliphatic resonance in polystyrene to the CH group. It would thus appear that although ring current effects due to aromatic groups are believed to be small and relatively unimportant in ^{13}C n.m.r.⁷, the suggestion⁶ that they may have considerable influence in this system does indeed seem to be justified.

Dependence of rate on monomer concentration in the radiation graft polymerization of styrene to polyethylene

Introduction

The radiation-initiated, free radical graft polymerization of styrene to polyethylene by the mutual irradiation technique has been extensively studied¹⁻⁶ but its kinetics have not been completely established, especially the dependence of grafting rate on monomer concentration. Various studies, although yielding interesting results, have been carried out in a manner precluding elucidation of the dependence of rate on monomer. Monomer concentration in a polyethylene sample has been varied in vapour phase grafting by suspending it in the vapour above a reservoir of liquid styrene for different time periods; subsequently, the polyethylene-styrene is irradiated while still suspended above liquid styrene. When polyethylene is placed directly in liquid styrene and the mixture irradiated, varying concentrations of monomer have been attained by diluting the styrene with a solvent such as methanol which does not itself swell polyethylene. The greater the relative amount of methanol employed, the greater the decrease in the concentration of styrene in the polyethylene. Using these approaches, Silverman and coworkers^{2,3} found the grafting rate increases initially with monomer concentration, reaches a maximum, and then decreases as monomer concentration increases further. The latter decrease has been attributed to a decrease in viscosity inside the polymer with increasing styrene concentration, resulting in an increased rate of termination relative to propagation. Similarly, Wilson⁴ found the grafting rate to increase in the order polyethylene > polypropylene > poly(4-methylpentene) while the styrene concentrations increased in the reverse order. We see here various experiments in which both monomer concentration and inside viscosity varied simultaneously, precluding elucidation of the dependence of rate on monomer.

Using styrene-benzene-alcohol mixtures, Wilson⁷ attempted to vary the monomer concentration while keeping viscosity constant by varying the alcohol used and its relative amount to obtain solutions having the same value of the Hildebrand solubility parameter. This promising approach was applied, however, by assuming the composition of styrene-benzene-alcohol absorbed inside a polyethylene sample ('inside' solution) to be the same as the composition of the solution in which the sample was placed ('outside' solution); further, that the amount of absorbed solution was independent of outside solution composition. Both assumptions are doubtful in view of previous work^{2,5} on the polyethylene-styrene-methanol system; in any case, experimental verification is needed. The most significant previous work is (for reasons which become clear below) probably that of Ballantine and coworkers⁸ who found the grafting rate to depend approximately on the 5/2-power of monomer concentration; the styrene concentration being varied by using styrene-benzene mixtures. In that study as in Wilson's, no attempt was made to determine the composition of the inside solution. This preliminary result, appearing without detailed experimental data and only as a brief paragraph in a Brookhaven

National Laboratory report, was overlooked for two decades by researchers who continued to assume¹⁻⁷ a first-power dependence of rate on monomer concentration. We report here the results of our study on the dependence of rate on monomer concentration for the polyethylene-styrene system.

Experimental and Results

Our experimental procedures were similar to those previously reported⁶. Styrene was washed with base followed by water, dried over sodium carbonate and magnesium sulphate and vacuum distilled; benzene was distilled at atmospheric pressure. Gulf Company 9614 polyethylene films (1 and 10 mil thick, both having density = 0.962 g/cm³; $\bar{M}_n = 19\ 000$, crystallinity of 79% as measured by density and d.s.c.) were washed with acetone and dried at 50°C under vacuum before use. To avoid problems associated with previous work on the dependence of rate on monomer concentration, it was necessary to choose the experimental system such that the inside styrene concentration could be varied without varying the inside viscosity. The use of benzene as a diluent for styrene was considered since benzene and styrene are very similar in solubility characteristics (the Hildebrand solubility parameters are 9.2 and 9.3 (cal/cm³)^{1/2}, respectively; the viscosity of benzene is 0.564 cP at 30°C, while that of styrene is 0.587 cP at 37.8°C)^{9,10}.

After equilibration with styrene or styrene-benzene mixtures at 25°C, 10 mil thick polyethylene samples were removed, blotted rapidly with absorbent paper to remove surface liquid and weighed to determine the amount of liquid absorbed by polyethylene. The extent of swelling of polyethylene by benzene-styrene was found to be 5.30% by wt independent of the benzene-styrene composition over the range 35-100 vol% styrene. (Although 1 mil films were used in the grafting experiments, the absorption studies were carried out with 10 mil films owing to the higher accuracy attainable with the thicker films. This did not introduce an error since both the 1 and 10 mil films have the same crystallinity and would have the same absorption characteristics; this was verified in a separate experiment.) To determine the composition of the inside solution, an equilibrated polyethylene sample was blotted, placed in a flask connected to a vacuum trap cooled by liquid nitrogen and the system evacuated to distill the inside solution into the cold trap. The composition of the inside solution, as determined by ultra-violet spectroscopy and refractive index measurements, was found to be exactly the same as the composition of the outside solution over the range of benzene-styrene compositions studied. Thus, the use of benzene-styrene mixtures allows one to vary the concentration of styrene inside the polyethylene while keeping constant the inside concentration of total liquid (benzene plus styrene). The inside viscosity is very close to being constant since the viscosity of benzene-styrene varies less than 10% over the range of compositions studied. An additional reason for choosing benzene as a diluent for styrene is that the *G* values for radical formation are similar for the two compounds¹¹. Thus, one expects the extent of homopolymerization relative to graft polymerization to be the same for

styrene–benzene mixtures as for styrene; further, the presence of benzene should not introduce appreciable energy transfer processes.

Graft polymerization was carried out as follows: 1 mil polyethylene samples were immersed in styrene or styrene–benzene in reaction tubes connected to a vacuum line, oxygen was removed by alternate freezing and thawing under vacuum, and the reaction tubes were sealed under vacuum. After equilibration at 25°C, the sealed reaction tubes were irradiated for specified periods at dose rates of 0.00076 and 0.037 Mrad/h using a J. L. Shepherd Mark I ¹³⁷Cs gamma source located in a room maintained at 23–25°C. The temperatures of the reaction mixtures rose slightly upon irradiation, usually to 26°C, as high as 27°C in a few instances. After irradiation, the polyethylene films were removed from the reaction tubes, washed with benzene followed by acetone, vacuum dried and weighed. The vacuum drying was carried out exhaustively (at 40–50°C at less than 1 mmHg pressure) until samples reached constant weight to ensure that all solvent and unreacted monomer was removed from the grafted polymer sample. The extent of graft polymerization in a sample was calculated as its percentage increase in weight. The results at the higher dose rate are shown in Figure 1; the course of the reaction at the lower dose rate was similar.

Initial rates were obtained by limiting grafting experiments to low conversions (10–15%) to avoid the auto-acceleration usually present in radical chain polymerization; high conversions would also involve significant changes in the nature of the polymer being grafted. The initial graft polymerization rates, determined by least-squares calculations, are shown in Table 1. Log–log plots of graft polymerization rate versus monomer concentration at the two dose rates are shown in Figure 2. Least squares calculations yielded slopes of 1.56 ± 0.04 and 2.61 ± 0.06 , at 0.00076 and 0.353 Mrad/h respectively.

In summary, we have established that the dependence of rate on monomer concentration for the radiation grafting of styrene to polyethylene is not first-order as previously assumed; the dependence is 3/2-order at the low dose rate and 5/2-order at the higher dose rate. Work is currently in progress in our laboratories to elucidate the mechanism(s) responsible for these effects, including a study of the rate dependence on monomer over a wider range of dose rates as well as the rate dependence on intensity. Further, since

our measured extents of grafting like those of other investigators probably include appreciable amounts of the homopolymer formed inside the polyethylene film⁶, an effort will be made to determine and separate the kinetics applicable to homopolymerization occurring inside the polymer from the kinetics of the graft polymerization process. The kinetics of the two processes are not necessarily the same; the results should help clarify the mechanism(s) applicable to our present results.

Solubilization of bovine elastin by a formic acid + salt method

The importance of elastin as a component of the connective tissue has directed a good deal of attention to its isolation. Procedures have, in the main, relied on its insolubility to chemical treatment. In an early and well known series of experiments, Hass *et al.*¹ have examined the isolation of elastin by use of formic acid to remove all other tissue components. This method is not now used since it can be shown that at least 60% of elastin can be solubilized in 88% HCOOH at 45°C if treatment is prolonged².

Of several methods for the partial degradation and solubilization of elastin, treatment by reflux in 0.25 M oxalic acid is the most widely used³. It has also been shown that elastin can be hydrolysed by use of a salt + alcohol mixture, the inorganic component acting as an accelerator⁴. Ioffe and Sorokin⁵ have also obtained a soluble elastin by reaction of isolated elastin with a solution of the mixed salts, CuSO₄ and Ba(OH)₂ at 37°C for 60 h. The rate of reaction was greatly reduced in the absence of the copper ion. The use of salts in aiding the hydrolytic cleavage of elastin is of interest especially in its relationship to the study of atherosclerosis. Elastin has a high affinity for calcium ions⁶ and Hall⁷ has found that calcium which is bound to the elastin matrix can act both as a crosslinking agent and as an activator of elastolysis.

Earland and Raven⁸ have examined the use of salt + formic acid mixtures for the solubilization of silk. They were able to obtain a partial solubilization with a range of formic acid + salt combinations. Since both silk and elastin have some similarity with high glycine and alanine amino acid compositions and also show a high degree of swelling in formic acid this method was considered as worth trying for elastin. Preliminary experiments, choosing salt combinations with formic acid from the list given by Earland and Raven⁸, showed that for all combinations tested (about 15), complete solubilization of bovine elastin could be achieved.

A short report is given of the results of a more detailed investigation of the use of 0.25 M solutions of CaCl₂, MgCl₂ and (NH₄)₂SO₄ in 98% HCOOH and an examination of some properties of the corresponding elastin solutions.

Part of the isolated bovine elastin which was used as the starting material was also solubilized by the oxalic acid method³ and provided a basis for comparison.

The isolation of elastin from bovine ligament followed the usual procedure² material for this study (E10) being obtained from a 1.5 year old animal. Details of the solubilization procedures are given in *Table 1*. Amino acid analyses of the soluble elastins showed no significant differences between the preparations and a satisfactory agreement was obtained with published data for bovine elastin³. The soluble elastins have been characterized by measurement of the coacervation temperature, t_c ³ and the limiting viscosity number, $[\eta]$ determined in buffer solutions of different pH but constant ionic strength¹⁰. (Full experimental details can be supplied if requested.)

It has been found that soluble elastins can be prepared using the Earland and Raven⁸ formic acid method in a similar yield but with fewer stages of reflux than the oxalic acid procedure³. Details of the preparations and a summary of the properties of the soluble elastin solutions are given in *Table 1*. The oxalic acid preparation, used as a reference, is designated E10.PDA. Gel electrophoresis measurements¹¹ showed that all the formic acid preparations contained an appreciable proportion of high molecular weight material. Coacervation was observed in all solutions of the elastins. A significant dependence of t_c ($\pm 0.2^\circ\text{C}$) on protein concentration was observed. The agreement between results for the reference preparation and those of Partridge *et al.*³ is quite close.

Although amino acid determinations made on these preparations reveals no significant differences physical measurements show them to be not identical. There are differences between the protein concentration-independent values of t_c , as shown in *Figure 1*, and in the viscometric results shown in *Figure 2*. The values of $[\eta]$ for α and β elastin (separated by coacervation) as obtained by Ksiezny *et al.*¹⁰ for oxalic acid solubilized bovine elastin are indicated in *Figure 2* by the broken lines.

Results for E10.PDA, for which the α and β components have not been separated, conform with those of Ksiezny *et al.*¹⁰ (α -elastin being the major component) and show a minimum value of $[\eta]$ in the range pH 4 to 6. With the exception of preparation E10.NH₄ a similar pH dependence is shown by the formic acid solubilized elastins. However, values of $[\eta]$ for E10.Mg and E10.Ca are significantly reduced and for the most part they are lower than the corresponding values for β -elastin.

As reported, these solutions show coacervation and con-

Table 1 Details of the preparation and properties of the solubilized elastins

Code	Reagent system	Stages of reflux	Liquid/solid ratio	Yield (% w/w)	$[\eta]$ * (ml/g)	t_c † (°C)

Solubilization of bovine elastin by a formic acid + salt method

The importance of elastin as a component of the connective tissue has directed a good deal of attention to its isolation. Procedures have, in the main, relied on its insolubility to chemical treatment. In an early and well known series of experiments, Hass *et al.*¹ have examined the isolation of elastin by use of formic acid to remove all other tissue components. This method is not now used since it can be shown that at least 60% of elastin can be solubilized in 88% HCOOH at 45°C if treatment is prolonged².

Of several methods for the partial degradation and solubilization of elastin, treatment by reflux in 0.25 M oxalic acid is the most widely used³. It has also been shown that elastin can be hydrolysed by use of a salt + alcohol mixture, the inorganic component acting as an accelerator⁴. Ioffe and Sorokin⁵ have also obtained a soluble elastin by reaction of isolated elastin with a solution of the mixed salts, CuSO₄ and Ba(OH)₂ at 37°C for 60 h. The rate of reaction was greatly reduced in the absence of the copper ion. The use of salts in aiding the hydrolytic cleavage of elastin is of interest especially in its relationship to the study of atherosclerosis. Elastin has a high affinity for calcium ions⁶ and Hall⁷ has found that calcium which is bound to the elastin matrix can act both as a crosslinking agent and as an activator of elastolysis.

Earland and Raven⁸ have examined the use of salt + formic acid mixtures for the solubilization of silk. They were able to obtain a partial solubilization with a range of formic acid + salt combinations. Since both silk and elastin have some similarity with high glycine and alanine amino acid compositions and also show a high degree of swelling in formic acid this method was considered as worth trying for elastin. Preliminary experiments, choosing salt combinations with formic acid from the list given by Earland and Raven⁸, showed that for all combinations tested (about 15), complete solubilization of bovine elastin could be achieved.

A short report is given of the results of a more detailed investigation of the use of 0.25 M solutions of CaCl₂, MgCl₂ and (NH₄)₂SO₄ in 98% HCOOH and an examination of some properties of the corresponding elastin solutions.

Part of the isolated bovine elastin which was used as the starting material was also solubilized by the oxalic acid method³ and provided a basis for comparison.

The isolation of elastin from bovine ligament followed the usual procedure² material for this study (E10) being obtained from a 1.5 year old animal. Details of the solubilization procedures are given in *Table 1*. Amino acid analyses of the soluble elastins showed no significant differences between the preparations and a satisfactory agreement was obtained with published data for bovine elastin³. The soluble elastins have been characterized by measurement of the coacervation temperature, t_c ³ and the limiting viscosity number, $[\eta]$ determined in buffer solutions of different pH but constant ionic strength¹⁰. (Full experimental details can be supplied if requested.)

It has been found that soluble elastins can be prepared using the Earland and Raven⁸ formic acid method in a similar yield but with fewer stages of reflux than the oxalic acid procedure³. Details of the preparations and a summary of the properties of the soluble elastin solutions are given in *Table 1*. The oxalic acid preparation, used as a reference, is designated E10.PDA. Gel electrophoresis measurements¹¹ showed that all the formic acid preparations contained an appreciable proportion of high molecular weight material. Coacervation was observed in all solutions of the elastins. A significant dependence of t_c ($\pm 0.2^\circ\text{C}$) on protein concentration was observed. The agreement between results for the reference preparation and those of Partridge *et al.*³ is quite close.

Although amino acid determinations made on these preparations reveals no significant differences physical measurements show them to be not identical. There are differences between the protein concentration-independent values of t_c , as shown in *Figure 1*, and in the viscometric results shown in *Figure 2*. The values of $[\eta]$ for α and β elastin (separated by coacervation) as obtained by Ksiezny *et al.*¹⁰ for oxalic acid solubilized bovine elastin are indicated in *Figure 2* by the broken lines.

Results for E10.PDA, for which the α and β components have not been separated, conform with those of Ksiezny *et al.*¹⁰ (α -elastin being the major component) and show a minimum value of $[\eta]$ in the range pH 4 to 6. With the exception of preparation E10.NH₄ a similar pH dependence is shown by the formic acid solubilized elastins. However, values of $[\eta]$ for E10.Mg and E10.Ca are significantly reduced and for the most part they are lower than the corresponding values for β -elastin.

As reported, these solutions show coacervation and con-

tain appreciable amounts of high molecular weight material whereas β -elastin is non-coacervating and of low molecular weight (about 3000). Thus measurement of $[\eta]$ for elastin solutions cannot serve as an unambiguous guide to molecular size and, without more evidence, cannot be used to characterize the fractionation of soluble elastins¹². Differences in $[\eta]$ and t_c may well indicate conformational variation by the elastin molecule in solution. Further clarification of the mechanism of coacervation by the solubilized elastin molecules is necessary before determination of t_c also can provide a method of characterization³.

However, the main objective of this study was to try the Earland and Raven⁸ formic acid method with elastin and this has been achieved beyond expectations. The oxalic acid method, although widely used, has no possibility for variation whereas the success of the formic acid solubilization procedure now makes it possible to consider detailed study of the mechanism of interaction between inorganic ions and the elastin matrix⁷ through examination of the properties of the solubilized products.

Conference Announcement

Deformation, Yield and Fracture of Polymers

Cambridge, UK, 29 March to 1 April, 1976

The third international conference on Deformation, yield and fracture of polymers will be held at Churchill College, Cambridge from 29 March to 1 April 1976 and is being organized by the Plastics and Rubber Institute on behalf of a number of collaborating bodies. A programme of thirty two contributions has been arranged under the following sessions: creep and yielding, fracture, crazing, rubbers and selected topics, crystal deformation, and a general session on selected topics. Further details and application forms may be obtained from Mr J. N. Ratcliffe, Plastics and Rubber Institute, 11 Hobart Place, London SW1W 0HL, UK.

Book Reviews

IUPAC International Symposium on Macromolecules

Edited by E. B. Mano

Elsevier, Amsterdam, 1975. 463 pp. \$46.25

In July 1974 a symposium on polymer science and technology was organized by the Brazilian authorities in collaboration with IUPAC, the programme dealing with polymerization processes, physical chemistry, polymer technology and, to meet a wider range of interests, with biopolymers. Abstracts of the contributed papers were available at the meeting and doubtless there will be fuller publication in due course, but in keeping with the practice at many IUPAC symposia main lectures on special aspects were presented by invited speakers and the present volume contains the text of these.

In his opening address Sir Harry Melville reviewed some current trends in polymer science, drawing attention to a number of areas meriting continued study: precise control of molecular weight, tacticity and unit sequence, network systems, surface properties, dimensional stability, superconductivity, degradation, and liquid rubbers. It is perhaps unfortunate that the book does not contain also the closing plenary lecture, 'Polymers worldwide', given by Professor Herman Mark.

The papers on polymer chemistry are on inclusion polymerization with special reference to the use of perhydrotriphenylene as the host compound (Farina) and on photopolymerization and photoresponsive polymers (Smets); cyclopolymerization is discussed by Butler, Porri reviews developments in polymerizing conjugated dienes using new uranium-based catalysts, and Stille outlines the synthesis of rigid polyphenylphenylenes and polyanthrazolines. In the physical chemistry section are papers by Meares on transport phenomena and their relevance to membrane separation and by Szwarc reviewing anionic polymerization and applications of living polymer processes. Infra-red spectroscopy is applied to a study of crystalline polyethylene (Krimm) and high-resolution ^{13}C n.m.r. for investigation of stereochemical configurations in vinyl polymers (Bovey), while Guillet discusses the role of molecular mobility in photochemical processes.

Polymer technology has seven papers which include a review of polyethylenes and the provision of polymers of improved fabrication performance (Foster), segment deformation in glassy polymers (Yannas) and new thermally stable aromatic or heterocyclic copolycondensates (Fontan), which paper regrettably gives no references. Okamura reviews his work on the production of synthetic fibres from modified PVC dispersions, and Morton outlines advances made with synthetic elastomers, especially the *trans*-polypentenamer, thermoelastic block copolymers and liquid rubbers. Work on the effects of fine structure on the pyrolysis behaviour of cellulosic materials is discussed by Lewin, and Ranby has a paper on teaching technology in Sweden.

The seven papers in the final section on biopolymers deal with receptor proteins for neuroactive drugs (Robertis), adenovirus proteins (Pereira), and controlled synthesis in enzyme studies (Merrifield). Synthesis in bacterial genes is described by Khorana and the use of ^{13}C n.m.r. in a study of mucopolysaccharides by Perlin. Polymeric carriers and immobilization of enzymes is the subject of a paper by Manecke, and Dawes discusses the function of poly(β -hydroxybutyrate) in micro-organisms.

In all, these collected papers provide a good picture of developments in polymer science, showing particularly the many fields of activity and methods of scientific approach. From these invited lectures one is able to appreciate the depth of the studies in progress as well as the ultimate use of the findings in practical terms, whether this be in plastics, fibre or rubber technology, the medical world, or other fields of endeavour.

While the book is handsomely bound and produced, the text itself consists of the photo-reduced typescripts as received from the various authors and editing has been minimal. This perhaps contributes to the originality of the contributions but it is a little disconcerting to encounter different sets of type-face throughout the book, a lack of explanation to a few of the diagrams and abbreviations, and to have no index. However, such direct use of the authors' scripts has enabled the book to be produced without delay, and in a rapidly developing field like that of macromolecules

this is a decided advantage which will outweigh the minor faults noted above.

At the price quoted the volume may prove expensive for purchase by an individual but the many papers give it considerable merit and it could with some benefit be used by those who wish to have brief but authoritative reviews on particular aspects or more generally to read of developments outside their areas of immediate interest.

R. J. W. Reynolds

Advances in polymer science, Volume 15 Springer Verlag, Berlin, 1975, 155 pp. \$27.80

The book contains four review articles, Oligomerisation of ethylene with soluble transition-metal catalysts by G. H. Olivé and S. Olivé. Stereochemistry of propylene polymerisation by A. Zambelli and C. Tosi, Structures of copolymers of high olefins by Y. V. Kissin and Mercaption-containing polymers by C. D. S. Lee and W. H. Daly. All four articles are reasonably well written and present an interesting account of the subject described.

The article of Olivé and Olivé discusses Ziegler-based systems (transition metal compounds plus aluminium alkyl compounds) as catalysts for the oligomerization of ethylene. It is a useful collection of facts but lacks clarity and conviction when talking about the mechanism of the processes concerned. The basic difficulty in trying to disentangle the mechanism of Ziegler catalysts is that there are too many possible structural options for the reactive centre in any given system. This produces reviews which are catalogues of data with little unambiguous evidence as to what exactly is going on. In this review it is implied that although there may exist monometallic catalysts which can oligomerize ethylene they are in general lacking in activity and require a cocatalyst, aluminium alkyls, to give effective systems. This is, of course, not completely correct as it is known that the system $\text{Br}_3\text{ZrC}_3\text{H}_5$ (*Adv. Catalysis* 1973, 23, 263) oligomerize ethylene to give 60–100 residues per α -olefin chain at very high rates indeed.

The kinetic analysis of these reactions does not take account of the fact that in many of these systems large amounts of 1-butene is formed and the postulate of a six-centre transition state seems unnecessary to account for the β -hydrogen abstraction process. The industrial side of ethylene oligomerization is also poorly dealt with. Most industrial processes do not use this type of chemistry, wax cracking has until recently been the preferred process but in new plants this is being replaced by 'ethylene growth' using aluminium alkyl chemistry.

The stereochemistry of propylene polymerization is a well written description of the ideas of Professor Zambelli and his colleagues in which they attempt to use the four centre transition state to explain the chemistry of Ziegler-Natta catalysts and their ability to control the stereochemistry of the insertion process. The mechanism they describe may well have some relation to real behaviour in polymerizations initiated by transition metal alkyls since the latter are essentially monometallic catalysts. However, Ziegler-Natta systems are almost certainly bimetallic and the choice of aluminium alkyl as cocatalyst can have a profound effect on the ability of the centre to stereoregulate.

The final contribution on polyolefins is a paper by the Russian scientist Y. V. Kissin on the structure of copolymers of the higher olefins. This is a very interesting review and collects together information on 1:1 copolymers of the common olefins, with some data on their fine structure derived mainly from infra-red studies. In view of the known difficulties of making many of these copolymers it is surprising that such a wide variety of types are now available for study. The work of Dr Turner-Jones on the 4-methyl pentene-1 copolymers is treated in detail and serves to illustrate, for all crystalline polyolefins, the effect of copolymerization on crystallinity, melting points, and infra-red spectra. The observations divide themselves into three principal groups: copolymers in which the comonomer side chain is rejected by the host crystal lattice, in these cases quite small amounts of comonomer reduce the crystallinity drastically; copolymers such as 4-methyl pentene-1/hexene-1 for example where the comonomer side chains can crystallize with the host lattice and crystallinity persists over the whole range of compositions; the least known system and probably the most useful are

those in which the comonomer is incorporated as a series of blocks so that the microstructure is made up of discrete phases. It has been observed with the latter systems that unusual mechanical properties are obtained. It would have been helpful if some information of this kind could have been given, but mechanical behaviour is not discussed.

In conclusion the book will be of interest to polymer chemists in general and particularly those interested in polyolefins.

D. G. H. Ballard

Ionic polymers

Edited by L. Holliday

Applied Science, London, 1975, 416 pp, £14

The most familiar examples of ionic polymers, the so-called 'ionomers', have enjoyed considerable commercial success over the past few years, a factor which has undoubtedly assisted in generating enthusiasm in this area. Present trends in research, as reflected in this book, are directed towards a wider understanding of both the essentially organic and inorganic ion-containing materials. An initial step in this development is the recognition of materials such as inorganic oxide glasses, metal dicarboxylates and crystalline silicate and phosphate minerals as polymers. A useful exchange of the concepts and the considerable body of knowledge available within these hitherto discrete areas of study with the field of organic polymers may then follow. As the introductory chapter of the book intimates, in only one or two topics of study, such as the glass transition temperature, have unifying semi-empirical relationships and correlations been established. Much progress has yet to be made to consolidate a cohesive study of ionic polymers on such a broad base as it is presented here.

Following the introductory chapter, in which classifications and general properties of ionic polymers are presented in a clear and logical way, there are seven further chapters each dealing with different types of ionic material. These chapters have different authors and each chapter emphasizes a different aspect of its subject. The chapters concerned with ionomers, carboxylated elastomers and crystalline silicates and phosphates are thorough and systematic reviews of the extensive literature on these materials

whereas the chapter on rigid, highly carboxylated ionic polymers is, for the greater part, an authoritative account of recently developed dental cements. However, the conformational changes and ion-binding phenomena which are referred to in the opening section of this account apply to dilute solutions and are inappropriate when discussed in the context of the concentrated systems encountered in these cements. There are two shorter chapters on metal dicarboxylates and the technology of polyelectrolyte complexes and the final chapter by N. H. Ray describes an essentially novel approach to the structure of inorganic glasses.

Taken as a whole the book is somewhat heterogeneous, but as a first step it represents a welcome development and the individual contributions are very useful in themselves. The book will be of interest to research workers and could provide some novel ideas on presentation of course work for teachers in materials departments. The book is well presented but its price will probably restrict it to appropriate departmental libraries for which it will be a good investment.

The final contribution on polyolefins is a paper by the Russian scientist Y. V. Kissin on the structure of copolymers of the higher olefins. This is a very interesting review and collects together information on 1:1 copolymers of the common olefins, with some data on their fine structure derived mainly from infra-red studies. In view of the known difficulties of making many of these copolymers it is surprising that such a wide variety of types are now available for study. The work of Dr Turner-Jones on the 4-methyl pentene-1 copolymers is treated in detail and serves to illustrate, for all crystalline polyolefins, the effect of copolymerization on crystallinity, melting points, and infra-red spectra. The observations divide themselves into three principal groups: copolymers in which the comonomer side chain is rejected by the host crystal lattice, in these cases quite small amounts of comonomer reduce the crystallinity drastically; copolymers such as 4-methyl pentene-1/hexene-1 for example where the comonomer side chains can crystallize with the host lattice and crystallinity persists over the whole range of compositions; the least known system and probably the most useful are

those in which the comonomer is incorporated as a series of blocks so that the microstructure is made up of discrete phases. It has been observed with the latter systems that unusual mechanical properties are obtained. It would have been helpful if some information of this kind could have been given, but mechanical behaviour is not discussed.

In conclusion the book will be of interest to polymer chemists in general and particularly those interested in polyolefins.

Ionic polymers

Edited by L. Holliday

Applied Science, London, 1975, 416 pp, £14

The most familiar examples of ionic polymers, the so-called 'ionomers', have enjoyed considerable commercial success over the past few years, a factor which has undoubtedly assisted in generating enthusiasm in this area. Present trends in research, as reflected in this book, are directed towards a wider understanding of both the essentially organic and inorganic ion-containing materials. An initial step in this development is the recognition of materials such as inorganic oxide glasses, metal dicarboxylates and crystalline silicate and phosphate minerals as polymers. A useful exchange of the concepts and the considerable body of knowledge available within these hitherto discrete areas of study with the field of organic polymers may then follow. As the introductory chapter of the book intimates, in only one or two topics of study, such as the glass transition temperature, have unifying semi-empirical relationships and correlations been established. Much progress has yet to be made to consolidate a cohesive study of ionic polymers on such a broad base as it is presented here.

Following the introductory chapter, in which classifications and general properties of ionic polymers are presented in a clear and logical way, there are seven further chapters each dealing with different types of ionic material. These chapters have different authors and each chapter emphasizes a different aspect of its subject. The chapters concerned with ionomers, carboxylated elastomers and crystalline silicates and phosphates are thorough and systematic reviews of the extensive literature on these materials

whereas the chapter on rigid, highly carboxylated ionic polymers is, for the greater part, an authoritative account of recently developed dental cements. However, the conformational changes and ion-binding phenomena which are referred to in the opening section of this account apply to dilute solutions and are inappropriate when discussed in the context of the concentrated systems encountered in these cements. There are two shorter chapters on metal dicarboxylates and the technology of polyelectrolyte complexes and the final chapter by N. H. Ray describes an essentially novel approach to the structure of inorganic glasses.

Taken as a whole the book is somewhat heterogeneous, but as a first step it represents a welcome development and the individual contributions are very useful in themselves. The book will be of interest to research workers and could provide some novel ideas on presentation of course work for teachers in materials departments. The book is well presented but its price will probably restrict it to appropriate departmental libraries for which it will be a good investment.

Universality approach to the expansion factor of a polymer chain

C. Domb

(Received 25 September 1975)

Attention is drawn to recent developments in the theory of critical point thermodynamics, which can be of great help in elucidating classical problems relating to the size and shape of a molecular chain, when intramolecular forces are taken into account. It is suggested that the two-parameter function used to describe the expansion factor, α^2 , of the end-to-end length of a polymer chain, is 'universal', i.e. the same for lattice and continuum models. Hence well-established numerical data of self-avoiding walks on lattices can be used to test various formulae which have been advanced for α^2 . By combining these numerical data with the well-known virial expansion, a new formula is proposed to represent the two-parameter function.

INTRODUCTION

A central problem in the theory of polymer chains in dilute solution is the effect of intramolecular forces, $V(r)$, on the shape and size of the chain. It is reasonable to represent the latter by a hard core repulsion and a longer range van der Waals type attraction; by analogy with a fluid we should then expect to find a 'gas-like' phase at sufficiently high temperatures, condensing into a 'liquid-like' phase at a sharply defined transition temperature¹. Special care is needed to explore the detailed behaviour in the transition region, and this has recently begun to attract increasing attention²⁻⁶.

In the 'gas-like' phase, the repulsive forces dominate and give rise to the excluded volume effect, which has been the object of much theoretical study for some 25 years. For this region, it has usually been assumed that the total intramolecular forces can (to a sufficient approximation) be replaced by a δ -function of appropriate strength $-\nu\delta(r)$, where:

$$\nu = \int [1 - \exp -\beta V(r)] dr, \quad (\beta = 1/kT) \quad (1)$$

and ν has the dimensions of volume. There has been little attempt to assess precisely how good is this approximation. Recent Monte Carlo work by Smith and Fleming⁷ has indicated that it may be significantly worse than is usually assumed. But as a first step, it would at least be useful, to have reliable information regarding the behaviour of this simplified model in which all the intramolecular forces are combined into a single parameter.

Unfortunately, the current theoretical picture of the behaviour of this model is very confused. At least twelve different formulae have been advanced, each claiming to represent the expansion factor in the end-to-end length:

$$\alpha^2 = \langle R_N^2 \rangle / \langle R_{N0}^2 \rangle = \langle R_N^2 \rangle / N \quad (2)$$

Some of these are illustrated in *Figure 1*, as a function of the dimensionless parameter:

$$z = \left(\frac{3}{2\pi a^2} \right)^{3/2} \nu N^{1/2} \quad (3)$$

where a , is the length of a unit of the chain. (This diagram follows Yamakawa⁸, except that α^2 is plotted rather than α^3 which has no direct physical significance.) All of the formulae assume that α^2 is a function of z only, say $\psi(z)$ (this is sometimes called the 'two-parameter theory'⁹). Such an assumption is rigorously valid in the limit $N \rightarrow \infty$, $\nu \rightarrow 0$, $\nu N^{1/2}$ finite, and there is evidence that it provides a reasonable general approximation for large N ¹⁰.

In this confused situation, it may seem presumptuous to put forward yet another formula for α^2 . We do so, only because we think that the remarkable progress in recent years in our understanding of critical point behaviour, has supplied general principles on which to base a reliable calculation of α^2 and other quantities related to the shape and size of the chain. Since many polymer theorists are unfamiliar with these developments we shall spend a few paragraphs discussing them.

CRITICAL POINT THERMODYNAMICS

There are a variety of physical phenomena associated with critical point or λ -point transitions, i.e. transitions involving no discontinuity in energy or entropy but discontinuities or singularities in higher derivatives of the free energy. The oldest and best known is the liquid-vapour critical point; other examples are the Curie point of a ferromagnet, and of an order-disorder transition in an alloy, the Néel point of an antiferromagnet, the λ -point of liquid helium, and the critical point for mixing of solutions. The transitions in solids involve regular crystal lattices, those in fluids have no lattice structure.

Despite the different types of microscopic interaction which give rise to critical points, the general behaviour follows a standard pattern. The most important characteristic, is a long range correlation just above the critical temperature T_c , and it is this correlation which provides an analogy with the mean square end-to-end length of a polymer chain (as will be elaborated shortly). For each particular system, an 'order parameter' is defined, in terms of which the detailed character of the long range correlation can be specified.

Theoretical models, introduced to represent particular systems, have been investigated in detail by several different

Figure 1a Some approximations to the expansion factor α^2 , for values of $z = 0-12$. A, Bueche-James: $\alpha^2 - 1 = 4\alpha z/3$; B, Fixman: $\alpha^3 = 1 + 2z$; C, Ptitsyn: $4.67\alpha^2 = 3.67 + (1 + 9.34z)^{2/3}$; D, Alexandrowicz-Kurata: $\alpha^5/5 + \alpha^3/3 - 8/15 = 4z/3$; E, Flory: $\alpha^5 - \alpha^3 = 3(3)^{1/2} z/2$; F, Yamakawa-Tanaka: $\alpha^2 = 0.572 + 0.428(1 + 6.23z)^{1/2}$; G, Fujita-Okita-Norisuye: $\alpha^5 - 0.4931\alpha^3 - 0.2499\alpha^{-1.332} \sin(1.073 \ln \alpha) - 0.5069\alpha^{-1.332} \cos(1.073 \ln \alpha) = 2.630z$; H, Bueche: $\alpha^4 - \alpha^2 = 48z(1 + 2/3\alpha^2 + 1/4\alpha^4)/69$; I, Modified Flory: $\alpha^5 - \alpha^3 = 4z/3$; J, Yamakawa: $\alpha^{6.67} = 1 + 4.45z$. z , is defined by equation (3). - - - -, is given by equation (20)

Figure 1b Some approximations to the expansion factor for values of $z = 0-250$. Curves B-J as for (a)

techniques. For a few models exact calculations have been possible, the best known being the classic solution of the two-dimensional Ising model by Onsager¹¹. For other models, numerical techniques have been developed which have proved highly effective¹², and good agreement with experiment has been achieved over a wide range. More recently, the renormalization group approach introduced

into the field by Wilson¹³ has provided a general theoretical framework for understanding the characteristic features of critical point behaviour. Numerical calculations using this approach agree well with the older more empirical calculations. Most theoretical and experimental workers in the field would subscribe to the view that, a basic understanding of the phenomena has been achieved, and reliable methods of calculation have been developed with which to calculate properties of interest and importance.

During the above investigations the idea of 'universality' has emerged, i.e. that certain features of critical behaviour are independent of the model for a variety of models. For example, it has been found that exponents which characterize critical behaviour and the function which specifies the equation of state in the critical region, do not depend on lattice structure for a given type of interaction. One might therefore reasonably expect such properties to apply equally to a continuum model.

A simple illustration of the above ideas is provided by the well-known properties of random walks on lattices, which correspond to a model of critical behaviour known as the Gaussian model. For a random walk of N steps on any lattice in any dimension, or in a continuum:

$$\langle R_N^2 \rangle = N \tag{4}$$

This is a property of wide universality, since it is independent both of lattice structure and dimension; it is related to the correlation length for the Gaussian model. A more typical result related to the specific heat near T_c , is the fraction of walks which are at the origin after N steps, given by:

$$p_N \sim AN^{-d/2} \tag{5}$$

Here the exponent is independent of lattice structure for a given dimension, although the amplitude depends on lattice structure. Likewise the shape of the walk¹⁵ for large N :

$$f(u) = \left(\frac{d}{2\pi} \right)^{d/2} \exp - \frac{d}{2} u^2 \tag{6}$$

is independent of lattice structure in a given dimension.

It might be of interest to specify in more detail how configurational properties, which are functions of N , are related to critical behaviour which depends on $(T - T_c)$. For any model of critical behaviour, an interaction parameter J must be specified, and if X is the thermodynamic property to be investigated and $\phi(N)$ an appropriate configurational property, it can readily be shown from elementary statistical mechanics that:

$$X(T) = \sum_{N=1}^{\infty} \phi(N) \exp - \beta NJ = \sum_{N=1}^{\infty} \phi(N) y^N \quad (y = \exp -\beta J) \tag{7}$$

Singular behaviour in $X(T)$ arises at a temperature T_c corresponding to the radius of convergence of this power series, and if the asymptotic behaviour of $\phi(N)$ is:

$$\phi(N) \sim N^{-h} \tag{8}$$

then that of $X(T)$ is:

$$X(T) \sim (T - T_c)^{-h-1} \tag{9}$$

Figure 2 Convergence of virial coefficients for various lattices to two-parameter value. (a) $k_1/h_0N^{1/2}$ vs. $N^{-1/2}$, points shown are values computed numerically: ●, Gaussian continuum model; ○, s.c. lattice; △, b.c.c. lattice; □, f.c.c. lattice; x, diamond lattice. (b) k_2/Nh_0^2 vs. $N^{-1/2}$: ●, Gaussian model; ○, s.c. lattice; △, b.c.c. lattice; □, f.c.c. lattice. It will be seen that there is convergence to a single value as $N \rightarrow \infty$ (the two-parameter value)

When $\phi(N)$ represents a mean square end-to-end distance, $X(T)$ represents a range of correlation.

In a set of models of ferromagnetism which have been much studied by renormalization group methods¹³, the interacting units consist of classical vector spins in n dimensions, and the exponents have been calculated as a perturbation series whose coefficients are functions of n . $n = 1$

corresponds to the Ising model, and de Gennes¹⁶ pointed out that the case $n = 0$ corresponds exactly to the problem of a self-avoiding walk on a lattice; the estimates of the exponents are then in good agreement with those obtained by numerical studies¹⁴. This is of direct relevance to the polymer problem.

UNIVERSALITY IN A POLYMER CHAIN

We shall now endeavour to show that the expansion factor α^2 as a function of z introduced earlier, is a universal function as $N \rightarrow \infty$. We must first specify a lattice version of the problem, and this is available in the Domb–Joyce model¹⁷ of a random chain on the lattice with an intramolecular interaction $-w\delta_{ij}$ between any pair of points of any configuration, i and j being the lattice sites occupied by the i th and j th points of the walk. The Boltzmann factor associated with any configuration of the chain is the product:

$$\prod_{i=0}^{N-2} \prod_{j=i+2}^N (1 - w\delta_{ij}) \quad (10)$$

There is an interaction between any points of the chain occupying the same site, and the model is the direct analogue of the continuum chain discussed earlier. We note, however, that when $w = 1$, no site can be occupied more than once, and the walk is self-avoiding.

We can expand α^2 as a perturbation series in w , for any lattice^{17,18} and for any N :

$$\alpha^2 = 1 + k_1w + k_2w^2 + k_3w^3 + \dots \quad (11)$$

where the leading term in k_r is of order $N^{r/2}$. The continuum model (1) can be expanded likewise in powers of v , and in fact, there is no difference between the form of the expansion for a lattice model and that for a continuum; by the choice of an appropriate generating function for returns to the origin in the corresponding random walk, both can be expressed in the same mathematical form. The virial expansion for the function $\psi(z)$ results from ignoring all but the term of highest order, $N^{r/2}$.

Our claim to universality for $\psi(z)$ is based partly on the evidence that with the exception of a particular numerical constant for each lattice, the virial coefficients are identical for all lattices and for a continuum chain. We have verified this to the third order, but we suspect that a proof should be possible to all orders. We illustrate this property in Figure 2; the first two virial coefficients are plotted as functions of $N^{-1/2}$, and it will be seen that by choosing a suitable scale factor, h_0 , the reduced coefficients become identical as $N \rightarrow \infty$. For a lattice h_0 is given by:

$$h_0 = \left(\frac{3}{2\pi} \right)^{3/2} \frac{g}{a^3} \quad (12)$$

where g is the volume per unit of the lattice, and a the length of a step of the walk. For the s.c., b.c.c., and f.c.c. lattices, g/a^3 has the values 1, $4.3^{-3/2}$, $2^{-1/2}$ respectively; for the diamond lattice there are two atoms per unit cell and the corresponding g/a^3 is $8.3^{-3/2}$.

We therefore conjecture that if we take as variable:

$$z = h_0N^{1/2}w \quad (13)$$

Figure 3 Convergence of numerical estimates for various lattices to the two-parameter value ($z = 1$). \square , f.c.c. lattice; \bullet , b.c.c. lattice; \times , s.c. lattice

the expansion factor α^2 is asymptotically the same function of z for all lattices. This can be tested by numerical estimates for various lattices^{10,18}, and a typical result is shown in Figure 3. The constant h_0 has been chosen to give the same function, $\psi(z)$, as that defined for a continuum earlier.

CALCULATION OF THE EXPANSION FACTOR

We now apply the above ideas to the estimation of $\psi(z)$. For small z , we can use the three known coefficients of the virial expansion⁸. We have recently recalculated these coefficients by an alternative method and have obtained a slightly different value for the third coefficient¹⁸ (details will be published elsewhere). However, even the knowledge of several more coefficients would be of little additional value, since the series is asymptotic and not convergent¹⁹. The physical basis for this is apparent, since the chain will collapse to a single link for an attractive force however small, i.e. for any negative ν or w .

Fortunately, we can make use of the lattice enumerations when $w = 1$, i.e. when the walk is self-avoiding. In this case the enumeration and extrapolation methods parallel those for the Ising model, for which great accuracy has been achieved; additional confirmation was supplied recently, when exact calculations for the susceptibility of the two-dimensional Ising model became available²⁰.

For the s.c., b.c.c., f.c.c., and diamond lattices the general asymptotic formula:

$$\langle R_N^2 \rangle \sim BN^{6/5} \quad (14)$$

has been conjectured¹⁴, the most accurate estimates of B being as follows^{21,22}:

$$\begin{aligned} B_{s.c.} &= 1.067, & B_{b.c.c.} &= 0.959, & B_{f.c.c.} &= 0.921 \\ B_{\text{diamond}} &= 1.283 \end{aligned} \quad (15)$$

We have pointed out that the existence of a single function $\psi(z)$ to describe α^2 is true only asymptotically as $N \rightarrow \infty$ and $w \rightarrow 0$. However, there is evidence^{10,18} that it is a reasonable approximation elsewhere, and we can furnish a numerical test when $w = 1$ using the values in equation (15). Equation (14) then implies that:

$$\psi(z) \sim bz^{2/5} \quad (16)$$

and combining with equation (13) we have:

$$b \approx Bh_0^{-2/5} \quad (17)$$

Estimates of b obtained from the data in equation (15) are given in Table 1, and the deviations from a constant value (less than 2%) provide an estimate of the error in the above approximation. We should note that because of the different values of h_0 for different lattices in relation (13), each lattice provides an estimate of $\psi(z)$ for a different range of z . The information available so far about this function is illustrated in Figure 4, and most of the approximations mentioned earlier differ markedly from the portion represented by the self-avoiding walks.

By using exact enumerations for small N for the above lattices and extrapolating¹⁰, it is possible to obtain an improved estimate of b , and we would like to suggest the value of 1.64, as providing the best fit to the data currently available. The portion of $\psi(z)$ corresponding to equation (16) is drawn in Figure 4, and it will be seen that there is little difficulty in interpolating the rest of the curve (shown dotted), to complete our estimate over the whole range.

When we come to compare our result with other estimates, we find that the closest fit over the whole range is provided by Flory's original formula²³:

$$\psi^{5/2} - \psi^{3/2} = \frac{3(3)^{1/2}}{2} z \quad (18)$$

Even though this does not give the correct value for any of the virial coefficients, the region covered by these coefficients is small. The subsequent modification by Flory and Fisk²⁴, in which the right-hand side of equation (18) is replaced by $9\sqrt{3}z/14$ so as to correct the first virial coefficient, is more seriously wrong in asymptotic behaviour. In fact, we consider that far too much attention has been paid to virial coefficients as a method of discriminating between the various closed form formulae.

To make our own numerical estimate more conveniently available, it is important to provide a closed form formula.

Table 1 Estimates of b from self-avoiding walk enumerations

Lattice	b
f.c.c.	1.648
b.c.c.	1.659
s.c.	1.663
diamond	1.682

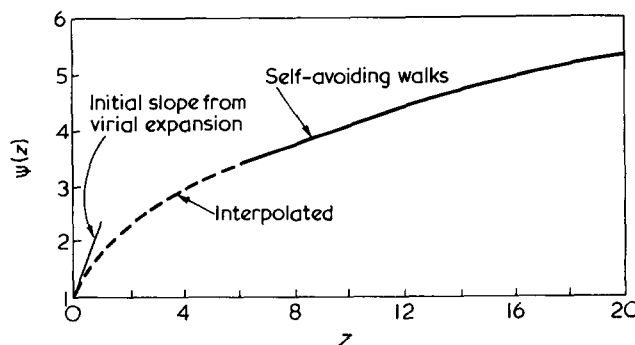

Figure 4 Estimation of $\psi(z)$ for the whole range of z : for small z , virial expansion $\psi \approx 1 + 4z/3$; for sufficiently large z , $\psi \sim 1.64z^{2/5}$; and interpolation in the intermediate range

Figure 5 Formulae for $\psi(z)$

The crudest approximation involving only two parameters endeavours to take account correctly of the first virial coefficient and the asymptotic form, equation (16):

$$\psi^5 = 1 + \frac{20}{3}z + 4\pi z^2 \quad (19)$$

It is because two parameters are required for such a fit that, no modification of a Flory type formula, equation (18), involving only one adjustable parameter, can be adequate.

A more refined formula takes account of the three known virial coefficients as well as the asymptotic formula, equation (18):

$$\psi^{15} = \left[1 + 10z + \left(\frac{70}{9}\pi + \frac{10}{3} \right) z^2 + 8\pi^{3/2} z^3 \right]^2 \quad (20)$$

Both of these formulae are drawn in *Figure 5* and they are in good agreement with the best numerical estimates. Since the latter may themselves be subject to errors of one or two percent, we feel that the formulae (19) or (20) can be used in most practical situations.

Formulae (19) and (20) do not provide a correct analytical representation of $\psi(z)$ near $z = 0$, since they give rise to a convergent rather than an asymptotic series. To provide a representation which is analytically correct, we could make use of some well-known asymptotic series, such as those for Bessel functions, and seek a formula of the type:

$$\psi = z^{2/5} \exp(4/5z) \left[aI_0 \left(\frac{1}{z} \right) + bI_1 \left(\frac{1}{z} \right) + cI_2 \left(\frac{1}{z} \right) \right]^{-4/5} \quad (21)$$

However, since the point at issue is somewhat esoteric, we have not pursued numerical estimates of the parameters in equation (21).

RADIUS OF GYRATION

A property of greater significance than the end-to-end length is the radius of gyration, $\langle S^2_N \rangle$, and by analogy with

equation (2) we can define an expansion factor arising from intramolecular forces:

$$\alpha^2_S = \langle S^2_N \rangle / \langle S^2_{N0} \rangle = 6 \langle S^2_N \rangle / N \quad (22)$$

Various formulae have been advanced for α^2_S as for α^2 , and an illustration analogous to *Figure 1* has been given by Yamakawa⁸.

The ideas and methods which have been described in the previous sections can be applied equally to α^2_S . Exact enumerations for small N have been undertaken, but the results have not yet been processed²⁵. However, data for self-avoiding walks are available^{14,26}, and therefore a reasonable first approximation can be derived.

We prefer to concentrate on the ratio:

$$\alpha^2_S / \alpha^2 = 6 \langle S^2_N \rangle / \langle R^2_N \rangle = \theta(z) \quad (23)$$

since this has a simple pattern of behaviour and rapidly approaches a limiting asymptotic value. In fact, estimates of this quantity for self-avoiding walks on different lattices were so close, that it was suggested that it might be a universal constant²⁶. However, it is clear from the general argument above that this cannot be rigorously correct, and the proper conclusion to draw is that $\theta(z)$ varies little with z , once z is greater than a particular value z_0 .

Only two terms of the virial expansion for α^2_S are currently available, and from these we deduce that for small z :

$$\theta(z) \sim 1 - 0.057z - 0.069z^2 \quad (24)$$

Using as our limiting estimate for large z the value, 0.933, we approximate to $\theta(z)$ by the formula:

$$\theta(z) = 0.933 + 0.067 [\exp -(0.85z + 1.39z^2)] \quad (25)$$

Since we have not checked against exact enumerations we put forward this approximation more tentatively than equations (19) and (20).

CONCLUSIONS

As stated earlier, we believe that the δ -function model of intramolecular interactions has several limitations. However, before it is possible to investigate these limitations in more detail, one must clear up the confusion which exists in the literature about the properties of this model. We feel that the formulae we have advanced have a reliable basis, and it would be useful if they could be tested by some alternative approach. The natural test which suggests itself is that of Monte Carlo enumeration²⁷, since one can ensure that the model tested corresponds exactly to the theoretical model. A preliminary treatment yielded results in modest agreement with the numerical extrapolations on which our formulae are based. We feel, however, that there is scope for a more comprehensive investigation.

ACKNOWLEDGEMENTS

The authors are grateful to Professor Manfred Gordon for reading and commenting on the manuscript, and to Dr Melville Lax for helpful discussion and correspondence.

Laboratorio di Ricerche-su Tecnologia dei Polimeri e Reologia, CNR, Via Toiano 2, Arco Felice, Napoli, Italy

(Received 22 July 1975; revised 19 September 1975)

Melt crystallization kinetics of some aliphatic polyamides, with variable amounts of intra-chain double bonds, was investigated by d.s.c. technique. Crystallization isotherms fit the Avrami equation, yielding for the Avrami parameter, n , values independent from the polyamide composition and close to 4. The values of the calorimetric crystallization rate, in the proximity of the melting point, were analysed using the secondary nucleation theory of Hoffman and Lauritzen. The equilibrium melting temperatures, T_m^0 , were found to increase regularly with increase in the amount of unsaturation. The free energy of formation of a nucleus of critical dimensions and the surface free energies σ and σ_e of the lamellar crystals were determined. The values were correlated with the copolymer composition. Under the same undercooling, an increase in the rate of crystallization with the amount of double bonds in the chain, is observed. This result is related to surface effects; corresponding lowering in the free energy of folding σ_e is found.

INTRODUCTION

The purpose of this paper is to investigate the effect of increasing chain flexibility, obtained by introducing intra-chain double bonds, on the rate of isothermal melt crystallization of aliphatic polyamides. This research is part of a more general project on the influence of constitutional and configurational defects on the structure and on the properties of polymeric materials¹. It seemed interesting, both from fundamental and technological points of view, to relate the amount of double bond unsaturation within polyamide chains, with half time of crystallization, Avrami exponent and kinetic rate constant. Further, we were also interested to observe the dependence of the energy of formation of a nucleus of critical dimensions and of the surface free energy of lamellar fibrillae of spherulites, on the amount of double bonds along the main chain.

EXPERIMENTAL

Materials

The polymers were prepared by interfacial polycondensation from 1,6-diaminohexane and the acid chlorides using a chloroform *n*-hexane mixture (1:1 v/v) as organic phase and sodium hydroxide as acid acceptor². They are reported in Table 1, along with their composition and in-

Table 1 Composition and inherent viscosity of the prepared polyamide samples

herent viscosities. The composition of the copolymers was determined by infra-red analysis, by using the absorbance ratio $A_{967\text{ cm}^{-1}}/A_{3300\text{ cm}^{-1}}$ of the *trans* double bond bending and of the N-H stretching respectively. The experimental ratios, were compared with those of calibration curve obtained with blends of the pure homopolymers (samples A and C in Table 1) of known composition. Alternatively, the composition was determined by analysis of the p.m.r. spectra of trifluoroacetic acid solutions of the copolymers. Peak area measurements of the olefinic protons at 5.62 δ and of the methylene protons adjacent to the nitrogen at 3.56 δ , were employed (tetramethylsilane as internal standard). The compositions determined by means of i.r. and p.m.r. techniques, agree fairly well. The average values are reported in Figure 1. The polymers of

Table 1 have comparable inherent viscosities (η_{inh} 2.0–2.5 in *m*-cresol at 25°C; *c*, 0.5 g/dl) except for samples B₄ and B₅, and show high molecular weight (\bar{M}_n 28 000 ± 1000 for sample C as determined by endgroup titration)³. Thus effects of the molecular weight on the crystallization kinetics should be negligible.

Thermal analysis

The isothermal crystallization kinetics was examined under a nitrogen atmosphere by means of a Perkin-Elmer DSC-1B differential scanning calorimeter using well dried polymer samples of 5–8 mg by wt. The following standard procedure was employed: the polymer sample, placed in the calorimeter cell was heated for 15–20 min to a temperature (T_1), 15–20 degrees above its melting temperature in order to destroy any traces of crystallinity. Subsequently the sample was rapidly cooled to the required crystallization temperature, T_c . The heat evolved was recorded as function of time and the weight fraction X_t of material crystallized at time t was calculated from the equation:

$$X_t = \frac{\int_0^t \left(\frac{dH}{dt} \right) dt}{\int_0^\infty \left(\frac{dH}{dt} \right) dt}$$

Zero time of crystallization was taken, as the time when the central light came on, indicating thermal equilibrium. A

typical curve of crystallization is shown in Figure 2. The apparent enthalpies of fusion, were calculated from the corresponding endotherm areas, by comparison with those of a weighted indium sample, which has a heat of fusion of 6.81 cal/g. The temperature scale was calibrated against high purity standards.

The maximum of d.s.c. endotherm of fusion, was assumed to be the melting temperature T_m of the polymer sample. In order to correlate melting and crystallization temperatures, T_m was determined for each of the samples after isothermal crystallization at T_c .

X-ray characterization

The X-ray diffraction patterns, in the wide angle region, were recorded by means of a diffractometer Philips 1050/25, using the $\text{CuK}\alpha$ radiation. As shown in Figure 3, the diffraction pattern has been numerically resolved into a broad diffuse halo and sharp diffraction. The mass crystallinity has been calculated in a traditional way, assuming the broad halo to be the amorphous contribution and the sharp peaks to be the crystalline contribution⁴. In the separation, we assume for the maximum of the amorphous halo, an angle of about 19 degrees. The thermodynamic enthalpy of melting, ΔH_F , has been determined by using the simplified relation:

$$\Delta H_F = \frac{\Delta H_F^*}{X_c} \quad (1)$$

where ΔH_F^* , the apparent enthalpy of fusion, is obtained by thermal measurements and X_c is the X-ray mass crystallinity. The values of X_c , ΔH_F^* and ΔH_F , as function of the composition of polyamides are reported in Table 2.

The two strongest reflections, observed in the traces of Figure 3, as deduced by X-ray spectra of oriented fibres, are equatorials being related to $(hk0)$ planes. The variations of the spacings d_1 and d_2 are shown in Figure 4, as function of the composition.

RESULTS AND DISCUSSION

Examples of crystallization isotherms of polyamides with different amounts of *trans* double bonds along the chain (samples B₄, B₅ and C of Table 1), are reported in Figure 5. From such curves the half time of conversion, $t_{1/2}$, of each polymer has been determined at various crystallization temperatures T_c .

Figure 3 Typical X-ray diffraction traces of a sample of copolyamide. The method followed for the separation of the contributions of amorphous and crystalline is also shown (see text)

Figure 4 Variations of the spacing d_1 , (■); and d_2 , (△), of the strongest reflections observed in the X-ray traces of polyamides with the copolymer composition

In Figure 6, the variation of $t_{1/2}$ with T_c for each polymer is shown. It is well known that, crystallization curves of polymers can be analysed by means of the Avrami equation⁵:

$$(1 - X_t) = \exp(-Zt^n) \quad (2)$$

In logarithmic form equation (2) is written:

$$\log[-\log(1 - X_t)] = n \log t + \log \frac{Z}{2.3} \quad (3)$$

In equations (2) and (3), X_t is the weight fraction of crystallized material at time t , Z is the kinetic rate constant, and n the Avrami exponent.

The crystallization kinetics of our polyamides, follow equation (3) up to a high degree of conversion at almost all crystallization temperatures. This is shown in Figure 7 where the quantity, $\log[-\log(1 - X_t)]$, is reported against $\log t$ for samples B₁, B₃ and C. Deviations at the end of the process may be due to secondary crystallization phenomena.

The values of the Avrami exponent n , graphically calculated from the slopes of the curves $\log[-\log(1 - X_t)] \rightarrow \log t$ are reported in Table 3, together with the values of the rate constant Z calculated by means of the relation:

$$Z = \frac{\ln 2}{t_{1/2}^n} \quad (4)$$

As shown in Table 3, the values of the Avrami parameter n are almost independent of the crystallization temperature and of the composition of the samples, and are very close

to 4. According to the theory⁵, n should be a combined function of the number of dimensions in which growth takes place, and also of the order of the time dependence of the nucleation process. Accordingly, n should assume a value of 4 when three-dimensional spherulitic growth units, develop from nuclei whose amount increases linearly with time. The values of Z reported in Table 3, have been obtained by assuming for n an integer value of 4 for all the polymers investigated.

Figure 6 Variation of half time of crystallization $t_{1/2}$ with the crystallization temperature for samples: Δ , C; \bullet , B₅; X, B₄; \blacksquare , B₃; \circ , B₂; \blacktriangle , B₁; \square , A

The equilibrium melting temperatures T_m^0 have been determined from plots of T_m against the crystallization temperature T_c according to equation (5):

$$T_m = T_m^0 \left(\frac{\gamma - 1}{\gamma} \right) + \frac{T_c}{\gamma} \quad (5)$$

where γ is a constant⁶.

Examples of plots of T_m against T_c , are shown in Figure 8, for samples B₃ and B₅. A linear trend is observed for all the polyamides examined. T_m^0 is graphically obtained from such plots, by extrapolating the experimental line to the point where $T_m = T_c$.

The values of T_m^0 are reported in Table 3. They increase regularly with the amount of unsaturation along the chain. The half time of conversion $t_{1/2}$, for the same value of the undercooling $\Delta T = T_m^0 - T_c$, decreases with increasing the

number of *trans* double bond along the chain. This trend is shown in Figure 9. The effect of the double bond concentration is more relevant at low values of ΔT .

* Estimated error in n is ± 0.4

According to the kinetic theory of polymer crystallization^{6,7}, the overall rate constant of crystallization Z , in the case of spherulitic growth units of lamellar type, may be obtained from the relation:

$$\frac{1}{3} \log Z + \frac{\Delta F^*}{2.3KT_c} = A_0 - \frac{\Delta\phi^*}{2.3KT_c} \quad (6)$$

In equation (6) ΔF^* , is the activation energy for the transport process at the liquid-crystal interface. ΔF^* is usually approximate to the activation energy of the viscous flow of melt polymer, ΔF_{WLF} . $\Delta\phi^*$ is the free energy of formation of a nucleus of critical dimensions, and K the Boltzmann constant.

When a coherent two-dimensional surface secondary nucleation process controls the radial growth of lamellar spherulites then $\Delta\phi^*$ may be expressed by the relation⁷:

$$\Delta\phi^* = \frac{4b_0\sigma\sigma_e T_m^0}{\Delta H_F \Delta T} \quad (7)$$

where σ and σ_e are the free energies per unit area of the surfaces parallel and perpendicular, respectively, to the molecular chain direction; ΔT is the undercooling; ΔH_F is the enthalpy of melting and b_0 is the distance of two adjacent fold planes. Plots of $(1/3) \log Z$ against $T_m^0/T_c \Delta T$, are shown in Figure 10, for some of the investigated polyamides. A linear trend is observed. According to equation

(6), this result indicates that the transport term is constant, in the proximity of the melting point, at least for the undercooling values investigated. The transport term ΔF^* was calculated by means of the approximate relation of Williams, Landel and Ferry⁸:

$$\Delta F^* = F_{WLF} = \frac{C_1 T_c}{C_2 + T_c - T_g} \quad (8)$$

* b_0 is assumed as equal to the d_2 spacing in the X-ray traces (see text)

‡ From the slopes of the curves $(1/3) \log Z$ against $T_m^0 / T_c \Delta T$

† From the slopes of the curves $(1/3) \log Z + \Delta F_{WLF} / 2.3RT_c$ against $T_m^0 / T_c \Delta T$

C_1 and C_2 are constants generally assumed equal to 4.12 Kcal/mol and 51.6 K respectively. For T_g we used for all polyamides the value of 323 K that is the glass transition of nylon-6,10⁹.

Plots of the quantity $(1/3) \log Z + \Delta F_{WLF} / 2.3RT_c$ against $T_m^0 / T_c \Delta T$, show for all samples a linear trend. Examples of such plots are reported in Figure 11, for A, B₃ and C polymers. The values of the quantity $4b_0\sigma\sigma_e / 2.3\Delta H_F$, calculated from the slopes of the lines of Figures 10 and 11, are reported in Table 4, for each of the polyamide examined. The two methods lead to differences in the value of the slopes of about 15%. This fair agreement, supports the assumptions made in the calculation of the transport term, ΔF^* .

The free energy of formation of a nucleus of critical dimensions $\Delta\phi^*$, calculated from the values of the slopes of Figure 10, continually decreases with the amount of unsaturation along the chain. This behaviour is shown in Figure 12 for various values of ΔT .

From the values of $4b_0\sigma\sigma_e / 2.3\Delta H_F$ reported in Table 4, the quantity σ_e can be calculated, if ΔH_F and b_0 are known. The estimation of b_0 , was based on the observation that in the case of nylon-6,8 the value of d_2 (3.84 Å) is close to the spacing of the (010) crystallographic fold planes of nylon-6,6. This strongly indicates that for our polyamides also, d_2 can be assumed as a measure of the distance between adjacent fold planes.

It is interesting to observe that d_2 increases with the amount of double bond along the chain as shown in Figure 4. The values of $\sigma\sigma_e$ are reported in Table 5 for each polyamide. The free energy σ of the lateral surfaces of the lamellar fibrillae was estimated by using the empirical relation:

$$\sigma = \alpha \Delta H_F b_0 \quad (9)$$

where the constant α is equal to 0.1 for all polymers⁶. From the values of $\sigma\sigma_e$ and σ , the folding free energy σ_e was calculated. The values of σ and σ_e are reported in Table 5.

As shown in Figure 13, σ_e drastically decreases with increase in the amount of unsaturations in the polyamide chain, whereas σ keeps practically constant. In fact, in the case of nylon-6,8 we found for σ_e an average value of 141 erg/cm², while for the completely unsaturated polyamide the value is lowered to 81 erg/cm². The value of σ is around 4 erg/cm², being about one tenth of σ_e .

CONCLUSIONS

The experimental results reported in the present paper show that the presence of intra-chain *trans* double bonds

Figure 13 Effect of the copolymer composition on the value of σ_e and σ : □, σ ; △, σ_e

along a polyamide backbone, strongly influence some kinetic and thermodynamic parameters of melt crystallization. In fact the equilibrium melting point T_m^0 of nylon-6,8, increases with increasing amount of double bonds within the chain ($T_m^0 = 514$ K for nylon-6,8 and 533 K for the nylon obtained by polycondensation of 1,6-diaminohexane with *trans*-octen-1,8-dioic acid). However, the thermodynamic enthalpy of melting does not seem to be affected, in a systematic way, by the amount of unsaturation.

The spacings of the most intense X-ray equatorial reflections of nylon-6,8 continuously increase with the amount of unsaturations within the chain. These results can be only explained if repeat units of:

type are able to cocrystallize, even if in the resulting polymer, the double bonds are not regularly spaced along the polymer chain. Moreover, under the same undercooling the rate of crystallization drastically increases with increasing % unsaturated comonomer. This phenomenon must be attributed partly at least, to the corresponding lowering observed in the values of the free energy of formation $\Delta\phi^*$ of a nucleus of critical dimensions.

The last finding is mainly related to surface effects. In fact, the free energy of folding σ_e is lowered by 44%, going from nylon-6,8 to the completely unsaturated nylon. Probably entropic effects due to the higher flexibility of the more unsaturated chains¹¹ on the surface of the lamellar fibrillae, may explain this behaviour.

Persistent internal polarization studies in poly(*N*-vinylcarbazole)/trinitrofluorenone charge transfer complex

P. K. C. Pillai and R. C. Ahuja

Department of Physics, Indian Institute of Technology, New Delhi-110029, India
(Received 23 July 1975; revised 27 October 1975)

Studies on the persistent internal polarization in poly(*N*-vinylcarbazole) (PNVC)/trinitrofluorenone (TNF) charge transfer complex are reported. This complex is known to be photoconducting and in the present investigation, the photoelectret charge has been studied as a function of applied voltage, intensity of illumination and time of polarization. A saturation effect is observed in each case. Also the possibility of the use of PNVC/TNF complex in PIP electrophotography has been explored and a comparison of the results of this investigation is made with the results obtained for PNVC.

INTRODUCTION

Poly (*N*-vinylcarbazole) (PNVC) is reported to be one of the best photoconducting polymers known at present¹⁻⁷. It has also been reported that this polymer exhibits photo-induced discharge and that its photoresponse may be strongly improved by doping with a wide variety of electron acceptors². Recently it has been reported that the action spectrum of PNVC could be shifted to the visible range by doping it with 2,4,7-trinitrofluorenone (TNF)⁷. This PNVC/TNF charge transfer complex also exhibits a high photosensitivity⁷.

The present investigation deals with the photoelectret (photopolarization and depolarization) characteristics of the PNVC/TNF complex. Photoelectret state in a photoconductor results from the simultaneous application of electric field and exciting radiation. The photogenerated carriers undergo a directional trapping under the influence of the electric field and a polarization is set up which persists even after the removal of the electric field and illumination. A study of this persistent internal polarization gives an insight into the electronic processes taking place in the photoconductor and also helps in the selection of photoconductor for electrophotographic applications.

A comparison of the results obtained for the PNVC/TNF complex with those of pure PNVC⁹, shows that the doped PNVC layer could give a better performance, when used in PIP electrophotography.

EXPERIMENTAL

Specimen preparation

PNVC, supplied by BASF (West Germany), is a colourless granular material containing 3-4% vinylcarbazole and anthracene. To remove these and other monomeric impurities, PNVC was dissolved in benzene and was precipitated in methanol several times. The purified PNVC was then mixed with 2,4,7-trinitrofluorenone (1:1 molar ratio) and dissolved in tetrahydrofuran. Good quality films can be obtained by pouring this solution over aluminium sheets and allowing it to evaporate in an atmosphere saturated with tetrahydrofuran vapours. The film is dried in an air oven at 50°C to remove the residual solvent.

Measurement technique

The experimental arrangement has been shown in *Figure 1*. The PNVC/TNF film (1 cm × 1 cm × 0.01 cm) was pressed between an aluminium electrode and a conducting glass electrode with the aid of teflon sheets and screws. The sample holder was then put in an earthed metallic chamber with provision for illumination with a 200 W tungsten filament lamp.

One of the electrodes was connected to an electrometer for low current measurements, whereas the other could be connected to the positive of a battery or earthed. The sample was exposed to light through the upper electrode in a direction parallel to the electric field and was polarized by illuminating it in the presence of an electric field. At the end of this operation, the electrode (previously connected to the power supply) was earthed and the resulting depolarization current was measured with respect to time. The depolarization current reduced to zero after certain time. Thus the charge of photoelectret could be calculated by integrating depolarization current with respect to time.

Figure 1 Experimental set up for photo and dark depolarization measurements

Figure 2 Depolarization characteristics of PNVC/TNF films for an applied electric field 50 kV/cm and time of polarization, $t_p = 1$ min. A, photo-depolarization, $I = 1000$ lux; B, dark depolarization

Figure 3 Photoelectret charge vs. polarizing voltage, $t_p = 15$ sec (—); $t_p = 4$ min (---): A, $I = 6500$ lx; B, $I = 1000$ lx; C, $I = 525$ lx; D, $I = 280$ lx

The photoelectret state of the PNVC/TNF has been studied under the following conditions: (a) time of polarization varying from 15 sec to 4 min; (b) polarizing voltage varying from 100 to 700 V; (c) intensity of illumination varying from dark to 6500 lx.

RESULTS

Figure 2 shows the dark and photodepolarization currents of PNVC/TNF film polarized for 1 min in an electric field of 50 kV/cm and at 1000 lx. The decay of charge is quite fast in dark and takes about 30 sec for the total decay. The

light decay is also quite fast initially but slows down afterwards, taking about 5 min for the current to reduce to zero. These characteristics help in determining the time of exposure required to obtain a particular image contrast, when the layer is to be used in PIP electrophotography.

Figure 3 shows the dependence of photoelectret charge (obtained by integrating the curves shown in Figure 2) on polarizing voltage. The charge increases linearly with voltage at low values and shows a tendency to saturate at higher values. However, the saturation effect is more noticeable at low intensities of light.

Figure 4 shows the variation of photoelectret charge with polarizing time. The initial variation is linear (for polarizing times up to 15 sec) but shows saturation effect for polarizing times beyond 1 min. The curves could approximately fit the relation:

$$P = P_{\max}(1 - e^{-t/\tau})$$

where t is the time of polarization and τ depends on the voltage and intensity of illumination during polarization.

Figure 5 shows the dependence of photoelectret charge on the intensity of illumination. Here, also the initial variation is linear (up to 50 lx) followed by saturation effect.

Figure 6 shows the dependence of $I_{\text{photo}}/I_{\text{dark}}$ on the applied field. It is seen that the value of $I_{\text{photo}}/I_{\text{dark}}$ is strongly field dependent. This is not surprising as the photogeneration efficiency in organic solids has been found to be strongly field dependent.

DISCUSSION

The charge transfer complex of poly(*N*-vinylcarbazole) with trinitrofluorenone is highly photoconducting throughout the visible spectrum⁷. The spectra of PNVC/TNF films show the appearance of new absorption bands which cannot be attributed to either PNVC or the dopant, indicating the formation of molecular complexes between carbazole rings and the dopant molecule¹⁰⁻¹¹.

Brackmann¹², Mulliken¹³, Briegleb¹⁴ and others have shown that molecular complex formation is due to charge transfer interaction between electron donor type molecules and electron acceptors. In the presence of radiation of the appropriate energy, an electron transfer occurs according to:

Figure 4 Photoelectret charge vs. polarizing time, $I = 6500$ lx (—); $I = 280$ lx (---). A, $V_p = 700$ V; B, $V_p = 500$ V; C, $V_p = 300$ V; D, $V_p = 100$ V

Figure 5 Photoelectret charge vs. intensity of illumination, $t_p = 4$ min (—); $t_p = 15$ min (---). A, $V_p = 700$ V; B, $V_p = 500$ V; C, $V_p = 300$ V; D, $V_p = 100$ V

Figure 6 I_{photo}/I_{dark} vs. applied voltage

The CT band may be calculated from the relationship:

$$h\nu_{CT} = I_D - E_A + C$$

where I_D is the ionization energy of donor. E_A the electron affinity of acceptor and C corresponds to the Coulomb energy of D^+A^- ionic couple. Ionized molecules (the radical ions D^+ and A^-) are formed at the excited state in more or less high concentration, depending on the ionization potential of D and A.

Charge transport in PNVC has been the subject of a number of investigations¹⁵⁻²⁰. Holes have been shown to dominate the conduction and the hole drift mobility was found

to be extremely low and strongly field dependent. With the addition of TNF to PNVC, charge transfer complexing takes place introducing absorption bands in the visible region. At sufficiently high TNF concentrations, electron transport dominates the conductivity⁴⁻⁶. The low mobilities indicate a high degree of localization of the carriers, which in turn suggests some form of intermolecular 'hopping' as the transport mechanism. The photogeneration efficiency in organic solids may be viewed as a two-step process²¹. In the first step the absorbed photon excites the electron from its ground state to some excited bound state. From this excited bound state, the electron may undergo thermalization/autoionization into a continuum state where it can conduct or may fall back to the ground state. The yield of electrons in the continuum state per absorbed photon is found to be field dependent making the photogeneration of carriers and the I_{photo}/I_{dark} in organic solids as observed in our case, field dependent.

A comparison of the results obtained for pure PNVC⁹ with that of PNVC/TNF charge transfer complex shows that the latter shows more photoelectret charge than the former. The difference is almost one order of magnitude. This increase can be attributed to the increase in the number of photoexcited carriers in PNVC/TNF. The action spectrum also shifts in the visible range in PNVC/TNF case. Also it is seen that to obtain the same amount of photopolarization, the magnitude of applied field, time of polarization and intensity of illumination required in the case of PNVC/TNF complex, are considerably lower than that of pure PNVC. The value of Q_{PE}/Q_{dP} (taken as the image contrast) comes to be 500 in the case of PNVC/TNF while for pure PNVC it was found to be only 100.

Relaxation controlled (case II) transport of lower alcohols in poly(methyl methacrylate)

H. B. Hopfenberg*, L. Nicolais, and E. Drioli

Istituto di Principi di Ingegneria Chimica, Università di Napoli, Naples, Italy

(Received 12 August 1975; revised 6 October 1975)

The remarkably consistent long term absorption data of Andrews, are shown to obey relaxation controlled (case II) transport kinetics for the absorption of methanol, ethanol, n-propanol, isopropanol, and n-butanol in glassy poly(methyl methacrylate). Andrews' data were obtained by monitoring gravimetric absorption, in 1 mm sheet specimens, under controlled conditions, for a period of years until absorption equilibria were established. Activation energies for the relaxation controlled (zero-order) absorption kinetics were calculated to be ~ 17 kcal/g mol and the enthalpy of absorption varied regularly and explicity with carbon number of the alcohol and with solubility parameter of the homologous penetrants. The dramatic monotonic increase of sorption rate with decreasing carbon number is analysed in terms of the increased concentration gradient which presumably develops as carbon number is decreased, rather than the more attractive theory that increased absorption rate is a direct function of decreased molar volume of the penetrant. Since the absorption kinetics are completely controlled by osmotic stress induced relaxations, molecular size of the penetrant does not directly affect the observed kinetics of penetration.

INTRODUCTION

In 1966, Alfrey *et al.*¹ described a second limiting transport process, frequently controlling absorption of organic vapours and liquids in glassy polymers, wherein diffusion *per se* played no part in the rate determining transport mechanism. Alfrey termed this behaviour case II transport, in contrast to the well understood and often described Fickian diffusion, which is termed case I transport.

For Fickian transport, the rate of absorption in slab or film geometries decreases continuously with time, owing to the continuous decrease of the driving concentration gradient. Conversely, for many cases involving penetration of glasses by organic penetrants, relaxation at a sharp boundary between uniformly swollen and essentially unplasticized polymers, provides a constant, rate determining step for the absorption. An extremely steep concentration gradient develops at the sharp and discernable boundary² between swollen and unswollen polymer and, in turn, a large, osmotically induced stress gradient drives the rate determining relaxations occurring in the region of the large gradient. In this second limiting case, the absorption proceeds at a constant rate independent of time or position.

In the course of a literature search supporting a cooperative research program between this Institute and the Department of Chemical Engineering, North Carolina State University concerning tensile and torsional stress biased relaxation controlled transport in glassy polymers, a significant paper³ by Andrews, Levy, and Willis was reviewed. The Andrews *et al.* paper reports absorption kinetics and equilibria of methanol, ethanol, n-propanol, isopropanol, and n-butanol in 1 mm sheet specimens of poly(methyl methacrylate) (PMMA). The protracted absorption kinetics were observed, in many cases, over periods of years.

The dedication, embodied in their work, has reaped the reward of data describing both absorption kinetics and equilibria which are not only completely consistent but provide a most convincing exposition of a relaxation controlled (case II) absorption process. The Andrews' data are quite extensive, involving five homologous lower alcohols over a significant temperature range. The focus of the Andrews paper was directed towards the role of absorption on environmental crazing and, therefore, a detailed interpretation of the absorption kinetics and equilibria was not attempted. Their brief discussion concerning mechanism of absorption did not include consideration of relaxation controlled (case II) absorption kinetics and a rather conventional treatment, involving plots of volumetric swelling *versus* square root time were presented to characterize the absorption kinetics.

Replotting the Andrews data, considering the well accepted⁴⁻⁹ relaxation controlled transport processes, frequently controlling organic penetrant absorption in glassy polymers, revealed, in all cases, an excellent fit with case II transport theory. Moreover, the highly temperature dependent absorption kinetics, the consistent trends concerning temperature dependence of the equilibria (enthalpy of absorption), and the rational correlation between molar concentration of penetrant at equilibrium and the observed kinetics prompted this rather in depth re-analysis of the extremely valuable data of Andrews' *et al.*

ANDREWS' EXPERIMENTAL PROCEDURE

Plane sheet specimens of 1 mm thick PMMA (ICI Ltd) were prepared with the approximate major surface dimensions 30 × 7 mm. The specimens were dried under vacuum for two hours at 348 K, prior to weighing in a stoppered container on a microbalance sensitive to 10^{-8} kg. Batches of three such specimens were placed in flasks containing

* Department of Chemical Engineering, North Carolina State University, Raleigh, North Carolina 27607, USA

Figure 1 Anomalous Fickian kinetics of n-propyl alcohol absorption in poly(methyl methacrylate) sheets. [Volume fraction or weight ratio, w_1/w_2 , as a function of $t^{1/2}$ ($T = 318$ K)]. Volume fraction ϕ_1 , \circ ; weight ratio w_1/w_2 , \square

Figure 2 Case II kinetics of n-propyl, i-propyl and n-butyl alcohol absorption in poly(methyl methacrylate) sheets. [Weight of alcohol per original dry sheet weight, w_1/w_2 , versus t ($T = 318$ K)] \circ , n-propyl alcohol; \square , isopropyl alcohol; \triangle , n-butyl alcohol

methyl, ethyl, n-propyl, isopropyl, and n-butyl alcohol controlled at 293 and 318 K. The specimens were periodically removed from their flasks, rapidly dried with filter and tissue paper, and weighed in the stoppered container. After weighing, the specimens were immediately returned to their respective flasks.

The volume fraction, ϕ_2 , of polymer in the PMMA-alcohol mixture was calculated as:

$$\phi_2 = (1 - \phi_1) = (w_2/\rho_2) (w_1/\rho_1 + w_2/\rho_2)^{-1} \quad (1)$$

where w_1 and w_2 are, respectively, the weight of alcohol in the swollen mixture and the original (dry) weight of PMMA, and ρ_1 and ρ_2 are, respectively, the density of alcohol at the test temperature and the density of PMMA³.

For this reinterpretation of the kinetic and equilibrium data, the weight fractions, molar concentrations and, in turn, weight of penetrant per dry weight of polymer, were back calculated from the volume fraction data reported by Andrews *et al.*

The undefended assumptions embodied in equation (1), (viz no volume change on mixing), are, of course, implicit in calculated values of molar concentrations, however, the calculated value of w_1/w_2 or $w_1/(w_1 + w_2) = \Omega_1$ eliminate

this assumption since w_1 and w_2 were actually determined experimentally.

RESULTS AND DISCUSSION

Kinetics

The absorption kinetics of lower alcohols in PMMA, presented by Andrews, Levy, and Willis³ were presented in plots of ϕ_2 , volume fraction of polymer as a function of $[\text{time}(t)]^{1/2}$ measured in $(\text{h})^{1/2}$. Typical results are presented here again in Figure 1, for n-propanol in PMMA as $\phi_1 = (1 - \phi_2)$, volume fraction of alcohol as a function of $t^{1/2}$. A plot of w_1/w_2 (for n-propanol) versus $t^{1/2}$ is also included in Figure 1 for comparison. Clearly, the transport is non-Fickian⁷, however, their conclusions regarding the seemingly complex nature of these kinetic processes may be unduly complicated.

Alternatively, plots of the weight of penetrant absorbed per original dry sheet weight, w_1/w_2 , versus linear t are presented in Figure 2 for n-propanol, isopropanol, and n-butanol. A similar plot for ethanol is presented in Figure 3. The data for methanol were too compressed in the graphical presentation of Andrews to permit meaningful re-interpretation.

The use of ϕ_1 , as an ordinate tends to depress ordinate values of relatively high values of ϕ_1 . The alternate, and more conventional choice of w_1/w_2 (or related mass quantities) has several advantages. The normalized mass ordinate requires no assumptions regarding volume changes associated with mixing and the mass readings are not only a direct consequence of the actual experimental measurements but also provide an unequivocal means for monitoring the related absorption of penetrant in either mass or mol units.

Figure 3 Case II kinetics of ethyl alcohol absorption in poly(methyl methacrylate) sheets. [Weight of ethanol per original dry sheet weight, w_1/w_2 , versus t ($T = 318$ K)]

Table 1 Activation energies for relaxation controlled transport of lower alcohols in PMMA

Alcohol	Activation Energy (kcal/g mol)
ethyl alcohol	17.6
n-propyl alcohol	17.4
isopropyl alcohol	16.7

**Figure 4** Van't Hoff plot of temperature dependence of absorption equilibria for ethanol in PMMA

The use of a w_1/w_2 ordinate would be preferred, especially for the analysis of presumed case II absorption since true linearity between amount of penetrant absorbed should only be observed on a plot of w_1/w_2 (rather than $w_1/(w_1 + w_2)$ or ϕ_1) versus t .

Moreover, use of the w_1/w_2 ordinate, in the case II (w_1/w_2 versus t plots), reveals an intriguing induction period which is maintained for approximately 4% of the total sorption. Ideal case II kinetics are maintained, thereafter, for ~90% of the total sorption period. In contrast, the plot of w_1/w_2 versus $t^{1/2}$ does not, in fact, fit true diffusion kinetics (e.g. w_1/w_2 versus $t^{1/2}$ linear) over any significant portion of the sorption history. The reduction in ordinate value associated with the use of ϕ_1 , rather than w_1/w_2 is apparent at the high swelling levels in *Figure 1*.

The brief induction period, apparent in *Figures 2* and *3* is, most likely, a manifestation of a relatively slow, diffusion controlled development of an ideal step concentration profile in the sheet specimen. Alternatively, this observed induction may be related to 'case-hardened' surface layers resulting from the specific thermal history imposed upon the specimens during sample preparation.

Activation energies for the apparently relaxation controlled transport process, were calculated by comparing the experimental times required to achieve an arbitrarily selected fractional sorption value at 293 K and 318 K. These calculations, of course, assume Arrhenius behaviour. This assumption, though well justified^{2,6,9} is required since sorption kinetics were reported for only these two temperatures. The results of these calculations are presented in *Table 1*.

These virtually identical activation energies are, in fact, much higher than typically reported activation energies for diffusion. This temperature dependence provides significant, independent support for the hypothesis that polymer

relaxations provide the rate determining step for absorption of the lower alcohols in PMMA. Moreover, the nearly identical values of the calculated activation energies are consistent with relaxations occurring in sheet specimens, swollen to essentially the same equilibrium penetrant volume fractions. The equilibrium concentration is maintained at the 'shoulder' of the concentration step. In contrast, activation energies for diffusion typically vary significantly with penetrant size.

Equilibria

Andrews *et al.*³ present a table of equilibrium volume fractions of the various alcohols in PMMA contacted with the liquid alcohols for 6 temperatures covering the temperature range, 293–338 K. If one makes the simplifying assumption that the enthalpy of mixing associated with the isothermal change of 1 mol of alcohol liquid dissolving in PMMA is constant and that Henry's law is obeyed over the temperature range studied, a value of the enthalpy of mixing may be extracted from the slope of semi-log of $\ln \phi_1$ versus $1/T$. These assumptions are exceedingly stringent and quantitatively unjustifiable, however, they permit a qualitatively comparative analysis of the temperature dependence of the equilibrium behaviour within this limited alcohol series.

Using these assumptions, the semi-log plots of $\ln \phi_1$ versus $1/T$ were constructed for the various alcohols. Typical results are presented for the case of ethanol in *Figure 4*. The calculated values of the enthalpy of mixing are presented in *Table 2* for the various alcohols.

The trend amongst these endothermic enthalpies of mixing is consistent with the theory that hydrogen bonding is the predominant intermolecular interaction in the bulk liquid and, furthermore, that hydrogen bonding is not the predominant intermolecular interaction involved with penetrant-polymer equilibration. Specifically, as carbon number of the alcohol is reduced, the hydrogen bonding in the liquid is presumably increased. In contrast, hydrogen bonding between alcohol and PMMA is relatively invariant amongst alcohols within this series, therefore, the enthalpy change between pure alcohol and swollen polymer increases as carbon number is reduced.

The theory that hydrogen bonding controls penetrant-polymer interactions, but plays a smaller role in the overall interaction between penetrant and polymer, is consistent with the observed trend of ΔH_{mix} as a function of carbon number of the alcohol as well as the observed correlation between ϕ_1 and $\Delta\delta$ (the solubility parameter difference between polymer and penetrant) for this alcohol series reported by Andrews, *et al.*³

In any event these equilibrium values should be considered with some reservation since the more rapidly equilibrating (higher temperature experiments) are presumably more reliable. The surprisingly large calculated values of

Table 2 Enthalpy of mixing lower alcohols in PMMA in the temperature range 293 to 338 K

Alcohol	ΔH_{mix} (kcal/g mol)
methyl alcohol	2.8
ethyl alcohol	2.6
n-propyl alcohol	2.1
isopropyl alcohol	2.1

Figure 5 Log-log plot of absorption rate, k_0 , (mg/cm² h) versus molar concentration of the various alcohols. [$T = 318$ K]

ΔH_{mix} are consistent with the possibility that the low temperature data do not reflect true equilibrium.

Relationship between the kinetics and the equilibria of absorption

Although the equilibrium weight, weight fraction, or volume fraction of penetrant absorbed varies only slightly with carbon number of the alcohol, there is a significant and regular variation in equilibrium molar concentration of the various alcohols in PMMA. The osmotic stresses and more importantly, stress gradients, which develop consequent to the equilibration of the swollen shell, are related monotonically to the molar concentration (rather than weight fraction or volume fraction) of the penetrant in the polymer. The relaxation processes, responsible for the rate determining sorption step, are in turn, driven monotonically by these osmotic stress gradients. These identical effects have been observed^{6,9,11,12} under controlled conditions for a single penetrant in a single polymer by varying systematically the penetrant activity. There is no means, however, of determining the magnitude of the concentration gradient driving the relaxations. Quite possibly the qualitative and quantitative details of the steep concentration gradients, which develop at the 'step' differ from alcohol to alcohol as a consequence of differing sorption affinities and varying diffusional penetration into the essentially dry core⁵.

Jacques and Hopfenberg⁹ reported a 10,000-fold increase in the rate of case II penetration of polystyrene-poly(phenylene oxide) blends associated with only a two-fold increase in equilibrium penetrant concentration of the

same penetrant. In their study, the penetrant concentration was changed by varying either the penetrant activity or the blend composition. The relationship between absorption rate and the molar concentration of alcohol is presented in Figure 5 for the normal alcohol series. Presumably, the higher absorption rates observed as molecular weight of the alcohol is reduced is a coincidental analogue of a diffusion controlled process.

CONCLUSIONS

The detailed data of Andrews *et al.* describing penetration of PMMA by a homologous series of lower alcohols are best described by case II relaxation controlled transport preceded by a brief diffusion controlled induction period during which a step concentration profile is established. Analysis of the temperature dependence of the sorption equilibria suggests that hydrogen bonding between penetrant and penetrant is well developed in the liquid phase whereas hydrogen bonding is not primarily responsible for equilibrium penetrant-polymer interactions.

Analysis of sorption kinetics of organic penetrants in polymeric glasses is served best by selecting a w_1/w_2 ordinate rather than a ϕ_1 ordinate. Moreover, selection of a linear time abscissa is indicated for absorption experiments where case II kinetics may predominate.

Thermal stabilities of poly(*N*-alkyl maleimides)

S. Matui

Department of Industrial Chemistry, Fukui Technical College, Fukui, Japan

and H. Aida

Department of Industrial Chemistry, Faculty of Engineering, Fukui University, Fukui, Japan

(Received 24 June 1975; revised 18 September 1975)

The thermal stabilities of polymaleimide (PMI), poly(*N*-methyl maleimide) (PMMI), poly(*N*-ethyl maleimide) (PEMI), poly(*N*-*n*-propyl maleimide) (PNPMI) and poly(*N*-isopropyl maleimide) (PIPMI) were studied over the temperature range 300° to 400°C under a constant flow of nitrogen. At the initial stage of degradation the following results were obtained: (1) the main chain of PMMI is the most stable among the poly(*N*-alkyl maleimides); (2) the weight loss of PEMI, PNPMI and PIPMI is larger than that of PMI and PMMI; (3) the five-membered imide of PMI is the most unstable among the poly(*N*-alkyl maleimides); (4) the crosslinkages are formed more easily in PMI and PMMI than in PEMI, PNPMI and PIPMI.

INTRODUCTION

N-substituted maleimides polymerize easily by means of free radical initiators¹, anionic initiators¹, γ -ray² and ultraviolet irradiation³. The physical properties of poly(*N*-substituted maleimides) have been studied by many investigators. Cubbon¹ reported on the stereospecific configuration of poly(*N*-alkyl maleimides); Sheremeteva *et al.*⁴ on the solution properties of poly(*N*-isobutyl maleimide) and Walker *et al.*^{5,6} reported on the dielectric relaxation of poly(*N*-alkyl maleimides) and poly(*N*-aryl maleimides), and on the nuclear magnetic relaxation of poly(*N*-amyl maleimide) and poly(*N*-dodecyl maleimide). These results indicate that *N*-substituted maleimide polymers have high softening points, considerable chain rigidity and region of oriented structure. However, the thermal degradation behaviour has not previously been studied. We report on a study of the thermal stabilities of poly(*N*-alkyl maleimides) over the temperature range 300° to 400°C, under a constant flow of nitrogen. The volatile product, the scission of a main chain, the weight loss, the cleavage of a five-membered imide ring and the side reaction have been investigated, and the degradation mechanism was discussed on the basis of the results.

EXPERIMENTAL

Polymer preparations

The *N*-alkyl maleimides except for maleimide were prepared from maleic anhydride by the method of Mehta *et al.*⁷ *N*-methyl maleimide was purified by recrystallization from ethyl ether; *N*-ethyl maleimide by sublimation under reduced pressure, and *N*-*n*-propyl maleimide and *N*-isopropyl maleimide by redistillation under reduced pressure. Maleimide was prepared from maleic anhydride by the method of Tawney *et al.*⁸ and purified by recrystallization from ethyl acetate.

The polymers were obtained by free radical polymerization, which was carried out in cyclohexanone as a solvent at 60°C for 5 h, in the presence of azobisisobutyronitrile as an initiator, under flow of nitrogen. After completion of

polymerization, the polymers were precipitated by pouring the solution into methanol, purified by fractional precipitation and dried *in vacuo* at 80°C. The solvent for polymerization of maleimide was dioxane and the precipitant was ethyl acetate.

The intrinsic viscosities of poly(*N*-ethyl maleimide) (PEMI), poly(*N*-*n*-propyl maleimide) (PNPMI) and poly(*N*-isopropyl maleimide) (PIPMI) were measured in acetone at 30°C by means of a Ubbelohde viscometer. Dimethylformamide was used for viscosity measurements of polymaleimide (PMI) and poly(*N*-methyl maleimide) (PMMI). The values of intrinsic viscosities are shown in Table 1.

The polymers have the following chemical structures.

R = H(PMI)
 = CH₃(PMMI)
 = CH₂CH₃(PEMI)
 = CH₂CH₂CH₃(PNPMI)
 = CH(CH₃)CH₃(PIPMI)

Degradation experiments

A boat holding the sample was placed at the centre of a Pyrex reaction tube in a furnace controlled at a constant temperature over the range 300°–400°C. The polymer powder was moulded into the form of a disc 10 mm in diameter and ~1 mm in thickness, under 1 t/cm² pressure, as the powder is scattered from the boat, when nitrogen gas passes through the reaction tube. The reaction tube was evacuated with vacuum pump (5 mmHg) to remove air before admitting the nitrogen gas. The degraded residue in the boat was used for measurement of weight loss, viscosity and crosslinkage. The condensates on the wall of the reaction tube were collected and isolated by column chromatography (developing solvent: ethyl acetate/benzene/acetone = 3:6:1; silica gel column). After purification, the chemical structures of the isolated substances were determined on the basis of the elemental analysis, infra-red spectra, molecular weight (cryoscopic method), number of double bonds (bromination titration method) and boiling and melting points.

The gaseous products of degradation were condensed in the side tube of a sealed Pyrex reaction tube, and the condensates were analysed by use of infra-red spectroscopy and gas chromatography.

RESULTS AND DISCUSSION

Weight loss

Plots of weight loss against time of heating are shown in Figure 1. Further, the initial rates of weight loss and the weight loss after 1 h at various temperatures, are given in Table 2. The weight loss under the same conditions increases in the following order:

PMI and PMMI are more stable than the other polymers.

Crosslinkage

Original PMI and PMMI are soluble in dimethylformamide, and PEMI, PNPMI and PIPMI are soluble in acetone.

On the other hand, the degraded polymers are partly soluble in each solvent. Therefore, the degraded polymers were separated into two fractions by refluxing them with an excess of solvent for 72 h. The results are shown in Table 3, where the values are the weight % of the fraction insoluble in solvent per weight of the original polymer. The amount of the insoluble fraction at the initial stage of degradation increases in the following order:

This order is the reverse one of the weight loss. It is thought that the stabilities of the maleimide polymers increase with an increase in the number of crosslinkages.

Change in viscosity

The intrinsic viscosities of the solvent-soluble fraction of degraded polymers were measured at 30°C. Plots of $[\eta]_t/[\eta]_0$ against time of heating are shown in Figure 2, where $[\eta]_0$ is the intrinsic viscosity of the original polymer, and $[\eta]_t$ is that of the solvent-soluble fraction of degraded polymer heated for t h. The drop of viscosity at the initial stage of degradation increases in the following order:

This order corresponds to that of the weight loss except for PMI. It is thought that the weight loss is caused primarily by the elimination of low molecular substances from the end of polymer chains; the details will be presented

Table 2 Weight losses of poly(N-alkyl-substituted maleimides)

later. The minima in the curves of PEMI, PNPMI and PIPMI seem to appear as a result of competition between the scission of main chains and the formation of crosslinkages.

Infra-red spectra of degraded polymers

The study of the infra-red spectra of the polymers degraded at 360°C shows that the characteristic bands⁹⁻¹¹ of five-membered imide ring of PMI (1770, 1710, 1370 and 1180 cm^{-1}) disappear, the intensities of the characteristic bands of PEMI (1790, 1700, 1350 and 1210 cm^{-1}) decrease remarkably, but those of PMMI (1770, 1710, 1370 and 1260 cm^{-1}); PNPMI (1790, 1710, 1350 and

1190 cm^{-1}) and PIPMI (1770, 1700, 1370 and 1220 cm^{-1}) scarcely decrease. When PMMI, PNPMI and PIPMI are degraded at 380°C, the intensities of the characteristic bands of PNPMI and PIPMI decrease remarkably, but those of PMMI scarcely decrease. From the above facts the stability of five-membered imide ring increases in the following order:

The five-membered imide ring of PMMI is the most stable in contrast to that of PMI.

The ratio of the optical density of characteristic band of five-membered imide ring to that of *N*-substituted group, against the degradation temperature is plotted in Figure 3. The *N*-substituted group of poly(*N*-alkyl maleimides) except for PMI, seems to break more easily than the five-membered imide ring with an increase in temperature above 340°C. On the other hand, PMI gives a reverse tendency, which suggests the unstability of its five-membered imide ring.

Formation of double bonds

The number of double bonds formed in the degradation products was estimated by use of bromination titration method. The results are shown in Table 4, where the values are the number of moles of double bond formed per 100 moles of the repeating unit. It was found that a few double bonds were formed in the chains of degraded polymers and volatilized substances.

Volatilized substances

The substances volatilized from polymers over the temperature range 300°–400°C, were analysed and the results are shown in Tables 5 and 6. At the initial stage of degradation below 360°C, *N*-substituted succinimide, dimer of *N*-substituted maleimide and trimer of *N*-substituted maleimide are chiefly produced from PMMI, PEMI, PNPMI and PIPMI. On the other hand, both succinimide and urea are chiefly produced from PMI. The result of PMI is the same as the results of poly(*N*-phenyl maleimide)¹², poly(*N*-*p*-tolyl maleimide)¹³ and poly(*N*-*p*-acetylphenyl maleimide)¹³, in which both *N*-aryl succinimide and urea compound are chief products. These facts show that the main chains of poly(*N*-alkyl maleimides) except for PMI, seem to break more easily than the side chains and the five-membered imide rings. Since no monomers were found in the degradation products, the end radicals of the polymer chains seem to be liable to abstract a hydrogen atom during de-

* Amount of carbon monoxide produced in 1 min after 30 min heating

gradation. At elevated temperatures, above 380°C, the substances of low molecular weight are produced by the cleavage of side chains, by the cleavage of five-membered imide rings or by the secondary reactions.

The amount of carbon dioxide and carbon monoxide estimated by usual methods are shown in Table 7, where the amount of carbon dioxide was determined by use of a titration method and the amount of carbon monoxide by means of Kitagawa A-type CO detector. Since the evolu-

tion of carbon dioxide and carbon monoxide is caused by the cleavage of five-membered imide rings, it seems that the stability of five-membered imide ring increases in the following order:

This order agrees with that obtained from infra-red spectra described previously.

Behaviour of degradation

PEMI, PNPMI and PIPMI give a similar behaviour of degradation, in which the main chains break easily, the weight loss is large, but the number of crosslinkages is slight and the five-membered imide rings are stable. The molecular weight drops rapidly during the first few per cent of weight loss. The initial drop in molecular weight may be caused primarily by random scissions in the main chains. The carbon atoms in the main chains of poly(*N*-alkyl maleimides) are tertiary and the C—C bonds in the main chains are in β -position to carbonyl groups. Furthermore, the degradation products from PEMI, PNPMI and PIPMI chiefly consist of *N*-substituted succinimide, dimer of *N*-substituted maleimide and trimer of *N*-substituted maleimide. However, no monomers are isolated. From the above results, it is assumed that the thermal scission of the C—C bonds in the main chains at the β -position is accompanied by inter- and intra-molecular hydrogen transfers. The intramolecular hydrogen transfers are caused by back biting reaction, in which the hydrogen atoms attached to 4-, 5- and 6-position carbon are abstracted by the end radicals.

Abstraction of the hydrogen atom attached to 5-position carbon leads to the formation of trimer of *N*-substituted maleimide.

Abstraction of the hydrogen atom attached to 6-position carbon leads to the formation of dimer of *N*-substituted maleimide.

The degradation behaviour of PMI and PMMI is different from that of PEMI, PNPMI and PIPMI. In PMI and PMMI the number of crosslinkages are relatively large and the weight loss is slight. At 320°C, no crosslinkages are formed in both PMI and PMMI. When the viscosities of the polymers degraded at 320°C are compared, the molecular weight

of PMI drops rapidly, while that of PMMI scarcely drops. The imide ring of PMI is the most unstable among poly(*N*-alkyl maleimides). Therefore, the main chain and the imide ring of PMI break easily, while those of PMMI are difficult to break. From these results, in the case of PMMI, the dissociation of the hydrogen atom from the tertiary carbon in the main chain may predominantly occur and may result in the formation of intermolecular crosslinkage.

(II) + (II) → intermolecular crosslinking

In the case of PMI the scission of both C—C bonds and C—H bonds in the main chain is accompanied by the scission of the imide rings, which results in the formation of urea and crosslinkage.

Urea and ammonia are detected as shown in Table 6. The stability of the imide ring depends upon the interaction between *N*-substituted and carbonyl groups. Matuo¹⁰ suggests that an electron-donating substituent is preferred in stabilizing the ionic structures in the imide ring.

The extent of stabilization of the ionic structures due to a substituent, R, is expected to be in the following order:

alkyl group > hydrogen ≅ aromatic group

This effect strengthens the C—N—C bonds in the imide rings of *N*-alkyl-substituted maleimides. From these facts, it is thought that the five-membered imide rings of poly(*N*-alkyl maleimides) except for PMI are significantly stable in comparison with the main chains.

Synthesis of narrow distribution polytetrahydrofuran

T. G. Croucher and R. E. Wetton

Department of Chemistry, Loughborough University of Technology, Loughborough, Leicestershire, LE11 3TU, UK

(Received 13 October 1975; revised 1 November 1975)

Bulk polymerizations of tetrahydrofuran (THF) have been studied kinetically at reaction temperatures in the range -10 to $+80^{\circ}\text{C}$ using *p*-chlorophenyldiazonium hexafluorophosphate initiator. Initiation has been studied to enable selection of a 'clean' initiation condition (95°C for 4 min). Factors causing broadening of the molecular weight distribution are discussed, the main causes of such broadening being chain transfer reactions and concurrent initiation with propagation. These could be minimized by using a low reaction temperature (-10°C). Molecular weight distributions were measured by gel permeation chromatography. Propagation rate constants were determined and found to increase with increasing temperature according to an Arrhenius expression giving an activation energy of 51 kJ/mol. The method will produce monodisperse samples of THF polymer over a wide molecular weight range from 5×10^3 to 10^6 .

INTRODUCTION

Tetrahydrofuran may be ring-opened using cationic initiators to give high molecular weight polymers of polytetrahydrofuran (PTHF); otherwise known as poly(tetramethylene oxide). The propagation stage is considered to proceed via a growing oxonium ion as follows:

Such reactions have been the subject of a number of original and review papers¹⁻⁴. It is well established that using PF_6^- as the counter-ion (X^-) in polar and aromatic solvents and in bulk enables high molecular weight products to be obtained, and a living system without termination can be observed⁵. A particularly facile initiator is *p*-chlorophenyldiazonium hexafluorophosphate⁶.

In this work we wished to prepare samples for model crystallization studies and it was a prerequisite that these should be monodisperse as well as cover a wide molecular weight range. The literature data on PTHF contain few records of the production of narrow distribution polymers despite the clear demonstration that the polymerization is a living system under rigorous conditions. Those that are mentioned are either low molecular weight products taken to low conversion⁷, or the very rapid dicationic systems of Smith and Hubin⁸.

It has been noted that the polydispersity ratio, which should commence as a Poisson distribution ($\bar{M}_w/\bar{M}_n < 1.1$ for low polymer) and broaden to the most probable distribution of 2 for a reversible polymerization at equilibrium, does in fact broaden much more rapidly than predicted⁵, and can attain a value much greater than 2.

The present work describes pertinent kinetic experiments which were undertaken to establish the origin of the high polydispersity ratio normally obtained for PTHF. These

results allow selection of initiation and growth conditions which lead to the production of narrow distribution polymers over a wide molecular weight range.

EXPERIMENTAL

All reactions were carried out under high vacuum, a pressure of 10^{-5} mmHg being generally obtained in a greaseless vacuum system. The reaction vessels were made of glass with a helical tube arrangement designed to maximize heat transfer to surrounding baths, and to allow good initial mixing (Figure 1). After cleaning with chromic acid the reactors were treated with a solution of dichlorodimethyl silane in chloroform (10% v/v), in order to minimize water pick up on the internal glass surfaces.

The initiator, *p*-chlorophenyldiazonium hexafluorophosphate, obtained commercially as Phosfluorogen A (Ozark-Mahoning Co., Tulsa, Oklahoma, USA), was purified by recrystallization from water as white plates⁶, and stored under vacuum. Tetrahydrofuran (Fison's SLR grade) was distilled under nitrogen, a middle cut being taken and stored under vacuum over calcium hydride. Before use it was vacuum distilled onto a complex of sodium/potassium alloy and α -methylstyrene to ensure complete removal of protonic species. Sodium ethoxide was prepared by the reaction of sodium metal upon ethanol in diethyl ether solution⁹.

Preparation of polymers

A given quantity of initiator was weighed into a reaction vessel such that its concentration would be 2×10^{-2} mol/l of monomer, and evacuated for several hours. A known volume of dry THF was distilled into the vessel at liquid nitrogen temperature. The reaction vessel was vacuum sealed and stored in liquid nitrogen until used.

Initiation followed the same procedure for all samples. The reactor was removed from liquid nitrogen and allowed to stand at room temperature for 4 min, by which time the monomer had melted. It was then transferred to a methanol bath at -10°C for 6 min with continual turning to en-

Figure 1 A helical glass reactor having an internal volume of approximately 40 ml, with a greaseless high-vacuum joint

sure homogeneous mixing of the reactants. Initiation was effected by placing the vessel in an oil bath at a high temperature for a specified time (usually 95°C for 4 min) during which time an intense purple colour developed. This active system was cooled rapidly in a bath at -10°C for 15 sec and then in liquid nitrogen for 15 sec, after which it was removed to a bath set at the required reaction temperature.

Termination was achieved by freezing the reactants rapidly in liquid nitrogen, opening the vessel and transferring the contents to a terminating solution. Initially this was a 10% (v/v) solution of acetic acid in THF, but in later reactions this was changed to a solution of sodium ethoxide in THF (5×10^{-2} mol/l).

Residual catalyst and catalyst fragments were isolated from the THF solution by adding distilled water, evaporating off the THF under a stream of nitrogen and extracting the polymer with benzene, thus removing any water soluble material. After removal of the benzene under nitrogen and drying for several days under vacuum, the weight of product was recorded. High molecular weight polymers could be isolated simply by precipitating with methanol, drying and weighing.

It should be noted that the coloration introduced at the initiation stage was still evident in the recovered products. It was assumed at first that this was caused by initiator residues, or by the formation of coloured by-products as suggested by Dreyfuss¹⁰. Accordingly a preparative gel per-

meation chromatograph was set up following the procedure of Mulder and Buytenhys¹¹ to purify the products further.

Purification of polymers

Preparative g.p.c. columns were set up using Bio-Rad SX-1 (high molecular weight) or SX-8 (low molecular weight) gels in toluene as solvent. The flow was gravity fed from a constant pressure reservoir; a syphon injection system was used together with infra-red monitoring of the effluent. A normal solute concentration of 5% (w/v) was injected. The gel was chosen so that the polymer molecular weight was above the exclusion limit of the gel, and was thus carried through the column in the excluded volume. Any low molecular weight impurities diffused into the substrate and were retained longer on the column.

This process was observed visually by the separation of the sample into two distinct bands, the coloured polymer band (red/purple) eluting first, followed by an orange/yellow band. U.v. and i.r. spectroscopy were performed on the polymer before and after this treatment, the traces being shown in Figure 2. The disappearance of the peak at $39\,000\text{ cm}^{-1}$ (256 nm) in the u.v. spectrum suggests removal of an aromatic species undergoing a $\pi \rightarrow \pi^*$ transition (local excitation of electrons in a benzene nucleus).

Molecular weight determinations

Average molecular weights were determined using a Waters Associates ALC/GPC 501 liquid chromatograph. Tetrahydrofuran was used as solvent at room temperature upon commercially available styragel columns. The instrument was calibrated with the familiar narrow distribution

Figure 2 (a) U.v. spectra of polymer ($\bar{M}_n = 7000$) in solution in ethanol (0.01%) showing disappearance of peak at $39\,000\text{ cm}^{-1}$ (256 nm) after passage of polymer through preparative g.p.c. column. A, crude polymer; B, purified polymer. (b) i.r. spectrum of polymer ($\bar{M}_n = 7000$), cast from chloroform onto KBr disc, showing no difference before and after passage through preparative g.p.c. column

polystyrene standards, and a conversion factor was calculated based on the hydrodynamic volume procedure proposed by Benoit and coworkers¹². For polystyrene (PS) and polytetrahydrofuran (PTHF) in THF having identical hydrodynamic volumes

$$\log[\eta]_{\text{PTHF}} M_{\text{PTHF}} = \log[\eta]_{\text{PS}} M_{\text{PS}}$$

where $[\eta]$ is the intrinsic viscosity and M is the molecular weight. The intrinsic viscosity can be written in terms of the unperturbed end-to-end distance $[\overline{r_0^2}]^{1/2}$ and the expansion factor α , with ϕ the universal viscosity constant¹³

$$[\eta] = \phi \left(\frac{\overline{r_0^2}}{M} \right)^{3/2} M^{1/2} \alpha^3$$

substituting for $[\eta]$ yields

$$\frac{M_{\text{PTHF}}}{M_{\text{PS}}} = \left(\frac{\overline{r_0^2}}{M} \right)_{\text{PS}} \left(\frac{M}{\overline{r_0^2}} \right)_{\text{PTHF}} \left(\frac{\alpha_{\text{PS}}}{\alpha_{\text{PTHF}}} \right)^2$$

Assuming $(\alpha_{\text{PS}}/\alpha_{\text{THF}}) = 1$ for these two polymers in the g.p.c. solvent (as proposed by Dawkins¹⁴ and taking literature values for $[\overline{r_0^2}/M]$ ¹³ we calculate the value 0.592 as a conversion factor, i.e.

$$M_{\text{PTHF}} = 0.592 M_{\text{PS}}$$

at a given elution volume. The determination of M_{PTHF} enables absolute molecular weights to be evaluated from the chromatogram.

An empirical correction for machine-broadening was made by comparing the $\overline{M}_w/\overline{M}_n$ ratios for polystyrene found from the instrument, to that given with these samples, and a plot of % correction *versus* log molecular weight made. Thus a correction for machine broadening could be made covering the entire molecular weight range of the instrument. A computer program was written to perform the tedious calculations, using the method of Pickett *et al.*¹⁵.

Factors causing molecular weight broadening

Equilibrium effects. Living PTHF chains eventually reach an equilibrium between monomer and polymer where the rates of propagation and depropagation become equal. The effect of having competing forward and backward reactions is, eventually, to spread the distribution of molecular weights until it reaches the Flory distribution ($\overline{M}_w/\overline{M}_n = 2$). Miyake and Stockmayer¹⁶ have calculated that for the anionic polymerization of styrene it will take 80 years to reach this polydispersity. Dreyfuss and Dreyfuss⁵ quote a corresponding value of 20 days for PTHF at 30°C. This reflects the fact that polymer is the favoured species at low temperature but as the ceiling temperature is approached the reverse reaction is progressively more favoured. Since broadening is observed even at low temperatures and to a higher degree than predicted the propagation-depropagation effect cannot be solely responsible.

Chain transfer reactions. Assuming a very low level of impurities in our rigorous system, the most likely chain transfer agents present are in-chain oxygens and counter ions.

This example shows chain transfer to polymer oxygen, which is really a special case of a dialkyl ether. Dreyfuss⁶ has shown dialkyl ethers to be effective chain transfer agents, and as can be seen from the above scheme this reaction leads to a randomization of molecular weights with no decrease in the rate of polymerization. Rosenberg² has suggested that, in the later stages of polymerization when monomer is becoming scarce, species I increases in concentration leading to a very large rise in viscosity, although association of active ends would cause a similar effect. Problems of this type will grow in severity as the conversion increase so most of this work was performed with conversions below 10%.

With many systems, reaction of the growing chain-end with counter-ion is a termination reaction, and this becomes a difficult problem when relatively unstable counter-ions, such as BF_4^- , are used. However, with PF_6^- as counter-ion, the reaction between them is envisaged as follows¹:

The PF_5 itself may act as an initiator¹⁷ and thus a transfer, rather than termination, reaction occurs. The effect of such a transfer reaction will again be to broaden the distribution of molecular weights, but in this case with a delay in the chain reaction and an alteration of the counter ion.

Slow initiation reactions The mechanism of initiation by trityl or diazonium salts has been the subject of much controversy but has been proposed¹⁰ as follows for the diazonium salt:

Dehydrogenation of THF to a furan or dihydrofuran occurs, along with the formation of the free acid of the counter ion (HPF_6), which is stabilized by complexing with monomer (HPF_6 is normally found as its diethyl ether complex, $\text{HPF}_6 \cdot 2(\text{CH}_3\text{CH}_2)_2\text{O}$). The acid complex then reacts slowly with additional monomer to form the propagating species, which should have an hydroxyl end group. It is further suggested that the intense colours observed during the initiation are formed by the acid catalysed resinification of the furan or dihydrofuran by-products. In the present work, however, a high degree of colouration is observed in

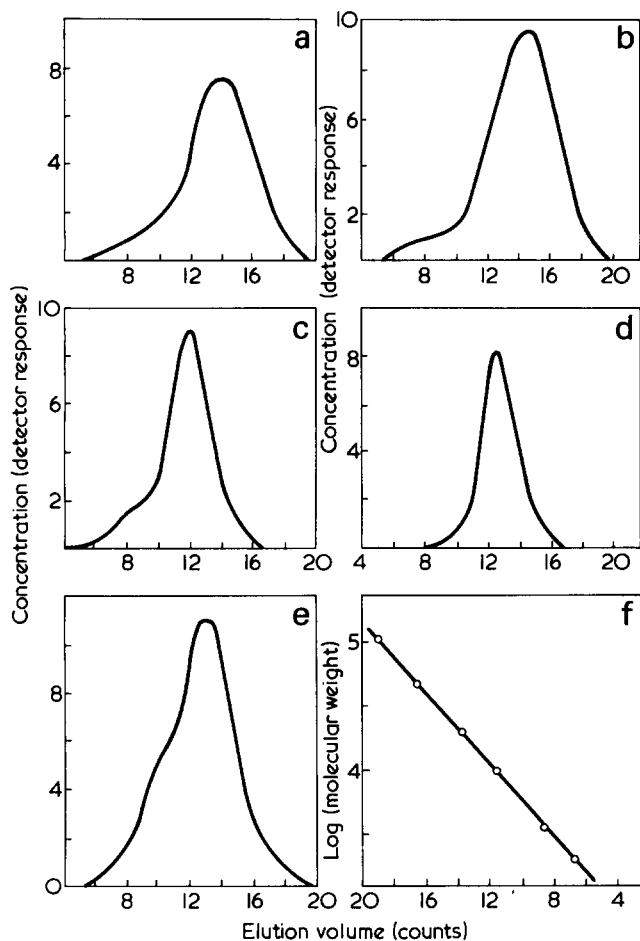

Figure 3 Gel permeation chromatograms (polymer concentration versus elution volume) showing effect of initiation temperature upon the molecular weight distribution. (a)–(c) initiated for 7.5 min; (d), (e) initiated for 5 min. (f) shows the calibration curve for the instrument (polystyrene standards). Initiation temperatures: (a) 85°C; (b) 90°C; (c) 95°C; (d) 95°C; (e) 100°C

the polymer even after preparative g.p.c., suggesting that the colour is chemically associated with the initiated chain end.

Ledwith and Sherrington³ have also suggested a homolytic decomposition reaction for the diazonium salt involving a chain reaction in the initiation process and leading to the aldehydic end group:

There is no conclusive evidence as to the chemical nature of the initiated chain-end.

Both of these reaction mechanisms involve a slow, rate-determining step, in line with the observed slow initiation at temperatures where the rate of propagation is reasonably fast. This will be a prime cause in broadening the molecular weight distribution, since centres initiated early in the reaction may grow to much longer chain lengths than those initiated later.

Ion pair structure. Whenever ions are present in solution their local environment will largely determine their rate of reaction. The following general scheme for the ions

R^- and X^+ in solution may be envisaged:

The order to reactivity of these ion pairs is expected to be: free solvated ions \geq loose ion pairs $>$ tight ion pairs.

Now consideration of the propagation reaction together with the knowledge that a ceiling temperature T_c exists for a given concentration of reactants such that ΔG (polymerization) = 0 at T_c , leads to:

$$k_p/k_B = A \exp[-\Delta H(T_c - T)/RT T_c] \quad (1)$$

and as ΔH is negative k_p/k_B decreases with increasing temperature, strongly near T_c . However, we observe the polymerization to increase in rate with temperature well below T_c thus signifying a progressive change from tight ion-pairing (or clustering) towards the free ion situation with increasing temperature.

The rate of addition of monomer is only approximately 1 monomer per chain per 6 sec at -10°C . Thus in the time taken to grow high polymer every chain end will fluctuate statistically between the various possible structures. Every chain will thus propagate at the same overall statistical rate and differences in ion pair structure will not lead to broadening with the present system.

RESULTS AND DISCUSSION

The preceding comments allow sensible interpretation of an initially complex pattern of results. Figure 3 shows the g.p.c. traces obtained for a series of bulk polymerizations with initiator concentrations of 1.75×10^{-2} mol/l identical in all respects except that they were initiated for 7.5 min (Figures 3a–3c) and 5 min (Figures 3d and 3e) at progressively higher temperatures before reacting at 0°C to approximately 2% conversion. A closely related series of experiments was carried out to investigate the effect of initiation time at each temperature. The results follow a similar pattern for all of the lower temperatures and are typified by the curves in Figure 4 for initiation at 60°C , followed by reaction at 0°C , to ~ 10 –15% conversion. The

Figure 4 Gel permeation chromatograms showing samples initiated for different times at 60°C and reacted for the same time (30 min) at 0°C . The molecular weight and distribution increase with increasing initiation time. Initiation times: A, 30 min; B, 15 min; C, 7.5 min

Table 1 Kinetics of polymerization followed at a series of low temperatures

	0.75	6.38
	1.00	8.91
	1.25	11.16
	1.50	13.80

significance of these results will become clear as we consider further evidence, but empirically it is seen (*Figure 3d*) that initiation at 95°C for 5 min followed by rapid quenching to a low reaction temperature gives a nearly monodisperse polymer ($\bar{M}_w/\bar{M}_n = 1.08$).

Using the clean initiation conditions (95°C for 4 min) the kinetics of polymerization were followed at a series of low temperatures, viz. -10°C, 0°C and 20°C, with molecular weight averages being measured in each case. The kinetic results are given in *Table 1*. Now at the high initiation temperatures ($[I_0] - [I]$) mol/l of initiator decomposes and we will assume each gives rise to a living polymer chain which grows predominantly during the time held at the low polymerization temperature. Then at the polymerization temperature the rate of monomer consumption is

$$\begin{aligned} \frac{-dM}{dt} &= k_i [I] ([M] - [M_e]) \\ &+ (k_p/n) ([I_0] - [I]) ([M] - [M_e]) \end{aligned} \quad (2)$$

The terms $([M] - [M_e])$ are the effective concentrations¹⁸ under conditions where the equilibrium concentration would be $[M_e]$ and n is the number of initiators required to start one chain. The first term on the right allows for consumption of monomer in further initiation reactions at the polymerization temperature. At low polymerization temperatures k_i is small and we will neglect the first term giving

$$\frac{1}{[I_0]} \ln \frac{[M_0] - [M_e]}{[M] - [M_e]} = \frac{f}{n} k_p t \quad (3)$$

where $f = ([I_0] - [I])/[I_0]$ is the fraction of catalyst decomposed under the initiation conditions. These conditions were constant with f/n , known approximately from the relation:

$$\frac{f}{n} = \frac{\text{yield}}{\text{molecular weight } [I_0]}, \text{ being } \approx 0.1.$$

Plots of $(2.303/[I_0]) \log ([M_0] - [M_e])/([M] - [M_e])$ against time are shown in *Figure 5*. Good straight lines re-

sult at -10 and 0°C, but at 20°C a positive deviation is present. Values of $(f/n)k_p$ at each temperature were calculated from the initial slopes, and the k_p values are shown, together with the $[M_0]$ and $[M_e]$ ¹⁹ values used, in *Table 2*.

A plot of $\ln k_p$ against $1/T$, using the three lowest temperature values of k_p from *Table 2*, is shown in *Figure 6*, along with the results from a high temperature set of single point determinations, as described later. A straight line results showing k_p increasing with increasing temperature with an activation energy (probably for ion pair dissociation) of 51.3 kJ/mol.

Number average molecular weights (\bar{M}_n) are shown plotted against time in *Figure 7*. At -10°C this yields a straight line, but at 0°C the plot falls away from a linear relation with time, whereas the conversion increases linearly. The logical interpretation of these data is that chain transfer reactions become more significant at higher temperatures. Accordingly the polydispersity ratios are all narrow for polymers at -10°C, but begin to broaden with time at 0°C. These values are given in *Table 3*.

Figure 5 Plots of $(2.303/[I_0]) \log ([M_0] - [M_e])/([M] - [M_e])$ versus time to test equation (3), and also to allow calculation of fk_p/n and hence k_p at each temperature: \circ , 20°C; \square , 0°C; \triangle , -10°C

Figure 6 Plot of $\ln k_p + \ln f/n$ versus $1/T$. The low temperature values (\circ), are obtained from Figure 5, the high temperature values (Δ), are obtained from single point measurements at each temperature. This plot yields an activation energy of 51.3 kJ/mol

Figure 7 Increase of molecular weight (\bar{M}_n) with time at temperatures of -10°C (\square , linear) and 0°C (\circ , falls away from linear relation due to the onset of significant chain transfer reactions)

Another series of kinetic experiments was carried out using the clean initiation conditions (95°C for 4 min) followed by propagation reactions at a series of temperatures (50° , 60° , 70° and 80°C) for the same period of time (10 min). A plot of % conversion against propagation temperature is given in Figure 8, and this shows a clear maximum in the yield at a temperature of 65°C . This plot is closely followed by the theoretical line shown in Figure 8 calculated using equation (3). Since the overall rate of polymerization passes through this maximum on cooling, it is necessary to quench the samples as rapidly as possible after the initiation stage. Equation (3) was used to calculate k_p from the single point at each temperature, and these are also plotted in Figure 6 where they clearly show good agreement with the extrapolation of the low temperature data. A significant inference from this result is that the assumption made

in deriving equation (3) is valid and $k_i [I]$ must be small compared with $k_p ([I_0] - [I])$. This is reasonable since at 95°C the initiation will be rapid, with some 20–40% (depending on the mechanism) of initiator used in starting chains. In addition the initiator will tend to decompose thermally as follows:

In the solid state this occurs at 150°C , but in solution this temperature will be reduced. Thus we propose that only a small concentration ($\sim 20\%$) of the starting concentration of initiator remains unreacted after treatment at 95°C for 4 min.

At temperatures below T_c , Figure 4 shows that molecular weight broadening occurs more rapidly as initiation time increases. It is clear from the preceding discussion that this is caused by continuous initiation during propagation, as the two rates are similar at these temperatures.

The choice of 95°C as the temperature of initiation may be explained with reference to Figure 3. At temperatures below 95°C , initiation and growth are occurring simultaneously throughout the initiation reaction, with chain transfer also occurring at longer reaction times, thus giving a very broad molecular weight distribution. At 95°C , however, the temperature is sufficiently far above the ceiling temperature to prevent significant growth from occurring, thus upon cooling and subsequent propagation a narrow molecular weight distribution occurs. Above 95°C further polymerization occurs in sealed reactors due to the increase in pressure which will favour the polymerization reaction if this occurs with a decrease in volume (as in the present case). This is equivalent to an elevation of ceiling temperature with pressure²⁰.

Table 3 Polydispersity ratios at different temperatures and reaction times

Temperature ($^\circ\text{C}$)	Polydispersity ratio after stated reaction times					
	1 h	2 h	3 h	4 h	6 h	8 h
-10		1.08		1.08	1.08	1.10
0	1.17	1.26	1.31	1.36	1.75	

Figure 8 Plot of conversion versus temperature for reactions of the same time (10 min, \circ) and also the theoretical conversion (---) predicted by equation (3)

In considering the significance of the present results in terms of the factors, listed earlier, which could produce molecular weight broadening we see that changing ion pair structure may well be the reason for the increase in chain transfer over propagation reactions as the temperature is raised. Competing initiation and polymerization reactions occur if initiation is attempted below T_c , but conversely the effect of a reversible reaction on broadening is not important well below T_c and at low conversions.

The method outlined is excellent for producing near monodisperse high molecular weight polymers. In the present work polymers as low as 5000 molecular weight have been produced still with good monodispersity. The disadvantage with low polymers is the high catalyst concentration required ($\sim 1:1$ based on polymer produced) with the inevitable difficulties of adequate separation of catalyst residues from the polymer. In the low molecular weight range we have found triethyloxonium hexafluorophosphate more convenient⁵.

CONCLUSIONS

Bulk tetrahydrofuran at low conversions obeys second order reaction kinetics with reversibility and no termination under high vacuum conditions. The propagation rate constant increases with temperature according to an Arrhenius relation with activation energy = 51.3 kJ/mol. Initiation rates also increase with temperature, but because of the reversibility of the polymerization reaction, initiation at 95°C (above the ceiling temperature) gives rapid production of active chains, but little growth. Rapid quenching to low temperatures (-10°C) then allows growth without simultaneous initiation, giving a near monodisperse system (typically $\bar{M}_w/\bar{M}_n = 1.08$). Selection of low temperatures for growth is necessitated largely because chain transfer to polymer occurs more predominantly as the temperature is raised giving increased polydispersity. The procedures outlined are particularly useful in producing polymers in the thousands to million molecular weight range with good monodispersity.

Analysis of relaxation processes in methacrylate polymers by thermally stimulated discharge

M. Kryszewski, M. Zielinski and S. Sapięha

Centre of Molecular and Macromolecular Studies, Polish Academy of Sciences, Łódź, Poland

(Received 1 August 1975; revised 7 October 1975)

An analysis of relaxation processes in poly(methyl methacrylate), poly(ethyl methacrylate), poly(isobutyl methacrylate) and poly(n-butyl methacrylate) by means of thermally stimulated discharge (t.s.d.), is presented. Distribution functions, calculated from the thermocurrent spectra using the Staverman-Schwarzl transform, are compared with semi-empirical distribution functions of Fuoss-Kirkwood and Havriliak-Negami. Distribution functions of β processes fit the first function very well and those of α processes fit the second distribution function. The distribution parameters are comparable with those in the literature. It is also demonstrated that the activation energy can be calculated from the initial rise by means of the Bucci, Fieschi and Guidi equation, if the proper correction coefficient is introduced, depending on the width of the distribution.

INTRODUCTION

In recent years the thermally stimulated currents (t.s.c.) and thermally stimulated depolarization (t.s.d.) techniques, applied to polymers, were used to evaluate trapping levels and other trap parameters in these materials. However, for dipolar polymers, t.s.d. is a very useful technique for elucidating their molecular parameters as relaxation frequencies, distribution functions and activation energies. Recent results of Van Turnhout¹ have shown, that it is possible to calculate these parameters from t.s.d. spectra. However, the authors did not focus their attention on the specific distribution functions for all relaxations¹⁻⁴, giving only examples^{1,2} of the calculation method, based on the simple, symmetric distributions of β and γ relaxations in PMMA.

All studies of dielectric properties of methacrylic polymers have led to the asymmetric distributions of relaxation times, at least in the glass transition temperature region. However, the shape of these distribution curves is still a subject for discussion. For this reason we have applied the t.s.d. method, which is considerably simpler, from the experimental point of view than other methods normally used, for determination of the characteristics of dipolar relaxation in polymers, giving some supplementary information related to the subject.

EXPERIMENTAL

Films of poly(methyl methacrylate) (PMMA), poly(ethyl methacrylate) (PEMA), poly(n-butyl methacrylate) (PnBMA) and poly(isobutyl methacrylate) (PiBMA) were investigated. Films were obtained by solvent evaporation from solution in chloroform, and their thickness was $\sim 20 \mu\text{m}$. After careful drying the solvent content in the polymer was negligible. The samples were then supplied with gold electrodes evaporated in a vacuum.

The t.s.d. measurements were carried out in a vacuum in the equipment described elsewhere⁵, at a constant heating rate, $4^\circ\text{C}/\text{min}$. The polarization field E_p and polarization time t_p , were constant for all experiments (150 kV/cm and 1 h respectively). The polarization temperature T_p was

altered depending on the T_g of the polymer. The influence of the heating rate on the t.s.d. peaks was in good agreement with theoretical predictions², and for our method the rate $4^\circ\text{C}/\text{min}$ was found most convenient. Because of the small thickness of the sample ($20 \mu\text{m}$), the temperature gradient across the sample was negligible.

The changes of temperature and field in the consecutive stages of the experiment: polarization, storage and t.s.d. measurements are presented in Figure 1.

RESULTS

T.s.d. spectra

Experimentally obtained spectra are discussed, assuming the Debye model of relaxation and a distribution in natural frequencies. For this type of relaxation one can obtain an

Figure 1 Time-temperature scheme of polarization, storage and t.s.d.: —, temperature changes; - - -, field changes

Figure 2 T.s.d. spectra of: A, PMMA; B, PnBMA; C, PiBMA; D, PEMA

Figure 3 Thermal cleaning of the PMMA spectrum. A, an overall spectrum; thermally cleaned peaks: α , B; β , C; β' , D

equation for the released t.s.d. current density, j^2 :

$$j/\epsilon_0 E = (\epsilon_s - \epsilon_\infty) \times a(T) \int_0^\infty F(T, t) \times f(\alpha_r) \times \exp \left\{ -\alpha_r \xi(T_s, T) \right\} d\alpha_r \quad (1)$$

where: ϵ_0 permittivity of vacuum;
 ϵ_s static dielectric constant;
 ϵ_∞ high frequency dielectric constant;
 $a(T)$ the temperature shift of the dipolar relaxation frequency;
 $F(T, t)$ the filling state function;
 α_r the natural frequency of dipolar relaxation;
 $f(\alpha_r)$ distribution function;
 $\xi(T_s, T) = s \int_{T_s}^T a(T) dT$ is the so-called 'reduced time' an analogue of time in similar equation for isothermal discharge;
 T_s storage temperature;
 s reciprocal of heating rate.

The temperature shift of the dipolar relaxation frequency $a(T)$ is defined by the equation $\alpha(T) = \alpha_r a(T)$ where α_r is constant and $\alpha(T)$ is the relaxation frequency. In the simplest case of Arrhenius shift, $a(T)$ is equal to $\exp(-A/kT)$, where A is the activation energy and k is the Boltzmann constant. The distribution function $f(\alpha_r)$ is the one normally used in the theory of dielectrics.

The filling state function is given by the following equation²:

$$F(T, t) = \{1 - \exp[\alpha(T_p) t_p - \alpha_r \xi(T_p, T_s)]\} \exp[-\alpha(T_s)(t_d - t_s)] \quad (2)$$

where: t_s , total time of field application; t_d , time, when t.s.d. begins. This function, dependent both on polarization and storage conditions, characterizes the filling state of the polarized sample. If the polymer sample is polarized completely, then $F(T, t) = 1$, and the t.s.d. spectrum is determined by the heating rate and such material parameters as $(\epsilon_s - \epsilon_\infty)$, α_r , $a(T)$ and $f(\alpha_r)$. Model calculations of Van Turnhout², show, that this condition is fulfilled if the polarization temperature is $\sim 20^\circ\text{C}$ higher than the T_g (for α relaxation). In all our investigations these requirements have been taken into consideration.

The t.s.d. spectra of the investigated polymers are presented in Figure 2. One can see, that for PMMA the α and β peaks are well resolved (the nomenclature of the relaxation processes is according to McCrum *et al.*⁶), but for all the three remaining polymers (PEMA, PiBMA and PnBMA), the β peak exists only as a shoulder on a low temperature tail of the α peak. T.s.d., however, has an exceptional ability to resolve overlapping peaks and in Figures 3 and 4, the spectra are well resolved with 'thermal cleaning technique'^{3,7}. This technique involves a partial discharge of the first peak up to some temperature T_1 . The temperature T_1 should be carefully chosen and usually, it corresponds to the valley between two peaks. In the next run, while only the second polarization is filled, an unperturbed peak due to the second process can be seen, and the remaining part of the first peak can be obtained by subtraction. The β peak in PEMA, isolated by this technique from the whole spectrum, is depicted in Figure 4. However, in the case of PMMA, attempts to isolate the β and α peaks were unsuccessful, as another peak was always seen (or an inflection on the falling shoulder of the β peak or on the rising shoulder of the α peak), independent of the choice of T_1 , between

Figure 4 Thermal cleaning of the PEMA spectrum. A, the overall spectrum; B, the thermally cleaned peak β

the maxima of the β and α peaks. Thus, by successive applications of 'thermal cleaning' it was possible to isolate three different peaks; the α and β peaks and another one, β' , located between them, with a maximum temperature of $\sim 50^\circ\text{C}$. (Figure 3) A similar process was observed by Mikhailov *et al.*⁸ by means of a.c. measurements and by Wittman *et al.*⁹ by means of dilatometric measurements, and it is ascribed to the presence of heterotactic sequences in conventional PMMA [evidence from high resolution n.m.r. studies¹⁰ suggests, that conventional PMMA may contain a fairly high degree ($\leq 60\%$) of syndiotactic sequences]. Vanderschueren⁴ also observed such a process in t.s.d. investigations of PMMA, and found, that it follows monomolecular kinetics, which in our case, indicates that it could be ascribed to another dipolar process.

Activation energies and distribution functions

There are several methods of calculating activation energies from the t.s.d. spectra. One can take into consideration the initial rise of thermocurrent, the half-width temperatures of the peaks or the least squares fit¹¹. In this work we have used the method proposed by Bucci, Fieschi and Guidi⁷ (BFG), which leads to the following equation:

$$A = -k \frac{d \ln \alpha(T)}{d(1/T)} \quad (4)$$

where:

$$\alpha(T) = j/P_s(T) \text{ and } P_s(T) = -s \int_{T_u}^T j \, dT, \quad (5)$$

T_u is the ultimate temperature, when j reaches zero. Unfortunately all these methods hold only for non-distributed polarizations. It was demonstrated by Van Turnhout², that for a distribution in natural frequencies in the case of the initial rise of thermocurrent in t.s.d.:

$$k \frac{d \ln j}{d(1/T)} = -cA$$

where c is a constant. The same holds for the BFG equation. Taking into consideration some particular distribution functions, it can be proved, that $c = 1$ for Wagner and Gevers distribution, and $c = m$ for Fouss-Kirkwood and Cole-Cole distribution functions¹², where m is a parameter of these distributions.

It is a common procedure in evaluating dielectric and mechanical relaxation data to introduce a distribution function, for it allows us to fit them to the Debye relaxation model. To calculate the distribution functions from the t.s.d. data, we have used the Staverman and Schwarzl approximation¹³ of the inverse Laplace transform of equation (2), taking into consideration only the second-order approximation. We have introduced the logarithmic distribution function², normalized to the maximum value:

$$L \left(\frac{\tau_r}{\tau_0} \right) = f(\ln \tau_r/\tau_0)$$

where $\tau_r = 1/\alpha_r$; τ_0 is the most probable value of τ_r

$$\frac{L_1 \left(\frac{\tau_r}{\tau_0} \right)}{L_m} = \left[\frac{T^2 j(T)}{T_m^2 j_m} \right]_{c'=1}$$

$$\frac{L_2}{L_m} = \frac{L_1}{L_m} - \left[\frac{T^2 d \left(\frac{j(T)}{j_m} \right)}{s T_m^2 dT} \right]_{c'=0.5}$$

where:

$$\frac{\tau_r}{\tau_0} = \frac{c' T^2 a(T)}{T_{\max}^2 \alpha(T_{\max})}$$

T_m, j_m are the temperature and current density values for maximum of t.s.d. peak, and T_{\max} is a temperature maximum of Debye relaxation for τ_0 .

For our calculations we have assumed that $T_m = T_{\max}$. To compare the results obtained with those found in dielectric and mechanical loss measurements, we have taken two of the semi-empirical distribution functions derived for interpretation of dynamic measurements. These are, symmetrical Fuoss-Kirkwood distribution¹²:

$$f(u) = \frac{m \cos(m\pi/2) \times \cosh(mu)}{\cos^2(m\pi/2) + \sinh^2(mu)}$$

and the two parameter asymmetrical Havriliak-Negami¹⁴ function:

$$f(u) = \frac{1}{\pi} \sin(\beta\theta) \times \{1 + \exp[-2u(1-\alpha)] + 2 \exp[-u(1-\alpha)] \cos \pi(1-\alpha)\}^{-\beta/2}$$

where:

$$\theta = \tan^{-1} \left\{ \frac{\sin \pi(1-\alpha)}{\exp[(1-\alpha)u] + \cos \pi(1-\alpha)} \right\}$$

for both distributions $u = \ln(\tau_r/\tau_0)$ and m, α, β are parameters of these functions.

All the numerical calculations of these equations were performed on a digital computer.

DISCUSSION

Of all dipolar processes revealed by the t.s.d. spectra, the β process in PMMA, which could be separated clearly, has the broadest distribution of relaxation times, and is also the most symmetrical one. For this case we could apply the Fuoss-Kirkwood distribution function. Distributions calculated from the spectra fit the Fuoss-Kirkwood function very well as can be seen in Figure 5.

The distributions of relaxation times for α processes in all four polymers are less symmetrical, than for β processes, as would be expected from dielectric measurements⁶, and they do not fit the symmetrical Fuoss-Kirkwood function. For this case we tried to apply another distribution function, derived by Havriliak and Negami¹⁴, which is a generalization of the two known and well documented functions of

Figure 5 Distribution function for: β relaxation in PMMA, \circ ; Fuoss-Kirkwood fit, —

Cole^{15,16}. The fits of this function to the α relaxation time distributions of all four polymers are presented on Figure 6, and the distribution parameters are summarized in Table 1.

The values of the distribution parameters are generally in fairly good agreement with those obtained from dielectric measurements, but there are some discrepancies between the distribution parameters obtained by Havriliak and Negami, and those obtained in the present work.

In our case, however, the fit to the experimental data is very good. Thus, because of the temperature dependence of the distribution parameters observed by Havriliak and Negami, these differences can be explained by the fact that our measurements are non-isothermal and the equivalent temperature is different from the one used by these authors.

The t.s.d. spectra exhibit only peaks corresponding to α , and in the case of PMMA to β dipolar relaxation processes too. By the 'thermal cleaning' technique, the hidden β' processes in PMMA, and β process in other polymers can be

Figure 6 Distribution functions for α relaxation in four investigated polymers (\circ) and Havriliak-Negami fits (—). (a) PMMA, $\alpha = 0.50$, $\beta = 0.30$; (b) PEMA, $\alpha = 0.45$, $\beta = 0.32$; (c) PiBMA, $\alpha = 0.23$, $\beta = 0.26$; (d) PnBMA, $\alpha = 0.24$, $\beta = 0.24$

Table 1 Parameters α and β of the Havriliak–Negami distribution function obtained from the fit to distribution of relaxation times of α processes in investigated polymers

Polymer	Distribution parameters	
	α	β

	α	β'	β	γ
PMMA	1.05	0.42	0.11	0.026
PEMA	0.58	0.24	0.080	0.034
PIBMA	0.53	—	0.072	—
PnBMA	0.56	0.20	0.093	0.035

Table 3 Experimental (A_{BFG}), corrected (A), and literature (A_{lit}) values of activation energies for β relaxation process in PMMA

A_{lit}	A_{BFG}	Correction coefficient m (Fuoss–Kirkwood)	$A = \frac{A_{\text{BFG}}}{m}$
0.76	0.103	0.14	0.74
0.76	0.088	0.12	0.73

made evident. However, on an Arrhenius plot of $\ln [j/P_s(T)]$ vs. $1/T$, according to BFG, one can find more straight line segments, than the number of visible peaks on the spectrum, thus allowing us to calculate the following values of apparent activation energies (Table 2).

As it was expected, calculated values are much lower than the values obtained by conventional methods, and it is clear that the coefficient c must be introduced (equation 6). Literature values of activation energies for the β process in PMMA and those obtained in the present work are compared in Table 3.

One can see, that there is a very good agreement between the corrected values of activation energies calculated from the t.s.d. spectra and the literature values.

Although it is not possible in this way to check if in the case of other relaxation processes (e.g. α process), the activation energy is calculated correctly; considering the results obtained for the β process, one should expect the way in which broadening of the peaks affect the apparent activation energy, to be similar.

Assuming that all dipolar processes found in methacrylate polymers are distributed, we can ascribe the processes, whose activation energies are presented in Table 2, to α , β' , β and γ dipolar relaxations respectively.

CONCLUSIONS

The results obtained lead to the conclusion, that thermally stimulated depolarization, is a very suitable method for the analysis of relaxation processes in polar polymers. The Staverman–Schwarzl transform, although it is only an approximation, seems to be accurate enough for calculating the distributions of relaxation times.

Measuring the activation energy from the initial current rise, by means of the more accurate method of Bucci, Fieschi and Guidi, allows us to calculate the distribution parameter of a symmetrical distribution or the right value of activation energy, if the distribution is known.

If any relation between the asymmetrical distribution parameters α and β and the correction coefficient c is found, this method can be extended also to the cases, where only the asymmetrical distribution function can be applied.

(Received 15 September 1975)

The rates of initiation for the copolymerization of styrene and methyl methacrylate at 50°, in different reaction media (bulk, acetone, dimethylformamide and dioxane) have been determined by using the isotopic labelling technique (¹⁴C - azobisisobutyronitrile). For all mixtures, except dioxane, the experimental data do not support the linear interpolation of the initiation rates, which is usually adopted in literature. In the whole range of monomer feed compositions, any modification of the reaction medium causes a relevant change of the initiation rate, so that the overall pattern is markedly modified. The strongest solvent effect is given by dioxane, which reduces the initiation rates for all monomer mixtures.

The radioactive tracer method also enables the determination of the modes of termination, which occur almost exclusively by combination for monomer feed compositions up to about 70 molar % of methyl methacrylate. The \bar{P}_w/\bar{P}_n ratios obtained by g.p.c. confirm the general trend of the termination mechanisms as a function of monomer mixture and reaction medium.

INTRODUCTION

In the past few years, we have undertaken a detailed study of the fundamental aspects of the radical copolymerization reaction¹⁻⁶, using, as a model, the pair styrene (S)-methyl methacrylate (MMA) polymerized in bulk^{3,4} and in solution^{5,6} [initiator, α , α' -azobisisobutyronitrile (AIBN)]. The aim of our study is to obtain a more precise knowledge of the kinetics and mechanisms which control the stages of initiation, propagation, and termination. Indeed, one of the less investigated features of radical copolymerization, which is still subject to a remarkable uncertainty, concerns the initiation reaction. On the other side, a deep knowledge of the kinetics of initiation is essential for any treatment of the overall copolymerization process. So far, it has usually been assumed⁷⁻¹², that the initiation rate R_i in catalyzed copolymerizations, is almost independent of the feed composition, although there is some evidence that for a few systems R_i is a function of the monomer mixture¹³⁻¹⁸.

As far as AIBN is concerned, the chemistry of its thermal, homolytic dissociation, is now well established¹⁹⁻²¹, whilst the role of the reaction medium on the decomposition rate, is still obscure. Earlier studies, showing insignificant variations of the decomposition rate constant in various solvents²²⁻²⁶, are conflicting with more recent reports²⁷⁻³³. The initiation stage in AIBN catalyzed thermal polymerizations can be depicted according to equations (1a) and (1b):

and the rate of initiation is given by equation (2):

$$R_i = 2fk_d[\text{I}] \quad (2)$$

where the initiator efficiency f , accounts for primary radical wastage, owing to the cage effect and, when present, to primary radical termination. Changes of monomers³⁴⁻³⁶, solvents³⁶⁻³⁸ and monomer concentrations³⁹, also in connection with actual changes in the viscosity of the medium⁴⁰⁻⁴³, cause significant variations of the initiation rate. Both k_d and f seem affected by the reaction medium. The physical interpretations of the kinetic deviations are based, among others, on cage effects⁴⁴, hot radical hypothesis⁴⁵ and complex formation²⁷⁻²⁹.

From the above considerations it follows that the modification of the reaction medium, owing to change of the solvent and/or to the variation of monomer feed composition, should affect the initiation rate of copolymerization in a considerable way. Influence of the reaction medium on the propagation stage⁵ and on the overall copolymerization rate⁶ for the system AIBN-S-MMA has already been found. A similar effect seems likely to be present also in the initiation step.

In order to clarify the kinetics of the initiation stage in radical copolymerization, we have carried out the present study using the radioactive tracer method, a technique which is widely utilized in the mechanistic studies of several polymerizations, but very seldom employed in copolymerization. Carbon-14 labelled azobisisobutyronitrile (AIBN-¹⁴C) was used as initiator and enabled determination of rates of initiation as well as modes of termination. Our copolymerization experiments were performed at 50°C either in bulk or in solution, and the solvents used were *p*-dioxane, acetone and *N,N'*-dimethylformamide (DMF).

Table 1 Values of $(fk_d) \times 10^6$ (sec⁻¹) at 50°C

		bulk	acetone	DMF	dioxane
S	a	1.44	1.42	1.31	0.97
	b	1.42	1.43	1.31	0.91
	c	1.46 1.46 ⁵⁴	1.45	1.31	0.93 1.00 ⁵⁵
MMA	a	1.01	1.03	1.48	0.94
	b	1.05	1.28	1.53	0.98
	c	1.11	0.97	1.42	0.93
		—	—	—	—

a Values calculated from equation (2)

b Values calculated from equation: $R_i = R_p^2 \delta_M^2 / [M]^2$, where δ_M represents the ratio $(2k_t/k_p^2)^{0.5}$, and the values for k_p , δ_M and $[M]$ are obtained from refs 4 and 6

c Values calculated from \bar{M}_n data⁵⁶ from equation: $R_i = R_p n m / \bar{M}_n$, where $n = 2$ for S and $n \sim 1.17$ for MMA (interpolated value)^{57,58}

EXPERIMENTAL

Materials

The purification of monomers, solvents and unlabelled initiator was carried out following previously described techniques^{4,5}. AIBN-¹⁴C was obtained through the courtesy of Professor S. Polowinski, Łódź, and possessed a specific activity of 0.476 mCi/g. A reverse isotope dilution analysis gave its radiochemical purity as $100 \pm 2\%$. The labelled product was suitably diluted with inactive AIBN and dissolved in acetone.

Polymerization procedure and polymer purification

All experiments were performed as described^{4,5}. In particular the ratios $[I]/[M]$ were kept sufficiently low to minimize any primary termination reaction or induced initiator decomposition. Solution polymerization was carried out using a monomer/solvent ratio equal to 1:2 (v/v). The polymerization temperature was $50^\circ \pm 0.05^\circ\text{C}$. Initiation due to photochemical reaction or to radiation from the isotope was carefully prevented. For all experiments the specific activity of the labelled initiator was equal to 2.06×10^{10} d/min mol. The polymers were precipitated twice using benzene or methyl ethyl ketone as solvents and methanol as precipitant⁵.

Characterization

Number average molecular weights, \bar{M}_n , were determined either by osmometry in toluene solution, using a Mechrolab mod. 501 high speed membrane osmometer operating at 30°C , or by g.p.c. in DMF solution at 80°C . The specific activities of initiator and polymers were assayed in toluene solution (20 ml) containing butyl PBD (0.5% w/v) as scintillator. Polymer concentration was in the range of 1–2%. A Packard Tri-Carb scintillation spectrometer type 3313 was employed. After subtraction of the background count, observed count rates were converted to dpm by the channels ratio method. Reproducibility was about $\pm 1.0\%$.

RESULTS AND DISCUSSION

Rates of initiation

The ratio between the specific activities of the labelled initiator, a_i , and the polymer, a_p , gives the kinetic chain

length ν , i.e. the number of monomer units per combined initiator fragment, given by equation (3):

$$\nu = a_i / 2ma_p \quad (3)$$

where the term 2 takes into account the fact that two primary radicals are produced from each molecule of initiator, and m is the molecular weight of the monomer. In copolymerization m is an average value, calculated on the basis of the molar composition of the copolymer⁹. Thus, rates of initiation can be unambiguously evaluated from the ratio between rate of polymerization and kinetic chain length:

$$R_i = (R_p/\nu) ([I]_0/[I]_{av}) \quad (4)$$

provided that initiator is not included in the polymer by other processes, such as chain transfer to initiator and primary radical termination, and proper corrections for any thermal initiation are considered. $[I]_{av}$ is the mean initiator concentration during the reaction period, and the ratio $[I]_0/[I]_{av}$ allows for the decrease in rate owing to initiator loss^{46,47}. At 50°C the thermal contribution to the copolymerization rate is sufficiently small to be disregarded in the whole range of monomer feed compositions^{4,6}. Also the primary radical termination reaction can be neglected in our experimental conditions, except for the system AIBN-S-acetone⁴⁸. On the other hand, literature data on the chain transfer constants to AIBN^{49–51}, can provide suitable corrections for the proper calculation of R_i .

As mentioned in previous papers^{4,6}, the overall rate of copolymerization, R_p , is strictly proportional to the square root of the initiator concentration and to the first power of total monomer concentration, except for the system styrene-acetone where a non-ideal kinetics has been found⁴⁸. Therefore the simplest kinetic scheme for radical polymerization⁵² and the derived relationships can be applied to our systems. In Figure 1, the initiation rates divided by the initial concentration of AIBN, are plotted as functions of monomer feed composition for the copolymerization experiments in (a) bulk; (b) acetone; (c) DMF and (d) dioxane; respectively.

From the patterns shown in Figure 1 it is evident that all reaction mixtures except dioxane, cause a complex variation of R_i , which does not follow the linear interpolation for monomer mixtures (broken lines) often suggested on literature^{4,16,53}. In fact, when bulk, acetone, and DMF are the reaction media, a more or less pronounced deviation from the broken lines is present. For dioxane, on the contrary, the differences between experimental points and the linear interpolation are very slight.

From the data of Figure 1 and using equation (2), it is possible to obtain the (fk_d) values, related to the homopolymerization of S and MMA in the various media, which are compared in Table 1 with literature data and other methods of evaluation.

The good agreement among the values of Table 1, obtained from the various equations, very strongly supports the reliability of the radiochemical method and its applicability to the copolymerization experiments. The data of Figure 1 and Table 1, show a remarkable influence of the reaction medium on the initiation rate in the polymerization of styrene and methyl methacrylate, as well as in their copolymerization. The $R_i/[I]_0$ values obtained in DMF solution are higher than those in the other media for the whole composition range, except for feeds very rich in styrene (95–100%), where the initiation rate in bulk gives the

Figure 1 Initiation rate divided by the initial concentration of AIBN as a function of the monomer feed composition in the various media: (a) bulk (b) acetone (c) DMF; (d) dioxane.

highest values. The strongest solvent effect is exhibited by dioxane, which gives the lowest rate of initiation for all feed compositions. The behaviour of the initiation rates in bulk and in acetone is juxtaposed: for styrene rich feeds the $R_i/[I]_0$ values are higher in bulk than in acetone, whereas an opposite trend is present in MMA rich mixtures.

For all compositions, any change of the reaction medium causes a very strong variation of the initiation rate. No easy correlation with the medium fluidity has been found, and this fact suggests that diffusion phenomena are not the only factors involved in the initiation stage of the radical polymerization. As compared to bulk, all solvents depress the initiation rate of styrene polymerization, in the following order: bulk \sim acetone $>$ DMF \gg dioxane. The very strong effect of dioxane, already found in previous papers^{54,55}, is fully confirmed, as the agreement between experimental and literature data of Table 1 clearly shows. Recent results concerning solvent effects on the propagation rate constant⁶ show a somewhat similar behaviour:

$$k_{p \text{ bulk}} \sim k_{p \text{ dioxane}} > k_{p \text{ DMF}} > k_{p \text{ acetone}}$$

i.e. here again the k_p for styrene is higher in bulk than in solution, but now the order of the solvents is completely reversed.

As far as MMA is concerned, the initiation rates are in the following order: DMF \gg acetone \sim bulk $>$ dioxane.

This behaviour, if compared to the trend of the propagation rate constants⁶, show consistent differences; in fact, $k_{p \text{ bulk}}$ is always lower than $k_{p \text{ solution}}$ and in the following order:

$$k_{p \text{ DMF}} \sim k_{p \text{ dioxane}} > k_{p \text{ acetone}} > k_{p \text{ bulk}}$$

At present the exact nature of these differences cannot be fully understood. However, besides the different chemical reactivities of the various radicals, diffusion phenomena, which are present in the initiation stage and are irrelevant during propagation, can provide a further qualitative explanation of the aforesaid phenomenon. The complex dependence of f_{AIBN} on chemical and diffusion mechanisms has been recently pointed out by Mayer⁵⁹. Also k_d , as indicated previously, shows unequivocal correlations with medium viscosity; recent results of Yokota and Kondo³⁶ confirm a marked decrease of the decomposition rate by increasing the viscosity of the mixture.

However, besides the diffusion effects on k_d and f , other factors should be considered in order to explain the data of Figure 1 and Table 1; different monomer reactivity toward primary radicals, monomer and radical solvation, solvent complexation, etc.

Modes of termination

The average number of initiator fragments per polymer molecule, n , can be evaluated using equation (5):

$$n = \bar{P}_n/\nu = (2a_p\bar{M}_n)/a_i \quad (5)$$

and can be used to calculate the modes of termination, i.e. the extent of combination and disproportionation, by means of the simple relationship:

$$\lambda = (2 - n)/n \quad (6)$$

where λ is defined as the fraction of polymer radicals undergoing disproportionation. Limitations and errors associated with this method are well known^{47,51,60}. Limitations are connected with the relevance of transfer reactions to initiation, monomer, and solvent (besides other sources of initiation and primary radical termination, as already discussed), whereas errors arise from the polymer purification techniques and the accuracy in molecular weight determination.

In Figure 2 a plot of n as a function of the feed composition for the various reaction media is given. It is evident that also, at 50°C, termination occurs almost exclusively by combination in a very large range of monomer mixtures (from 0 to about 70% MMA), thus confirming previous findings at 60°C. It is also clear that the reaction medium does not play any relevant role on the termination mechanism.

These results, based on the radiochemical assay technique, are fully supported by our data of molecular weight distributions obtained by g.p.c.⁵⁶. As is well known, the ratio of \bar{P}_w to \bar{P}_n ranges from 1.5, if termination is solely by combination, to 2 for complete disproportionation of radicals. From the whole set of data it seems definitively confirmed, despite some recent arguments⁶¹, the general opinion that termination for styrene takes place solely by combination⁶². For MMA, the value of $\lambda \sim 0.71$, interpolated from the data of Bamford *et al.*^{57,58}, is still the most reliable among the many different values reported in literature.

Figure 2 ○, n and ●, \bar{P}_w/\bar{P}_n values as functions of the monomer feed composition in the various media: (a); bulk, (b) acetone; (c) DMF; (d) dioxane.

Studies on the formation of poly(ethylene terephthalate): 6. Catalytic activity of metal compounds in polycondensation of bis(2-hydroxyethyl) terephthalate

Kosuke Tomita

Research and Development Center, Unitika Ltd, 23 Kozakura, Uji, Kyoto 611, Japan

(Received 15 September 1975)

The rate parameters (p and d values) associated with the rate constants of propagation and thermal degradation reactions in the polycondensation process of bis(2-hydroxyethyl) terephthalate (BHET) in the presence of various metal compounds as catalysts at 283°C, calculated from the time dependence of the molecular weight of the formed polymer, were used to evaluate each metal compound in its catalytic activity. These logarithms of the p and d values were correlated by linear relationships (mountain-shaped) with the stability constants ($\log \beta_1$) of dibenzoyl methane (DBM) complexes of the corresponding metal species. Consequently, the stability constant of DBM complex of each metal species was found to be very useful in forecasting the catalytic activity of the metal compound. The compound of metal species with values of $\log \beta_1$ about 12 was most active as the catalyst on the propagation reaction and that of values about 11 was most active on the thermal degradation reaction.

INTRODUCTION

In the production of high molecular weight poly(ethylene terephthalate) (PET) by polycondensation of bis(2-hydroxyethyl) terephthalate (BHET), at a temperature of ~280°C under reduced pressure, the presence of a catalyst is essential.

A knowledge of the catalyst in the polycondensation of BHET is important for the polyester fibre industry, but at the present time little is known about the mode of catalytic activity, owing to difficulties in the kinetic treatment of the polycondensation.

The author¹ proposed a kinetic expression for the polycondensation process: p - d analysis, and in the present study, this method of analysis has been used to derive rules governing the catalytic activity of metal compounds in the BHET polycondensation process.

EXPERIMENTAL

Reagents

BHET was synthesized from dimethyl terephthalate (DMT) and ethylene glycol (EG), using a mole ratio (EG: DMT) of five, with sodium acetate (1×10^{-2} mol/mol DMT) as a catalyst at 200°C. Pure BHET (m.p. 109°C) was obtained by repeated recrystallization of the product from water.

All the catalysts were metal acetates. Commercial products (guaranteed reagent grade) were used without further purification. Antimony (III) acetate was synthesized according to the method of Nerdel and Kleinwächter², and aluminium acetate by the method of Pande and Mehrotra³.

Polycondensation

The reaction of 0.3 mol BHET and 3×10^{-5} mol metal acetate was carried out in an open system with stirring (120 rev/min) under reduced pressure (0.02–0.05 mmHg),

at a temperature maintained at 283°C using a dimethyl phthalate vapour bath. At suitable intervals reaction mixture was sampled.

Determination of molecular weight

The intrinsic viscosity $[\eta]$ was measured, using a phenol-tetrachloroethane (1:1 w/w) mixture as a solvent at 20°C. This was converted to molecular weight by means of the following relation⁴:

$$[\eta] = 7.55 \times 10^{-4} \bar{M}_n^{0.685}$$

EVALUATION OF CATALYTIC ACTIVITY

Zimmermann⁵ investigated polycondensation of BHET, and compared the activities of some catalysts from the value of the relative viscosity (η_{rel}) and the number of the carboxyl end group of the polymer formed after the definite reaction time. This is, however, too simple as a means of evaluation, and is insufficient to correlate catalytic activity with reaction mechanism.

Catalytic activity must be evaluated from a kinetic point of view and for the polycondensation process of BHET, the following rate equation, p - d analysis, was proposed in a previous paper¹:

$$n = \frac{1}{1 + pt} + dt \quad (1)$$

where n is a mole number (a reciprocal of degree of polymerization) of a polymer, p is a rate parameter for the propagation reaction and d is a rate parameter for the degradation reaction; p and d are associated with the rate constants of these two reactions, respectively. The author applied equation (1) to the polycondensation process of BHET with various metal acetates as catalysts, and calculated p and d

Figure 2 Application of $p-d$ analysis to data for cobalt acetate and antimony acetate in Figure 1: ○, Co; ●, Sb

values for each catalytic system. These values were regarded as kinetic parameters of the catalytic activity.

RESULTS AND DISCUSSION

Figure 1 shows that the time dependence of the molecular weight of the polymer formed with various metal acetate catalysts varies in a remarkable and complicated manner. As reported¹, the propagation reaction, (the polycondensation reaction), and the degradation reaction, (the pyrolysis reaction), occur simultaneously in the polycondensation process. By means of $p-d$ analysis the effect of metal species on both of the reactions can be clarified.

Application of $p-d$ analysis.

Some examples of the application of equation (1) to the experimental values in Figure 1 are shown in Figures 2-4. In these three Figures each point represents an experimental value and the full lines represent equation (1) after fitting the parameters p and d . From these Figures it is evident that equation (1) is in good agreement with the experimental results. The obtained p and d values are summarized in Table 1. The catalyst having a large p accelerates the propagation reaction, and that having a large d accelerates the degradation reaction. Accordingly, Table 1 shows the characteristics of each catalyst: e.g. titanium acetate markedly accelerates both reactions; antimony acetate considerably accelerates the propagation reaction and slightly accele-

Al	47	5.0
None	19	3.5

Figure 5 Time dependence of the melt viscosity of PET obtained with titanium acetate, antimony acetate or zinc acetate as a catalyst: \circ , Ti; \triangle , Sb; \bullet , Zn

rates the degradation reaction; zinc acetate forms a contrast to antimony acetate, etc.

Zimmermann⁵ by the means of evaluation mentioned above, concluded that titanium compound slightly accelerated the degradation reaction, in disagreement with the author's conclusion. In order to resolve this question, the melt viscosity of the polymer was investigated. According to Tuckett⁶, in a random degradation reaction a plot of $\log \eta$ (η is the melt viscosity) vs. time should be linear, and of slope related to the rate constant for the degradation reaction. For the purpose of comparison, the time dependence of the melt viscosity of the polymer obtained (with titanium acetate, zinc acetate or antimony acetate as a catalyst) was followed with a rheometer at 280°C (Figure 5). The results show that titanium acetate is a very active catalyst on the degradation reaction and lend support to the author's conclusion derived from the d value. This suggests that Zimmermann's means of evaluation of catalytic activity is incorrect.

Ordering of catalytic activity

The values of p and d in Table 1 make possible the evaluation of the catalytic activity of the metal compounds in the polycondensation process of BHET, and also a discussion of the ordering factor of catalytic activity.

The author⁷ found that the stability constant of dibenzoyl methane (DBM) complex of each metal species was an excellent ordering factor and was very useful in forecasting the catalytic activity of the metal compound in the transesterification of dimethyl terephthalate (DMT) with ethylene glycol (EG). This result was consistent with the proposed mechanism of catalytic action, especially with the reaction intermediate.

The ordering factor may be discussed from the same point of view. The propagation reaction proceeds by the nucleophilic attack of hydroxyl end groups upon ester carbonyl groups in 2-hydroxyethyl benzoate end groups. The reaction intermediate is regarded as a complex formed by coordination of the ester carbonyl group to the metal species. This coordination lowers the electron density of carbonyl carbon atom and facilitates the nucleophilic attack of the hydroxyl group upon this positively polarized carbon atom. This reaction scheme is essentially similar to that of the transesterification of DMT with EG⁷. On the other hand, in the degradation reaction, the reaction intermediate is also regarded as a complex formed by coordination of the ester, carbonyl group to the metal species. This coordination increases the positive character of the α methylene group adjacent to carboxylate group and facilitates 1,2-elimination reaction by E_i mechanism.

Consequently, the author considered adopting the degree of facility of coordination of ester carbonyl groups to metal species as the ordering factor of catalytic activity of metal compound⁷, and attempted to apply the stability constant of DBM complex to the ordering of catalytic activity of the metal compound in the polycondensation process of BHET. The stability constants of DBM complexes ($\log \beta_1$) were shown in ref 7 with respect to the metal species except for Ti. The value for Ti, 11.7, was calculated from the value of the rate constant in the transesterification of DMT with EG by titanium acetate as a catalyst (1×10^{-4} mol/mol DMT), since a linear relationship (mountain-shaped) exists between the logarithmic rate constants in the transesterification of DMT with EG by metal compounds as catalysts and $\log \beta_1$ of the corresponding metal species⁷. Such calculation is generally suitable for the determination of unknown σ value in Hammett relationship^{8*}, and is significant in view of the above hypothesis that the transesterification of DMT with EG and the polycondensation of BHET are similar in their reaction intermediates or in their mechanisms of catalytic action.

The p and d values after subtracting those for the reactions without catalyst are plotted as $\log p$ and $\log d$ against $\log \beta_1$ in Figures 6 and 7.

Consequently, it is concluded that the stability constant of DBM complex is the correct ordering factor of the catalytic activity of the metal compound in the polycondensation process of BHET, and this result supports the above view about the mechanism of catalytic action of the metal compound.

The straight lines in Figures 6 and 7 are mountain-shaped similarly to that in the transesterification of DMT with EG, and their peaks appear in $\log \beta_1$ about 12 for p , and 11 for d . These relationships suggest catalytic effect of so-called 'volcano-shaped activity order'¹⁰. The drop in catalytic activity is produced by the stronger or weaker bond between the catalyst and the reactant, and $\log \beta_1$ is

* The catalytic effect of the metal compound on the formative reaction of PET is the same as that due to an electron withdrawing substituent, and $\log \beta_1$ is regarded as corresponding to σ value in Hammett relationship⁹.

Figure 6 Values of p in the polycondensation process of BHET with various metal acetates as catalysts against $\log \beta_1$ of DBM complexes of the corresponding metal species

Figure 7 Values of d in the polycondensation process of BHET with various metal acetates as catalysts against $\log \beta_1$ of DBM complexes of the corresponding metal species

regarded as corresponding to the bond strength between metal species (catalyst) and benzoyl group (reactant). The optimum catalytic activity requires the optimum bond strength, that is, the optimum value of $\log \beta_1$.

The optimum values of $\log \beta_1$ for p and d differ from each other. Furthermore, as mentioned above, the transesterification of DMT with EG is a similar nucleophilic substitution reaction to the propagation reaction in the polycondensation process, but in the former the optimum value of $\log \beta_1$ was about 10 (see ref 7) and differs from that in the latter.

It is difficult to understand the cause for the above shifts in the optimum value of $\log \beta_1$ in detail, but this is most likely due to a difference in the bonding state of each reactant. For example, the comparison of BHET or its polycondensate to DMT in terms of their end groups suggests that the electron density of benzoate carbonyl group is lower in 2-hydroxyethyl benzoate group than in methyl benzoate group. This is as a result of the terminal hydroxyl group: electron withdrawing, and hydrogen bond effect. Accordingly, it may be concluded that the bond strength of methyl benzoate to the metal species is stronger, and that the optimum value of $\log \beta_1$ is lower in the transesterification of DMT with EG than in the propagation reaction of the polycondensation process of BHET.

ACKNOWLEDGEMENTS

The author wishes to thank Professors Seizo Okamura and Toshinobu Higashimura (Kyoto University) for their interest in this work and their helpful criticism of the manuscript, and Mr Hiroaki Ida (Unitika Ltd) for his powerful cooperation in this work.

Polymerization of tetrafluoroethylene in acetic acid photoinitiated by metal carbonyls

C. H. Bamford and S. U. Mullik

Department of Inorganic, Physical and Industrial Chemistry, University of Liverpool, Liverpool, L69 3BX, UK

(Received 17 October 1975)

Tetrafluoroethylene may be polymerized in acetic acid at ambient temperatures and pressures close to atmospheric with photoinitiation by transition metal carbonyls, notably $\text{Mn}_2(\text{CO})_{10}$, $\text{Re}_2(\text{CO})_{10}$ and $\text{Os}_3(\text{CO})_{12}$. A kinetic study of the reaction photoinitiated ($\lambda = 435.8 \text{ nm}$) by $\text{Mn}_2(\text{CO})_{10}$ is presented. The rate of polymerization is proportional to the square root of the incident intensity and the order in tetrafluoroethylene concentration is ~ 1.4 , over the range $0.78\text{--}2.60 \text{ mol l}^{-1}$. The decay coefficient of $\text{Mn}_2(\text{CO})_{10}$ is linear in C_2F_4 over the range studied (up to 0.45 mol l^{-1}). These and other observations indicate that the dependence of the rate of initiation on $[\text{C}_2\text{F}_4]$ in acetic acid is much less 'sharp' than in other systems examined. Occlusion phenomena are not marked under the conditions used. Polymers prepared in this way show the infra-red absorption near 2000 cm^{-1} characteristic of $(\text{CO})_5\text{MnCF}_2\text{CF}_2$ —end-groups, confirming that the initiating radicals have the structure $(\text{CO})_5\text{MnCF}_2\dot{\text{C}}\text{F}_2$. In our experiments no evidence of chain-transfer to acetic acid could be found, a result which we attribute to the polar properties of the medium and the propagating radicals. The polymerization is powerfully retarded by benzene, which enters into addition and H-abstraction reactions with the fluorinated radicals; a simple kinetic treatment is presented. Photoinitiation by benzoyl peroxide is shown to be accompanied by retardation. Tetrafluoroethylene may also be copolymerized with the aid of the present technique and some results with ethylene and vinyl acetate are briefly described. It is noteworthy that in the copolymerization of C_2F_4 and C_2H_4 chain-transfer to acetic acid has been detected.

INTRODUCTION

Relatively little detailed information has been reported on the kinetics and mechanism of polymerization of tetrafluoroethylene. There are some obvious reasons for this: (1) the polymer is insoluble in common liquids, so that complications arising from occlusion phenomena would be expected during polymerization; (2) hydrogen-abstraction reactions between diluent and the highly reactive propagating radicals normally result in powerful retardation; (3) some conventional initiators cannot be used satisfactorily with tetrafluoroethylene and (4) the low boiling point of the monomer introduces practical difficulties in polymerization studies.

It has been reported¹ that the use of perfluorinated saturated media (e.g. perfluoro-methylcyclohexane) leads to relatively high reaction rates and polymer yields. Copolymerizations of C_2F_4 have also been carried out in these liquids². Initiation in such systems has been effected by azobisisobutyronitrile¹ or perfluorobutyryl peroxide². In some instances³, initiation by fluorinated peroxyacids prepared *in situ* by interaction of a fluorinated acid anhydride with hydrogen peroxide was used. Tabata and his colleagues⁴⁻⁷ have investigated the radiation-induced polymerization and copolymerizations of tetrafluoroethylene in fluorinated liquids such as $\text{CF}_2\text{ClCFCl}_2$, CF_2Cl_2 and CHF_2Cl .

The possibility of employing acetic and/or formic or sulphuric acids as reaction media together with redox initiation was reported by Bro and Schreyer⁸. With sulphuric and acetic acids, these workers used $\text{NaHSO}_3 + \text{KBrO}_3$ and $\text{TiCl}_3 + \text{NH}_2\text{OH}$, respectively, as initiators. Temperatures

in the range -40 to $+30^\circ\text{C}$ and pressures between 20 and 200 atmospheres were preferred.

Although polymerization in non-aqueous media is clearly feasible, the techniques commonly used are based on aqueous systems, generally with initiation by a peroxy disulphate and at super-atmospheric pressures⁹.

We have already reported¹⁰ the bulk polymerization of tetrafluoroethylene at -93°C photoinitiated by transition metal carbonyls, notably $\text{Mn}_2(\text{CO})_{10}$ and $\text{Re}_2(\text{CO})_{10}$. We have subsequently observed that polymerization can readily be carried out in acetic acid at ambient temperatures and pressures close to atmospheric with the same type of initiation. In the present paper we report a kinetic investigation of this polymerization with photoinitiation by manganese carbonyl. As far as we know, no other studies of the photoinitiated polymerization of tetrafluoroethylene in the liquid phase are described in the literature.

EXPERIMENTAL

Materials

Tetrafluoroethylene, methyl methacrylate, manganese carbonyl and rhenium carbonyl were purified as described in earlier publications¹⁰⁻¹². Molybdenum carbonyl and ruthenium carbonyl [$\text{Ru}_3(\text{CO})_{12}$] were sublimed in vacuum at room temperature and at 80°C , respectively. Tungsten carbonyl and osmium carbonyl [$\text{Os}_3(\text{CO})_{12}$] were used without purification. Acetic acid (AR), ethyl acetate (AR) and benzene (BDH Research Grade) were twice distilled in vacuum with retention of the middle fraction. Benzoyl peroxide was twice precipitated in methanol from chloroform and dried in vacuum at room temperature.

Figure 1 Photoinitiated polymerization of tetrafluoroethylene in acetic acid; dependence of rate on $I_0^{1/2}$. Initial concentrations (mol l^{-1}): C_2F_4 , 2.60; $Mn_2(CO)_{10}$, 1.03×10^{-3} . $\lambda = 435.8$ nm, $I_0(\max) = 3.58 \times 10^{-7}$ einstein $l^{-1}s^{-1}$, $25^\circ C$

Apparatus and techniques

All experiments were carried out in a laboratory illuminated by inactive (sodium) light. The optical system was virtually the same as that previously described¹⁰. The polymerization was studied gravimetrically at $25^\circ C$ in Pyrex reaction vessels (external and internal diameters 13 and 9 mm, respectively) of capacity 9.5 ml. Quantum inputs to the reaction mixture and rates of decay of manganese carbonyl under various conditions were measured as reported earlier¹¹.

Measurements of the solubilities of C_2F_4 and C_2H_4 in various solvents were made as described by Bamford and Mullik¹¹ to allow concentrations in the liquid phase to be calculated. Values of the absorption coefficient β defined by these authors were found to be at $25^\circ C$: tetrafluoroethylene-acetic acid, 2.23×10^{-2} mmHg $^{-1}$; tetrafluoroethylene-benzene, 2.49×10^{-2} mmHg $^{-1}$; tetrafluoroethylene-ethyl acetate, 1.31×10^{-2} mmHg $^{-1}$; ethylene-acetic acid, 8.60×10^{-2} mmHg $^{-1}$. A correction to allow for the increase in volume accompanying the solution of tetrafluoroethylene in acetic acid was made with the aid of density data for liquid C_2F_4 given by Sherratt¹³.

RESULTS AND DISCUSSION

Kinetics of polymerization

Manganese carbonyl has the same absorption spectrum in acetic acid, methyl methacrylate, ethyl acetate and benzene solutions, suggesting that no significant interactions occur with any of these solvents. Addition of C_2F_4 does not produce any change.

Figure 1 shows that at constant $[C_2F_4]$ (2.60 mol l^{-1}) the mean rate of polymerization ω is proportional to the square root of the incident intensity I_0 , as expected for an uncomplicated free radical polymerization obeying the relation:

$$\omega = k_p k_t^{-1/2} [M] \mathcal{I}^{1/2} \quad (1)$$

in which k_p , k_t are the rate coefficients of propagation and second-order termination, respectively, \mathcal{I} is the rate of initiation and M represents monomer. Thus, although the system becomes heterogeneous during polymerization, there do not seem to be any significant occlusion phenomena, which would increase the intensity exponent above 0.5¹⁴. The highly swollen condition of the polymer which is precipitated is probably responsible for this behaviour.

The order of the overall polymerization in monomer was determined for $[C_2F_4]$ in the range 0.78–2.60 mol l^{-1} . The data presented in Figure 2 are consistent with a value 1.4–1.5, which in the absence of occlusion effects implies a strong dependence of the rate of initiation on $[C_2F_4]$ over the range studied. In this respect the system is very different from the $Mn_2(CO)_{10} + C_2F_4$ system with methyl methacrylate as solvent, since in the latter the rate of initiation is only weakly dependent on $[C_2F_4]$ for $[C_2F_4] > 0.2$ mol l^{-1} , approximately¹¹. We shall return to this point later.

The rate of consumption of manganese carbonyl was measured spectrophotometrically as previously described¹¹ over a range of $[C_2F_4]$; in all cases good first-order rate coefficients k were obtained. They are plotted against $[C_2F_4]$ in Figure 3, which indicates that over the range studied ($[C_2F_4] < 0.45$ mol l^{-1}) k is linear in $[C_2F_4]$. This type of dependence is again very different from that encountered¹¹ in methyl methacrylate solution, for which k is shown as a function of $[C_2F_4]$ in Figure 3 (with k on a scale reduced by a factor 10). Clearly, for a given $[C_2F_4]$, k is much greater in methyl methacrylate solution and the approach to a plateau value found with this solvent is not apparent with acetic acid according to the data presented in Figure 3.

An order of 1.5 in $[C_2F_4]$ for the overall polymerization requires, according to equation (1), that $\mathcal{I} \propto [C_2F_4]$, or, since in all other systems studied $\mathcal{I} = k [Mn_2(CO)_{10}]$, that k should be directly proportional to $[C_2F_4]$. A long extrapolation of the straight line in Figure 3 to $[C_2F_4] = 2.60$ mol l^{-1} (the highest $[C_2F_4]$ in Figure 2) gives $k = 66.7 \times 10^{-4} s^{-1}$ (for $I_0 = 9.85 \times 10^{-6}$

Figure 2 Photoinitiated polymerization of tetrafluoroethylene in acetic acid; order in $[C_2F_4]$. $[Mn_2(CO)_{10}] = 1.03 \times 10^{-3}$ mol l^{-1} initially. $\lambda = 435.8$ nm, $I_0 = 3.58 \times 10^{-7}$ einstein $l^{-1}s^{-1}$, $25^\circ C$

Figure 3 Dependence of decay coefficient of $Mn_2(CO)_{10}$ on $[C_2F_4]$. $[Mn_2(CO)_{10}] = 8.5 \times 10^{-4}$ mol l^{-1} , initially. $\lambda = 435.8$ nm, $I_0 = 9.85 \times 10^{-6}$ einstein $l^{-1}s^{-1}$, $25^\circ C$. A, acetic acid solution; B, methyl methacrylate solution¹¹ ($\times 10^{-1}$). Individual values: \bullet , benzene solution; \square , ethyl acetate solution

Figure 4 Infra-red absorption spectra of polymers prepared in acetic acid. ---, PTFE; —, copolymer $C_2F_4 + C_2H_4$ (no. 4, Table 3)

einstein $l^{-1}s^{-1}$). For the incident intensity in the experiments in Figure 2, $I_0 = 3.58 \times 10^{-7}$ einstein $l^{-1}s^{-1}$, this becomes $2.42 \times 10^{-4}s^{-1}$ (since k is normally proportional to I_0 for weak absorption¹¹). Thus the initial rate of consumption of $Mn_2(CO)_{10}$ for $I_0 = 3.58 \times 10^{-7}$ einstein $l^{-1}s^{-1}$, $[C_2F_4] = 2.60 \text{ mol } l^{-1}$ and $[Mn_2(CO)_{10}] = 1.03 \times 10^{-3} \text{ mol } l^{-1}$ should be, on this basis, $2.42 \times 10^{-4} \times 1.03 \times 10^{-3} = 2.50 \times 10^{-7} \text{ mol } l^{-1}s^{-1}$. However, the absorbed intensity in the experiments of Figure 2 is only 1.24×10^{-7} einstein $l^{-1}s^{-1}$. Hence this extrapolation would lead to a quantum yield of $[Mn_2(CO)_{10}]$ decay and initiation of polymerization close to 2. Although this would be possible in principle, a quantum yield of initiation exceeding unity has never been observed^{11,15,16}, so that we believe the linear extrapolation is inappropriate. We shall assume that in the experiments of Figure 2 the limiting value of k is reached at $[C_2F_4] = 2.60 \text{ mol } l^{-1}$ and is equal to $0.92 \times 10^{-4}s^{-1}$, corresponding to unit quantum yield of initiation. The highest $[C_2F_4]$ at which k can be measured directly with the equipment available is $0.45 \text{ mol } l^{-1}$ (Figure 3); here k adjusted for the conditions of Figure 2 is $3.2 \times 10^{-5}s^{-1}$. The behaviour of k in the range of $[C_2F_4]$ between 0.45 and $2.60 \text{ mol } l^{-1}$ is not known, but we may note that the dependence on $[C_2F_4]$ is given by a mean order (determined from the extremes) of 0.75. Since the rate of initiation would show the same order in $[C_2F_4]$, the polymerization reaction in the range we are considering should have a mean order of $1 + (0.75/2) = 1.38$. This is probably consistent with the data in Figure 2 within the limits of experimental error.

In interpreting the data in Figure 2 we have neglected the possibility of primary termination. This calls for comment, especially since rather low monomer concentrations were used in some of the experiments in Figure 2¹⁷. If primary termination were significant the true order in $[C_2F_4]$ would be lower than the value 1.4–1.5 deduced from Figure 2 and this would clearly have implications on the nature of the $\mathcal{J} - [C_2F_4]$ relation. In the experiments in Figure 2 the relatively low value of the incident intensity would minimize primary termination¹⁷. Further, conclusions about the unusual nature of the $\mathcal{J} - [C_2F_4]$ relation do not depend on Figure 2 alone since Figure 3 also indicates that this relation is markedly different from that in systems previously studied. Figure 1 shows that with $[C_2F_4] = 2.60 \text{ mol } l^{-1}$, the rate of polymerization is proportional to $I_0^{1/2}$, so that primary termination is not important under these conditions¹⁷. In our opinion, primary termination is not a significant process in these investigations.

These considerations illustrate the important role played by the solvent in photoinitiating reactions between $Mn_2(CO)_{10}$ and C_2F_4 . A few scattered data available for benzene and ethyl acetate solutions (Figure 3) also support this view.

From Figure 2 we see that with $[C_2F_4] = 2.60 \text{ mol } l^{-1}$ the rate of polymerization is $6.02 \times 10^{-4} \text{ mol } l^{-1}s^{-1}$ while \mathcal{J} , calculated on the basis of unit quantum yield as discussed above, is equal to $1.24 \times 10^{-7} \text{ mol } l^{-1}s^{-1}$. Inserting these values in equation (1) we find that at $25^\circ C$:

$$k_p k_t^{-1/2} = 0.66 \text{ mol}^{-1/2} l^{1/2} s^{-1/2}. \quad (2)$$

The mean kinetic chain length in the polymerization under these conditions is 4894, so that if transfer is negligible and termination occurs by combination the molecular weight of the polymer is 9.78×10^5 .

We now briefly consider the value of $k_p k_t^{-1/2}$ given in equation (2). This is greater than the corresponding value¹⁸ for methyl methacrylate (in bulk monomer) by a factor of 11, and for acrylonitrile¹⁹ in solution by a factor of 9, approximately. On the other hand, values of $k_p k_t^{-1/2}$ up to 0.69 and 0.72 $\text{mol}^{-1/2} l^{1/2} s^{-1/2}$ have been reported¹⁹ for methyl acrylate and ethyl acrylate, respectively. Thus the figure for C_2F_4 given in equation (2) does not appear unreasonable, especially when it is recalled that slight occlusion¹⁴ would reduce k_t and so increase $k_p k_t^{-1/2}$. Hisasue *et al.*⁷ have presented results from polymerization studies of C_2F_4 in chlorofluorocarbons from which a value of $k_p k_t^{-1/2} = 4.2 \text{ mol}^{-1/2} l^{1/2} s^{-1/2}$ at $0^\circ C$ may be deduced. This appears to be outside the range normally encountered in the free radical polymerization of olefinic monomers and may be unreliable owing to the intervention of unquantifiable occlusion phenomena (see below).

We believe that there is little chain-transfer in the polymerization of tetrafluoroethylene in acetic acid solution. No acetic acid residues could be detected in the polymers by infra-red spectroscopy. Such residues would lead to absorption near 1730 and 3000 cm^{-1} , but the spectrum of PTFE in Figure 4 shows no corresponding bands. On the other hand, when tetrafluoroethylene and ethylene are copolymerized in acetic acid solution the resulting copolymers show definite absorption at 1730 cm^{-1} (spectrum of a copolymer of $C_2F_4 + C_2H_4$ in Figure 4) suggesting the incorporation of acetic acid residues by chain-transfer involving radicals with terminal ethylene units. Further, in our experience, chain-transfer in the polymerization of C_2F_4 always appears to be accompanied by extensive retardation and very low polymer yields. These views are in agreement with the work of Bro and Schreyer⁸, who concluded that polytetrafluoroethylene of high molecular weight may be prepared in acetic acid.

The data presented above gain in significance when it is recalled²⁰ that hydrogen abstraction from hydrocarbons by perfluoroalkyl radicals is often faster than the corresponding reaction of alkyl radicals by a factor of $10^2 - 10^3$. It would seem that the relatively low reactivity of propagating polytetrafluoroethylene radicals towards acetic acid must be attributed in the main to the operation of polar factors²¹. Thus the presence of the strongly electronegative carboxyl in the molecule would discourage hydrogen abstraction from the CH_3 group by the propagating radicals which themselves bear a positive charge on the carbon atoms carrying the unpaired spins^{21,22}. In this connection it is interesting to contrast the behaviour of acetic acid with that of cyclohexane. Polymerization of C_2F_4 in the latter

Table 1 Retardation by benzene. $[C_2F_4] = 2.60 \text{ mol l}^{-1}$; $[Mn_2(CO)_{10}] = 1.03 \times 10^{-3} \text{ mol l}^{-1}$; $I_{abs} = 1.24 \times 10^{-7} \text{ einstein l}^{-1}\text{s}^{-1}$; $\lambda = 435.8 \text{ nm}$

$[benzene] \times 10^4$ (mol l ⁻¹)	$\omega \times 10^4$ (mol l ⁻¹ s ⁻¹)
0.00	6.12

is virtually impossible on account of extensive chain-transfer and retardation. As will be reported subsequently²³, the compounds $(CO)_5MnCF_2CF_2H$ and (I) are major reaction products and clearly have their origin in hydrogen abstraction from cyclohexane by the primary radicals $(CO)_5MnCF_2\dot{C}F_2$.

Retardation by benzene

A remarkable feature of the polymerization of tetrafluoroethylene in acetic acid is its sensitivity to the presence of benzene, which acts as a powerful retarder. Observations are presented in Table 1.

It appears that a concentration of benzene as low as $2.5 \times 10^{-4} \text{ mol l}^{-1}$ reduces the rate of polymerization by a factor of 2, approximately. At concentrations of benzene higher than those given in Table 1 no polymer is formed. On removing the volatiles after reaction at high benzene concentration a viscous liquid product remains. The n.m.r. spectrum is consistent with the presence of several components originating from interactions between benzene and $(CO)_5MnCF_2\dot{C}F_2$ radicals involving both addition and H-abstraction²³. Since the radical products of these reactions are not sufficiently active to reinitiate polymerization strong retardation ensues. Evidently the reactions of the primary and propagating radicals, not only with cyclohexane but also with benzene, are strongly reminiscent of the behaviour of perfluoroalkyl radicals^{20,24,25}.

A simple kinetic scheme consistent with the data on retardation of benzene is given below.

The structure $(CO)_5MnCF_2\dot{C}F_2$ is assigned to the primary radicals (R_0) on the basis of earlier work^{10-12,15}. These radicals appear as terminal groups in the polymer and show characteristic infrared absorption near 2000 cm^{-1} as is evident from Figure 4. Details of the initiation process are not included since they are not necessary for present purposes. In relation (3) B, B represent benzene and a radical derived from benzene either by addition of a fluorocarbon radical or by hydrogen abstraction, respectively. It is assumed that the different types of B radical have similar reactivities.

Relation (4) is readily deduced from relation (3) by application of the steady-state hypothesis:

$$\frac{1}{\omega^2} = \frac{2k_z}{k_p[C_2F_4]\mathcal{J}} \frac{[B]}{\omega} + \frac{k_t}{k_p^2[C_2F_4]^2\mathcal{J}} \tag{4}$$

Figure 5 is a plot of $10^{-7}/\omega^2$ against $[B]/\omega$ and shows that relation (4) conforms to the experimental results fairly satisfactorily. From the slope of the straight line in Figure 5 we find that

$$\frac{2k_z}{k_p[C_2F_4]} = 9.09 \times 10^6 \text{ mol}^{-2}\text{l}^2\text{s}$$

Inserting the values $[C_2F_4] = 2.60 \text{ mol l}^{-1}$ and $\mathcal{J} = 1.24 \times 10^{-7} \text{ mol l}^{-1}\text{s}^{-1}$ we estimate that at 25°C :

$$\frac{k_z}{k_p} = 1.46 \tag{5}$$

Equation (5) illustrates quantitatively the high reactivity of benzene towards the propagating radicals.

It is to be expected that other aromatic compounds would behave as retarders in a similar way. This has been found to be so with benzoyl peroxide (Bz_2O_2) when employed as photoinitiator. Results are presented in Figure 6. Although a linear relation between ω and $[Bz_2O_2]^{1/2}$ is

Figure 5 Retardation of photoinitiated polymerization of C_2F_4 in acetic acid by benzene (B). Plot of results in Table 1 according to equation (4). obtained, the line does not pass through the origin. An increasing extent of retardation as $[\text{Bz}_2\text{O}_2]$ increases would explain this observation.

Earlier work on solution polymerization

We now discuss briefly the work of Tabata and colleagues⁴⁻⁷ to which reference has already been made. For the bulk polymerization Tabata *et al.*⁴ mention a 'remarkable post polymerization. . . even in the liquid phase' and comment that this is 'a rare case'. They also remark that 'there are large differences in activation energy between in-source

and postpolymerizations, as in the case of solid-state polymerization. Propagation may be accelerated through vibrational excitation by sub-excitation electrons during irradiation'. They state⁶ that in polymerization in solution in monochlorodifluoromethane 'propagation reactions are extremely different in in-source and postpolymerizations'. It is our opinion that the results obtained by Tabata and co-workers illustrate the operation of occlusion phenomena¹⁴, and can be completely interpreted in terms of such phenomena. Thus, postpolymerization in a system in which the polymeric product is insoluble is to be expected, and is certainly not 'a rare case'. The 'differences' between the propagation reactions in-source and out-of-source may also be readily accounted for by occlusion and we do not believe that the observations reflect any mechanistic change in the propagation processes. In a later paper⁷ Tabata *et al.* note that the 'remarkable after-effect' is due to occlusion. However, it is clear that in these papers, the essential point that, in polymerizations in which occlusion is important, the rate coefficients are not constant¹⁴, has not been appreciated, so that quantitative conclusions are suspect.

Photoinitiation by other transition metal carbonyls

An examination of the efficiencies of a number of transition metal carbonyls as photoinitiators for the polymerization of tetrafluoroethylene in acetic acid led to the results presented in Table 2.

The group VI carbonyls are relatively ineffective; their efficiency is greater in the presence of CCl₄, under which conditions CCl₃ is the initiating species²⁶. In group VII both Re₂(CO)₁₀ and Mn₂(CO)₁₀ are very active and, of the group VIII carbonyls, Os₃(CO)₁₂ is much more effective than Ru₃(CO)₁₂. The efficiency of the latter increases markedly in the presence of CCl₄.

Copolymerization of tetrafluoroethylene in acetic acid

A few experiments were carried out to examine the possibility of photoinitiated copolymerization of tetrafluoroethylene with ethylene and vinyl acetate (VA) in acetic acid. Results are presented in Table 3.

All the polymers were shown by infra-red spectroscopy to contain units of both monomers. The infra-red spectrum of copolymer no. 4 (Table 3) is shown in Figure 4.

These experiments show that the technique described is convenient for preparing copolymers of tetrafluoroethylene.

Synthesis and thermal characterization of hafnium polythioethers

Charles E. Carraher, Jr.

University of South Dakota, Department of Chemistry, Vermillion, South Dakota, 57069, USA

(Received 15 September 1975)

Hafnium polythioethers were synthesized utilizing both the aqueous solution and interfacial condensation techniques. Synthesis is general and fairly rapid being complete within 1 min.

Several products exhibit reasonably good weight retention (70% at 1000°C) but all show poor low temperature stabilities with degradation beginning about 100°C. Initial degradation to ~250°C is via an internal non-oxidative pathway where as degradation at higher temperatures occurs via an oxidative mode in air.

INTRODUCTION

We have been involved in the synthesis and characterization of metal containing polymers generally via the condensation of organometallic halides with Lewis bases^{1,2}. Recently we reported the synthesis of titanium polythioethers of form I where $M = \text{Ti}^{3-4}$. Here we report the initial synthesis of the corresponding hafnium polythioethers where $M = \text{Hf}$ and on preliminary thermal characterization of the products.

The synthetic routes chosen are the interfacial and aqueous solution techniques (i.e. low temperature condensation procedures) since the hafnium containing moiety, Cp_2HfCl_2 , is soluble in both a number of organic solvents and water and since many organometallic reactants and products are unstable at even moderately high temperatures resulting in many undesirable reactions occurring.

Synthesis of group IVB $M-S$ bonds is known and briefly reviewed in ref 3.

EXPERIMENTAL

Dicyclopentadienylnhafnium dichloride was obtained from Strem Chemicals, Inc., Danvers, Mass.; dimercaptopropionate (ethylene-bis-3-mercaptoacetate) from Evans Chemetics, Inc., Darlen, Conn.; all other dithiols were obtained from Aldrich Chemical Co., Milwaukee, Wis. and used without further purification.

Polymerization apparatus⁵ and procedures^{3,4} are analogous to those reported in detail elsewhere. Briefly, polymerizations were conducted utilizing a 1 qt (1.137 dm³) Kimex emulsifying jar set on a Waring Blendor. The phase containing the dithiol and added base were added through a hole in the jar lid using a large mouthed funnel to rapidly

stirred solutions containing Cp_2HfCl_2 in solution. Polymer precipitated rapidly as a white powdery solid.

Infra-red spectra were obtained using KBr pellets with Beckman IR-10 and Perkin-Elmer 273-B spectrophotometers. Bands characteristic of a repeating unit of form I are found. For instance all the spectra exhibit bands in the region of 1440, 1015 and 815 cm^{-1} , characteristic of the Cp group. Bands about 3000 to 2800 cm^{-1} characteristic of aliphatic C-H stretching are present derived, from the dithiol containing moiety. Spectra of dimercaptopropionate and dimercaptoacetate exhibit bands in the 1750–1735 cm^{-1} region, characteristic of the carbonyl stretching vibration. Spectra of the pure dithiols show bands about 2600–2500 cm^{-1} characteristic of the S-H stretch and about 720–680 cm^{-1} characteristic of the C-S stretching vibration. The former band is not present in spectra of polythioethers, and the latter band is shifted downward (~680–640 cm^{-1} , when detectable) consistent with observations made for bondings to metals by Lewis bases as diols. Elemental analysis is also consistent with a structure of form I. For instance for the product with 1,8-octanedithiol. Hf: calc, 37%; found, 39%.

Attempts were made to dissolve the polythioethers in numerous solvents by placing ~1 mg in a small test tube containing about 2 ml of solvent. As in the case of the analogous titanium polythioethers and many other similar organometallic polymers, solution was not effected in any solvent. Solvents tried included water, carbon tetrachloride, chloroform, DMF, DMSO, α -chlorotoluene, octane, 1-ethyl-2-nitrobenzene, triethyl phosphate, ethyl sulphide, *o*-dichlorobenzene, 2-nitropropane, dioxane, benzene, acetone, xylene and acetonitrile. This lack of solubility is unfortunate and presents a major obstacle to characterization of the products and evaluation of molecular weight. Even so it does not eliminate uses where solution is not necessary.

Thermal characterization was effected using the 950 Dupont TGA and a d.s.c. cell fitted onto a 900 Dupont Thermal Analyzer console. Air and nitrogen gas flows were maintained at 0.3 to 0.2 l/min. Samples were ground to

Table 1 Yield as a function of dithiol

Dithiol	Yield (%)	
	(interfacial)	(aqueous solution)
Dimercaptopropionate	78	35
Dimercaptoacetate	78	53
1,2-Ethanedithiol	51	57
1,3-Propanedithiol	59	
1,6-Hexanedithiol	58	31
1,8-Octanedithiol	29	

Reaction conditions: interfacial systems: Dithiol (0.50 mmol) with Et_3N (1.00 mmol) in 15 ml of water added to rapidly stirred ($\sim 23,000$ rev/min no load) solutions of Cp_2HfCl_2 (0.50 mmol) in 15 ml chloroform at 27°C for 1 min stirring time. Aqueous Solution Systems: as above except Cp_2HfCl_2 is contained in 15 ml of water instead of chloroform

fine powders to aid in obtaining reproducible results. A linear baseline compensator was used with the d.s.c. cell to ensure a constant energy baseline. A Mettler H20 semi-micro balance was employed for weighing the d.s.c. samples. D.s.c. measurements were made using samples contained in open aluminium cups, allowing free flow from the sample of volatilized gases thus more closely simulating the conditions under which t.g.a. measurements were made.

Visual thermal characterization was effected to 300°C using a Fisher-Johns melting point apparatus and what is called a static, open system where the sample is simply left in the open on a cover slide. This closely simulates conditions under which the d.s.c. and t.g.a. measurements (in air) were carried out. Observations were also made using what can be referred to as a dynamic, closed system, where about 10 p.s.i. is applied to samples placed between two cover slides. Conditions in the latter observations more closely simulate bulk and 'use' conditions and measurements obtained under inert atmospheres. The temperature at which colour change begins is similar for both systems but the colours vary markedly. Additionally the product from 1,8-octanedithiol melted using the dynamic, closed system. All materials were powders at 300°C .

RESULTS AND DISCUSSION

Reasons for using Cp_2HfCl_2 as the hafnium containing moiety are:

(1) Cp_2HfCl_2 is used as a catalyst or cocatalyst in certain commercial processes. Additionally, inclusion of the Cp_2Hf moiety generally imparts better u.v. stability to materials. Such properties might be imparted to polymers containing the Cp_2Hf unit.

(2) Cp_2HfCl_2 has been successfully condensed in analogous systems to form polyesters and polyethers.

(3) It is the only commercially available hafnium compound of the form R_2HfX_2 .

(4) It is stable in air, soluble in a number of organic solvents and hydrolyses in water to give $\text{Cp}_2\text{Hf}^{2+}$, which is active in condensations with Lewis bases⁶.

Condensation is general occurring in good to moderate yield for both the aqueous and interfacial systems (Table 1). Reaction, while rapid, reaching a plateau in yield ~ 1 min, is slower than for many similar condensations where reaction is complete within ~ 10 sec⁶.

The synthesis of hafnium polythioethers was also desired since other hafnium polymers synthesized by us have showed generally markedly better thermal stabilities than the

corresponding titanium products. Several titanium polythioethers exhibited moderate weight retention (less than 30% weight loss to $\sim 1000^\circ\text{C}$). Thus the analogous hafnium products might exhibit good weight retention.

D.s.c. and t.g.a. results appear in Figures 1-3. Several items should be noted.

(A) There appears to be no general trend with respect to weight retention as a function of atmosphere or dithiol.

(B) The products exhibited both kinetically and non-kinetically controlled weight retention plateaus. For instance, the plateau exhibited in the 600° to 800°C range (in nitrogen) for the product with dimercaptopropionate is not kinetically controlled (i.e. weight retention is time independent) whereas the weight retention in the 120° to 600°C range is kinetically controlled (i.e. weight retention is time and heating rate dependent).

(C) Several products showed 70% plus weight retention to 1000°C . This is considered fairly good. In considering weight retentions with many organometallic polymers the amount of organic material retained is important. The end thermal degradation product in air is HfO_2 . Table 2 shows values of '%- HfO_2 ' which is the % weight retention expected if only hafnium dioxide were left. The difference between the theoretical HfO_2 % weight retention and actual weight retention is taken to be a crude measure of organic material retained. Thus for the product with dimercaptopropionate at 650°C in air there is 70% actual weight retention compared to 39% HfO_2 theoretically possible, giving a gross organic weight retention of $\sim 31\%$ or about 45% of the remaining weight.

(D) Products begin to degrade at $\sim 50^\circ$ to 100°C , thus while they exhibit moderate high temperature (400° to

Figure 1 T.g.a. thermograms for products of Cp_2HfCl_2 with 1,2-ethanedithiol (●), 1,3-propanedithiol (○), 1,6-hexanedithiol (+), 1,8-octanedithiol —, dimercaptopropionate (Δ), and dimercaptoacetate --- in air with a gas flow of 0.3 l/min at a heating rate of $30^\circ\text{C}/\text{min}$

Table 2 Yield as a function of stirring time

Stirring time (sec)	Yield (%)	
	(interfacial)	(aqueous solution)
5	55	6
15	67	20
60	78	53
300	78	53

Reaction conditions are the same as Table 1 employing dimercaptoacetate at different stirring times

1100°C range) stability, they show poor low temperature stability. This weight loss is often accompanied by the production of a 'thiol-like' odour indicating loss of sulphur containing segments.

(E) Thermal degradation up 150° to 250°C appears to be identical in air and nitrogen, indicating an internal type of degradation via a non-oxidative mode(s). After this the degradation modes are quite dissimilar with degradation in air occurring via an oxidative mode(s).

Degradation probably occurs by a complex pathway(s) as indicated by the asymmetries and irregularities present in both the d.s.c. (mainly) and t.g.a. thermograms making quantitative measurements difficult to interpret. Thus ΔH values reported in Table 3 must be viewed as simply gross values indicative of composite, possibly only net, heat content change values.

Four endgroups are possible, they are: Hf-OH, Hf-Cl, R-SH and an endgroup formed from the condensation of Hf-Cl with Et₃N. All products exhibit bands in the 3600 to 3000 cm⁻¹ region characteristic of the Hf-OH group. The presence of S-H endgroups is not indicated because of the lack of bands in the 2600-2500 cm⁻¹ region. Presence of endgroups containing the Et₃N moiety is not indicated due to the absence of bands characteristic of this moiety. The assignment of bands characteristic of the

^a Convention utilized: exothermic values are reported as positive values, endothermic values as negative values

Hf-Cl unit is unsure, probably occurring about the 400 to 200 cm^{-1} range. Within this range the products exhibit a number of unassigned bands, thus identification is not presently possible. Thus there exists at least Hf-OH end-groups, indicative of the importance of Cp_2HfCl_2 hydroxylation.

New slit die rheometer: some results with a butadiene–styrene block copolymer*

Jean L. Leblanc

Chimie Industrielle Minérale, Faculté des Sciences Appliquées, Université de Liège, B-4000 Liège, Belgium

(Received 27 May 1975; revised 23 July 1975)

The slit die rheometer described, is a modification of the extrusion part of a Zwick rheometer (piston apparatus with constant applied pressure). The new slit has a variable depth, and pressure–temperature transducers are flush mounted at the die wall. The duct is 85 mm long and has a rectangular cross-section, 10 mm wide; four depths are available (0.50, 0.75, 1.00 and 1.50 mm). The hydraulic system gives pressures ranging from ~80 to 430 kg/cm², and the volumetric flow rate is determined by collecting extrudate samples. Some results are presented on Solprene 415, a butadiene–styrene block copolymer. Parabolic pressure profiles are accepted along the longitudinal distance of the die. A method is proposed to linearize the pressure gradient, in order to calculate the wall shear stress. A flow curve is obtained which is not strictly described by a power law relation.

INTRODUCTION

Extensive use has been made of the capillary rheometer, to determine the rheological properties of viscoelastic fluids, especially polymer melts. Because of the facility of analyzing experimental data and the possibility of achieving high levels of shear, the capillary rheometry has shown a growing development, for scientific studies as well as for industrial testing. Another geometry as simple as the capillary rheometer, is the system of two parallel plates of infinite width, in practice the geometry of a rectangular cross-section, with the so-called slit die rheometer.

Twelve years ago, several researchers^{1–3}, reported pressure and velocity profile measurements with slit dies. More recently, Han and coworkers^{4,8,9} constructed a slit type instrument with flush mounting of pressure transducers on the die wall. They demonstrated further^{5–7,10}, that the slit and capillary rheometers, produce essentially the same information and pointed out the existence of an ‘exit pressure’ during extrusion, from the measurements of wall normal stress distributions in the axial direction. With such measurements, Han was able to propose a method of determining the viscous and elastic properties of polymeric melts. This method consists essentially of obtaining the viscous property from the slope of the axial normal stress distribution, and the elastic property from the exit pressure. The exit pressure is the extrapolation value of wall normal stress to the exit of the die, from pressure readings within the duct.

In this connection, recent papers from Han and Drexler¹¹, describe rectangular slit dies with glass windows on either side, permitting the observation of stress birefringence patterns during extrusion. Their birefringence technique, together with measurements of wall normal stresses, give the stress distributions in the duct.

Some recent experimental studies have also been reported on the extrusion of polymer melts, through dies of rectangular cross-section^{12,13} and it is expected that the slit die

rheometry will show a similar development to capillary rheometry.

A SLIT DIE WITH VARIABLE DEPTH

The apparatus described here is a large modification of the extrusion part of a Zwick Z 4.1 C rheometer. In fact, we only use the hydraulic system of the Zwick rheometer, to provide and maintain the applied pressure to the piston. This piston is moving in a heated barrel of 30 mm diameter. A slit die of special design has been constructed which is connected to the end of the barrel.

The variable depth slit die is made of stainless steel and is composed of a main part and a cap separated by calibrated spacers, as shown in *Figure 1*. There is a set of spacers which enable the depth of the slot to be varied. The duct is 85 mm long and the rectangular cross-section, 10 mm wide; four depths are available: 0.50; 0.75; 1.00 and 1.50 mm. The cap has three pressure tap holes along the longitudinal axis. The dimensions of the slot and the positions of pressure–temperature transducers are indicated in *Figure 2*. The melt pressure transducers are ‘mounted flush’ with the slot wall, in such a manner that there is no ‘dead space’ between the tip of the transducer and the flow channel. This kind of mounting avoids flow disturbances, stagnations of the melt and possible hole effects. The main part and the cap are constructed in such a way that the slit has an entrance angle of 82 degrees, which prevents stagnation at the entry of the die. A general plan of the system is given in *Figure 3*.

The pressures and temperatures were measured with Dynisco TPT-432-A transducers. Pressure readings are recorded with a Riken Denshi model F-72T X–Y₁, Y₂ recorder, so that pressure–time curves are automatically plotted during the extrusion. Both the barrel and the die are electrically heated and especially insulated to prevent heat loss. The temperatures of the barrel and the die are separately checked with contact-thermometers or with thermocouples – Pyrectron KY(CORECI) indicating controllers. Both drive Thyristor-operated thermal regulators. The temperatures of the barrel and the die are controlled to remain within 1°C of the desired temperature.

* Part of this paper was presented at the British Society of Rheology meeting on Rheometry: methods of measurement and analysis of results, held at Shrivenham, April 1975.

Figure 2 Slit dies dimensions and locations of pressure holes. (a) Longitudinal section; (b) transverse section

The hydraulic system of the Zwick rheometer provides pressures ranging from 80 to 430 kg/cm², and the volumetric flow rate is determined by collecting extrudate samples. This was later used to calculate apparent shear rate.

RESULTS AND DISCUSSION

Presented here are preliminary results with a butadiene-styrene block copolymer (Solprene 415 supplied by Phillips petroleum company). Characteristics of Solprene 415 are given in Table 1.

All results presented below, are obtained at a melting temperature of 175°C. Several experiments have been carried out with all the various depths and with the variation of the applied pressure, measuring the volumetric flow rate, and with automatic pressure recordings. Figures 4, 5, 6 and 7 show the axial pressure profiles in die of different depths, with the shear rate at the wall used as a parameter. In these Figures, values of the pressure plotted for a longitudinal distance of 95 mm (from the exit of the die), correspond to applied pressures in the barrel, and are not taken into account to draw axial pressure profiles. Thus, with no assumption about die entrance loss, it is possible to set out a parabolic curve for each set of three measured pressures, which responds to the general equation:

$$P = ax^2 + bx + P_0$$

Figure 4 Axial pressure profiles in slit die for Solprene 415 at 175°C. Slit die: L , 85 mm; b , 10 mm; d , 0.5 mm. Values for $\dot{\gamma}$ (sec^{-1}): A, 6.58; B, 3.30; C, 2.38; D, 1.546; E, 0.995; F, 0.598; G, 0.299

where P is the pressure and x the longitudinal distance from the exit of the die. For each pressure profile, coefficients a and b are computed by making linear regression of $(P - P_I)/(x - x_1)$ versus $(x - x_1)$, where x_1 is taken equal to 10 (pressure transducer's position I) and P_I is the corresponding pressure. Straight lines are so obtained from which the slope gives a , and the zero intercept gives $(2ax_1 + b)$ and thus b . The third coefficient which corresponds to the 'exit pressure' P_0 is calculated by introducing experimental values. By using a Hewlett-Packard HP-55 programmable computer, great precision is obtained in determining the values of the coefficients and more accurate pressure profiles can be drawn. As an example, results are given in Table 2 for the slit die of 0.50 mm thickness.

The following observations can be made from Figures 4–7: (a) between measurement positions I and III, the pressure gradient is *not* strictly constant within the longitudinal distance; (b) the shape of the pressure profiles is clearly dependent on the flow rate, and varies with the die geometry; (c) non-zero 'exit pressures' are obtained by extrapolating the parabolic curves (i.e. by calculating the P_0 coefficient of the parabolic equation).

Concerning the shape of pressure profiles, it seems that the deeper the slot, the less 'linear' are the curves. Moreover, the pressure drop at the entry (largest part seems to be given by the difference between the applied pressure in

the barrel and the measured pressure in position III) is more important as the shear rate increases; but at constant shear rate, the pressure drop at the entry, increases as the slit depth decreases. These observations agreed very well with the results of Han and Charles for capillary flow of molten polymers¹⁵ and are well understood since the greater the cross-section of the capillary/cross-section of the barrel ratio, the smaller the pressure drop at the entry.

Inside the die, the pressure profiles are parabolic, but in such a manner that they become approximately linear as the longitudinal distance (from the exit of the die) decreases. Non-linear pressure profiles have also been reported for polystyrene at 200°C by Han, Charles and Philippoff in their first publication^{4(a)}. This was attributed to under developed flow; the criterion used to ascertain whether or not the flow is fully developed, being the constancy of the pressure gradient; but no explanation was given for these non-linear pressure profiles. It must be noted that for high viscosity materials such as polymer melts, it is doubtful as to whether fully developed flow can be achieved. Although flow birefringence observations in slit die¹¹ reveal that, at a distance of about twice the slit thickness from the die entrance, isochromatic fringe patterns become parallel to the slit wall (at least for the studied polymers, i.e. polyethylene, polypropylene and polystyrene). In the system we present here, the first pressure measurement after the die entrance (P_{III}) is at a distance of 22, 14.7, 11 and 7.3 times the slit thickness from the die entrance, for depths of 0.50, 0.75, 1.00 and 1.50 mm, respectively. However, it is pos-

Figure 5 Axial pressure profiles in slit die for Solprene 415 at 175°C. Slit die: L , 85 mm; b , 10 mm; d , 0.75 mm. Values for $\dot{\gamma}$ (sec^{-1}): A, 39; B, 11.5; C, 3.84; D, 2.33; E, 1.28; F, 0.613

Figure 6 Axial pressure profiles in slit die for Solprene 415 at 175°C. Slit die: L , 85 mm; b , 10 mm; d , 1 mm. Values for $\dot{\gamma}$ (sec^{-1}): A, 105; B, 43.4; C, 21.6; D, 7.81; E, 3.26; F, 1.53; G, 0.723

sible that with the Solprene 415 butadiene-styrene block copolymer used, the importance of the elastic component of the material does not permit a fully developed flow to be achieved within a length equivalent to at least 22 times the slit die thickness. It is also possible that the parabolic shape of pressure profiles is typical of highly elastic polymer melts. With the parabolic equations, we compute for each pressure profile, in the manner described above, it is clear that the extrapolation to the exit of the die is reasonable, because at the present time no 'exit effects' have been shown off.

In spite of the extrapolation procedure used, it appears from Figures 4 to 7 that, at constant shear rate, the exit pressure increases while the depth of the slit decreases, and in conformity with the works of Han and coworkers⁴⁻⁹; who observed strict linearity in pressure profiles for slot of 0.13-0.25 mm depth, it seems that important 'exit pressures' are only available with a very thin slit.

The wall shear stress τ_{wc} in a slit die may be given, in a classical manner, by:

$$\tau_{wc} = \frac{bd}{2(b+d)} \cdot \left(\frac{\partial P}{\partial x} \right) \quad (1)$$

where $\partial P/\partial x$ is the pressure gradient along the axis, b the slit width and d the slit thickness¹⁶. This equation gives a mean corrected wall shear stress, including the edge correction, and if the pressure gradient is determined by pressure measurements inside the die, no Bagley correction (extrapo-

lation to zero pressure of plots of pressure versus L/d ratio at given shear rate) is necessary. When the slit becomes very thin, the wall shear stress is obviously given by.

$$\tau_w \approx \frac{d}{2} \cdot \left(\frac{\partial P}{\partial x} \right) \quad (2)$$

This simplified equation has been used by Han⁸ for slit dies of b/d ratios equal to 10 and 20.

Since, in our experiments, pressure profiles are not straight lines, a problem of linearization appeared in calculating wall shear stresses. A first approximate method is to assimilate the smooth pressure curves between P_I and P_{III} to straight lines and obtain the pressure gradient by:

$$\frac{\partial P}{\partial x} = \frac{P_{III} - P_I}{64} \quad (3)$$

since $x = 64$ mm between pressure transducers I and III. A more rigorous method is to use the parabolic equations we determine for each pressure profile. First derivative gives the pressure gradient by:

$$\frac{\partial P}{\partial x} = 2ax + b \quad (4)$$

at any fixed value of x . In this manner we compute the pressure gradient taking $x = 42$ (the transducer's position

II; halfway of the die) and the difference between pressure gradients calculated by the first or the second method appears only at the fourth decimal. As an example of corrections introduced by using equations (1) to (4), some results are given in Table 3 for the slit of 1.5 mm thick, for which the differences are the more important.

For the determination of shear stresses, we use pressure gradients as calculated by equation (4). Table 4 gives an idea of differences introduced by use of equation (1) (edge correction included) or equation (2) (no edge correction), for the slit die, 1.5 mm thick, and for the slit die, 0.5 mm. The error arising from use of equation (2) is 15% (of τ_{wc} values) for the 1.5 mm slit and 5% for the 0.5 mm slit. Edge effects are thus not negligible and use of the simplified equation (2) to calculate shear stresses can introduce serious errors in determining flow curves. We have thus used equation (1) to calculate the wall shear stress.

The apparent shear rate at the wall $\dot{\gamma}_{wa}$ has been calculated using:

$$\dot{\gamma}_{wa} = \frac{6Q}{bd^2} \quad (6)$$

where Q is the volumetric flow rate (mm³/sec) and b the slit width. Plots of $\log \tau_{wc}$ versus $\log \dot{\gamma}_{wa}$ are drawn and the slope is measured for each experimental apparent shear rate, in order to apply the Rabinowitsch correction, so that the true wall shear rate $\dot{\gamma}_w$ is given by:

$$\begin{aligned} \dot{\gamma}_w &= \dot{\gamma}_{wa} \left(\frac{2}{3} + \frac{1}{3} \cdot \frac{\partial \log \dot{\gamma}_{wa}}{\partial \log \tau_{wc}} \right) \\ &= \left(\frac{2n+1}{3n} \right) \dot{\gamma}_{wa} \end{aligned} \quad (7)$$

where $n = \partial \log \tau_{wc} / \partial \log \dot{\gamma}_{wa}$.

We have then constructed a flow curve by plotting τ_{wc} versus $\dot{\gamma}_w$. Figure 8 shows the flow curve of Solprene 415 melt at 175°C, plotted with extrusion data of the four slit geometries. It is clear that the different slit dies give consistent results, when edge corrections are included in the calculation of shear stresses. The flow curve in Figure 8 is the 'best' curve it is possible to draw through experimental data. In order to test the validity of a power law relation, to describe the behaviour of Solprene 415 in the studied

Figure 8 Flow curve of Solprene 415 at 175°C. ●, 0.50; △, 0.75; □, 1.00; ▼, 1.50 mm

Figure 9 Melt viscosity versus shear rate for Solprene 415 at 175°C. ●, 0.50; △, 0.75; □, 1.00; ▼, 1.50 mm

range of shear rates, we compute by linear regression the power function:

$$\tau = k \cdot \dot{\gamma}^n$$

which may be adjusted to the set of experimental points $[(\dot{\gamma}_i, \tau_i), i = 1, 2, \dots, p]$. The power law index n is given by:

$$n = \frac{\sum (\ln \dot{\gamma}_i)(\ln \tau_i) - [(\sum \ln \dot{\gamma}_i)(\sum \ln \tau_i)]/p}{\sum (\ln \dot{\gamma}_i)^2 - [\sum (\ln \dot{\gamma}_i)^2]/p}$$

and k is given by¹⁷

$$k = \exp \left(\frac{\sum \ln \tau_i}{p} - n \frac{\sum \ln \dot{\gamma}_i}{p} \right)$$

We thus obtain a power law:

$$\tau = 0.5751 \dot{\gamma}^{0.2314}$$

which is plotted in Figure 8 (broken line). It seems that the behaviour of Solprene 415 is not strictly described by

a power law relation. In plotting the melt viscosity against shear rate, as shown in Figure 9, it may be seen that Solprene 415 is in the non-Newtonian flow regime over the range of studied shear rates.

CONCLUSIONS

The slit die rheometer with variable depths, constructed with a Zwick rheometer gives acceptable results in studying the melt flow properties of polymers. With the depths actually available, it is quite possible to obtain flow curves and viscosity functions for shear rates ranging from 10^{-1} to 10^2 sec^{-1} , hence in the non-Newtonian region. Moreover the apparatus permits to plot pressure profiles along the die, with the possibility to extrapolate up to exit pressure.

ACKNOWLEDGEMENTS

The author would like to thank Professor K. Gamski for helpful discussions and for the Zwick rheometer placed at his disposal. He is indebted to Mr C. Courard and coworkers for machining of the slit die. Thanks are also due to Mr R. Fayt for Gel permeation chromatography experiments, and to Miss D. Degeimbre for her support in determining characteristics of the sample. The author wishes to acknowledge the Phillips petroleum company (Technical Centre at Overijse, Belgium) for providing the Solprene sample.

Thermal analysis of heat set poly(ethylene terephthalate) fibres*

H.-J. Berndt and Adelgund Bossmann

Textilforschung Krefeld, D-4150 Krefeld, Frankenring 2, W. Germany

(Received 16 July 1975; revised 23 October 1975)

Differential thermal analysis (d.t.a.) has been used for characterization of the thermal history of poly(ethylene terephthalate) (PET) fibres. The latter were treated under a variety of temperatures and times in a manner similar to conditions employed in conventional textile processing. The d.t.a. revealed an endotherm at temperatures below the main melting peak of the fibre polymer, related directly to temperature and time of thermal treatment, even with yarns that were heat set for less than 0.2 sec (e.g. false twisting process). The maximum of this low temperature endotherm is a direct measure of the effective temperature (T_{eff}) that has been acquired by the PET fibres during the thermal processing. In practice, several thermal treatments are often involved in textile processing. Results of this work imply that PET fibres subjected to a second heat treatment will show an additional low temperature endotherm on d.t.a. scanning, provided that the structural characteristics formed in the first thermal process are not neutralized in the second thermal process and recrystallizable material is still present in the fibre polymer.

INTRODUCTION

In order to attain a PET yarn or fabric with certain properties, the drawn PET filament will be subjected to various processing steps while heat is applied. During these thermal mechanical processing operations, changes in the state of order in the polymer occur via a decrease in internal stresses and reorganization of polymer segments. A recrystallization and an after-crystallization will concurrently take place. The solid phase transitions in the PET fibre polymer can be detected by d.t.a. traces¹⁻⁴. Multiple melting peaks during d.t.a. scanning have been reported⁵⁻⁸ for annealed PET bulk polymer. The PET samples were heat treated for periods varying from several minutes (5 min) to several hours (24 h) at different temperatures to study the effect on thermograms in d.t.a. Between the glass transition temperature and the main melting peak at about 260°C, a low temperature endotherm was observed. The position of this low temperature endotherm is reported to be related to the temperature to which the PET polymer has been exposed prior to d.t.a. scanning⁵⁻⁷. An increase in time of treatment during annealing at a constant temperature causes an increase in the low temperature d.t.a. endotherm⁵.

Roberts⁵ ascribed this low temperature endotherm to melting of chain folded crystals, and the main melting peak to melting of bundle-like crystals. More recent work by Roberts⁹ and Holdsworth and Turner Jones⁸ discounted this chain folded and bundle-like crystal endotherms hypothesis because of the change in the relative areas of the two endotherms with change in d.t.a. heating rate. A change in heating rate from 4 to 64 K/min⁹ causes not only an increase in intensity of the low melting endotherm but also an increase in temperature on the d.t.a. trace. These changes are considered to be due to structural changes taking place during d.t.a. scanning according to the heating rate^{8,9}. These studies were mainly carried out on bulky polymer annealed for a fairly long time (from ~5 min to several hours).

Wiesener⁴ who investigated thermally treated drawn PET fibres, also found an increase in temperature of the low temperature endotherm when the PET fibres were subjected to increasing setting temperatures. However, also in this investigation the PET fibres were treated for 10 to 240 min.

Our concern is to investigate the changes of structure in PET fibres as brought about under the influence of various processing operations. For practical significance, time during the different heat setting processes varies from 0.2 sec (e.g. false twisting) to 4 h (e.g. heat setting of heavy technical fabrics). The feasibility of d.t.a. to define the thermal prehistory of PET fibres as produced under ordinary commercial thermal processing is, therefore, studied. Good understanding of the structural changes as generated in PET fibre polymer under various conditions would be useful to predict the specific parameters of the heat setting process; an aspect which is needed to attain desirable and reproducible quality.

EXPERIMENTAL

Material

The materials used in this study are exclusively commercial drawn PET filament yarns of different origins. The yarns were heat set at temperatures varying from 110° to 230°C under simultaneous constant tension (0.0–0.1 N/tex) during setting. The time of treatment varied from 0.5 sec to 240 sec in hot air and up to 90 min during a high temperature dyeing process. In order to meet these setting demands, special heat setting equipment was developed¹ to control the process parameters, temperature, tension and processing time.

False twisted textured yarns are also used to study in particular, the effect of heat setting for very short times on structural changes in PET fibres.

Figure 1 D.t.a. traces of PET fibres heat set at 180°C for 20 sec; d.t.a. heating rates (K/min): A, 5; B, 10; C, 15; D, 20; E, 25; F, 30

Differential thermal analysis

Samples (5–6 mg) of PET yarn were accurately weighed into an aluminium sample pan. The covers of the sample pans were provided with small holes to allow for evaporation of finishing agent and to maintain atmospheric pressure during d.t.a. scanning. The measurements were made with the sample in air, since prior tests have demonstrated that the heat of reaction is generally not influenced by atmospheric oxygen. The thermograms of the PET yarns samples were run on a Du Pont Differential Analyser, Type 900 using the d.s.c. cell. A good resolution was needed to observe the heat of fusion, which did not always appear as a peak rather than as a deflection in the slope of the d.t.a. trace. A heating rate of 30 K/min and a sensitivity range for ΔT of 0.1 or 0.2 K/in were chosen.

RESULTS AND DISCUSSION

Heating rate

The change of d.t.a. traces on increasing heating rate is shown in Figure 1. A PET yarn sample was isothermally treated at 180°C for 20 sec at zero tension and d.t.a. traces obtained at various heating rates. An increase in the partial melting peak temperature and a change in the low temperature endotherm are observed with increasing instrument heating rate. On running the fibre sample at a low heating rate (5 K/min), a small fusion endotherm with a poorly resolved maximum at 183°C is found, whereas a heating rate of 30 K/min leads to a fusion endotherm over a broad temperature range with its maximum at 190°C. This change in the endotherm and peak temperature is indicative of a reorganization taking place during scanning⁸.

The change on d.t.a. traces due to heating rate can be explained by the theory of Zachmann and Stuart¹⁰, who found that only imperfect crystals are formed at low crystallization temperatures (180°C, 20 sec). On heating, the perfection of the crystals formed at low temperatures increases owing to partial melting and recrystallization. At low heating rates a kinetic balance of melting and recrystallization will occur which is not detectable in the thermogram baseline. However, if the heating rate is high enough the faster melting process exceeds the slower recrystallization process, producing the increase in the low temperature endotherm. The increase in the partial melting peak temperature with increasing heating rate is apparently due to the fact that the crystals may be heated faster than the melt-crystal interface can progress towards the interior and the crystals melt at a higher temperature¹¹.

Heat setting temperature

D.t.a. traces of a PET yarn 10tex/36 filaments isothermally heat set at various temperatures are shown in Figure 2. The yarn samples were treated for 20 sec at zero tension. The thermograms were run at a sensitivity range of $\Delta T = 0.2$ K/in. They show a distinct partial melting peak prior to the main melting peak at 256°C. The partial melting peak appears 10°C above the machine temperature of thermal setting. With increasing machine temperature the maximum of this peak increases linearly on the d.t.a. temperature scale. These results suggest that the imperfect crystals in the fibre polymer melt on heating in the d.t.a. at a given heating rate just above the temperature at which they were formed during heat setting. The maximum of the partial melting endotherm is directly related to the setting temperature and is defined as the effective temperature T_{eff} .

If the PET fibre is exposed to a further heat process like a high temperature dyeing at 130°C for 90 min, an addi-

tional low temperature endotherm in the d.t.a. trace is observed at a constant temperature of 170°C (Figure 3). The increase in temperature of 40°C on the d.t.a. temperature scale above the dyeing temperature is caused by the hydrothermal treatment. Schefer¹² found that a hydrothermal treatment causes a higher heat setting effect on PET than hot air does. The d.t.a. traces indicate that the partial melting peak due to the first thermal process, vanishes in cases where the T_{eff} of the succeeding process exceeds the T_{eff} of the first process. Only PET yarns which have adopted a T_{eff} in the first thermal process sufficiently above T_{eff} of the second thermal process (so as not to be masked by an overlapping effect) show a partial melting peak from the first thermal process and a second one from high temperature dyeing.

Repetitive measurements on replicate samples showed good agreement. The mean deviation from 3 or 4 values did not exceed $\pm 1^{\circ}\text{C}$. Results proved also to be instrument independent. Measurements carried out in other laboratories on different instruments were in good agreement and reproducible to $\pm 1^{\circ}\text{C}$.

Time of treatment

Commercial drawn PET yarns of different origin were heat set for various times (0.5 to 240 sec) at a constant temperature (180°C) using zero tension. The observed partial melting peaks (T_{eff}) are plotted as a function of log time in Figure 4. The results indicate that increasing the time of treatment from 0.5 to 5 sec is accompanied by a large difference between the effective temperature and the

machine temperature. That is, with such a short time of treatment the PET yarns do not adopt the machine temperature. Further prolongation of time caused a linear increase in the effective temperature with log time, owing to after-crystallization.

The dependence of the effective temperature on the heat setting temperature, dwell time and high temperature dyeing is shown in Figure 5. The heat setting temperature reveals a linear relation with T_{eff} . A change in dwell time causes a parallel shift on the ordinate indicating that a decrease in dwell time decreases T_{eff} . The effective temperature due to a high temperature dyeing process at 130°C is drawn as a horizontal line at 170°C . This indicates that this process wipes out any structural features of the fibre polymer which are due to thermal treatments with effective temperatures below that of the high temperature dyeing. It follows from this that the intensity of a thermal treatment should not be characterized by machine data but rather by its effective temperature which indicates changes in the state of order in the polymer brought about by thermal treatment.

Tension during heat setting

To study the effect of tension during heat setting, PET filament yarn was treated at different specific tensions varied from 0.0 N/tex to 0.1 N/tex. The setting temperature (200°C) and time (20 sec) were kept constant. The thermograms of these samples are shown in Figure 6a. It is observed that the tension during heat setting influences the partial melting peak. An increase from zero tension to 0.02 N/tex causes a decrease in temperature of the partial melting peak. The result leads to the assumption that the stresses developed in the non-crystalline regions during heat setting cause a less uniform crystal size distribution in the PET polymer, thereby lowering the partial melting peak temperature.

If the same material is subjected to a high temperature dyeing process an additional partial melting peak at 170°C is observed as shown in Figure 6b. In this case the premelting peak, at 170°C increases slightly on the d.t.a. tempera-

ture scale with increasing tension. The slight increase in temperature of the endotherm leads one to speculate that the thermodynamically less stable lower melting structures brought about by thermo-setting under tension, melt and recrystallize under the conditions of the dyeing process, as a consequence they cause an improved crystal size distribution and increased molecular orientation in the non-dyed fibre.

This example illustrates that the d.t.a. method should not be used exclusively for identification of fault analysis to explain the cause of the structural changes of PET fibres. The results of d.t.a. measurements should be rather supported by other methods e.g. temperature dependent change of

length (t.m.a.)² or thermal shrinkage force¹³ to characterize the state of structural order.

Application of d.t.a. to fault analysis

Two further examples indicate the feasibility of fault analysis by the d.t.a. method.

Figure 7 shows d.t.a. traces of false twisted yarns heat set at the indicated temperatures for 0.2 sec. A less distinguished but still well detectable partial melting peak is observed at about 25°C below the machine temperature. A following steam setting process intensifies an endotherm at 170°C, in cases where the yarn was exposed to machine temperatures less than 210°C, whereas yarns false twisted at higher temperatures (220° or 230°C) show two separate partial melting peaks in the d.t.a. thermogram. While the first peak at 170°C reflects the effect of steaming, the second one could be associated with the false twisting process itself. In Figure 8 d.t.a. thermograms are shown of textured yarns from a streaky dyed fabric. The first d.t.a. trace demonstrates the behaviour of the lightly dyed material and the second one of the deeper dyed material. Comparing the two traces one can suppose that the lightly dyed material has a less broadened endothermal peak, indicating that during false twisting the yarn adopted a T_{eff} which is comparable with that of the high temperature dyeing. On the other hand the deeper dyed yarn adopted a T_{eff} during false twisting which is about 15°C higher. The difference in T_{eff} could be traced back to differences in heat transfer and/or differences in temperature of heating.

In another case difficulties were encountered when a heavy technical PET fabric were placed on a cylinder thermosetting machine. During thermal treatment the fabric began to drag. D.t.a. measurements made on the material showed (Figure 9) that the fabric did not adopt the same temperature throughout the whole width. As a result different shrinkage forces were developed in the various regions of the fabric and led to dragging. Checking the temperature distribution in the machine by direct measurements confirmed the d.t.a. results.

CONCLUSION

The results of this work illustrate the feasibility of using d.t.a. measurements as an aid to determine the temperature effect which influences the properties of a PET product.

A partial melting peak prior to the main melting peak was observed on commercial PET fibres which were heat set at various temperatures and times, even if the latter were fractions of a second, as in a false twisting process. The position of the partial melting peak on the d.t.a. temperature scale determines the effective temperature (T_{eff}) of the PET fibre. This effective temperature corresponds to a structural feature which is generated by a thermal treatment of the material.

The effective temperature acquired by the PET material is not necessarily equal to the machine temperature since it relies on many different factors such as transfer of heat, medium, and dwell time.

However it cannot be said that d.t.a. should be used independently of other techniques to analyse the state of order of PET or to optimize the process technology.

ACKNOWLEDGEMENTS

This project is part of the programme of the process technology research group at the textile research centre at Krefeld. The authors acknowledge the experimental assistance by members of the group and are grateful to Professor Dr G. Valk and Dr G. Heidemann for valuable discussions.

Stored elasticity in flowing solutions of polyisobutylene as measured by recoil

J. Schurz and H.-G. Müller*

*Institut für Physikalische Chemie der Universität Graz und Sonderforschungsbereich 41 (Chemie und Physik der Makromoleküle), A-8010 Graz, Austria
(Received 16 July 1975; revised 10 October 1975)*

Recoil measurements in capillary flow are performed with solutions of polyisobutylene in toluene and used to calculate a shear modulus G . The shear rate dependence of G is explained in terms of a stiffening function and a network destruction function, the first contribution dominating in the measured range. Good agreement is found for recoil in both the capillary and in a rotational viscometer.

INTRODUCTION

Concentrated solutions of high polymers are generally of the network type, in which a continuous network is formed by the molecular strands, by means of so-called 'entanglements'. The bonding at these crossing points may consist of geometrical entanglements of coils penetrating each other, or of secondary bonding at the interface of the molecular coils, which overlap at their periphery only. Further, the networks have to be regarded as temporary, the number of entanglement (resp. bonding) points being a function of the shear rate acting.

One of the most important properties of such a network solution, is its elasticity. The stored elasticity in a flowing solution can be measured via the normal force effects, or directly by means of recoil. Such recoil measurements are possible in both the rotational viscometer and the capillary viscometer. Unfortunately, there is little experience on how well measurements by various methods agree. Therefore, in this paper, we shall report some measurements with toluene solutions of technical (unfractionated) polyisobutylenes, using direct observation of recoil in the capillary and in the rotational viscometer.

EXPERIMENTAL

The substance

We used technical grade polyisobutylene (unfractionated), obtained from BASF-Ludwigshafen (Oppanol B). The sample Oppanol B 200 was used. Small pieces of the material were swollen in toluene for 24 h, then the remainder of the solvent was added and the solutions rotated on a turning wheel for several weeks. In this way, concentrations of 0.01 to 0.08 g/ml (1–8%) were prepared. Polyisobutylene/toluene solutions prepared in this way have excellent stability. No viscosity variations could be found even for two year old solutions.

The sample had a M_w of $3,55 \times 10^6$ and a M_n of 6×10^5 . Intrinsic viscosity in toluene was 575 ml/g at 25°C. All measurements described were carried out at 25°C.

Apparatus

Recoil measurements were carried out both in a rotational viscometer and in a capillary viscometer. For the

first mentioned method, a commercially available instrument was used (Haake Rotovisco, plus elasticity equipment); these measurements have been described in detail somewhere else¹. For capillary recoil, we used an instrument of our own design², which consisted of an attachment to our high pressure capillary viscometer, which has been amply described in the literature, and which is commercially available (Anton Paar K. G., Graz, Austria).

The connection between the viscometer unit and the horizontally positioned measuring capillary, is made by a three-way cock with a T-bore (see Figure 1). In position 1, it connects the pressure vessel containing the sample, with the measuring capillary; in position 2, it provides a connection between the measuring capillary and atmospheric pressure. The measuring capillary is fixed in such a way, that the moving liquid thread can be observed visually by means of a microscope, with 30 fold magnification (Messmikroskop no. 35496 by Zeiss, Jena). The microscope is mounted on an optical bench. It can be shifted in such a way as to follow the liquid thread, whereby small shifts are accomplished by operating the worm drive of the microscope stage; larger shifts are made by moving the microscope along the optical bench. The capillary is equipped with markings at 10, 20 and 30 cm length. For a measurement, the liquid is allowed to flow until its meniscus just touches one of the markings. Then the three-way cock is turned very quickly by 90°, so that the liquid thread is connected with atmospheric pressure at both ends; as a consequence it will recoil, i.e. the meniscus will retract. The amount of recoil can be measured by means of the crosslines in the microscope, which are shifted from the original position of the meniscus to the new one by means of the microscope rack and pinion, which has

Figure 1 Recoil attachment, schematically. Three way cock: (a) position 1; (b) position 2

* Present address: Donnerburgweg 11, D-33 Braunschweig, West Germany.

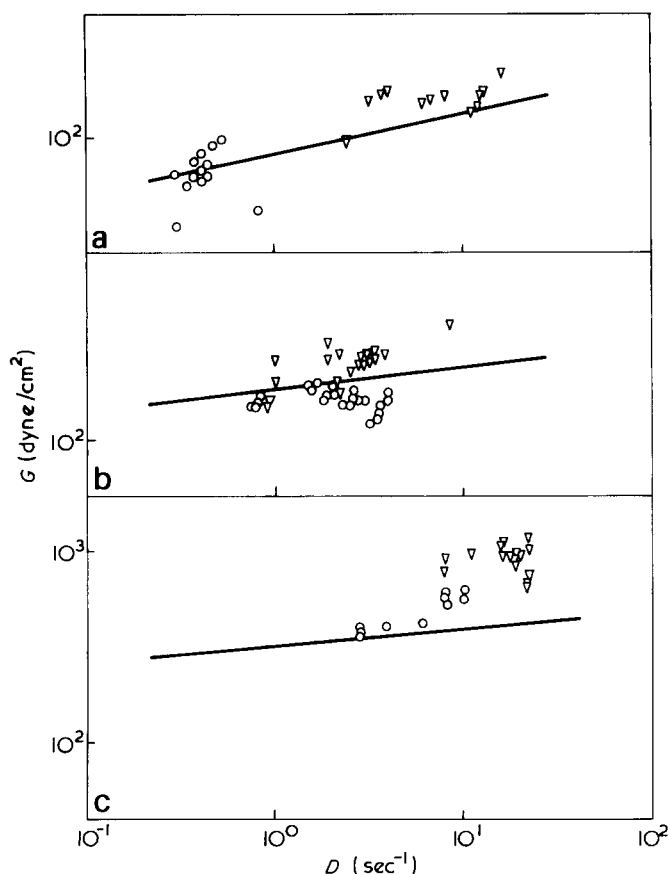

Figure 2 Shear modulus G calculated from recoil for polyisobutylene/toluene. —, recoil measurements in the rotational viscometer Rotovisco. (a) $c = 0.03$ g/ml, $\text{tg}\alpha = 0.22$; (b) $c = 0.04$ g/ml, $\text{tg}\alpha = 0.12$; (c) $c = 0.05$ g/ml, $\text{tg}\alpha = 0.1$

an accuracy of 1/100 mm. This construction allowed the recoil as a function of the length of the liquid thread in the capillary to be tested also. A possible source of error is the fact, that during recoil the shape of the meniscus in the capillary will change. It is slightly concave during flow at small shear rate; after cessation of the flow, the shape changes to a more pronounced concave one. With higher shear rate, the meniscus of the flowing liquid is planar, and only at rest the usual concavity is reformed. In all cases, the amount of recoil was determined at the centre of the profile, that is in the axis of the capillary. Furthermore, in these recoil experiments, the surface tension effects will provide an additional source of error. However, since the capillary is open to the air at both ends, we may expect similar effects at both free surfaces, so that they will cancel in a first approximation.

The evaluation of the data was carried out in the usual way⁴. The shear rate D and shear stress τ were calculated from:

$$D = \frac{4Q}{\pi R^3}; \tau = \frac{Rp}{2l}$$

where: R , radius of capillary; l , length of capillary; Q , flow volume per second; p , driving pressure.

No Weissenberg correction was applied. The recoil length Δl was used first to calculate the recoil volume $V = R^2 \times \pi \times \Delta l$, and this figure was used to derive the recoverable shear S according to Philippoff:

$$S = \frac{4 \times \Delta V}{\pi R^3}$$

From S , a shear modulus G was obtained according to:

$$G = \frac{\tau}{S} = \frac{R^2 p}{8l\Delta l}$$

The resolution of our recoil measurements was 10^{-2} mm. Smaller recoil effects could not be detected in our apparatus. The ratio τ/D is called apparent viscosity and designated by η' .

RESULTS

Dependence of recoil on the flowing volume

First, the amount of recoil was measured as a function of the length of the flowing liquid thread in the capillary, whereby this length was varied between 10 and 33 cm. By adjusting the driving pressure, we kept the shear rate constant for all experiments. It turned out that the amount of recoil is independent of the flowing volume, it is a constant figure and therefore not connected with any variation of the free volume of the flowing liquid, as perhaps caused by the pressure release. If that be the case, the recoil should rise with increasing length of the liquid thread. The absence of such an effect supports the view, that the recoil is caused by elastic effects.

Systematic recoil measurements

The results of our recoil measurements for the sample polyisobutylene B 200 in toluene, for different shear rates and the concentrations 0.03, 0.04 and 0.05 g/ml are shown in Figure 2. In this figure, our results from recoil measurements in the rotational viscometer Rotovisco are also included; they are drawn as solid lines. The shear rate represents the value calculated at the moment of pressure release, thus at the start of the recoil. The data are given in terms of a shear modulus G calculated according to the formulas given above, and presented as a log-log plot.

The results show, that this method of recoil measurement is obviously afflicted with very large inaccuracies, so that the scattering of the measuring points is considerable. Furthermore, these experiments showed that in this way, recoil can only be measured in a limited shear rate range. The reason for this limitation is, that only with a relatively slowly flowing liquid thread, is it possible to stop the flow exactly at the marking of the microscope, which is necessary for the evaluation of the recoil. Furthermore, the accuracy is reduced due to the variation of the shape of the meniscus during recoil.

In spite of all these shortcomings, we note that the measurements in both the rotational viscometer and in the capillary agree satisfactorily. In view of the fact, that agreement of elasticity measurements in instruments so different in measuring principle has hardly been observed so far, we regard this as a support of the general validity of our data. In the small shear rate range we could measure, the shear modulus varies with D^w , w being positive and having the values 0.22, 0.12 and 0.10 for the solutions with concentration 0.03, 0.04 and 0.05 g/ml.

DISCUSSION

The shear rate dependence of the shear modulus is governed by two effects, a stiffening factor $f_1(D)$, which takes into account incomplete relaxation of the network strands and thus will enhance G , and a factor $f_2(D)$, which lowers the

Table 1 Polyisobutylene B 200/Toluene

c(g/ml)	w	u	v
0.03	0.22	2	-1.78
0.04	0.12	2	-1.88
0.05	0.10	2	-1.90

modulus due to network destruction by hydrodynamic forces, which will reduce the number of network points. Thus we may write:

$$G = G_0 \times f_1(D) \times f_2(D) \quad G_0 \text{ value of } G \text{ when } D = 0 \\ \text{(modulus at rest)}$$

If we now use the following notations:

$$G = k \times D^w, \text{ experimental function;}$$

$$f_1(D) = A \times D^u, \text{ stiffening factor;}$$

$$f_2(D) = B \times D^v, \text{ network destruction factor;}$$

we must have:

$$w = u + v \text{ or } v = w - u$$

If we assume $u = 2$ (taken from the dynamic theory of Rouse), we arrive at the following results (see Table I).

Therefore, assuming $u = 2$ we obtain for v , negative values between -1.78 and -1.9 . That means, the network destruction takes place proportional to D^{-v} , whereby v is close to 2. In any event it can be stated, that the increasing function $f_1(D)$ predominates in this range, over the decreasing function $f_2(D)$, so that the overall picture shows a slight increase of the shear modulus G with increasing shear rate.

The level of the shear moduli measured in our D -range is about 10^2 to 10^3 dyn/cm², as seen in Figure 2. This is considerably lower than the G_0 values obtained in an elastoviscometer⁵ (10^4 to 10^5 dyn/cm²). This reflects the fact, that in the flowing solution, significant network destruction must take place.

Effect of pressure on phase transition and morphology of bulk poly(*trans*-1,4-butadiene)

Tsuyoshi Kijima*, Mikio Imamura and Naoshi Kusumoto

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto, Japan

(Received 28 August 1975)

The effect of pressure on the melting, solid–solid transition, and crystallization of poly(*trans*-1,4-butadiene) (PTBD) was investigated using the pressure range of 1–3000 kg/cm². D.t.a. measurements showed that, the melting and transition temperatures increase with increasing pressure, whose pressure coefficients are 38°C per 1000 kg/cm² and 22°C per 1000 kg/cm², respectively. These values were in fairly close agreement with those calculated from the Clausius–Clapeyron equation. Morphological studies using electron microscope and small-angle X-ray scattering method revealed that, the samples crystallized with relatively small supercoolings under normal or high pressure, are formed of distinct lamellae 400–800 Å thick. The lamellar thickness was inappreciably dependent on crystallization pressure. The significant effect of pressure on crystallization was recognized in a tendency of the crystallinity to increase, with increasing crystallization pressure. This pressure effect was explained by the mechanism that, the increased pressure might make the packing of molecular chains in liquid, more dense and that the secondary crystallization might be accelerated, to increase the lateral dimensions of lamellae.

INTRODUCTION

Poly(*trans*-1,4-butadiene) (PTBD) is known to have some marked features of structure, molecular motion, and chain flexibility. The molecular chains of this polymer are considered to have relatively high flexibility¹. PTBD undergoes the first-order solid–solid transition, from one crystalline modification (form I) to another form (form II)²; particularly form II, which is stable at temperatures above 76°C and under atmospheric pressure, and is a so-called plastic crystal, in which the molecular chains are free to move and rotate around the molecular axes^{2,3}. In connection with these basic features, a variety of interesting findings have been reported on the morphology^{4–6}, mechanical properties⁵, and calorimetric properties^{6,7}.

The morphology of PTBD single crystals has been studied by several authors by electron microscopy^{4,5}, n.m.r.^{5,6} and calorimetric measurements⁶. However, very few papers have been published concerning the super-structure of PTBD crystallized in bulk. In addition, the effect of pressure on the phase transition of PTBD is of interest if the above mentioned features of the polymer are taken into account. Although there is a report on the solid–solid transition of PTBD under high pressure⁸, no studies have been reported on the effect of pressure on the crystallization and melting.

Therefore, attempts were made to clarify the morphology of PTBD crystallized from the melt at various pressures, along with the pressure dependence of the melting and solid–solid transition temperatures.

EXPERIMENTAL

Material

PTBD was extracted from the original material of Ube Kosan Co. Ltd. with benzene and then precipitated with

methanol, which was filtered and dried to form an aggregate of the polymer. The aggregate was melt-pressed at 160°C and then slowly cooled to room temperature to form thin plate. The intrinsic viscosity of the PTBD in toluene solution at 30°C was 0.967, which yields $M_v = 2.8 \times 10^4$. The infra-red (i.r.) spectrum of this polymer gave >95% *trans* content.

Figure 1 High pressure d.t.a. cell

* Present address: National Institute of Inorganic Materials, Tsukuba, Ibaragi, Japan.

Figure 2 D.s.c. (—) and volume vs. temperature (O) curves of PTBD under normal pressure

Differential thermal analysis (d.t.a.) under elevated pressure

Figure 1 shows the d.t.a. cell, which was designed in a similar manner to that developed by Takemura *et al.*¹⁰. The cell has a chamber of 100 mm in length and 10 mm in diameter, with openings at both ends. One of the openings was connected with a pipe, which was led to the pressure intensifier; the other was closed by a plug containing two metal-sheathed chromel–alumel thermocouples. A few mg of fused PTBD sample were fixed to the junction of the element wires at one end of one of the thermocouples, and the epoxy resin (Araldite) was fixed to that of the other thermocouple, as a reference material. The PTBD was covered with epoxy resin to keep out the pressure transmitting fluid under elevated pressure and temperature. Silicone oil (Toshiba TSF 431) was used as the fluid. The temperature of the d.t.a. cell was controlled manually in an oil bath.

Measurements were conducted with the sample, crystallized from the melt under normal pressure by cooling from 160°C to room temperature at the rate of 1°–2°C/min, while the sample was being fixed to the thermocouple. The normal heating rate of 4°C/min and the pressure range of 1–3000 kg/cm² were used. Measurements in the cooling process were performed with a cooling rate of 1°–3°C/min.

Preparation of pressure crystallized samples

A sheet of the polymer was wrapped in Teflon film and coated with epoxy resin (Araldite), and then it was put into the d.t.a. cell filled with silicone oil. After being precompressed to an appropriate pressure, the sample was heated up to a prescribed temperature to bring about the molten state, and then the pressure was increased rapidly to a predetermined value and held for 3 h. The crystallization temperature was controlled within ±1°C. After gradual cooling to room temperature, the pressure was removed and the sample was taken out.

Some samples were prepared from the melt under normal pressure by isothermal crystallization at various temperatures.

Sample characterization

The characterization of the PTBD samples obtained was carried out by using various methods under normal pressure as follows. Density measurement was conducted by the flotation method, with an aqueous solution of calcium chloride at 25°C. The viscosity of samples in toluene solution was measured at 30°C and i.r. measurement was performed by the KBr pellet method, using a Hitachi/Perkin-Elmer Model 125 spectrophotometer at room temperature. Wide- and small-angle X-ray scattering patterns were taken by the usual method using CuK α rays at room temperature.

In order to determine some thermodynamic quantities upon melting and solid–solid transition, dilatometric and calorimetric measurements under normal pressure were conducted on the sample crystallized for 3 h at 125°C and at normal pressure (sample D). The density of this sample at 25°C was 1.017 g/cm³. This gave a value of 84.3% for the degree of crystallinity, by taking the density of the crystalline region as 1.037 g/cm³¹¹ and that of the amorphous region as 0.926 g/cm³¹². Dilatometry was performed with a heating rate of 1°C/min. Differential scanning calorimetry (d.s.c.) was carried out with a scanning rate of 5°C/min, by using a Rigaku Denki Thermoflex. The temperature and the peak areas were calibrated with indium standard.

RESULTS AND DISCUSSION

Thermodynamic quantities upon melting and transition under normal pressure

Figure 2 shows the dilatometric and the d.s.c. curves under normal pressure for sample D. Each curve exhibits two transitions. The one at the higher temperature side is the melting point and the other is the solid–solid transition (form I to form II). The volume, enthalpy and entropy of melting and those of transition were obtained from these data. Table 1 lists the values of these thermodynamic quantities without and with making crystallinity corrections.

Suehiro *et al.*¹³, reported that the fibre period of PTBD crystal, changes from 4.83 to 4.66 Å and the nearest inter-chain distance, from 4.65 to 4.90 Å at the transition point. These data give a value of 7.17×10^{-2} cm³/g for ΔV_{tr} , in close agreement with 8.05×10^{-2} cm³/g in Table 1.

Table 1 Thermodynamic quantities of transition and melting at normal pressure for PTBD

Stellman and Woodward⁶, obtained values of ΔH_{tr} , ΔH_m , ΔS_{tr} and ΔS_m for the bulk crystallized PTBD samples, the average values of which were 26.7 cal/g, 13.7 cal/g, 0.078 cal/K g, and 0.035 cal/K g, respectively. These values are in good accord with those uncorrected for the degree of crystallinity in Table 1, but 0.1–0.2 times smaller than the values for purely crystalline PTBD.

Pressure effect on melting and transition

Figure 3 shows the d.t.a. curves as a function of pressure for the sample crystallized by slow cooling under normal pressure. Each curve shows two endothermic peaks, one due to solid–solid transition and the other due to melting.

The melting and transition temperatures defined by each peak temperature are plotted against pressure in Figure 4. The values of dT_m/dP and dT_{tr}/dP , are 38°C per 1000 kg/cm² and 22°C per 1000 kg/cm², respectively, at normal pressure and they tend to decrease with increasing pressure. A value of 22°C per 1000 kg/cm² for dT_{tr}/dP is larger than 17.5°C per 1000 kg/cm², reported by Takemura *et al.*⁸.

The Clausius–Clapeyron, equation (1), for melting ($k = m$) or solid–solid transition ($k = tr$) enables us to calculate the values of dT_m/dP and dT_{tr}/dP using the data on volume and entropy changes:

$$\frac{dT_k}{dP} = \frac{\Delta V_k}{\Delta S_k} \quad (1)$$

The value of dT_m/dP for PTBD at normal pressure, was calculated as 41.1°C per 1000 kg/cm² using the data on ΔV_m and ΔS_m in Table 1. This value is fairly close to 38°C per 1000 kg/cm² experimentally obtained. The calculated value of dT_{tr}/dP at normal pressure was 21.1°C per 1000 kg/cm², in fair agreement with 22°C per 1000 kg/cm² directly measured.

The experimental value of dT_m/dP for PTBD is about 1.7 times larger than that of dT_{tr}/dP . Referring to the data of Table 1, the large difference between the values of dT_m/dP and dT_{tr}/dP for PTBD, can be explained by the fact that the entropy of melting is smaller than that of transition by about 53%, although the volume of melting is smaller than that of transition by only about 10%. The value of dT_m/dP for PTBD is also fairly large in comparison with that for the extended chain crystals of polyethylene (26°C per 1000 kg/cm²), according to one of the authors¹⁴. The values of ΔS_m and ΔV_m per mole of bond, for PTBD are

taken as 0.564 cal/K and 0.986 cm³, respectively, according to Table 1, and those for polyethylene are taken as 2.32 cal/K and 2.56 cm³, respectively¹⁴. Hence, the value of ΔV_m per bond for polyethylene is about 2.6 times as large as that for PTBD, whereas the values of ΔS_m per bond of the former is about 4.1 times as large as that of the latter. This fact is compatible with the large value of dT_m/dP for PTBD compared with that for polyethylene.

The d.t.a. traces for melting and transition of PTBD, showed a remarkable tendency to decrease in peak area with increasing pressure, as seen in Figure 3; the melting peak no longer appeared at 3000 kg/cm². This fact suggests that the enthalpy and entropy of melting and those of transition might decrease remarkably with an increase of pressure. This is not inconceivable, if the considerably small entropies of melting and transition per bond, at normal pressure for PTBD compared to the entropy of melting per bond of many other polymers¹⁵ are taken into account.

Lamellar structure of PTBD crystallized at normal and high pressures

Table 2 lists the density at 25°C, degree of crystallinity, and the melting and transition temperatures under normal pressure of PTBD samples crystallized for 3 h at various temperatures (T_c) and at various pressures (P_c); the melting temperature at 3000 kg/cm² was estimated as 210°C from the extrapolation of T_m – P curve indicated by a broken line in Figure 4. For reference, the recrystallization and retransition temperatures in the slow cooling process from the melt are plotted against pressure by solid circles in the same Figure. Some data on sample D were previously described.

Wide-angle X-ray scattering patterns (WAXS), were taken on the starting sample prepared from the melt by slow cooling under normal pressure and sample F crystal-

lized at 2000 kg/cm². The five reflections observed in both patterns were found to give nearly the same d -spacings, as shown in Table 3. This fact indicates that no new crystalline modification is formed by pressure crystallization. The i.r. spectra of pressure-crystallized samples, showed no significant changes against the starting sample, suggesting that the thermal deterioration of samples during the crystallization processes are negligible. The d.s.c. traces under normal pressure for samples F, G, and C were similar to that of sample D shown in Figure 1. The melting and transition temperatures, T_m and T_{tr} , determined from the peak positions in each d.s.c. curve are shown in Table 2.

Figure 5 shows, the electron micrograph of replica of a fracture surface of sample G crystallized at 3000 kg/cm² and at 200°C. In the micrograph, some sets of long lamellae of 400–600 Å in thickness, can be seen to extend in parallel or spheroidally. The lamellae are also noticed to be remarkably uniform in thickness, which suggests that sample G will yield a discrete small-angle X-ray scattering (SAXS) pattern. The SAXS pattern of sample G shows a discrete diffraction ring in the larger angle range, whereas a trace of a more intense diffraction ring is seen in the smaller angle range (around the centre). Provided that the discrete diffraction in the larger angle range is a first-order diffraction, the long period of 270 Å is obtained. This value, however,

is too small compared with the lamellar thickness observed above. On the other hand, if the large-angle diffraction is assumed to be the second order of the more intense diffraction found in the smaller angle range, it yields a value of 540 Å for the first period, in agreement with the lamellar thickness determined microscopically. The fact that the SAXS pattern of sample G exhibits a uniform ring, not a spotty one, suggests that the observed lamellae are constituent parts of spherulites. Similar lamellar structure is found on the surface replica of sample F crystallized at 170°C under 2000 kg/cm² (Figure 6) and that of sample D crystallized at 125°C under normal pressure (Figure 7). On the other hand, the lamellar structure of sample C crystallized at 65°C under normal pressure, is less distinct and the lamellae are shorter in lateral dimension and poorly oriented in comparison with samples crystallized with smaller supercoolings, as shown in Figure 8. Clearly the less developed lamellar structure of sample C is reflected in the relatively low crystallinity shown in Table 2. Sample C also gave a discrete SAXS pattern, and for each sample, the lamellar thickness observed by electron microscope and the long period determined from the SAXS pattern, were found to be consistent with each other, as shown in Table 2.

The above data and observations show some characteristics of melt-crystallized PTBD. The density data indicates that PTBD readily yields considerably high density or crystallinity by the melt-crystallization. The very high density

Figure 8 Electron micrograph of a fracture surface of PTBD crystallized at 65°C under normal pressure (sample C). Scale bar represents 1 μm

or crystallinity is also consistent with the fact that highly developed lamellar structure is observed as mentioned above. The PTBD samples crystallized at relatively small supercoolings, were found to be formed of distinct lamellae 400–800 Å thick. Such a distinct lamellar structure with the same order in thickness, was observed for the melt-crystallized polyethylene with low molecular weight, whose lamellae were found to be composed of extended chains¹⁶. The PTBD lamellae observed above, on the contrary, can be regarded as being composed of folded chains,

since the fully extended chain length of the PTBD with $M_v = 2.8 \times 10^4$, is about 2600 Å. The significant effect of pressure on crystallization of PTBD can be evidently found in the crystallinity data in Table 2; samples G and F crystallized at elevated pressure exhibit increased crystallinity, compared to sample D crystallized at normal pressure, although the lamellar thicknesses of the former two are rather smaller than that of the latter. The increase of crystallinity with increasing pressure, will be ascribable to the increase in lateral dimension of lamellae, as suggested by the morphology of sample C with low crystallinity in Figure 8. This may be explained by the mechanism that the increased pressure might make the packing of molecular chains in liquid more dense and thus the secondary crystallization might be accelerated to increase the lateral dimension of lamellae.

ACKNOWLEDGEMENT

We wish to thank Professor M. Takayanagi in Department of Applied Chemistry of Kyushu University for supplying the polymer and making the high pressure apparatus available.

Notes to the Editor

Microstructure of poly(2-vinylpyridine): correlation between ^{13}C and ^1H n.m.r. determinations

M. Brigodiot, H. Cheradame, M. Fontanille* and J. P. Vairon†
Ecole Francaise de Papeterie, 44 Avenue Felix Viallet, 3800 Grenoble, France
(Received 10 October 1975)

First attempts of structure determination on poly(2-vinylpyridine) (P2VP) by 60 MHz p.m.r. led only to essentially qualitative conclusions: a broad peak with a low field shoulder was observed for α and β chain protons and the intensity of the shoulder increased with increasing isotactic content of the polymer^{1,2}.

Further examinations at 100 MHz of isotactic P2VP samples^{3,4} have shown that the low field peak corresponds to the isotactic H_C methine resonance. When the spectra were run at 140° – 160°C in *o*-dichlorobenzene, fine structures were observed leading to two multiplets centred at ~ 8.0 and 7.4τ , and assigned respectively to H_C and H_A, H_B . A theoretical spectrum was calculated using a single coupling constant between the α and β protons ($J_{AC} = J_{BC} = J_{AC'} = J_{BC'} = 7 \text{ Hz}$) and was in fair agreement with the two observed multiplets. Isotactic $\alpha, \text{trans-}\beta\text{-}d_2\text{-poly(2-vinylpyridine)}$ was also prepared and the H_C quintet disappeared from the spectrum, supporting thus the above assignment⁴.

$^{13}\text{C}\text{-}\{^1\text{H}\}$ resonance spectra of atactic and isotactic P2VP were recently published^{5,6}. One of these studies⁵ was devoted to relaxation times and side group motions and does not report on tacticity measurements. The other study⁶ showed that the quaternary carbon C_2 of the pyridyl ring was the most stereosensitive. The C_2 resonance line split into three peaks, which, according to the expected structures of polymers studied, were assigned to iso-, hetero- and syndio-tactic triads in the order of increasing field. We recently used the ^{13}C n.m.r. for tacticity determinations of different P2VP samples and some discrepancies appeared between preceding assignments and our results. It was thus interesting to correlate the ^1H and ^{13}C analyses in order to test the validity of the method. We report here on a careful re-examination of the 25.15 MHz $^{13}\text{C}\text{-}\{^1\text{H}\}$ and 250 MHz ^1H spectra of poly(2-vinylpyridine) samples of different tacticities.

EXPERIMENTAL

Polymer samples

Isotactic P2VP (A) was prepared by anionic polymeriza-

* Laboratoire de Recherches sur les Macromolécules de l'Université Paris-Nord, Place du 8 Mai 1945, 93206 Saint-Denis Cedex, France.

† Laboratoire de Chimie Macromoléculaire associé au CNRS, Université Pierre et Marie Curie-4, Place Jessieu, 75230 Paris Cedex 05, France.

tion in benzene solution with $\text{C}_6\text{H}_5 \text{Mg Br}$ as initiator. Atactic P2VP samples (B) and (C) were prepared anionically at -78°C in THF solution, using respectively Na^+ and K^+ as counter-ions. Atactic P2VP samples (D) and (E) were prepared by radical polymerization at 60°C using AIBN as initiator, either in bulk (D) or in 30% (v/v) methanol solution (E).

N.m.r. analysis

P.m.r. spectra were run at 250 MHz in CDCl_3 or CD_3OD solutions (10% w/v) at room temperature using a Cameca 250 MHz spectrometer. The $^{13}\text{C}\text{-}\{^1\text{H}\}$ spectra were observed at 25.15 MHz at room temperature in CD_3OD solution (observation of aromatic carbons) and CDCl_3 solution (observation of chain carbons) with noise proton decoupling and internal lock on deuterium using either Jeol PFT 100 or Varian XL 100-12 WG FT spectrometers. Tacticity measurements were done by integration for ^1H spectra and by cutting and weighing the paper for ^{13}C spectra. Overlapping peaks were hand resolved.

RESULTS AND DISCUSSION

As the proton spectrum of isotactic P2VP was run at room temperature we obtained only the envelopes of the two expected multiplets with a beginning of fine structure appearance (Figure 1). No fine structure at all was observed for the atactic samples as the resonance of (mr + rr) methine protons H_C overlap with (r + m) methylenic protons H_A and H_B . But, for all samples, the isotactic (mm) α -proton H_C triad is fairly well separated from the broad pattern due to CH_2 (m + r) dyads and CH (mr + rr) triads, allowing an easy measurement of peak areas and the determination of the isotactic triad content of the different polymers ($[\text{mm}] = 3a_I/(a_I + a_{II})$, see Figure 1).

Chain and pyridyl ring carbons are differently stereosensitive, depending on the solvent used. The best sensitivity was observed for the ring carbon C_2 in methanol solution and for the chain carbons in CDCl_3 solution, as was previously reported by Lukovkin *et al.*⁶

The C_2 triad pattern is sufficiently resolved to measure accurately the areas of the three main peaks. As shown in Figure 2 a comparison between isotactic and atactic P2VP spectra leads to an unequivocal triad assignment. Thus the triad content of each sample can be directly determined from the C_2 pattern. Each of these triad resonances exhibit pentad effects and a tentative assignment of pentad placements may be provided at least for iso and heterotactic sequences (Figure 2). In the isotactic polymer (A), the most probable mmmm pentad appears at the lowest field position of the mm resonance pattern and, in the atactic samples, the relative importance of the lowest field shoulder of the mr peak increases with increasing isotactic content of the

Figure 1 Chain protons 250 MHz spectra of (a) isotactic (sample A); (b) atactic (sample B) and (c) atactic (sample E) poly(2-vinylpyridines) (CD_3OD solution at 25°C)

polymer, leading to a mmmr assignment for this shoulder. The proposed order is more doubtful for syndiotactic pentads.

In the isotactic P2VP sample, CH and CH_2 chain carbons appear as two single and well separated resonance lines, whereas in atactic samples the corresponding peaks split into two multiplets (Figure 3). The CH patterns exhibit the expected triad effect, but the syndiotactic triad resonance overlaps the heterotactic one and cannot be accurately resolved. The complex multiplet corresponding to the methylenic chain carbon is so poorly resolved that we cannot provide, the mmm tetrad position apart, any reasonable assignment. It can be seen in Table 1 that the tacticity determinations by ^1H and ^{13}C n.m.r. are in good agreement, supporting thus the above assignments.

Figure 2 $^{13}\text{C}-\{^1\text{H}\}$ spectra of C_2 pyridyl ring carbon observed at 25.15 MHz in $\text{CD}_3\text{OD}/\text{CH}_3\text{OD}$ solution at 25°C (TMS and methanol as internal standards). (a), sample D; (b), sample E; (c) samples B (—) and C (---); (d), sample A

For radical polymerizations (in bulk or even in solution) propagation mechanisms appear to be controlled by a Bernoulli trial process ($4is/h^2 \sim 1$) whereas for anionic polymerization they deviate noticeably from Bernoullian statistics. Unfortunately the lack of resolution does not allow the determination of tetrads and pentads contents and Markov or Coleman-Fox statistics cannot be tested for the predominantly isotactic polymers.

The observed ^{13}C chemical shifts (see Figures 2 and 3) agree closely with those reported by Chachaty *et al.*⁵ but they are somewhat different (~ 1 ppm) from those given by Lukovkin *et al.*⁶. The major discrepancy with the results of these last authors concerns the assignment of the C_2

triad pattern. Their analysis of a polymer prepared in the same conditions as those used for our sample D (see Table 1) led to a predominantly syndiotactic Bernoullian distribution ($P_m = 0.22$) with a very low isotactic triad content (2%), in complete disagreement with our own analysis of the same type of polymer (sample D, $P_m = 0.53$). As in the spectrum published by Lukovkin the isotactic peak appears as a very weak shoulder, the assigned *h* peak might most probably be the true isotactic one. Thus the assigned *s* peak might be the overlapping of the hetero- and syndiotactic ones. We observed the same chemical shifts difference (~ 12 Hz) between the peaks we assigned *i* and *h* as between the peaks Lukovkin assigned *h* and *s*, whereas we observed a 6 Hz difference between the peaks we assigned *h* and *s*. This observation supports the above explanation.

In conclusion a good correlation is observed between the ^1H and ^{13}C n.m.r. determinations of poly(2-vinylpyridine) microstructure. The 25.15 MHz ^{13}C spectra allow the estimation of triad contents and the propagation of the 2VP radical polymerization appears to be controlled by a Bernoullian process. Higher field ^{13}C n.m.r. observation will probably lead to quantitative pentad and tetrad determinations and this will give information on the non-Bernoullian propagation of 2VP anionic polymerization. This is not only depending upon the active centres dissociation equilibrium but also upon an assumed specific penultimate solvation of the sodium counterion⁹ which might strongly influence the propagation statistics. We have presently undertaken a higher field re-examination of different anionic samples of P2VP.

(Received 9 September 1975)

Studies on the crystalline morphology of α -poly(L-alanine), (PA), clearly showed the existence of sheaves consisting of platelets about 150 Å thick, stacked on edge¹, so that it can be inferred that re-entrant folding must occur, owing to the length of a single macromolecule much greater than 150 Å. The same behaviour is displayed by other biopolymers²⁻⁴ and by a wide variety of synthetic polymers⁵⁻⁷. On the other hand, it is widely believed that a polypeptide chain folds in a physiological environment or, in general, in a solvent according to the laws of thermodynamics. In this connection high ΔH^0 values, achieved from potentiometric measurements, seemed to point to the presence of compact hydrophobic states, in the case of the sequential copolymers poly(L-leucyl-L-leucyl-L-aspartic acid)⁸ and poly(L-leucyl-L-leucyl-L-lysine)⁹. The experimental results agree with the formation of α -helical segments, strongly stabilized by hydrophobic interactions and suggest the existence of a rather ordered structure, which may be characterized by chains folding back and forth on themselves.

In order to gain information about possible models of folding, we undertook van der Waals energy calculations on PA, which has the advantage of possessing the hydrophobic methyl group, and no degrees of freedom in the side chain, if CH₃ is considered as one atom. Intramolecular¹⁰⁻¹⁴ as well as intermolecular^{15,16} potential energy calculations were previously performed for regular helical conformations of PA.

The crystal structure of the α -helical PA has been investigated by many researchers¹⁵⁻²⁰ and it has been found to be formed by 50% of 'up-pointing' and 50% of 'down-pointing' right-handed helices arranged in a hexagonal cell with $a = 8.55$ Å, $c = 70.3$ Å. The unit cell contains 47 alanine residues in 13 turns, and the C atoms of the methyl groups, belonging to the 'up' and 'down' chains, are displaced -0.52 Å and rotated 15.1 degrees²⁰. The unit height and twist are $h = 1.495$ Å and $t = 99.57$ degrees respectively,

and the helix is defined by the torsion angles $\phi = -57.4^\circ$, $\psi = -47.5^\circ$ and $\omega = -179.8^\circ$ in agreement with the convention of Klyne and Prelog²¹, which will be used later on.

First, we performed van der Waals energy calculations on the right-handed α -helix of PA built up with the coordinates of Parry and Suzuki²², given in Table 1 together with those of Arnott and Dover²⁰ in parentheses for comparison. The α -helix parameters are: $h = 1.5$ Å; $t = 100^\circ$; $\phi = -51.45^\circ$; $\psi = -52.74^\circ$; $\omega = 180^\circ$. The coefficients of the potentials employed in the generalized form:

$$V(r) = a \exp(-br)/r^d - cr^{-6}$$

were previously reported²³. The system taken into account is illustrated in Figure 1, where both A and C represent 18, 36 or 54 monomers in α -helical conformation and B is the part involved in the minimization procedure (see below), carried out as a function of five rotation angles $\psi_1 - \psi_5$. The van der Waals energy was computed by considering

Figure 1 Scheme of the system considered in the calculations. C_β represents the methyl group

Interaction between sequential polypeptides and sodium deoxycholate

E. Corsi, M. D'Alagni* and E. Giglio

Istituto di Chimica-fisica, Università di Roma, 00185 Roma, Italy
 (Received 9 September 1975; revised 23 October 1975)

The sequential copolymers poly(L-leucyl-L-leucyl-L-aspartic acid) (PLLAA) and poly(L-leucyl-L-leucyl-L-lysine) (PLLL) were previously studied in aqueous solution^{1,2} as well as in mixtures of water with an organic solvent³ by spectroscopic and potentiometric measurements. A conformational transition from a charged to an uncharged state was detected for both copolymers. The ΔH_{98}° and ΔS° values are 6173 cal/mol and 26.0 cal/deg mol for PLLAA and 2784 cal/mol and 11.7 cal/deg mol for PLLL. These high values seem to indicate the presence of compact macromolecules, characterized by α -helical segments and stabilized by hydrophobic forces evidenced, also, in both random⁴⁻⁶ and block⁷ copolymers.

The deoxycholic acid molecule shows a hydrophobic side with three protruding methyl groups, which give rise to a strong binding with apolar and highly polarizable moieties, and a polar side with two hydroxyl and one carboxyl groups, which are able to form a complicated network of hydrogen bonds in crystals of choleic acids⁸.

It is well known that the sodium deoxycholate (DCANa) is customarily used in order to solubilize biological membranes, interacting with both phospholipids⁹ and proteins^{10,11}.

We have investigated by circular dichroism (c.d.) spectra the PLLAA-DCANa and PLLL-DCANa aqueous solutions for the following reasons:

(a) Strong interactions can occur between the two copolymers and DCANa, owing to the presence in each compound of polar and apolar groups. The sequential polypeptides could be considered as simplified models of proteins, allowing us to gain some information on the solubilization mechanism exerted by the bile salt.

(b) The interactions between DCANa and PLLAA or PLLL may be competitive with the intramolecular ones in each copolypeptide. Thus conformational changes could be detected in the macromolecules.

First, we have recorded c.d. spectra of PLLAA and DCANa over a wide range of molar ratios without a significant variation in the molar ellipticity values. From the c.d. spectrum of an aqueous solution of PLLAA, $c = 1.4172 \times 10^{-4}$ mol/l and pH = 6.19, the presence of two negative maxima centred at about 220 nm and at 206 nm, and a cross-over at 198 nm are inferred. The molar ellipticity values, expressed as degree cm²/dmol, are $[\theta]_{220} = -9200$ and $[\theta]_{206} = -16400$. The c.d. spectrum of an aqueous solution of PLLAA-DCANa, 1:1 molar ratio, $c = 0.7086 \times 10^{-4}$ mol/l and pH = 6.62, shows the same characteristic cross-over and band positions with $[\theta]_{220} = -9100$ and $[\theta]_{206} = -16100$. At this pH in an aqueous solution of PLLAA the macromolecules are charged for about 20%¹. Since the two spectra nearly coincide, it is reasonable to conclude that the DCANa does not influence the PLLAA conformation. The solutions appear to be much more stable during the time than those of PLLAA.

Different behaviour at pH = 10.25 is displayed by PLLL-DCANa, as compared with PLLL, which at the same pH has about 15% of ionized groups². $[\theta]$ in the 198-230 nm region abruptly increases by adding DCANa and, at the same time, the negative dichroic characteristic bands of the α -helix are red shifted as well as the cross-over and the positive maximum, which, however, lie in a region where DCANa contributes (see *Figure 1*). Therefore, the remarkable decreasing of the α -helix content indicates a strong binding between PLLL and DCANa. Furthermore, the PLLL-DCANa solutions, after few hours, give rise to a precipitate, containing all the PLLL, since the supernatant solution does not show any appreciable dichroism above 200 nm. The above-mentioned conformational change, caused by DCANa, is reversible. The very similar, full and broken curves of *Figure 2* refer to solutions of PLLL and PLLL-DCANa, after removal of the bile salt, at similar pHs. The qualitative behaviour of PLLL is satisfied and the third curve of *Figure 2* shows that $[\theta]$ below 232 nm increases at pH ~ 9 , as already observed for PLLL².

Interaction between sequential polypeptides and sodium deoxycholate

E. Corsi, M. D'Alagni* and E. Giglio

Istituto di Chimica-fisica, Università di Roma, 00185 Roma, Italy
 (Received 9 September 1975; revised 23 October 1975)

The sequential copolymers poly(L-leucyl-L-leucyl-L-aspartic acid) (PLLAA) and poly(L-leucyl-L-leucyl-L-lysine) (PLLL) were previously studied in aqueous solution^{1,2} as well as in mixtures of water with an organic solvent³ by spectroscopic and potentiometric measurements. A conformational transition from a charged to an uncharged state was detected for both copolymers. The ΔH_{98}° and ΔS° values are 6173 cal/mol and 26.0 cal/deg mol for PLLAA and 2784 cal/mol and 11.7 cal/deg mol for PLLL. These high values seem to indicate the presence of compact macromolecules, characterized by α -helical segments and stabilized by hydrophobic forces evidenced, also, in both random⁴⁻⁶ and block⁷ copolymers.

The deoxycholic acid molecule shows a hydrophobic side with three protruding methyl groups, which give rise to a strong binding with apolar and highly polarizable moieties, and a polar side with two hydroxyl and one carboxyl groups, which are able to form a complicated network of hydrogen bonds in crystals of choleic acids⁸.

It is well known that the sodium deoxycholate (DCANa) is customarily used in order to solubilize biological membranes, interacting with both phospholipids⁹ and proteins^{10,11}.

We have investigated by circular dichroism (c.d.) spectra the PLLAA-DCANa and PLLL-DCANa aqueous solutions for the following reasons:

(a) Strong interactions can occur between the two copolymers and DCANa, owing to the presence in each compound of polar and apolar groups. The sequential polypeptides could be considered as simplified models of proteins, allowing us to gain some information on the solubilization mechanism exerted by the bile salt.

(b) The interactions between DCANa and PLLAA or PLLL may be competitive with the intramolecular ones in each copolypeptide. Thus conformational changes could be detected in the macromolecules.

First, we have recorded c.d. spectra of PLLAA and DCANa over a wide range of molar ratios without a significant variation in the molar ellipticity values. From the c.d. spectrum of an aqueous solution of PLLAA, $c = 1.4172 \times 10^{-4}$ mol/l and pH = 6.19, the presence of two negative maxima centred at about 220 nm and at 206 nm, and a cross-over at 198 nm are inferred. The molar ellipticity values, expressed as degree cm²/dmol, are $[\theta]_{220} = -9200$ and $[\theta]_{206} = -16400$. The c.d. spectrum of an aqueous solution of PLLAA-DCANa, 1:1 molar ratio, $c = 0.7086 \times 10^{-4}$ mol/l and pH = 6.62, shows the same characteristic cross-over and band positions with $[\theta]_{220} = -9100$ and $[\theta]_{206} = -16100$. At this pH in an aqueous solution of PLLAA the macromolecules are charged for about 20%¹. Since the two spectra nearly coincide, it is reasonable to conclude that the DCANa does not influence the PLLAA conformation. The solutions appear to be much more stable during the time than those of PLLAA.

Different behaviour at pH = 10.25 is displayed by PLLL-DCANa, as compared with PLLL, which at the same pH has about 15% of ionized groups². $[\theta]$ in the 198-230 nm region abruptly increases by adding DCANa and, at the same time, the negative dichroic characteristic bands of the α -helix are red shifted as well as the cross-over and the positive maximum, which, however, lie in a region where DCANa contributes (see *Figure 1*). Therefore, the remarkable decreasing of the α -helix content indicates a strong binding between PLLL and DCANa. Furthermore, the PLLL-DCANa solutions, after few hours, give rise to a precipitate, containing all the PLLL, since the supernatant solution does not show any appreciable dichroism above 200 nm. The above-mentioned conformational change, caused by DCANa, is reversible. The very similar, full and broken curves of *Figure 2* refer to solutions of PLLL and PLLL-DCANa, after removal of the bile salt, at similar pHs. The qualitative behaviour of PLLL is satisfied and the third curve of *Figure 2* shows that $[\theta]$ below 232 nm increases at pH ~ 9 , as already observed for PLLL².

* Centro di Studio per la Chimica dei Recettori del CNR, c/o Università Cattolica, via Pineta Sacchetti 644, 00168 Roma, Italy, and to whom enquiries should be addressed.

Figure 1 C.d. spectra of aqueous solutions of: —, PLL, $c = 1.8420 \times 10^{-4}$ mol/l, pH = 10.30; ----, PLL-DCANa (1:1 molar ratio), $c = 1.9640 \times 10^{-4}$ mol/l, pH = 10.25. The c.d. spectrum of DCANa, $c = 4.212 \times 10^{-4}$ mol/l, pH = 10.21, is shown in the right upper part of the Figure

The PLLAA-DCANa and PLL-DCANa systems have been studied within the range of about one pH unit around 6.8 and 9.8 respectively. In this range the percentage of ionized groups varies from about 14 to 62% for PLLAA¹ and 15 to 55% for PLL² at 25°C. Contemporaneously, the $[\theta]$ changes for the two systems are of the same order of magnitude as for PLLAA and PLL without DCANa at the same pHs.

The experimental data may be explained by supposing that the DCANa molecules interact in different ways with PLLAA and PLL. The bile salt molecules are mainly bonded to the leucyl residues of the acid copolymer with their hydrophobic side, while the charged carboxyl groups may repel each other. Thus the greater solubility of PLLAA-DCANa may be ascribed to the outer polar groups in contact with the aqueous environment. On the other hand the

Figure 2 C.d. spectra of aqueous solutions of: —, PLL, $c = 1.9640 \times 10^{-4}$ mol/l, pH = 4.59; ----, PLL, $c = 1.9640 \times 10^{-4}$ mol/l, pH = 4.44, after interaction with DCANa and subsequent dialysis; - · - · - ·, as for the broken curve but pH = 9.00

NH_2 and NH_3^+ of PLL may form hydrogen bonds and electrostatic interactions with the hydrophilic side groups of the DCANa molecules, which protrude their apolar face towards the polar surrounding medium, causing precipitation.

Radiation curing of unsaturated polyester resin

K. Sędziński

Akademia Techniczno-Rolnicza, ul. Olszewskiego 20, 85-225 Bydgoszcz, Poland

(Received 29 September 1975; revised 11 November 1975)

Some tests on the influence of irradiation parameters on the properties of unsaturated polyester resins have been undertaken. A commercial resin (Polimal 109) which is a 35% styrene solution of unsaturated polyester, was used. Two radiation devices, the BK-6 equipment and the equipment for rating radiometers, were used to cure the resins. Radiation device BK-6 is equipped with 6 radiation sources of ^{60}Co gamma rays which are placed around the irradiated substance. The radiation device for rating radiometers is equipped with one source of ^{60}Co and a collimator which gives a parallel beam of gamma rays.

These tests¹ lead to the following conclusions:

(1) For radiation hardening of the Polimal 109 resin the delivery of 0.5×10^4 J/kg (0.5 Mrad of gamma rays energy) is necessary. This minimum dose does not, however, guarantee the hardening of the surface which is in contact with the air.

(2) The determined properties (hardness, compressive strength, bending strength, softening point determined by Vicat's method) of the Polimal 109 resin, hardened by radiation curing, do not depend fundamentally either on

the value of the absorbed dose of the gamma rays within the range 0.5×10^4 to 8.0×10^4 J/kg (from 0.5 to 8.0 Mrad) or on the value of the gamma rays dose rate within the range 0.0347 to 0.2778 W/kg (12.5 to 100 krad/h). This conclusion was arrived at by statistical analysis.

(3) The resin hardened in the radiation device BK-6 proved to have a 25% higher softening point, 8% higher compressive strength and 9.5% lower bending strength in comparison with resin hardened with parallel beam of gamma rays.

The difference in the properties of the same resin hardened in two radiation devices at the same dose rate of gamma rays can be explained by the different geometry of the absorption of the energy of the gamma rays, which is the result of the different 'source of radiation — irradiated substance' geometry systems.

Book Reviews

Structure and properties of oriented polymers

Edited by I. M. Ward

Applied Science, Barking, 1975, 500 pp. £18

Partly as a result of commercial importance, there has been considerable activity and progress in studies of the structure and properties of oriented polymers. Clearly no one volume could account for all aspects of such systems, and the present volume is largely concerned with the fundamental aspects of orientation, its measurement and its interpretation in macroscopic and molecular terms. Professor Ward has obtained an excellent blend of contributions from leading scientists in industry, government research and university.

The book contains thirteen chapters, the first being a clear and concise introduction by Holliday and Ward to the occurrence and nature of orientation and the techniques which may be used in its elucidation. This is followed by an account by Peterlin of molecular aspects of crystallites and oriented material which, although brief, is rich in basic information. Having set the basis, there are three aspects of oriented polymers which are considered at length with great clarity which occupy the remainder of the book being: (i) molecular aspects as studied by spectroscopic and related methods (Ch 3 to 6, approximately one third of the book); (ii) macroscopic aspects of mechanical and viscoelastic behaviour (Ch 7 to 11, approximately one third of the book) and (iii) illustrative and up-to-date aspects of the production of oriented films and fibres and of ultra-high modulus organic fibres (Ch 12 and 13, approximately one sixth of the book). Whilst it is not possible to review here the details of any of these accounts, it is appropriate to indicate some of their aims. The chapter by Stein and Wilkes (92 pages) is mainly concerned with optical birefringence, X-ray and light scattering methods, beautifully illustrated with many examples (e.g. spheru-

lite deformation) and contains a valuable account of the theory of X-ray and light scattering processes. The chapters by Read (u.v. visible and infra-red dichroism) by Bower (fluorescence and Raman spectroscopy) and by Folkes and Ward (nuclear magnetic resonance) describe the current situation with regard to the understanding of orientation in molecular terms, are written with authority and clarity and set the stage for further work on this exciting topic. Holliday (Ch 7) deals with calculated values for chain stiffness and their relation to the experimental moduli for a wide range of polymers. Hadley and Ward (Ch 8) and Hadley (Ch 9) are concerned with low-strain mechanical properties of oriented polymers while Darlington and Saunders (Ch 10) discuss anisotropic creep behaviour and Duckett (Ch 11) anisotropic yield behaviour. All five chapters place considerable emphasis on experimental results and their interpretation in terms of the structure and texture of the various polymers. The Chapter by Schuur and Van der Vegt on the practical aspects of the orientation of films and fibrillation is a delight, its clarity and choice of contemporary material make it one highlight of many in this excellent book. Finally, Chapter 13 by Carter and Schenk describe the preparation of certain ultra-high modulus fibres (e.g. poly(*p*-benzamide)) which are also thermally stable materials. We note here that solutions of such polymers form liquid crystal phases and this aspect may open up new approaches to fibre formation. The editor and the authors are to be congratulated for arriving at a systematic and readable account of a class of material involving so many variables. Its readership spans fibre and film scientists, post-graduate polymer scientists and engineers, and post-graduate scientists involved with other oriented materials. One anticipates that this book will become the standard text on the fundamentals of oriented polymers and will stimulate further research work.

G. Williams

Comprehensive Chemical Kinetics
(Volume 14, Degradation of Polymers)
Edited by C. H. Bamford and C. F. H. Tipper
Elsevier, Amsterdam, 1975, 562 pp. \$83.50

The degradation of polymers is currently attracting a great deal of attention both for the continuing reason that new materials are constantly being developed and applied in even more hostile environments and also for a variety of rather novel reasons like the development of degradable polymers for the control of environmental pollution and the control of flammability in plastics for use as structural materials. It is therefore not unreasonable that in this series on chemical kinetics, of the two volumes in section 5 entitled 'Polymerisation Reactions', one volume should be devoted entirely to polymer degradation.

This book comprises four large chapters which are devoted to the fundamental rather than the technological aspects of four major aspects of polymer degradation and written by three authors who are highly regarded internationally for their current activities in the field. The first two chapters, on thermal and high energy degradation respectively, are written by Dr C. David of the Free University of Brussels, the third, on photodegradation by Professor G. Geuskens, also of the Free University of Brussels and the last, on oxidative degradation by Dr J. F. Rabek of the Royal Institute of Technology in Stockholm.

About 20% of the first chapter is devoted to a general discussion of experimental methods and the kinetics of thermal depolymerization and the remainder to the specific reactions of a wide variety of polymers. The second chapter begins with a description of some general aspects of polymer radiolysis, interaction of high energy radiation with matter and the theory of cross-linking and degradation. Thereafter individual polymers are discussed specifically from the point of view of trapped free radicals, chemical effects and mechanical properties. The structure of chapter 3 is similarly based on the discussion of the reactions of individual polymers together with sections on general principles of photochemistry, experimental methods, stabilization, and photophysics of polymers. In his conception of chapter 4, Dr Rabek took rather a different view. Thus after emphasizing the importance of hydroperoxides in the oxidation process he continues: 'This chapter is mainly concerned with the chemical and physical factors that are responsible for the formation of hydroperoxides during the induction period and that influence the mechanism of polymer oxidation. A detailed discussion of the oxidation of various polymers is not included since two excellent books dealing with this subject are published'.

These three authors have succeeded admirably in combining together to produce an authoritative, critical and very readable account of the major growth areas of polymer degradation. It is unfortunate that its price will preclude purchase by most individuals so that it will be largely confined to libraries rather than the desks of practicing scientists where it belongs.

N. Grassie

Advances in polymer science
Edited by Z. A. Rogovin
Wiley, New York, 1975, £14.70

This book is a translation of a collection of essays by Russian scientists on various aspects of polymer science.

The text tends to be written in a very wordy style which makes reading difficult. Some chapters appear to be out of date by as much as four years. For example, Dr Andrianova's chapter on Large Deformation in Crystalline Polymers makes no mention of the recent developments in the production of ultra high modulus PE via solid state cold drawing techniques as described by Professor Ward of Leeds University. Also there is no mention of the work of Wunderlich (USA) and Bassett (UK) on high pressure annealing of polyethylene. A second feature is that the range of subjects is extremely broad and includes the physical, chemical, biomedical and industrial aspects of polymer science. The advantages of such a book is that the previews include summaries of Russian work, which is not readily available, and enables an assessment to be made of Russian polymer science.

An interesting discussion by S. G. Entelis and others considers the problem of characterization of oligomers with functional groups according to their functionality. The review summarizes the basic

equations used and the role of the number average (f_n) and weight average (f_w) functionalities of Stockmayer which are derivable from these. Experimental methods of characterization are compared, including the measurements of f_w from gelation studies f_n from the cross-link density measurements, and the use of gel-permeation chromatography (g.p.c.). The latter, which is the most important method, is only described in a limited way by reference to the original Terry and Rodrigues paper in the Journal of Polymer Science published in 1968. Modern g.p.c. units with multichannel i.r. detectors are the most direct way of tackling this problem and merited more detailed discussion. Final sections in this chapter include a summary of some Russian work on relations between distribution of functionality and mechanical properties.

The article by E. F. Razvodovskii reviews the literature since 1962 on synthetic polymers in pharmacology. There is an interesting discussion of antisilicosis activity and structure of poly(*N*-oxides) including some Russian work in this field on the relationship between molecular weight of poly(2-vinyl pyridine *N*-oxide) and antisilicosis activity. Another group of biologically active polymers are the 'ionenes', – a class of polymers with a quarternary *N*-atoms in the main chain. These exhibit bactericidal properties, curane-like and antiheparin activity. One important aspect associated with putting drug molecules onto a polymer chain is that a reduction in toxicity occurs. This is not a new idea since it transpires that the arsenicals such as Salvarsan owe their low toxicity to the fact that they are substituted poly(arsenic oxides); a fact not appreciated at the time of their discovery.

The paper by Amerik and Krentsel on the Role of Anisotropic States in Polymerization Processes summarizes and compares work on polymerization in the crystalline and paracrystalline states and in liquid crystals and matrices of various kinds. In most cases polymerization prefers to occur at the interface of two phases or at temperatures close to a phase transition.

Finally two aspects of the use of spectroscopy to study polymers are discussed at some length. One of the more interesting of these is that of A. L. Buchachenko and others which is concerned with the use of stable radicals for studying molecular motions based on the line widths of electron paramagnetic resonance (e.p.r.) spectra due to rotary and translatory motions of the radicals. Using organic radicals differing in shape, dimensions and structure of their molecules but containing the same paramagnetic fragment $>N-O$ it has been shown that the diffusion depends on the glass transition temperature T_g , indicating a dependence on the segmental motion of the polymer molecules. The parameters which can be measured using this technique include: the temperature of unfreezing of the radicals (T_u); activation energies (E), and pre-experimental factors (V_0) of the rotational frequencies of radicals in polymers. Data for different radical types and their behaviour in amorphous, crystalline and cross-linked polymers are presented and discussed.

D. G. H. Ballard

Polymer Engineering
H. Leverne Williams
Elsevier, Amsterdam, 1975, 166 pp. £14.75

My first impression of this book, written for use by 'the young Chemical Engineer entering industry' was quite favourable. It is short, it is well bound, it is easy to read, there are plenty of bold line diagrams in the text, there are very few equations and the references are limited to major works. Above all during the early chapters the author is intent on pointing out that this effect is useful because rather than concentrating on problems.

Professor Williams carried me with him through the early chapters on the nature of high polymers and their morphology. This seemed just the sort of information which the young chemical engineer would find useful to aid his learning processes in an industrial environment. However when the author reached the sections on deformation and flow, the area in which the references claim that he has a special competence, he loses my sympathy entirely.

I suppose one can forgive an author for introducing his own notation rather than using one of the many types which have become standard. However, it is irritating to find that he changes notation from chapter to chapter (p 84, 127) and downright disturbing when the same nomenclature is used in sequential chapters (η in chapters 6 and 7) to mean different things (at least I hope that he means different things).

Then there are the contradictions like high molecular weight polymer increasing viscosity (when describing solution viscosities) and decreasing viscosity when considering drag reduction, and the gratuitous theoretical explanations of such effects which may sound alright when spoken quickly but do not bear being put into print in such a text especially when the concept of Reynolds turbulence (surely one of the most commonly used formulae in chemical engineering) receives not a word.

Finally, in a chapter on viscoelasticity there is the agony of statements like the reciprocal of Young's modulus is compliance (p 87) and the implication (p 91) that relaxation and retardation behaviour are the same thing by different names. Such things are not to be expected when the author cites Professor Ferry's treatise as his prime source, and it would be much better to say nothing at all rather than to suggest ideas which will subsequently be difficult to remove.

Thus in two chapters the author undid the confidence which his approach had shown in the early part of the book so that I cannot recommend it at all.

F. N. Cogswell

Polymer Chemistry — an Introduction

M. P. Stevens

Addison-Wesley, Reading, Mass., 1975, 458 pp.
\$17.50

In contrast to the situation of even five years ago, the lecturer giving a course in polymer science can now choose from several excellent course texts. The present book is intended as a text book for an introductory course in polymer chemistry at the undergraduate or postgraduate level, but differs in being written from the viewpoint of organic rather than physical chemistry.

The fifteen chapters of this book form three main sections. The first occupies 100 pages and is a brief discussion of the physical chemistry of polymerization reactions and of the physical properties of polymers. This is the weakest section and any realistic course would require supplementary reading. Its balance can also be criticized; for example, flame-retarding additives receive almost twice as much space as the discussion of glass-transition temperatures. The second section, occupying 109 pages, gives a concise and well written account of the addition polymerization of vinyl and diene monomers and of the chemical reactions of vinyl polymers. Most of the material in this section is covered in other standard texts. It is in the third section that the book really comes into its own. This section, covering 216 pages, is a discussion of non-vinyl polymers, beginning with polyethers, ending with natural polymers and covering every conceivable polymer type in between. It is well written, concise and readable and successfully avoids being a 'preparation and properties' catalogue. It is an excellent treatment of an area of polymer science which is much less well covered elsewhere.

Because of the strong bias towards organic chemistry I would find it difficult to consider this book as a primary course text but would give it strong recommendation as supplementary reading. The high price of even the paperback edition, implies that few students will buy it although it should be in any library associated with polymer science teaching. It would probably have been a more useful book if the first section had been omitted and the price reduced to correspond.

N. C. Billingham

Creep, viscoelasticity and creep fracture in solids

J. Gittus

Applied Science, Barking, 1975, 725 pp. £25

I think that this is a very good book indeed and illustrates the unity of the science of the behaviour of solid materials. Its subject matter, is to review comprehensively diffusion creep in crystals and polycrystals and to relate this to flow in glasses. This is followed by consideration of creep due to dislocation glide in metals and in non metals, with, for the latter, some histories of various important systems, e.g. various transition metal oxides and uranium carbide.

A relationship is then noted with creep within the earth's mantle. Irradiation induced deformation due to volume or length changes and the resultant creep under stress is next considered.

At this stage the author pauses and notes with truth 'today it is possible to become deeply involved with theories of dislocation creep in metals without having more than a hazy notion of the part played by elastic strains of various types. Of course the converse is also true and experts on the viscoelastic behaviour of polymers are only now beginning to be aware of the role which dislocation theory may play in helping to rationalize the behaviour of the materials with which they are concerned'. Dr. Gittus goes on to instruct these two types of scientist of materials and he is well equipped to do so having made contributions to irradiation creep. Nimonic alloys and to the flow of foundry sand, himself.

Succeeding chapters deal with viscoelastic models, which are very well explained, viscoelasticity in metals and in non metals; here the kinetic theory of rubber elasticity is dealt with and viscoelasticity in amorphous polymers with important ones, such as PVC, polystyrene, PMMA being dealt with in detail. Then metals and alloys of high creep strength are dealt with and the behaviour of Nimonic and specific refractory metals, e.g. W, Mo, Nb, dealt with individually.

Theory and experiment of superplastic effects which occur principally in metals and offer a low temperature forming process analogous to drawing of polymers consumes Chapter 11 and creep fracture Chapter 12 which includes among other things wedge cracks in crystalline materials and crazing in glassy polymers. Before a final discussion of a mechanical equation of state, a chapter is devoted to the effects of environment which includes oxidizing metals, segregation to grain boundaries, stress corrosion (environmental stress cracking) and effects of humidity on the creep of concrete.

As Sir Monty Finnieston says in his introduction, Gittus' courage must be admired in taking on so vast a task. I think both that and his success. Many may cavil at the treatment of their speciality but I think the sweep is right and the judgement good. A fine comprehensive and up-to-date work which should be on the shelves of all scientists of materials who can afford it.

A. Kelly

Organic polymeric semiconductors

Ya. M. Paushkin, T. P. Vishnyakovo, A. F. Lunin
and S. A. Nizova

Wiley, New York, 1975, 242 pp. £10.10

Experiments on small molecules had made it clear by 1955 that an increase in the number of conjugated double bonds induces increased semiconduction in crystalline organic substances, and shortly afterwards the enhancing effect of charge-transfer complexation was also established. Around 1959 the subject was taken up by Russian polymer scientists, who embarked on a large programme of synthesis of conjugated linear polymers, with the object of increasing the conductivity still further. By and large, this work may be criticized in that the products were amorphous and not well characterized, and the electrical conduction measurements were rather scrappy. This translation provides a valuable service in gathering together all the references, and reviewing all the results, previously only available in the Russian language. However, the whole book smacks of scissors and paste-pot, and as a scientific contribution it leaves much to be desired. Indeed, the reviewer makes so bold as to assert, that it falls far below the high standards established in this field by that great pioneer of organic semi-conductors, the Soviet scientist, Academician Terenin. Accordingly, it emphatically cannot be recommended to postgraduate students or anyone else who seek a scientifically intelligible and coherent account of conduction in polymers. But it will provide a valuable *vade mecum* for laboratories active in the field to this early Russian synthetic work, much of which will no doubt bear further consideration or even repetition, in the light of the rapid advances now occurring in the science of organic single crystals as metallic conductors. So it would perhaps be churlish not to thank the translators for their efforts, while chiding the authors for the absence of any coherent account of the physics of their problem, their lack of any grasp of the international literature, and the slips and other blemishes which the expert eye can detect in this book.

D. D. Eley

Comprehensive Chemical Kinetics
(Volume 14, Degradation of Polymers)
Edited by C. H. Bamford and C. F. H. Tipper
Elsevier, Amsterdam, 1975, 562 pp. \$83.50

By and large, this work may be criticized in that the products were amorphous and not well characterized, and the electrical conduction measurements were rather scrappy. This translation provides a valuable service in gathering together all the references, and reviewing all the results, previously only available in the Russian language. However, the whole book smacks of scissors and paste-pot, and as a scientific contribution it leaves much to be desired. Indeed, the reviewer makes so bold as to assert, that it falls far below the high standards established in this field by that great pioneer of organic semi-conductors, the Soviet scientist, Academician Terenin. Accordingly, it emphatically cannot be recommended to postgraduate students or anyone else who seek a scientifically intelligible and coherent account of conduction in polymers. But it will provide a valuable *vade mecum* for laboratories active in the field to this early Russian synthetic work, much of which will no doubt bear further consideration or even repetition, in the light of the rapid advances now occurring in the science of organic single crystals as metallic conductors. So it would perhaps be churlish not to thank the translators for their efforts, while chiding the authors for the absence of any coherent account of the physics of their problem, their lack of any grasp of the international literature, and the slips and other blemishes which the expert eye can detect in this book.

Recent advances in polymer science
(*Polymer Symposia No. 46*)
Wiley, New York, 1974, 366 pp. £9.75

This volume includes 23 papers read at a symposium held at Princeton in 1973, in memory of Professor Arthur V. Tobolsky. The volume also includes a short tribute and bibliography of Tobolsky's publications.

Tobolsky was a distinguished polymer scientist and an outstanding teacher, and the contributions to this volume are largely by his former students and coworkers. His major contribution to polymer science was to the subject of the relationship between properties and structure and in particular, the mechanical and viscoelastic behaviour of polymers. The latter subject forms the main theme of the symposium, which includes several papers on the synthesis and viscoelastic properties of block copolymers, the properties of cross-linked systems, dielectric relaxation, and also contribution of technical interest on adhesion, blown films and resin coatings. The volume is a fine tribute to an eminent scientist.

Irradiation in Chemical Processes. Recent Developments

M. W. Ranney
Noyes Data, New Jersey, 1975, \$36

This book represents an attempt to supply detailed technical information which has been extracted from the more recent US patent literature in this field. An author's quote 'By indicating all the information that is significant and eliminating legal jargon and juristic phraseology, this book presents an advanced, technically oriented review of irradiation in chemical processes'.

On the whole the technical contents of the book support the authors' claim. There are many creditable aspects. It is unfortunate that there are also several features present which detract from the books' overall merit.

This volume is largely poorly presented. As an example, the first chapter which deals with general chemical synthesis contains, on average, one significant error every two pages. Indicative are incorrect formulae, incomplete sentences, meaningless terminology, inconsistency in units, and incorrect units (density measured as lb/ft). Chapter 2 contains the statement that the coefficient of linear expansion at 73°F of solid polytetrafluoroethylene has a value of 5.5×10^5 inches.

The method of processing used to produce this book, whilst undoubtedly cutting costs and providing useful information in a relatively short time, does so at the expense of the presentation. Data in the tables are difficult to read without very careful scrutiny. The depth of print is variable and the quality of paper unbecoming a book of this price. It is doubtful if any of the sections in the book have been proof read in a conscientious manner.

Despite these faults, the book has much to recommend it. The subjects are dealt with in six sections of varying length, depending on the importance of the technique of irradiation to the particular application. Each chapter contains a wealth of up-to-date material which should be of value to industrial and academic researchers alike. The detail given is such that this volume could provide the basis of many research programmes. The contents cover a range of interests from general chemical synthesis through polymer processes, coatings and printing inks, the application of radiation to composites and specific applications. Various types of irradiation procedure are covered in depth. Those sections which proved particularly useful to the reviewer included coatings and printing inks (in which radiation induced processes are becoming firmly established) and polymer grafting techniques where there are definite signs of future commercial exploitation.

On the basis of its contents this book deserves wide circulation. However, it is the unwarranted number of errors which will detract from its appeal. It is difficult to understand how any volume could have reached publication with so many mistakes in the text. The concept of abstracting the patent literature, properly presenting the information in a digestible form and maintaining continuity is an attractive one which could be adopted in other disciplines. One hopes that in such instances, the proof reading will be much more thorough than is the case here.

Conference Announcement

The Outlook for Polymer Science
UMIST, Manchester, 24 and 25 March 1976

The Sixth Biennial Manchester Polymer Symposium will be held at UMIST on 24 and 25 March 1976 and is being organized with the support of British polymer manufacturers to mark the retirement of Professor Geoffrey Gee CBE, FRS as Sir Samuel Hall Professor of Chemistry in the University of Manchester. The aim is to survey the achievements and assess prospects for future developments in four areas of polymer science with which Professor Gee has been associated: preparation of polymers with desirable structures; mechanisms of polymerization reactions; thermodynamics of polymer solutions; and mechanical properties of polymers in relation to their chemical structures. The programme will consist of the following lectures:

- Achievements and prospects in polymer science: introduction to the symposium
Professor G. Allen (Imperial College, London)
- Molecular design of polymers
Dr A. H. Willbourn (ICI Plastics Division, Welwyn Garden City)

- Some aspects of the stereoregulation in the stereospecific polymerization of vinyl monomers
Professor P. Pino (Federal Institute of Technology, Zurich)
- Intermolecular forces in polymer synthesis — from Lewis acid complexes to exciplexes
Dr A. Ledwith (University of Liverpool)
- Progress and problems in the thermodynamics of polymer solutions
Professor W. H. Stockmayer (Dartmouth College, USA)
- Mechanical motions in amorphous and semi-crystalline polymers
Dr R. F. Boyer (Midland Macromolecular Institute, USA)
- Structure and properties of multiphase polymer systems — perspectives on present status and future potential
Dr S. L. Aggarawal (General Tire, Akron, USA)
- Glassy polymers
Professor Sir S. F. Edwards (Science Research Council, London)

Texts of the lectures presented will be published in POLYMER later this year. Further details may be obtained from The Registrar, University of Manchester Institute of Science and Technology, PO Box 88, Manchester M60 1QD, UK.

Structure refinement of α -poly(L-methionine): X-ray and conformational analysis

F. Colonna-Cesari and S. Premilat

Laboratoire de Biophysique, Université de Nancy 1, Centre de premier Cycle, Case Officielle No. 140, 54037, Nancy Cedex, France

(Received 1 July 1975; revised 10 November 1975)

Using the agreement function between observed and calculated X-ray intensities of the fibre pattern as a constraint in the packing energy minimization, a structure is proposed for the α -helix of poly(L-methionine). This structure has a negative packing energy, is in good agreement with X-ray data, and consists of three different side chain conformations. A model for the packing of randomly up and down pointing polypeptide chains is proposed.

INTRODUCTION

In a previous paper¹, the unit cell of the crystalline lattice of poly(L-methionine) (PLM) (see Figure 1) in its α form was determined from X-ray fibre patterns, but no precise model could be proposed from these crystallographic data. As in the case of other α -helical polypeptides [poly(L-alanine), poly(γ -chloro-benzyl-L-aspartate). .] the existence of a strong meridional reflection near $1/4.4 \text{ \AA}^{-1}$ suggests that 3 consecutive side chains adopt different conformations^{2,3}. It would be of interest to know the extent to which these conformations differ. Takeda and coworkers³, using crystallographic methods only (without refinement) tried to establish a model with 3 distinct consecutive side chains for the α -helical form of poly(β -chlorobenzyl-L-aspartate), but their final model displays identical conformations for each of them. It might be thought that the method developed by Arnott and Wonacott⁴ would be powerful enough to solve this problem. As shown in the present paper, however, the determination of the twelve χ torsional angle values, is not possible with the help of X-ray data only; extra information is clearly needed.

This additional information may well be drawn from the necessity to obtain a structural model which corresponds to a minimum of the packing energy. On this basis, we have established a model for the side chains conformation of the α -helical form of PLM in the fibrous state.

EXPERIMENTAL

From a concentrated chloroform solution of PLM in which a few drops of dichloroacetic acid were added to avoid aggregates, very thin highly birefringent fibres are obtained by dipping and slowly removing a spatula. The most crystalline fibres are selected under a polarizing microscope, bundled into a super-fibre of 90 to 100 μm diameter and fixed to a metallic holder with araldite. The crystalline order is improved by annealing the sample *in vacuo* for 2 h at 150°C .

A cylindrical camera of 29 mm radius, evacuated with a rotary pump, is used with Ni filtered $\text{CuK}\alpha$ radiation ($\lambda = 1.542 \text{ \AA}$). Sets of 3 superposed films are exposed at a time for a period of 1 h to 15 days, in order to measure reflections in the entire density range. Integrated intensity measurements are achieved with a Joyce-Loeble densitometer.

For each diffraction arc a radial densitometer trace is obtained. The background contribution is estimated empirically and the observed integrated intensity is obtained by measuring with a planimeter the area between the densitometer trace and the background estimation. Corrections are then applied to obtain the I_{obs} values of the observed intensities directly comparable to the calculated values⁵.

X-RAY RESULTS

Figure 2 shows three X-ray diffraction patterns of the same sample taken under different experimental conditions. They consist of 62 measurable reflections whose corrected intensities I_{obs} are given in Table 5, and of strong streaks

Figure 1 Reciprocal lattice rotation diagram of PLM

Figure 2 X-ray diffraction photograph of PLM; cylindrical camera of 29 mm radius (a) The fibre axis is vertical and normal to the beam; (b) the fibre axis is tilted 10° from the normal to the beam to show the intense 4.40 Å meridional reflection; (c) the fibre axis is horizontal and tilted 31° from the normal to the beam to show the 1.500 Å meridional reflection

on a few layer lines, suggesting some randomness of the chain sense²; their positions in the reciprocal space are reported in Figure 1. The unit-cell may thus be considered as statistical and contains one up pointing half helix and one down pointing half helix.

The equatorial spacings, together with the existence of two meridional reflections at 4.40 ± 0.01 Å and 1.500 ± 0.002 Å indicate a hexagonal lattice with $a = 11.490 \pm 0.005$ Å and $c = 70.5 \pm 0.1$ Å. The two meridional reflections may be indexed as (0 0 16) and (0 0 47) respectively as in poly(L-alanine). Thus the helical symmetry is 47/13. The (0 0 16) reflection being due to side chains, we may suppose that their structure can be well approximated by a 16/13 helix with the same c value as the 47/13 helix related to the peptidic backbone. In fact the 47/13 helix can also be approximated by a 18/5 helix. The only slight difference lies in the layer lines location, but nothing is changed as far as the Bessel function indices are concerned, since we only consider the first index for each layer line, as shown in Table 1. If the same approximation is made with the 16/13 helix we can consider, in agreement with Takeda and coworkers³ that the side chains pack roughly in a 6/5 helix, in order to accommodate the 6-fold symmetry of the packing interactions. In this approximation, the asymmetric unit of the 6/5 helix consists of exactly 3 consecutive side chains; it is, however, only an approximate model as $16 \times 3 = 48$ and not 47. The side chains helix does not have exactly the same periodicity as that of the peptidic backbone, as already shown by Elliott and Malcolm². As a consequence, the significant layer lines of the two systems may sometimes slightly differ (Table 1), but for the sake of simplicity we only consider the 47/13 helix significant layer line system. This will be taken into account when computing theoretical intensities (see Appendix).

From these crystallographic data we attempt to locate the sulphur atom with the cylindrical Patterson method of McGillavry and Bruins⁶. Contrary to Takeda and coworkers work, no information on the sulphur location is available as the sulphur peaks overlap those due to the second order of the α -helical backbone. Another attempt is then made with the electronic density projection method; but no resolution comparable to that given by Vainshtein⁷ for poly(γ -methyl glutamate) can be obtained. We are thus induced to build an *a priori* molecular model and to try

and accord the theoretical diffraction spectrum with the experimental data.

THE STRUCTURE REFINEMENT FROM X-RAY DATA

Molecular and crystal parameters

Each α -helix divides into two parts: first, the polypeptide backbone including the C_β atoms, which is assumed to keep the 47/13 symmetry and whose asymmetric unit is one peptide group $[-NH-C_\alpha H_\alpha - C_\beta - C' O -]$; secondly, the side chains. In a first approximation, we may suppose, as Takeda and coworkers did, that the side chain atoms also lie on 47/13 helices, which is what we call the 'pure' α -helical case. When 16/13 helices are considered, their asymmetric units consist of the three consecutive side chain sequences $[H_\beta H_\beta - C_\gamma H_\gamma H_\gamma - S_\delta - C_\epsilon H_\epsilon H_\epsilon]$.

The following parameters are needed to define the molecular model: (1) fixed molecular parameters, such as bond

lengths and bond angles given by a mean on the data found in literature (Figure 3). (2) variable molecular parameters (Figure 3): the internal rotation angles ϕ , ψ , ω and χ_1 , χ_2 , χ_3 , χ_4 when only 47/13 symmetry is concerned or χ_i^j ($i = 1,4, j = 1,3$) when 16/13 symmetry is concerned, the bond angle $\tau = \angle \text{NC}_\alpha\text{C}'$. (3) variable packing parameters (Figure 4): the absolute rotation α of the two half up pointing and down pointing helices about the c axis ($\alpha = 0$ when the C_α up of the asymmetric unit is on the a axis, α sense is anticlockwise).

The relative rotation β of the down pointing helix with regard to the up pointing helix ($\beta = 0$ when the C_α of the up pointing and down pointing part of the asymmetric unit have the same equatorial projection, the β sense is clockwise). The relative translation t of the down pointing helix with regard to the up one ($t = 0$ when the two C_α of the up and down part have the same z coordinate, the positive t are along the down axis).

To these parameters we add two temperature factors: an overall temperature factor B_1 applied to every atom and an additional one B_2 applied only to the side chain atoms. In the most general case (47/13 plus 16/13 symmetries) we have to consider not less than 21 parameters.

Refinement procedure and results

Many authors choose the crystallographic R factor as a test function even when dealing with fibres; others⁴ prefer to derive a least square function. In this paper we choose the correlation factor ρ defined by:

$$\rho = \sum_i (|F_i^c| - |\bar{F}^c|) (|F_i^o| - |\bar{F}^o|) / \sigma_o \sigma_c$$

where i is running over all the reflections measured, $|F_i^c|$ is the modulus of the calculated structure amplitude for reflection i , $|F_i^o| = (I \text{ obs})^{1/2}$ for the same reflections. $|\bar{F}^c|$ and $|\bar{F}^o|$ are the means of these two sets, σ_o and σ_c their standard deviation. We want to minimize the function $\Phi = 1 - \rho^2$. This choice was carried out first, as ρ has a clear physical meaning and is now extensively used⁸ and secondly because no scaling factor needs to be introduced more or less artificially in the optimization process.

Contrary to Arnott's procedure no helical constraint is used in the optimization. The helical constraints are directly included in the helix building program by solving the Miyazawa's equations⁹ with a Newton procedure. The

values of ϕ and ψ are then automatically determined each time ω and τ vary in a region where the α -helix is defined. The helix is set up in its own coordinate system by a simple matrix transformation. The 8 helical parameters used by Arnott and Wonacott¹⁰ (ϕ , ψ , ω , τ , θ_x , θ_y , θ_z , D) are therefore reduced to ω and τ . However the derivatives with respect to ω and τ are not simple and must be evaluated numerically, but they are scarcely used in our problem. All the other derivatives are calculated analytically.

Instead of the simple least square matrix method, we use the conjugated gradient method of Fletcher and Powell¹¹, since our starting structures are too far from the optimum one.

Optimization of the Φ function leads to many possibilities in so far as the part of the information due to side chains is relatively weak in the X-ray diagram compared to that due to the α -helical backbone, as confirmed by the diffuse cylindrical Patterson function. This may be due to some necessary disorder affecting side chains included in interactions between helices of same polarity, as we shall show below. Since, on the other hand, the packing energy E is more sensitive to the conformation of the side chains than to that of the peptidic backbone, by optimizing the packing energy we should obtain some satisfactory starting structures for ulterior optimization of Φ .

CONFORMATIONAL ENERGY ANALYSIS

In fact simple empirical packing energy calculation seldom yields realistic structures. For example, Fu and coworkers¹² have determined several stable conformations for poly(β -chlorobenzyl-L-aspartate) by energy analysis. It turns out that the conformation derived from X-ray analysis by Takeda *et al.*³ has the less favourable energy.

In this work we obtained similar results with PLM; structures obtained by optimization of E only give poor Φ values and *vice versa*. The reason lies mainly in the difficulty to find all the minima of a several variable function. On the other hand, a coupled optimization of E and Φ at

Figure 4 The parameters α and β and their rotation senses. $A^+(r_j, \phi_j, z_j)$ represents the equatorial projection of a given atom in the up pointing helix and $A^-(r_j, -\phi_j - \beta + \alpha, -z_j - t)$ the projection of the homologous of A^+ on the down pointing helix. C_α^+ and C_α^- are the origins respectively for the up and down helices; $-t$ is the translation of C_α^- relatively to C_α^+

Figure 5 The different lattice models, with as many up pointing chains \odot as down pointing chains \circ . Parallel interactions (---); antiparallel interactions (—)

the same time will certainly present much less minima. And it must yield a structure energetically favourable and in agreement with X-ray data.

Potentials

We use the 6–12 Lennard–Jones potentials published by Scheraga¹³, with increased van der Waals radii as used previously¹⁴. In the exploration phase a cut-off of 4 Å is used on these interactions to save computer time, and 7 Å in the final computations. Electrostatic interactions are calculated without cut-off with a dielectric constant of 1 and the partial charges of the monopole approximation are taken from the paper of Poland and Scheraga¹⁵. Torsional energy around covalent bonds and τ angle deformation energy are calculated from the values published by Scheraga¹³. The hydrogen bond potential is taken from Poland and Scheraga¹⁵.

Molecular packing model

At this step, it is necessary to suppose an hexagonal arrangement of the randomly up and down pointing chains corresponding to the X-ray model, simple enough to allow quick energy calculations.

Let us consider the interactions of a given up pointing helix with its 6 first neighbours. They divide into two types: parallel interactions when the up pointing helix interacts with other up pointing helices and antiparallel interactions when it interacts with down pointing helices. First, we can consider a model in which each site of the hexagonal lattice is randomly occupied by an up or a down pointing helix. In this case, interactions between helices are also randomly distributed; it is impossible to conceive a 6/5 helical symmetry for the side chains, induced by the hexagonal lattice, or some correlations in the helices orientations. The diffraction pattern would be similar to that of the tobacco mosaic virus¹⁶.

In fact, the existence of a hexagonal lattice and of a 6/5 helical symmetry for the side chains implies some local

order. In other words, one type of interaction must be more frequent than the other.

In this way, they are, on average, two consecutive helices with the same sense in the nearest neighbouring of a given helix: this is sufficient to ensure the existence of the (4.4 Å) reflection characteristic of the 16/13 or 6/5 helical symmetry. In addition, this predominant type of interaction, by imposing its own local order, ensures that the helices are correlated in orientation. This allows the existence of a crystalline order. This predominant type of interaction is therefore responsible for the X-ray diffraction pattern. As energy calculations show that electrostatic interactions between parallel helices are 10 kcal/mol-residue less favourable than those between antiparallel helices, we suggest that antiparallel interactions predominate in the helices arrangement. Regular lattices, with as many up as down pointing helices but in which antiparallel interactions are twice as numerous, can be built as shown in Figures 5a and 5b. Nevertheless these regular models give orthorhombic unit cells and are not consistent with the existence of streaks. So, we suggest that the actual lattice may look like that of Figure 5c, i.e. mixture of models I and II of Figure 5a and b, consistent with the hexagonal lattice and streaks. The necessary presence of parallel interactions implies some disorder in the conformation of the side chains involved. This type of lattice thus contains an important 'amorphous phase' which could be at the origin of the strong diffuse halo on the X-ray patterns.

As pointed out above, the antiparallel interactions alone are responsible for the Bragg reflections. The following model is then sufficient to undertake energy calculations: an up pointing helix surrounded by 6 down pointing helices. The antiparallel interactions alone are taken into account. We construct such an arrangement with the middle of an up pointing helix of 9 residues and 6 down pointing helices of 15 residues. Further, the first 3 residues of the up pointing helix are facing the middle residues of the down pointing helices.

Figure 6 Arrangement of up and down pointing chains used for energy calculations

Table 2 Conformational parameters for the five areas of minimum intramolecular energy

	χ_1 (degrees)	χ_2 (degrees)	χ_3 (degrees)	χ_4 (degrees)	E_i (kcal/mol residue)
(1)	180	160	60	60	-11.38
(2)	180	40	60	20	-10.63
(3)	-160	-160	-60	60	-10.25
(4)	-100	-160	-60	-20	-7.96
(5)	-160	120	-60	20	-6.27

In the calculations, the packing energy E by residue is divided into two parts: (a) E_i the intramolecular energy of a helix, calculated as the energy of interaction of the 3 first residues of the middle helix with themselves and with the remaining residues divided by 3; (b) E_R the intermolecular energy calculated as the energy of interaction of the 3 first residues of the middle helix with the down pointing helices divided by 3.

The molecular parameters used as variables in the calculation of E are the same as those used for X-ray refinement (α , β and t being now defined as shown by Figure 6).

Given a set of parameters (ω , τ , χ_i^j , α , β , t , $B_1 B_2$) we can now calculate Φ , the test function for X-ray data, and E at the same time.

Results of energy calculations

To eliminate side chains conformations giving high intramolecular energies we first build energy maps of a pure 47/13 α helix where χ_1 and χ_2 are varied from 20° to 20° for values of χ_3 equal to 60° , 180° and -60° and χ_4 equal to 60° , 20° and -20° . We thus obtain five areas of negative intramolecular energy (see Table 2).

In order to eliminate very unfavourable conformations (such as extended side chains of very high intramolecular energy) a shallow optimization is performed on E starting from these areas, always with the pure α -helical conformation. As expected, no conformation gives a negative value for E associated with a good Φ value. Nevertheless they yield reasonable starting points for the coupled optimization and allow the elimination of unlikely structures.

COUPLED REFINEMENT

Method

As discussed above, if we do not want to go astray in local minima of E providing poor agreement with X-ray data, we must use a coupled or simultaneous minimization of E and Φ . The mathematical problem is therefore: to find a set of conformational and packing parameters so as to minimize E with the imperative condition that $\Phi \leq \sigma$ [or $\rho \geq \rho_\sigma = (1 - \sigma^2)^{1/2}$], where σ is a given positive number smaller than 1. This problem is very similar to the protein refinement problem. In this paper we prefer to deal with the constrain $\Phi \leq \sigma$ by a Lagrangian method, more powerful than the oversimplified penalty minimizations used in this type of work^{17,18}. For this purpose, we use the conjugated gradient method published by Haaroff and Buys¹⁹ to solve non-linear constrained minimization problems. A series of constrained optimizations is undertaken in which σ is lowered from 0.50 to 0.20 (or ρ_σ increased from about 0.70 to 0.90) by small steps, to drive the parameters gently towards regions leading to lower energies consistent with $\Phi \leq \sigma$.

Results

Starting from points obtained by the previous E optimization, the coupled optimization procedure is first applied to the 'pure' α -helical conformation.

When a conflict arises between Φ and E optimizations, the next step is carried out with side chains in the 16/13 symmetry. The optimization is stopped when a further decrease in σ leads to stationary values for E and Φ or conflicts with a further optimization of E .

As ρ reaches a values of 0.85, we refine B_1 and B_2 to obtain $B_1 = 9$ and $B_2 = 3$. We keep $B_1 = 9$ in the next steps but $B_2 = 0$ so that the role of side chains in the Φ optimization does not decrease too artificially.

A final refinement is made on ω and τ leading to some improvement, mainly in the intramolecular energy E . We verify too that no other values for α , β and t give new solutions. Finally, two conformations (Table 3) reached the final stage. For both of them $\rho = 0.88$, but one of them (b) is eliminated as it does not account for the small values of the (1 0 13) reflection, an important fact of the diffraction pattern (it also has the greater energy). So, we propose the conformation (a) of Table 3 as a probable structure for PLM α -helices in the fibrous state. The corresponding atomic coordinates of the asymmetric unit are given in Table 4. Figure 7 shows equatorial projection of this structure and Table 5 gives the calculated X-ray intensities.

DISCUSSION AND CONCLUSION

The examination of the results of Table 3 and 5 shows that the model we proposed is still coarse ($\rho = 0.88$, $R \approx 0.4$),

Figure 7 Equatorial projection of the structure (a) of Table 3

in particular the 200 reflection is too weak. This region of the reciprocal space is very sensitive to the position of the side chains atoms. A possible explanation of this discrepancy may be that in the actual asymmetric unit the 'up and down' half helices have different geometrical parameters in particular different χ angles. Thus, in the real structure, the S atoms, in particular, are not exactly, in the same relative position for the up and down pointing chains. This fact may affect the intensity of the reflections near the reciprocal space origin.

A second reason may be that we have not taken into account the postulated existence of an 'amorphous phase' for some side chains. As a consequence, the relative intensity due to the side chains is over estimated and must be a cause of error. We did not want to introduce these supplementary parameters which will make the calculations too unwieldy.

Nevertheless our results show that the hypothesis of a 16/13 (or more simply 6/5) symmetry for the side chains of an α -helix in the fibrous state is correct, since it allows an improvement of ρ and E as well. Besides, we show that, by considering the agreement function Φ as a constraint of the packing energy optimization problem we avoid the reefs found when separate optimizations are done or simple penalty methods used. We thus obtain a structure in rather good agreement with X-ray data and a good packing energy. We think that this procedure of constrained optimization could be applied to industrial synthetic polymers and perhaps to protein refinement problems.

Moreover, close examination of the packing mode of α -helices in hexagonal lattice shows that it is a rather complicated statistical array, including an amorphous phase which could only crystallize in lattice with orthorhombic unit cells. Analogous regular systems have been observed for mixture of poly(D and poly(L-benzyl-glutamates)²⁰ and ω helices of poly(β -benzyl-L-aspartate)²¹, but have never been observed in enantiomorphous α -helical lattices.

APPENDIX

Fourier Transform of double helical symmetry chains with random up-down polarities

In the general case, the Fourier transform of a macromolecular helix, with ν asymmetric units in t turns, is yielded by the formula derived by Cochran *et al.*²²:

$$F(R, \psi, l/c) = \sum_n \sum_{j \in A} f_j J_n(2\pi R r_j) \exp \left\{ i[n(\pi/2 - \phi_j) + (2\pi l z_j/c)] \right\} \exp(in\psi)$$

$$\text{or } F(R, \psi, l/c) = \sum_n (A_n + iB_n) \exp(in\psi) \quad (\text{A1})$$

where r_j , ϕ_j , z_j are the cylindrical coordinates of the atom j of the asymmetric unit A , f_j the atomic scattering factor of the atom j , R , ψ , l/c are the cylindrical coordinates of a point in the reciprocal space and n is running over all the J_n Bessel function indices occurring on the layer line l and given by the selection rule:

$$l = nt + m\nu \quad (\text{A2})$$

where m is an integer.

We consider now a statistical unit cell with a half up helix superposed to a half down helix whose relative positions are defined by α , β and t as defined by Figure 3. For each atom u of the up helix whose coordinates are $(r_u, \phi_u + \alpha, z_u)$ there is a corresponding atom on the down helix whose coordinates are: $[r_u, -(\phi_u + \beta) + \alpha, -(z_u + t)]$

If we put $\Phi_u = -n\phi_u + 2\pi l z_u/c$

$$\gamma = n\beta - 2\pi l t/c$$

from (A1) we obtain:

$$A_n = \cos[n(\pi/2 - \alpha) + \gamma/2] \sum_{u \in U} f_u J_n(2\pi R r_u)$$

$$\cos(\Phi_u - \gamma/2)$$

$$B_n = \sin[n(\pi/2 - \alpha) + \gamma/2] \sum_{u \in U} f_u J_n(2\pi R r_u)$$

$$\cos(\Phi_u - \gamma/2)$$

where U is the asymmetric unit of the up-helix. Putting:

$$\Gamma = n(\pi/2 - \alpha) + \gamma/2$$

and

$$F_n = \sum_{u \in U} f_u J_n(2\pi R r_u) \cos(\Phi_u - \gamma/2)$$

we obtain:

$$\begin{aligned} F(R, \psi, l/c) &= \sum_n (A_n + iB_n) \exp(in\psi) \\ &= \sum_n F_n \exp[i(n\psi + \Gamma)] \end{aligned}$$

If the asymmetric unit consists of two different helices characterized in relation (A2) respectively by n_1 and n_2 , we obtain for (A1):

$$\begin{aligned} F(R, \psi, l/c) &= \sum_{n_1} F_{n_1} \exp[i(n_1\psi + \Gamma_1)] + \\ &\quad \sum_{n_2} F_{n_2} \exp[i(n_2\psi + \Gamma_2)] \end{aligned}$$

with

$$F_{nk} = \sum_{j \in U_k} f_j J_{nk}(2\pi R r_j) \cos(\Phi_j - \gamma_k/2)$$

where

$$\Phi_{jk} = -nk\phi_j + 2\pi lz_j/c$$

$$\gamma_k = nk\beta - 2\pi lt/c$$

$$\Gamma_k = nk(\pi/2 - \alpha) + \gamma_k/2$$

if first Bessel indices only are significant we obtain:

$$\begin{aligned} I = FF^* &= F_{n_1}^2 + F_{n_2}^2 + 2F_{n_1}F_{n_2} \cos[(n_1 - n_2)\psi \\ &\quad + \Gamma_1 - \Gamma_2] \end{aligned}$$

As in a fibre diagram we only measure $I^c = \langle FF^* \rangle_\psi$ the mean over ψ of FF^* , we thus have:

$$I^c(R, l/c) = \langle FF^* \rangle_\psi = F_{n_1}^2 + F_{n_2}^2 \text{ if } n_1 \neq n_2$$

[or if the layer lines systems are not exactly superposed on the layer line l (see text)]

$$= (F_{n_1} + F_{n_2})^2 \text{ if } n_1 = n_2$$

Morphological study of chain-extended growth in polyethylene:

1. Crystallization

D. C. Bassett and B. A. Khalifa*

J. J. Thomson Physical Laboratory, University of Reading, Reading RG6 2AF, UK

(Received 10 October 1975)

Polyethylene crystallizes from the melt at pressures of a few kbar as lamellar crystals whose thickness extends over at least two orders of magnitude from a few hundred of Å to μm . The average value in bulk unconstrained polymer in these experiments is ~ 4000 Å but this value progressively decreases to ~ 200 Å as thinner and thinner specimens are used. Morphological evidence shows no discontinuity of physical texture throughout this range but reveals, by the occurrence of parallel changes in the thinnest films and the bulk polymer, that the entire spectrum of lamellar thicknesses is associated with crystallization into the hexagonal phase. This implies on the one hand, that lamellar thickness is not a suitable measure to distinguish the so-called chain-extended and chain-folded modes of crystallization of polyethylene and, on the other, that the very large effect of constraints needs to be included in theories of polymeric crystallization.

INTRODUCTION

The problem presented by the crystallization of molten polyethylene at high pressure (~ 5 kbar) has been greatly changed by recent work. The main issue used to be to understand why growth under such conditions produced crystals so different, notably by being an order of magnitude thicker, from those formed at atmospheric pressure¹. Various possible reasons were suggested for this, among them a change from chain-folded to bundlelike nucleation², enhanced lamellar thickening³ and a continuous large increase of fold surface free energy with pressure⁴. However, all of these proposals were incompatible with the results of further work, in particular the demonstration that chain-extended crystallization of polyethylene is independent of chain-folded crystallization and is favoured by longer molecules^{5,6}. Instead the underlying reason, according to Bassett and Turner, is that at high pressures and moderate supercoolings polyethylene crystallizes into a new intermediate phase by chain-extended crystallization, and only transforms into the orthorhombic structure at low pressures and/or temperatures^{7,8}. By contrast, chain-folded crystallization is direct precipitation of orthorhombic polyethylene from the melt.

This hypothesis has now, in our view, been shown to be correct by the identification of the new (hexagonal) phase using high pressure, high temperature X-ray diffraction and the correlation of its formation with the characteristic appearance and properties of the chain-extended polymer⁹. It must be stated, nevertheless, that the original proposals of Bassett and Turner based on volumetric and d.t.a. data showing that fusion and recrystallization of polyethylene at 5 kbar proceeded in two stages have been questioned by other workers. Kanetsuna and coworkers have interpreted their volumetric data in terms of only part of the polymer forming a 'super-extended structure'¹⁰⁻¹². This seems to us incompatible with the X-ray evidence, and their more complex data^{11,12} to be a consequence of the complicated

fractionation between the two processes as chain-folded growth gives way to chain-extended with increasing pressure. On the other hand, Yasuniwa *et al.* do discuss their high pressure d.t.a. data in terms of a new phase, but again which only consists of a portion of the sample, and which they speculate may be a nematic high pressure phase¹³. This interpretation is refuted by the same objection as previously and, in particular, a nematic structure is inconsistent with the sharp X-ray line observed⁹.

The recognition that chain-extended growth of polyethylene is crystallization of a new phase immediately prompts the question of whether it is possible to describe both chain-folded and chain-extended crystallization as the same process modified only by the differing properties of the orthorhombic and hexagonal phases. Collected results show that, *prima facie*, this appears to be the case. Data for chain-extended polyethylene (CEPE)^{14,15} and also for PTFE¹⁶ conform to the formalism of kinetic theory as well as does chain-folded polyethylene, with the large lamellar thicknesses stemming essentially from the low entropies of fusion. The facts do not appear to support the contention of Wunderlich that there is one growth mechanism for chain-folded polymers and another for chain-extended¹⁷. Nevertheless, detailed study of both CEPE and PTFE has revealed important new aspects of behaviour which, if there is to be but one theory of polymeric growth, will need to be incorporated into kinetic theories. The new context in which we now see CEPE is, therefore, as a model system for the study of polymeric crystallization which, because of its great lamellar size, allows the study of new aspects of behaviour.

The purpose of this series of papers is to document certain of these new features and also to fill in more of the morphological record of chain-extended growth in polyethylene. Unlike most other topics in polymeric crystallization, our knowledge of CEPE owes comparatively little to morphological investigation, beyond the appreciation of the large crystal size. This is because the existence of the hexagonal phase leaves little other clear indication in the physical texture. Nevertheless a wide range of such studies

* Present address: Faculty of Science, Ain Shams University, Cairo, Egypt

has been made in this laboratory aimed initially at preparing isolated chain-extended crystals and more recently at clarifying aspects of chain-extended growth. The initial results of this work were often apparently confusing although at one point they contributed importantly to the deduction that chain-extended growth was independent of chain-folded⁵. Now, however, the features can be viewed in their new perspective. In this paper we are concerned with the morphological distinction between chain-folded and chain-extended growth not only in bulk but also in thin films and the demonstration that with suitable constraints lamellar thicknesses resulting from crystallization of hexagonal polyethylene can be depressed by an order of magnitude.

The second paper¹⁸ discusses the annealing of bulk polyethylene at high pressure, correcting certain mistakes in the literature; annealing in thin films is the subject of the third paper¹⁹. In a fourth paper²⁰ we present data from various techniques to illustrate the nature of chain-extended lamellae.

PRELIMINARY EXPERIMENTS

The experiments described in this series of papers had their beginnings as long ago as 1966 when a preliminary survey was undertaken into the practicability of preparing isolated 'extended-chain' crystals. The first approach²² was to co-crystallize polyethylene and $n\text{-C}_{32}\text{H}_{66}$ hoping that subsequent removal of the latter, in the manner of Keith *et al.*²¹ would leave behind relatively isolated chain-extended crystals. It turned out that behaviour at low concentrations was akin to that reported for other solutions and not until the polymer was in a proportion $>\sim 40\%$ did crystallization at several kbar produce the expected melting point of $\sim 140^\circ\text{C}$ ²²; these results are in agreement with a fuller investigation by Treiber *et al.*²³. At this concentration the texture was far too compact for ready microscopic examination so that this approach was taken no further until the thin film work described in Part 4 of this series²⁰.

Subsequently, following the discovery that high-pressure annealing transformed solution-grown polyethylene crystals (sedimented in mats) into lamellae 2000 Å and more in thickness^{24,25}, individual crystals of the same preparations, but suspended either in the supposed non-solvent 2-butoxy-ethanol or in silicone oil were also annealed at ~ 5 kbar (1 bar = 10^5 N/m²). Surprisingly this never gave thick (>1000 Å) lamellae; instead crystal thickening occurred to an extent reminiscent of atmospheric behaviour, with a legacy of oriented holes²², as described in the more detailed work of Roe *et al.*²⁶. This rather remarkable effect had no obvious explanation and parallel behaviour became apparent in unpublished work of Bassett and Phillips who examined thin films of three fractionated polyethylenes recrystallized at 5 kbar using techniques similar to our own. Once again while bulk samples acquired the high crystal thicknesses, melting points and densities expected at this pressure, for the thinnest films in the same runs, lamellar thicknesses remained at a few hundred Å. It was not then clear how, if at all, such thin layers, which clearly contained molecules having many folds, were related to the thick, chain-extended laminae found in the bulk polymer. At the same time, there had to be an increase in lamellar thickness for thicker films but examination of increasingly thick films to the maximum penetration of 100 kV electrons showed no obvious discontinuity in behaviour. Particular possible causes for recrystallized lamellae being so thin were then looked into, viz. the restricting effect of the sub-

strate and of the lack of appropriate nuclei. Thus, for the latter 'shish-kebab' structures were provided as possible promoters of chain-extended growth but in no case was the resulting lamellar thickness sufficiently influenced to account for the disparity. It appeared, therefore that a whole spectrum of crystal thicknesses was formed during high pressure crystallization, with thicknesses increasing for thicker specimens. This trend was definitely established for films 3 μm and more in thickness by replication of fracture surfaces²⁷. Moreover, because of a similarity in texture in the optical microscope it seemed that the whole spectrum of layer thicknesses down to hundreds of Å should be associated with chain-extended growth²⁷.

Prior to this time, however, the meaning of the term chain-extended polyethylene was not well defined especially as the conformational definition of containing fully-extended molecules was known not to apply¹⁴. It was then found that for crystallized (as opposed to annealed) samples, the combination of texture in the polarizing microscope and melting point gave a working distinction between specimens of 'chain-extended' and 'chain-folded' polyethylene². This in turn led to the demonstration that chain-folded and chain-extended growth are independent processes^{5,6} which we now recognize to be crystallization from the melt into the orthorhombic phase and into the hexagonal phase of polyethylene respectively⁷⁻⁹.

Using these definitions we now re-examine the thin film morphologies of pressure-crystallized polyethylene and find evidence which supports the contention that even layers only a few hundred Å thick result from crystallization into the hexagonal structure and so can properly be regarded as part of the chain-extended texture.

RESULTS

Samples of three commercial linear polyethylenes Rigidex 2 and Rigidex 9 (BP Chemicals Ltd) and Hifax 1900 (Hercules Powder Co.) in the forms of (a) bulk pellets, (b) thin (~ 3 μm) sections, (c) solvent-cast films, and (d) solution-grown crystals deposited on a substrate have been recrystallized under conditions listed in Table 1 while immersed in the pressure-transmitting silicone fluid inside the piston and cylinder apparatus described previously⁶. The oil penetrates specimens to a slight extent, but this is not responsible for the effects described because they are also found with different systems e.g. employing encapsulation in water.

The basic morphological difference between chain-folded and CEPE is illustrated in Figure 1, which shows four sections of Rigidex 9 initially 3 μm thick, recrystallized at high pressures and then viewed optically between crossed polars. These were specimens crystallized at 2.60 and 2.87 kbar where small changes in crystallization conditions cause a changeover from one growth régime to the other. The crystallization procedure was first to impose a pressure of 1.5–1.6 kbar, secondly to increase the temperature from ambient until it was controlled at the required value (which had to be above the melting point at the initial pressure used) and thirdly to increase the pressure to that chosen for crystallization. This third step produces adiabatic heating which can under suitable circumstances cause substantial rises in temperature²⁸; care was taken therefore to limit this transient rise to ~ 3 K. Finally, after the elapse of the chosen time (usually 2 h) heaters were switched off and the samples were cooled under pressure at an initial rate of ~ 2 K/min.

Table 1 Crystallization conditions

Run	Crystallization				Melting points (°C)

Figure 1 Optical distinction between chain-folded and chain-extended textures in polyethylene revealed between crossed polars. Samples of Rigidex 9 crystallized at: (a) 2.87 kbar and 200.5°C; (b) 2.87 kbar and 190°C; (c) 2.60 kbar and 193.5°C; (d) 2.60 kbar and 185°C. Sample (a) appears mostly chain-extended, (d) is entirely chain-folded while (b) and (c) are mixtures

Figure 2 Transmission micrograph of a specimen as in Figure 1a taken with 1 MV electrons. Notice the development of contrast in the highly irradiated area

Figure 1a is of a 3 μm section of the linear polyethylene Rigidex 9 after recrystallization between glass cover slips. It has the coarse, spikey appearance of CEPE, although as the PAF (peak area fraction, approximately the fraction of chain-extended material⁶) of a bulk sample crystallized alongside was 0.6, it is likely to contain $\sim 40\%$ of chain-folded material also. By increasing the supercooling from 10 to 20 K at this pressure the PAF drops to 0.1 and Figure 1b is clearly a mixed product. So too is Figure 1c whose sample was grown at a supercooling of 11 K but at the lower pressure of 2.6 kbar; the PAF was 0.25. Figure 1d, however, is entirely chain-folded; the PAF is zero and the growth conditions are 2.6 kbar and 20 K supercooling.

At this optical level, the textural differentiation is unmistakable but this needs to be reconciled with the preliminary electron microscope observations. For this purpose, the 1 MV microscope was used, whose electron beam readily penetrates such 3 μm thick specimens as in Figure 1. Thus Figure 2 is a low-magnification image of the specimen of Figure 1a which shows similar contrast to that photograph but only within the area subjected to a high electron intensity. Evidently the contrast is a result of mass transport caused by radiation damage and relates only at second-hand to that originally present, behaviour which is similar to that known to occur in other systems²⁹. The intrinsic contrast in specimens appears initially to be zero and is always relatively low in such an energetic electron beam. Better contrast resulted when specimens were stained with a caesium salt. The results of this are seen in Figure 3.

The stainant used is unusual and originated from other work in this laboratory³⁰. It has been found possible chemically to attach chlorophosphoryl groups selectively to chain-folds of polyethylene lamellae, by reacting the suspended crystals with phosphorus chloride at 60°C through which oxygen was bubbling³¹. A similar technique was

used here, with the polyethylene sections immersed in the activated reagent for 6 h, washed with *o*-dichlorobenzene and then stored for 1 week in a solution of Cs metal in dry methanol.

With the improved contrast of such specimens, it is possible to see, as in Figure 3, details of lamellar arrangements in both chain-extended and chain-folded regions. Although the gross features of Figure 3a and 3b appear rather different, and obviously correspond to the differing optical appearances between crossed polars (Figures 1a and 1b) already in Figure 3c, the fine detail suggests that there is a continuous range of lamellar thicknesses present. At the same time, the comparison with Figure 3d is less distinctive and suggests how earlier difficulties in distinguishing transmission micrographs of chain-extended and chain-folded growth may have arisen. For comparison fracture surface replicas of these same samples are illustrated in Figures 3e and 3f. It is noteworthy in these how the thicker chain-extended layers are revealed in the mixed (but mainly chain-folded) sample in Figure 3f. This agrees with previous experience that the tendency is for chain-folded lamellae not to be evident in fracture surfaces¹⁴. For this reason measurements of lamellar thickness from fracture surfaces tend to be of the chain-extended component alone. In this case, the (number) average thickness parallel to *c*, measured in our standard way¹⁴, is 1770 and 2040 Å for samples PC88 and 89 (Table 1) respectively. Notice also the greater number of fibres pulled from the surface during replication in Figure 3f than in Figure 3e, an effect which in agreement with earlier observations is more prevalent for thinner layers of the same polymer¹⁴.

We turn now to crystallization in very thin films and in particular to the recrystallization on various substrates of solution-grown crystals. We consider in detail only monolayer crystals ~ 150 Å thick, although by the use of multilayer crystals, axialites and solvent-cast films, progressively thicker films have been prepared. These did not, however, appear to introduce any fundamentally new features.

The crystals shown in Figure 4 were grown from a solution of Rigidex 9 in xylene (fuller details are given in Part 3¹⁹) and sedimented on carbon-coated mica sheets which in turn were suspended alongside other specimens in runs PC121, 117, 128 and 129 (Table 1); metal shadowing was applied subsequently after washing off the remaining silicone oil with xylene. Figure 4 shows that recrystallization at 5.5 kbar produced similar features throughout the readily accessible crystallization range, i.e. from supercoolings of 11 to 20 K.

The resulting morphology is one of small islands, lying within the outline of the original crystals, with systematic changes in density (number/unit area). There are often, though not always, fewer in what were the original {100} sectors. In most cases the region of the central pleat where the hollow pyramidal lamellae have collapsed is more or less free of islands. But islands bounding these regions, and also those in the {100} sectors tend to be thicker than elsewhere; also, where lamellae overlap, or where there are growth pyramids, islands are fewer, thicker and many-layered.

In contrast, Figure 5 shows the results of recrystallization at 2.6 kbar and at the two supercoolings of 11 and 20 K in the same runs PC109 and 110 giving the specimens

Figure 3 Electron microscopic detail of chain-folded and chain-extended specimens similar to those in Figures 1a and 1b. (a) and (c) are detail of a stained predominantly chain extended sample; (b) and (d) refer to a mostly chain-folded one. Fracture surface replicas of the same samples are shown in (e) and (f)

Figure 4 Results of recrystallizing solution-grown Rigidex 9 polyethylene lamellae on a substrate at 5.5 kbar and crystallization temperatures of: (a) 245.5°; (b) 243.5°; (c) 241.5°; (d) 240.5°C

in Figures 1c and 1d. Besides Rigidex 9, crystals of Rigidex 2, which has a wider molecular weight distribution than Rigidex 9 and in particular twice as many (5% as against 2.5%) in excess of 10^6 , and Hifax 1900 are shown for comparison. For bulk Rigidex 9, crystallization at the higher temperature gave 25% of chain-extended component, but none at 20 K of supercooling (Figures 1c and 1d). The molecular weights of Rigidex 2 and Hifax 1900 are higher than Rigidex 9, so that one would expect the proportion of CEPE to increase for constant crystallization conditions. In contrast to behaviour at 5.5 kbar where Figure 4 showed that morphology was insensitive to crystallization temperature, there are marked differences in Figure 5 with both temperature and molecular weight. It will be shown in the discussion how these are consistent with expectation.

DISCUSSION

It is a remarkable fact that of two polyethylene samples crystallized side by side at high pressure the one recrystallized as a thin film should contain lamellae an order of magnitude thinner than the average values for the other, recrystallized in bulk. Such an effect in polymers is unprecedented. We shall argue that it is a demonstration, in a suitable model system, of the very considerable influence constraints can exert on polymeric crystal growth.

Before the results can be taken at face value, however,

it has to be shown that in both cases the polymer crystallized into the hexagonal phase. Were it the case that for thin films the polymer precipitated as the orthorhombic form then thin layers would be expected, but at some film thickness there would have to be a substantial increase of lamellar thickness as crystallization switched to the hexagonal structure. Much effort has been spent looking for such a change without success; no evidence has been found for a discontinuity in lamellar thickness with specimen size. On the contrary there appears to be a continuous increase, with the fine structure of specimens a few hundred Å thick essentially similar to that of 3 μm slices of known chain-extended polymer (Figure 3). It appears, therefore, that the thin layers found for thin specimens are part of the spectrum of lamellar thicknesses produced by crystallization of the hexagonal phase, i.e. chain-extended growth in continuation of the trend previously found in thick films²⁷.

To a certain extent this conclusion can be substantiated by a study of the optical appearance of polyethylene films of varying thicknesses recrystallized at high pressure, showing a continuity in the characteristic chain-extended appearance in polarizing and phase-contrast images. What appears to us conclusive proof, however, is provided by the morphology of specimens as in Figures 4 and 5 where changes in the appearance of thin films alter in a predictable way to parallel changes in adjacent bulk samples when crystallization of the hexagonal structure gives way to the orthorhombic.

Figure 5 Results of recrystallizing various solution grown polyethylene lamellae on a substrate at 2.6 kbar and two temperatures. (a), (b) Rigidex 9; (c), (d) Rigidex 2; (e), (f) Hifax 1900. (a), (c) and (e) were recrystallized at 193.5°C and (b), (d) and (f) at 185°C

The morphology of thin polymer films crystallized on a substrate is undoubtedly influenced by the surface as e.g. the behaviour of the central pleat caused by collapse of the hollow pyramidal structure during sedimentation. Nevertheless such differences are not likely to vary substantially with changing conditions of recrystallization so that for such alterations in morphology we may look to details of nucleation and growth.

Previous work^{6,8} on the relationship between chain-folded and chain-extended growth in bulk polyethylene has shown

that the nucleation and growth rate of the hexagonal phase from the melt increases with molecular weight at a given pressure for the three polyethylenes studied here, while the lowest pressure at which the hexagonal phase forms from the melt decreases with molecular weight. In addition, there is a limit in the region of 4000 below which polymer does not appear capable of forming the hexagonal phase at 5 kbar. If we assume that these relationships also apply to recrystallization in thin films, then the nature of the observed changes in morphology can be accounted for.

At 5.5 kbar, practically all the molecules within Rigidex 9 are capable of crystallizing into the hexagonal phase and do so rapidly at the supercoolings of the experiments of *Figure 4*. One expects, therefore, a comparatively large number of nuclei of the hexagonal phase virtually independent of crystallization temperature within the range covered, and that many of these will be independent growth centres because of the constraining effect of the substrate. On going to lower pressures the anticipated trend should be fewer chain-extended nuclei and fewer growth islands initiated by them because with decreasing pressure only the longest molecules remain capable of nucleating the hexagonal phase. This is what is found in *Figure 5a*, though here one must seek to locate the ~75% of chain-folded material expected from the PAF of the bulk polymer. Although not every crystal in a population is identical, that shown in *Figure 5a* is typical. We infer, therefore, that any chain-folded growth must have occurred around the same centres as the chain-extended. Indeed these islands contain multiple lamellae and even growth pyramids which are not nearly so much in evidence in *Figure 4* and suggest different details of growth.

For *Figure 5b* we have a clear change of appearance — many fewer, and also thinner, islands. This is to be expected if growth is now chain-folded because the restrictions on nucleation will then be removed. We thus conclude that there are observable changes which are consistent with established trends of behaviour, even in lamellae only a few hundred Å in thickness produced by recrystallization at high pressures. This conclusion can, moreover, be reinforced by showing that the same trends in behaviour with molecular weight hold for thin films as for bulk polymer.

The high molecular weight Hifax polymer illustrated in *Figures 5e* and *5f* is known to be able to crystallize chain-extended at lower pressures than Rigidex 9. It is not surprising therefore, that *Figure 5f* should resemble *Figure 5a*, for, in terms of chain-extended nucleation, conditions are likely to be rather similar. In *Figure 5e*, we have still more extension as is clearly evident from the coarsely branched habit characteristically found in high molecular weight chain-extended polyethylene.

Rigidex 2, the polyethylene used in *Figures 5c* and *5d* is broader in distribution than Rigidex 9 encompassing both lower and higher molecular lengths than that polymer. We may, therefore, expect the high molecular tail to render *Figure 5d* intermediate in character between *Figures 5b* and *5f* and *Figure 5c* between *Figures 5a* and *5e*; this is clearly so. On the other hand, the low molecular weight tail is likely to be more fluid and crystallize last, with a tendency to fill interstices between growth centres. *Figures 5c* and *5d* give the impression that this may also be happening.

The conclusions we draw from the very wide spectrum of lamellar thicknesses given by crystallization with the hexagonal phase are three. First, it is evident that lamellar thickness alone is not sufficient to diagnose chain-extended as opposed to chain-folded crystallization of polyethylene. This is a point on which much confusion has arisen, stemming from the unfortunate initial description of polyethylene recrystallized at high pressures as 'extended-chain'. This is not true, in general, in a configurational sense as the typical product does contain folded molecules¹⁴. Moreover, although to have a thickness exceeding 2000 Å confers properties of melting point and density which are a reasonable approximation to those for fully-extended molecules³², this is not a useful distinction between low and high pressure phenomena. The distinction between these

two cases, as has been shown, is rather one of crystallization into different phases⁷⁻⁹. Nor is there any other length which can be used to divide off one form of crystallization from the other. We have here lamellar thicknesses for chain-extended samples of a few hundred Å, which is less than dimensions readily reached for chain-folded crystallization. Even for bulk samples, the average chain-extended crystal thickness has previously been shown to fall as low as 800 Å⁶, substantially less than figures measured for long term chain-folded crystallization at 1 bar³³.

Secondly, the range of lamellar thicknesses produced in these experiments by isothermal crystallization at 5 kbar by variation in specimen size is far wider than that previously reported for kinetically controlled (chain-folded) crystallization with any variable. It follows that, for chain-extended growth, lamellar thickness is a function of pressure, temperature, molecular weight⁸ and specimen size. It is not specified sufficiently by supercooling alone as is the case at atmospheric pressure. The spread of average values of lamellar thickness is in excess of 1 order of magnitude from ~4000 Å in bulk polyethylene to <400 Å for the crystals of *Figure 4* while a second order of magnitude is involved if one considers the thicknesses of individual lamellae which have long been known to reach 4 μm¹ while substantially thicker ones have been reported more recently¹⁰. Evidently constraints of a kind are involved which in this particular model system are able to reveal the extent of their influence, whereas in a more familiar system, e.g. chain-folded polyethylene, there is much less scope for depression of crystal sizes. It is difficult to state precisely what these constraints may be, but the factors are clearly not limited to the influence of a substrate as the thickness of lamellae in *Figures 4* and *5* persists into the higher layers present. One possibility might be memory effects in the melt, but recent studies using neutron scattering give little support to speculations of retention of order in molten polyethylene³⁴.

Finally, these results are not obviously compatible with existing theories of kinetically controlled growth which consider lamellar thickness as determined (except for relatively minor readjustments) when a molecule adds to the growth face of a lamellae. It is hard to see how such a process can be influenced by constraints associated with specimen size. As has now been shown directly⁹, however, the thickest chain-extended crystals grow outwards behind a narrowed edge, i.e. they only attain their final thickness at a roughly similar distance behind the growth face. This presumably involves a cooperative process and as such will, in principle, be susceptible to effects of specimen size. The scale of the effects actually revealed is, nevertheless, remarkable and shows a new facet to the character of kinetically controlled polymeric crystallization.

Morphological study of chain-extended growth in polyethylene:

2. Annealed bulk polymer

D. C. Bassett, B. A. Khalifa* and R. H. Olley

*J. J. Thomson Physical Laboratory, University of Reading, Reading RG6 2AF, UK
(Received 10 October 1975)*

The morphology of initially spherulitic, chain-folded polyethylene has been observed after specimens had been annealed at temperatures up to and including the melting point at 5.35 kbar. The pattern of the various phenomena corresponds to a transition from orthorhombic to hexagonal structures prior to melting in accordance with other recent work. Certain errors in the literature are corrected and additional evidence is provided for the view that the molecular mechanism of annealing in polyethylene is little different from local melting followed by recrystallization provided the effect of constraints is recognized.

INTRODUCTION

The discovery of the hexagonal phase of polyethylene and the demonstration that its crystallization from the melt is responsible for chain-extended growth¹ have important implications also for the understanding of high-pressure annealing of polyethylene. This is a topic which has been somewhat controversial partly because of certain errors in the supposed facts and partly because in ignorance of the existence of the hexagonal phase, the essential basis for understanding the various phenomena was not available. Nevertheless, previous work from this laboratory concerned with the annealing at 5 kbar of drawn polyethylene², was able to reconcile the conflicting factual records and also, by anticipating the existence of the new phase, to discuss the subject in its new perspective. In this paper we are similarly concerned with spherulitic polymer and reach conclusions which reinforce those of the earlier work. In addition, the stage is prepared for the microscopic investigation described in Part 3³ and further evidence is provided that lamellar thickening resulting from annealing polyethylene can be regarded as a consequence of localized melting followed by recrystallization provided the effect of environmental constraints is considered.

EXPERIMENTAL

The experiments have been carried out, using the equipment and procedures described previously², on the linear polyethylene Rigidex 9 (BP Chemicals Ltd). The results of annealing for 15 min at 5.35 kbar are summarized in Table 1. The temperatures quoted are the average ones over the period, with the maximum deviations from this figure. In the three cases where this was larger than 0.25K, the highest temperature occurred in the middle of runs PC43 and PC92 but at the end of experiment PC101; probably it is the maximum temperature attained which is significant.

The picture which emerges is one of steadily increasing lamellar thickness with increasing annealing temperature, in agreement with earlier work^{2,4,5}. (In retrospect it is quite clear that the reason why Fischer and Puderbach⁶ did not

observe large thicknesses in polyethylene annealed at high pressures is that they did not anneal to sufficiently high temperatures.) Associated with this thickening are parallel increases in density and atmospheric melting point which compare favourably with the earlier work on drawn Rigidex 2 (BP Chemicals Ltd). One minor difference related to the broader molecular weight distribution of Rigidex 2 is that there is only one low melting peak for Rigidex 9, at 124°C, involving a constant 7% of the polymer. This is known to be caused by shorter (and/or possibly defective) molecules and compares with two fixed and one variable peak found after annealing drawn Rigidex 2.

The morphological counterparts to these changes are illustrated in Figures 1 and 2. Figure 1a shows small lamellae just resolved in a fracture-surface replica at the lowest annealing temperature. (The drawn fibres are pulled from the sample during replication; their number decreases with increasing chain-extension.) Figures 1b to 1e are similar, showing thickening and widening of lamellae and (a characteristic feature of annealed as opposed to crystallized material) a zig-zagging of the fracture-induced striation along *c*. For Figures 1f and 1g the annealing temperatures fall within the span of the melting peak recorded by high pressure d.t.a. (Figure 3) and Figure 1h is of a sample which had been completely molten. Figure 1 has to be considered together with Figure 2 which shows the optical appearance between crossed polars of ~3 μm slices of Rigidex 9 which were annealed between glass coverslips alongside the samples of Figure 1. Figures 2(a) to 2d show that the familiar

Figure 1 Fracture-surface morphologies of initially spherulitic polyethylene after 15 min annealing at 5.3 kbar and the following temperatures: (a) 238°C; (b) 242°C; (c) 244°C; (d) 248°C; (e) 250°C; (f) 253°C; (g) 254°C; (h) 256°C

Figure 2 Optical texture seen between crossed polars of samples corresponding to those in Figure 1

Figure 3 High pressure d.t.a. trace of the melting of the initially spherulitic polyethylene used, at 5.3₅ kbar and a heating rate of ~ 1.7 K/min

gross texture of small, banded spherulites is invariant to 248°C and only begins to alter towards the appearance of chain-extended, recrystallized polyethylene seen in Figure 2(h) when annealing takes place in the melting region (Figures 2e to 2g).

Figure 2 conflicts with the assumptions of Gruner *et al.*⁷ who did not test the point directly but believed that spherulitic texture and chain orientation were lost with the melting of chain-extended lamellae at 242°C at 5.1 kbar (equivalent to 246°C at 5.35 kbar) and that lamellae remained superheated for a further 3K rise in temperature. This is not true; for initially chain-folded Rigidex 9 Figure 3 shows a final (hexagonal) melting peak centred at 253.5°C. Instead, the work of this and previous papers substantiate fully the initial claim of Rees and Bassett^{4,5} that chain orientation and gross spherulitic texture persist when chain-extended polyethylene lamellae are formed by annealing chain-folded ones at high pressure.

A major innovation in the present work is that the lengths recorded in Table 1 have been derived not just from fracture surface data as in the past but also by the nitric acid/g.p.c. method. This is now a standard method in this laboratory and by providing an independent means of assessing chain extension is contributing importantly to the various aspects of work on chain-extended polyethylene. The experimental procedure follows the pioneering work of the Bristol group⁸ in applying the Palmer–Cobbold technique to polyethylene.

The technique used was to encapsulate polyethylene samples of 20–50 mg with 10 ml of fuming nitric acid in universal containers sealed with PTFE discs. Reaction was allowed for three days at 60°C after which samples were washed for several hours with water, 1:1 water–methanol, methanol and dichloromethane successively and then dried. Subsequently, molecular weights of the degraded products were determined by gel permeation chromatography (g.p.c.) using a Waters Associates 200 instrument with *o*-dichlorobenzene at 130°C as solvent and a system of four columns with nominal exclusion limits of 10⁶, 10⁵, 10⁴ and 10³ Å. Standard polystyrene fractions were used for calibration and samples were injected as 2 ml portions of 0.2% solutions in *o*-dichlorobenzene.

Figure 4b shows a typical g.p.c. trace of a nitrated sample and that it compares sensibly with the melting endotherm (Figure 4a) of the original sample. In Figure 5 the differential weight and number-average distributions derived from the g.p.c. data are superposed on the fracture surface

data for the same samples measured in our usual way⁹. The general agreement between the two techniques is good (this applies also to crystallized samples) and supports all previous conclusions on chain-extended polyethylene derived from fracture surface data alone. Agreement is best between the weight-average g.p.c. data and the number-average fracture surface histograms, but the fracture surface data do not generally show the longest or the shortest lengths recorded by the g.p.c. technique. The reasons for this are discussed in detail elsewhere¹⁰; here we merely observe that longer lengths than the crystal thickness will be measured by the g.p.c. if not all folds are cut during nitration, also the thinnest, least well-defined lamellae might be expected to be underrecorded in fracture surfaces. It is likely that only the thicker layers have been selected in Figure 5a where the fracture surface data are higher than the melting point and density would suggest, although in previous work with oriented samples² this difficulty did not obviously

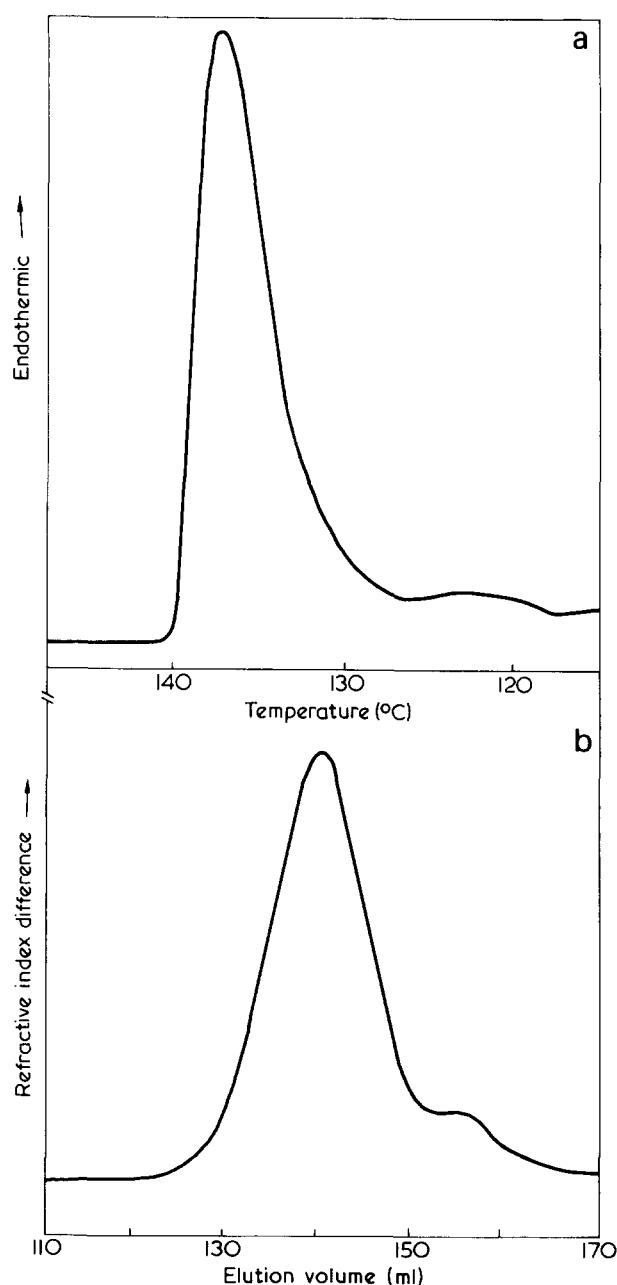

Figure 4 A comparison of (a) the d.s.c. melting endotherm with (b) the g.p.c. molecular length distribution of the sample of Figure 1d

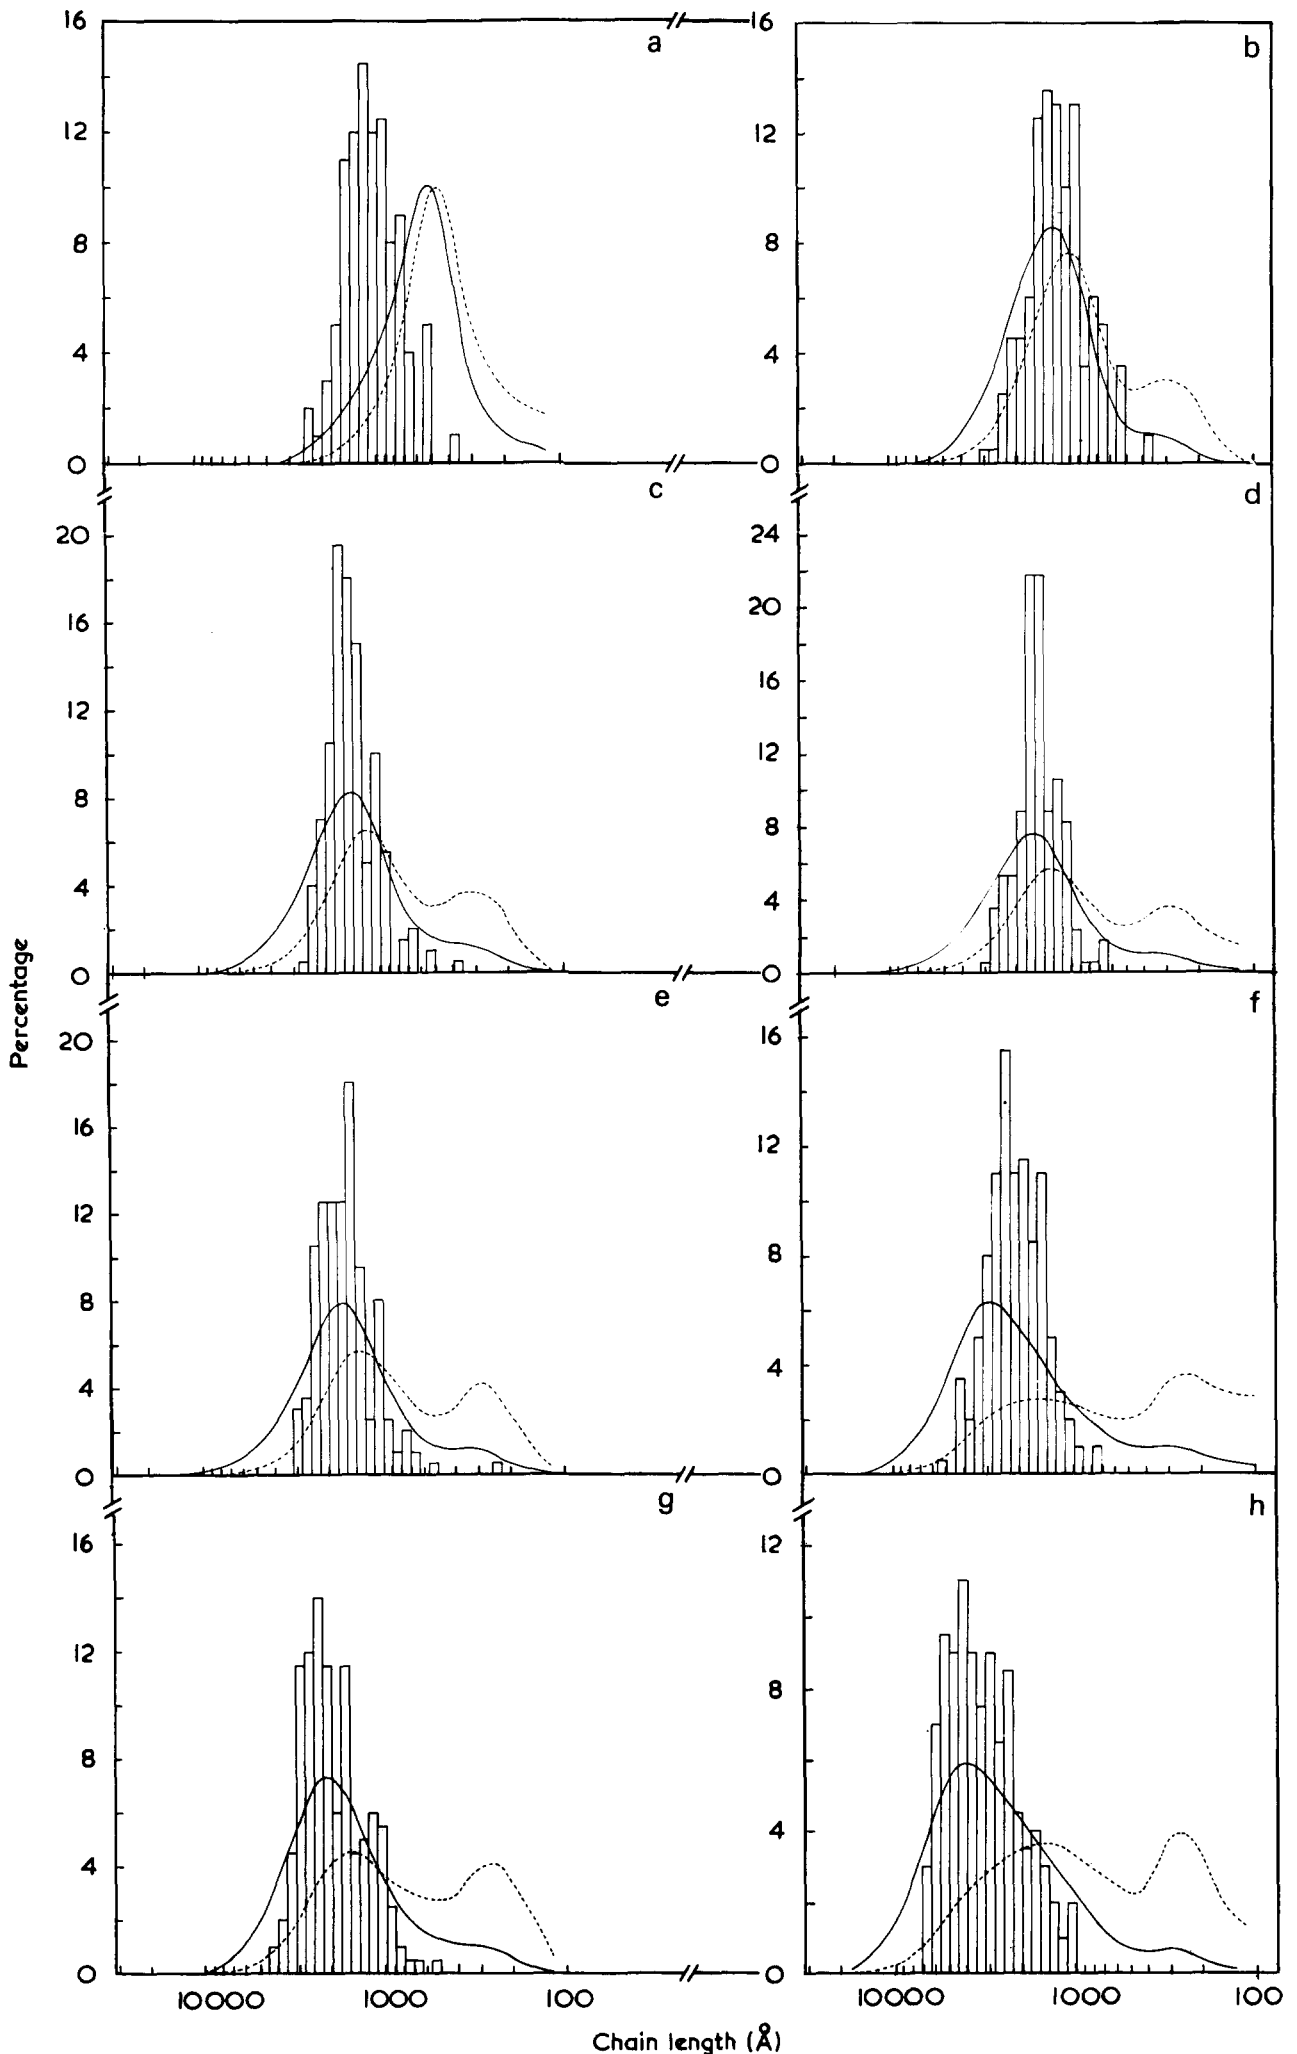

Figure 5 Chain extension of the eight samples of Figure 1 assessed in three ways. □ (histograms), fracture surface data; —, weight-average g.p.c. data of nitrated samples; ····, corresponding number-average data

arise. We thus have an illustration of how the nitric acid/g.p.c. method can be more reliable than that of fracture surfaces. Both techniques, however, are agreed in showing that run PC92 is out of sequence in that the lamellar thickness is apparently too high; this is, in fact, not unexpected for the temperature variation during annealing as will be discussed later. The run serves, therefore, as an example of how well the new and old techniques reinforce each other.

DISCUSSION

High pressure d.t.a. data show two endothermic peaks in the melting range of chain-folded Rigidex 9. At 5.35 kbar *Figure 3* shows that for the particular samples of these experiments, the maxima are at 241°C, which represents the phase change from orthorhombic to hexagonal and 253.5°C when the hexagonal structure melts. This knowledge places the topic in a new context, first discussed by Bassett and Carder², whose interpretation we shall follow.

Both endothermic peaks described are much wider than the instrumental broadening and both are noticeably skewed to lower temperatures; these effects are mainly consequences of the wide molecular weight distribution. Unpublished work (Morris and Bassett) has shown that for a series of coarse polyethylene fractions whose mode molecular weights increased from 10^4 to 10^5 , the maxima of the corresponding two endothermic peaks for chain-extended samples increased from 237° to 245°C and from 245° to 258°C respectively. Peak positions also vary with crystal thickness, but this is a smaller effect; previous work¹¹ measured an increase to 242.75°C in the lower temperature peak for chain-extended as opposed to chain-folded Rigidex 9, but no corresponding significant variation in the hexagonal melting temperature.

We may, accordingly, describe the effects of increasing the temperature of Rigidex 9 polyethylene through the annealing range at 5.35 kbar as follows. Until the temperature approaches within a few degrees of 240°C, the entire sample remains in the orthorhombic structure. It is not surprising, therefore, that annealing experiments confined to this range^{6,12} should find high-pressure behaviour to be similar to that at 1 bar. Above a temperature which depends upon the precise lower molecular weight tail of the sample but for these specimens is ~232°C according to *Figure 3*, the orthorhombic to hexagonal transition begins to occur, during which crystals of ~4000 molecular weight polymer and above transform, at successively higher temperatures, into the hexagonal structure. The shortest molecules, however, appear not to be capable of forming the hexagonal phase at this pressure. Instead they become molten, in this same region of temperature, and distribute themselves between the remaining lamellae. It is here that they recrystallize (as randomly oriented chain-folded lamellae) on the return to lower pressures and temperatures and where they have been shown to be responsible for brittle fracture in a slightly higher molecular weight polyethylene². As is to be expected, the proportion of material in the corresponding atmospheric low-melting peak at 125°C soon rises with annealing temperature to an effectively constant figure (of 7% of the total area under the peak). This proportion may be used to estimate that the shortest molecules which can form the hexagonal phase at this pressure are ~350 Å long. Assuming all molecules are linear, the lowest 7% of the molecular weight distribution of Rigidex 9 falls below 3800; for Rigidex 2 which has a similar mode but a broader overall distribution the corresponding pro-

portion is 11%. This latter figure is in agreement with melting endotherms observed in previous work on annealing drawn Rigidex 2 at 5.35 kbar where two additional atmospheric low-melting peaks were recorded which have not been observed in this work on Rigidex 9. It was shown that these were also due to short molecules² but the precise reason for the multiplicity has not been investigated. Nevertheless, with its approximately constant proportion of polymer, the atmospheric melting peak at $132 \pm 1^\circ\text{C}$ at 1 bar found for Rigidex 2 probably also consists of a particular species of short and/or defective molecules. The remaining peak which, with increasing annealing temperature above 247°C increases in proportion and also melting point (to a maximum of ~140°C) is particularly interesting. Such behaviour would be expected of molecules, probably with molecular weights from 4000 to 10 000, which had entered the hexagonal phase but then melted out in greater numbers and for longer lengths as the temperature rose. If they were then unable to recrystallize (into thicker crystals) at the annealing temperature but could do so, into the hexagonal phase, on subsequent cooling, the observed behaviour would follow. The higher the annealing temperature, the more material would be involved and because of its higher molecular weight, which would raise both the temperature of recrystallization and the ultimate thermodynamic melting point, the higher melting the final segregated product would be. All three low melting peaks never constituted more than 20% of the whole for Rigidex 2; our g.p.c. measurements show that 20% of this polymer lies below a molecular weight of 9500.

For the present experiments, little or no separation of low molecular weight polymer was detectable after annealing at 238°C, but the final value of 7% segregation is already present according to both d.s.c. and g.p.c. measurements after annealing at 242°C. Annealing is by then taking place in the hexagonal phase of lamellae interleaved with molten shorter molecules. This is a region of gradually increasing lamellar thickness, density and atmospheric melting point. By 244°C, when the orthorhombic to hexagonal phase transition is complete, few lamellae are less than 1000 Å thick (*Figure 5c*), the overall density exceeds 0.992 g/cm³ and the d.s.c. melting point is close to 140°C. Also as reported by Rees and Bassett⁴, and in agreement with high pressure optical microscopy, there is no change in the gross optical appearance of samples between crossed polars (*Figure 2*). This is now readily understandable because this texture depends on the orientation of the *c* axis and it has been shown that this is common to the two phases¹.

The first sign of a change in optical appearance comes with the beginning of final melting, i.e. the higher temperature peak in *Figure 3*. Thus portions of the sample annealed at 250°C (*Figure 2e*) resemble small elements of the coarse texture characteristic of polyethylene recrystallized into the hexagonal phase^{13,14}. Doubtless a proportion of the material is melting-regions of shorter molecules at lower temperatures and then recrystallizing, possibly slightly at the holding temperature but predominantly on subsequent cooling. This proportion evidently increases at still higher temperatures but, until melting is complete (by 256°C) recrystallization must occur in part into a matrix of solid polymer. As is still to be discussed, but is quite evident from *Figure 2g*, this is a process which depends sensitively upon the precise treatment given to a sample.

The molecular mechanisms induced by annealing crystalline polymers, particularly those responsible for the in-

crease in lamellar thickness are by no means generally agreed upon. Sensitive calorimetry at atmospheric pressure has detected the prolonged evolution of heat once samples are raised to temperatures above that at which they were prepared¹⁵ doubtless due to the improvement of crystalline order; indeed increased order of fold surfaces has been shown to result independently¹⁶. Still higher temperatures are needed before changes in X-ray long period are found¹⁷. These occur very rapidly, apparently in the solid state (hence 'solid state thickening') but with increasing temperatures the slower time-scales involved clearly show that in polyethylene there is first disorganization then reorganization¹⁸. Even the very beginning of lamellar thickening has been pointed out to behave as though it were being triggered by melting of the material¹⁶. This is the simplest hypothesis and we have argued that once the effect of constraints on crystallization is recognized, it is consistent with the available evidence^{2,19}. Because of what is now a considerable weight of evidence showing, we believe, that the molecular mechanism of annealing in polyethylene cannot be very different from local melting, possibly of only a few fold stems, followed by rapid recrystallization, to thicker (and stabler) layers, we shall consider them to be identical unless and until future evidence shows the hypothesis to be untenable. In so doing, however, we do not mean to exclude *a priori* other models based on an apparently similar picture, notably that of Sanchez *et al.*³⁰.

Work at high pressures brings much new evidence to support this point of view reinforcing, as it does, the close parallel between annealing and recrystallization behaviour even in conditions far removed from familiar work at 1 bar. At least three authors^{6,12,21} have drawn attention to the closely similar X-ray long periods of polyethylene after annealing in the orthorhombic phase at low and high pressures at the same temperature interval below the melting point. Moreover, once annealing occurs in the hexagonal phase, then lamellar thicknesses show substantial increases corresponding to those found for recrystallized chain-extended polyethylene. This is to be expected on a melting-recrystallization hypothesis, but does not obviously follow from other mechanisms proposed, e.g. solid-state thickening or fold-length doubling²² when a fold migrates through a crystal layer. Furthermore, there is the similar response of both processes to constraints shown by the investigation of thin films described in Part 1²³ and Part 3³.

The continuing increase of average lamellar thickness with annealing temperature is likely to result from a combination of several factors. The first is that melting and recrystallization occur at a higher temperature, which is well known to give thicker crystals. In addition, the higher the temperature the higher the molecular weight of polymer involved and this, according to studies of chain-extended crystallization, will tend to give thicker crystals¹⁴. The actual size of lamellae formed at a given temperature is, however, strongly dependent upon the physical environment, an effect we shall refer to briefly as due to constraints. Such constraints are likely to decrease with increasing annealing temperatures and this constitutes a third factor favouring increased lamellar thickness.

With runs (f) and (g), annealing occurs well within the final melting peak. Here samples will remain partly molten at the annealing temperature, although the longer they are held there, the greater the chance of some recrystallization at temperature. The remaining portion which will generally be of low molecular weight must recrystallize on cooling and it will do so within the constraints of a solid mat-

rix. The factors affecting lamellar thickness are those described above viz. molecular weight, temperature, time and fewer constraints; the actual value resulting is likely to depend sensitively on details of the treatment. Thus in run (f) the temperature reached its maximum after 5 min and then slowly decayed, in contrast to a uniform temperature in (g); under these conditions one might well expect (f) to have recrystallized at a higher temperature and with fewer constraints than (g) in keeping with the increase in lamellar thickness found.

The origin of the increased average thicknesses in (f) and (g) is the appearance of lamellae thicker than 3000 Å (Figure 5), then in (h), for material which was fully molten, still thicker lamellae to 7000 Å appear. The underlying factor here also appears likely to be constraints as is well illustrated in Figure 2g where lamellae growing with the constraint of pre-existing oriented nuclei are substantially smaller and thinner than those adjacent which formed from apparently unconstrained melt. Once such constraints disappear, lamellar thickness will take its full value. This effect of constraints is crucial to the interpretation of annealing as melting plus recrystallization; if it is neglected the thesis fails. Nevertheless, its effect has been clearly demonstrated e.g. in the previous²³ and following³ papers. Indeed that it should occur in both cases is yet further reinforcement of the view that the two processes are essentially the same.

The conclusions of this paper are therefore, twofold. First, that the apparently anomalous behaviour of polyethylene annealed at high pressures can be readily understood in terms of a transition to the hexagonal phase prior to melting. Secondly, that the high pressure evidence provides substantial support for considering the molecular mechanism of annealing as essentially local melting followed by recrystallization.

Morphological study of chain-extended growth in polyethylene:

3. Annealing of solution-grown lamellae

B. A. Khalifa* and D. C. Bassett

J. J. Thomson Physical Laboratory, University of Reading, Reading RG6 2AF, UK

(Received 10 October 1975)

Solution-grown lamellae of three commercial polyethylenes of differing molecular weight ranges have been annealed on substrates at high pressures. The polymers transform to the new high-pressure phase before melting but the new lamellar thicknesses reached remain much below those found for the bulk material. Electron diffraction patterns support the identification of the new phase as hexagonal and it is concluded that the effects of annealing polyethylene in an unusual context are close to those which would have been produced by local melting followed by rapid recrystallization.

INTRODUCTION

This paper presents observations made on solution-grown lamellae of three linear polyethylenes after annealing on a substrate at 5.35 kbar. It is shown that the initial orthorhombic structure transforms into the newly discovered hexagonal form prior to melting so that the detailed morphologies found are justifiably described as 'chain-extended'. Nevertheless, the lamellar thicknesses attained by annealing polyethylene lamellae initially ~ 150 Å thick on a substrate at high pressure are substantially less than those produced in adjacent unconstrained bulk polymer. This parallels behaviour found for recrystallization in thin films at high pressure which besides reinforcing the close similarity between the two processes provides a further illustration of the exceedingly large effects constraints can have on polymeric crystallization behaviour.

* Present address: Faculty of Science, Ain Shams University, Cairo, Egypt

EXPERIMENTAL AND RESULTS

All the experiments have been carried out on lamellar crystals of the three linear polyethylenes Rigidex 9 and Rigidex 2 (BP Chemicals Ltd) and Hifax 1900 (Hercules Powder Co. Inc.) as illustrated in *Figure 1*. These were grown from 0.01% solutions in xylene by a self-seeding technique whereby a suspension of previously grown crystals was heated to 103°C at 0.1 K/min and then transferred to an isothermal bath held at 85°C. The truncated lozenges thus formed were sedimented on carbon-coated mica substrates and annealed at 5.35 kbar alongside the bulk samples described in Part 2¹. The annealing conditions and procedures are, therefore, those set out in the previous paper except that annealing at the lowest temperature, 238.25 ± 0.25 °C for 15 min, was carried out in run PC86 rather than PC43.

Afterwards, the pressure-transmitting silicone fluid was washed off with xylene and crystals shadowed prior to electron microscopic study. The appearance of reasonably typical annealed morphologies for Rigidex 9, Rigidex 2 and

Figure 2 Typical morphologies after annealing Rigidex 9 crystals for 15 min at 5.3₅ kbar and the following temperatures: (a) 238°; (b) 242°; (c) 244°; (d) 248°; (e) 250°; (f) 253°; (g) 254°; (h) 256°C

Hifax 1900 at each annealing temperature is displayed in *Figures 2, 3 and 4* respectively. These should be compared not only with each other but also with *Figures 1 and 2* of Part 2¹ illustrating the bulk material. It should also be emphasized that, though not all crystals show exactly similar changes and the selection of one or even a few for illustration is necessarily subjective, the trends with temperature and molecular weight are unmistakable.

DISCUSSION

Studies of polymer lamellae annealed on solid surfaces generally reveal not only intrinsic properties of the crystals themselves but also features due to interaction with the substrate. It is apparent that crystal layers which touch the substrate behave differently from those which do not and, also, that smaller layers having proportionately larger surface energy/volume ratios undergo changes before their wider neighbours.

The major change effected by annealing polymer crystals is one of lamellar thickening² which can often be seen to proceed preferentially where there are differences in layer thickness, to be initiated at particular sites, e.g. at intralamellar steps and to leave a legacy of crystallographically oriented holes related to the original directions of fold packing. Additionally, in the presence of a substrate, there are effects due to the degree of mutual contact of crystal and underlying surface plus others due to deformation during deposition, especially that involving collapse of non-planar structures. Annealing in suspension can usefully avoid this last complication, indeed the lack of constraint has allowed the adoption of otherwise unknown habits^{3,4}. Nevertheless a substrate does have the advantage of retaining for examination small scale structures left when lamellae break up, which would quite possibly have been missed in suspension and certainly have lost their spatial relationships. So it is in this work where the changes seen go beyond those found for annealing in suspension⁵ and parallel those observed in bulk polymer annealed adjacently¹. They provide further evidence that lamellae 200–300 Å thick do transform into the hexagonal phase but show also that the constraints of a substrate and small specimen size depress the resulting average layer thicknesses by factors typically of 3 to 4.

The first marked changes in morphology are apparent after annealing at 230°C and 5.35 kbar, conditions under which these polyethylenes remain orthorhombic⁶. It is not surprising, therefore, that these changes, viz. lines perpendicular to the prism faces, are those which are well known at 1 bar³ and have also been observed in other work at high pressure confined to the orthorhombic phase⁵. The molecular orientation also behaves similarly in that 020 becomes the strongest reflection in diffraction patterns taken with the electron beam perpendicular to the specimen plane. This is characteristic of the well known rotation of the unit cell about the *b* axis which can also be seen in upper layers as crumples along *b* (*Figure 5c*)⁷.

Before discussing higher annealing temperatures in detail, it needs to be shown that for these thin lamellae just as for the bulk specimens of the previous paper, there is a transition into the hexagonal phase⁸ before melting. Two pieces of evidence show this. First, there is a clear change in morphology between 254°C and 256°C (in each of *Figures 2, 3 and 4*) corresponding to melting. This is at least 10K higher than would be expected for melting of the orthorhombic phase at this pressure even before taking into account crystal size effects but coincides with the melting point of

hexagonal bulk polymer for which depression due to lamellar thickness is known to be small⁶. Secondly, there is the characteristic three fold twin orientation shown in *Figure 5b* for a crystal of Rigidex 9 (*Figure 5a*) annealed at 245°C and 5.35 kbar in related experiments. This is an effect which was looked for previously in bulk polymer⁶ and is to be expected after the sequence orthorhombic → hexagonal → orthorhombic polyethylene.

What were the {110} and {200} planes in orthorhombic polyethylene become identical {10.0} planes in the hexagonal structure. For the reverse transformation there are, in consequence, three orientations of the orthorhombic cell available for each hexagonal {10.0} plane which are shown in *Figure 6* on the assumptions (i) that the *c* axis is invariant, and (ii) that the orientation of the plane considered remains unaltered. According to *Figure 6a*, 110 twinning will then lead to two additional unit cell orientations in the final orthorhombic texture with the new ⟨020⟩ directions OB' rotated by ±2α away from the original OB where 2α (=67°30') is the angle between (110) and (1 $\bar{1}$ 0) planes. Similarly *Figure 6b* shows that replacement of {110} by {200} or *vice versa* gives additional orientations of ⟨020⟩ at ±β where β (=56°15') is the complement of α. However, assumption (ii) cannot be exact for it can only hold for one set of planes in a particular region. In practice, therefore, one anticipates a spread of orientations for 020 spots around the 0° and ±60° rotations with respect to the original orthorhombic lamella; this is present in *Figures 5b and 5d*. These diffraction patterns also suggest that assumption (i) may not always hold either. Although high-pressure diffraction has shown that the *c* axis direction is common to orthorhombic and hexagonal phases in bulk polyethylene⁸, nevertheless there is also evidence that this is not always maintained locally. This is shown, in particular, by the characteristic zig-zagging of the *c* axis found in annealed bulk polymer¹ and adopted, perhaps, as a means of increasing chain-extension within a given lamellar thickness. So, whereas 020 has the expected three fold orientation, *Figures 5b and especially 5d* show that there can be a tendency for the only 110 and 200 spots present to be those of the initial orientation. As the 020 reflections are also the strongest, it is probable that the new unit cell orientations at ±60° have also undergone an additional rotation about *b*, causing *c* to move away from the lamellar normal. Such a rotation, familiar in other contexts^{7,9}, if of more than a few degrees would remove zero-layer reflections other than 0*k*0 from the patterns in the way observed. The evidence of *Figure 5*, therefore, supports the identification of the high-pressure polyethylene phase as hexagonal⁸ and indicates that in the new orientations the *c* axis tends to have been rotated away from the lamellar normal about *b*.

It follows that, notwithstanding the considerable morphological differences, the annealing of solution-grown polyethylene lamellae at high pressures passes through the same three stages as that of bulk material, viz. annealing in the orthorhombic phase, then in the hexagonal phase and finally melting. The first of these has already been discussed but the changeover to the second leaves no sharp alteration in the morphological record. There are no d.t.a. data to show directly when the phase transition occurs in thin films, but the appearance of the twinned diffraction pattern has been detected in the case of Rigidex 9 after annealing at temperatures as low as 236°C (*Figures 5c and 5d*). This is at the lower end of the d.t.a. peak for bulk material¹ and shows that, despite the difficulty of anticipating to what extent the effect of the substrate offsets the lowering of transition

Figure 3 As Figure 2, but for Rigidex 2 crystals

Figure 4 As Figure 2, but for Hifax crystals

temperatures by lamellar thickness, the change to the hexagonal structure occurs, in these experiments, at approximately the same temperatures in thin layers as in bulk.

The main change in appearance in this region is the disintegration of once continuous lamellae into small islands confined within the original outlines but increasing in thickness, with intermediate stages of multiply connected shapes. According to Figures 2, 3 and 4 this transformation occurs, as would be expected, at slightly higher temperatures for higher molecular weight polymer. Once definitely within the hexagonal phase, at temperatures between 242° and 250°C, it is noticeable that where two layers overlap the islands are approximately twice as wide and that annealing of three or more overlying layers, as in the central pleat, gives a continuous sheet without holes. It follows, as shadow lengths confirm, that these islands are ~500 Å thick, although they are not generally flat-topped but rounded and thinnest at the edges. The outlines of higher layers are much softened with only the thickest pleats still readily discernible whereas annealing in the orthorhombic phase to say, 230°C (Figures 3a and 4a) leaves them much better defined.

It may be inferred from this that, on annealing, a system of lamellae will adopt a sufficient thickness, if necessary at

the expense of creating additional side surfaces (holes), but once this has been reached further thickening, which could give lamellae of at least the maximum thickness of the initial aggregate, is subordinated to the reduction of total energy which a uniform layer gives with its minimal side surfaces. The thickness adopted is considerably less than that found in thicker aggregates of identical lamellae treated similarly showing that for annealing, just as for recrystallization of polyethylene at high pressures¹⁰, specimen size exerts a considerable influence on lamellar thickness.

Such an effect is, perhaps, not so surprising in the case of annealing because most of the explanations suggested for lamellar thickening envisage it as a cooperative process. Following our previous work^{1,10}, it is also compatible with regarding annealing as local melting followed by rapid recrystallization because of the similar effect of specimen size which, in our view, is associated with the thickening of lamellae close to the growing edge.

The effect of local deformation on annealing behaviour is noticeable in subsidiary features, all of which are found in Figure 3c. Here material is denuded from an accidental scratch running vertically through the centre of the picture, from both {110} and {100} sector boundaries and around the edges of the central growth pyramid; the last two sites

Figure 6 Possible twinning schemes for a polyethylene crystal undergoing the sequence of transitions orthorhombic \rightarrow hexagonal \rightarrow orthorhombic

are those where deformation will have been concentrated during sedimentation. As deformed regions will have lower melting points, material in them would be expected to become mobile earlier during annealing and so to move towards adjacent undeformed regions.

Finally, we come to the melting region. By 256°C all three polymers have melted and show the appropriate crystallized morphologies¹⁰ (Figures 2, 3 and 4). Of particular interest, however, is the transformation region revealed at 253° and 254°C, temperatures lying within the region of the final high pressure d.t.a. melting peak of each bulk polymer. Features here are a filling in of the original outline and the clear demarcation of what were once the {100} sectors in some, but not all, lamellae. Figure 3g shows that infilling growth has occurred around a very few centres and, moreover, at a thickness close to that of the original lamellae. These centres are almost certainly unmolten higher molecular weight material acting as nuclei for subsequent growth of shorter molecules during cooling in agreement with earlier work¹¹ and in a way familiar from atmospheric 'self-seeding'¹². In this way one can explain why Hifax alone, with its dearth of short molecules, fails to show the effect at 253°C and why Rigidex 9, having fewer very long molecules should have fewer nuclei and so be more 'filled in' than Rigidex 2 at 253°C.

The distinction of the {100} sectors at this stage is interesting and reminiscent of a well known effect at 1 bar ascribed to 'early melting or other transformation' related to lattice differences stemming from different directions of fold packing in different sectors^{13,14}. In the present case the demarcation appears due to the demarcation of sector boundaries already remarked on, which isolates various sectors in favourable conditions, plus a later melting of the {100} sectors. Thus in Figure 2f especially it can be seen that flow associated with melting has occurred in {110} domains but not in one {100} sector. This is consistent

with the greater thickness (and smaller number) of islands in the {100} sectors, though whether this itself is due to inherent differences between sectors or relates to details of lamellar collapse and contact with the substrate is not entirely clear. Eventually, however, flow does occur in these sectors too (Figure 3g) and then it leaves a pattern with lines parallel to *b*, in a similar way to collapse features in the {100} sectors (Figure 1) implying that the second suggestion may well be correct.

That the original crystal outline is virtually completely filled in during recrystallization shows the lamellar thickness is close to the original ~ 150 Å. Here, however, crystallization must have been into the hexagonal phase because, having shown that recrystallization from the melt at this pressure normally is into the new phase, then it follows that this must be also true of the more rapid self-seeded recrystallization occurring at a higher temperature during cooling. We have, therefore, still further evidence that the crystallization of hexagonal polyethylene at a given temperature and pressure encompasses layer thicknesses down to the 100 Å level. Conversely, the lamellar thickness is not determined mainly by the crystallization temperature but varies by at least an order of magnitude with specimen size and constraints.

In a similar way, we have abundant evidence that annealing thin polyethylene films at high pressures does not produce the thick lamellae characteristic of the bulk. Both effects deny us routes of preparing isolated thick chain-extended crystals of polyethylene. But at the same time, the parallel behaviour of both annealing and recrystallization treatments in an unusual context provides important reinforcement for the view that, at least in polyethylene, the changes produced by annealing are essentially those produced by local melting followed by rapid recrystallization. The other main conclusion of this paper is that electron diffraction patterns provide independent confirmation that the structure of the high-pressure phase of polyethylene is indeed hexagonal.

Polymer Institute of the Slovak Academy of Sciences, Dúbravská cesta, 809 34 Bratislava, Czechoslovakia

(Received 22 July 1974)

The effect of the quality of solvent on the unperturbed chain dimensions \bar{r}_0^2 of perfectly isotactic poly(vinyl alcohol) (iso-PVA) was studied by means of some model calculations according to the matrix method of Flory *et al.* These investigations were based on the assumption that the quality of solvent affected mainly the energy of the intramolecular hydrogen bond, while the magnitude of the interactions between other groups, hardly varied with the change of solvent. The individual conformation energies in a chain of iso-PVA were estimated from the analysis of structurally similar polymers, as well as the results obtained with 2,4-pentandiol. It was found that the characteristic ratio $C = \bar{r}_0^2/nl^2$ increased in non-polar solvents, with energy of the intramolecular hydrogen bond stabilizing the stretched zig-zag conformation of chain. Conversely, the characteristic ratio, monotonously decreased with increasing polarity of solvent to the value of about 6, typical of a flexible random coil. The existence of an analogous relationship, valid for other polymers, able to form an intramolecular hydrogen bond in the chain, was also discussed.

INTRODUCTION

The study of the configurational characteristics of polymer chains, usually involves, explicitly, merely the dependence of these characteristics on temperature. At the same time it is assumed tacitly that these characteristics, for instance the unperturbed dimensions of chains, do not depend on the quality of solvent. This assumption seems to be fulfilled sufficiently for the non-polar polymer-solvent systems. With increasing interest in the study of polar synthetic polymers and biopolymers the experimental evidence¹⁻¹⁰, for the invalidity of this assumption in above systems, accumulates.

Provided fixed bond angles and bond lengths are assumed to be present in the skeleton of the chain, its dimensions are determined by the corresponding conformation energies. In general, at a given temperature, these conformation energies depend on intramolecular, as well as intermolecular interactions, with the solvent and other polymer chains. As for polar low-molecular compounds, this fact is well known and described in the literature¹¹⁻¹⁴. An analogous phenomenon may also be expected, in the case of polymer chains; while a small shift in the position of the potential minima of internal rotation about the bonds in the skeleton of the chain, may affect the unperturbed dimensions of this chain.

A formal description of the effect of solvent on unperturbed dimensions based on statistical mechanics, was developed formerly by Lifson and Oppenheim¹⁵. In other approaches to configurational statistics¹⁶⁻¹⁸, this effect was not taken into consideration explicitly, and the intramolecular origin of the conformation energies of the chain

was particularly emphasized. It is of interest to try to estimate the solvent effect for individual polymers theoretically, by using the recent matrix method of Flory¹⁸ based on statistical mechanics.

Poly(vinyl alcohol) with regular isotactic structure, is a convenient model for theoretical study of the effect of solvent on unperturbed dimensions. The possible formation of an intramolecular hydrogen bond providing a side backbone in the chain, with zig-zag stretched conformation, is the decisive factor which affects the set of stable conformations in the chain. But it is well known that the energy of an intramolecular hydrogen bond, depends very much on the polarity of solvent and therefore, the formation of intermolecular hydrogen bonds usually prevails in polar solvents. It may be concluded from this that the polarity of a solvent affects the competitive equilibrium between the formation of intramolecular and intermolecular hydrogen bond in the case of the iso-PVA chains, also. Therefore, this study is a theoretical investigation of the relationship between the unperturbed dimensions of iso-PVA and the parameter ω_2 , characterizing the magnitude of the interaction between two neighbouring OH groups in the chain. We suppose that such a simplified computation could give a true picture of the characteristic features of the effect of solvent on the unperturbed dimensions of the chains for real iso-PVA.

THEORETICAL

Model

The model of rotational-isomeric states, taking into account the interaction of the nearest neighbouring groups in a linear chain, was in the last decade, successfully applied to the correlation of various configurational properties of a great number of polymers¹⁸, including the dimen-

Figure 1 All-trans planar conformation of a portion of isotactic poly(vinyl alcohol) chain

Figure 2 Newman projections of the three rotational states of skeletal bond i , and the associated statistical weight factors: (a) *trans* T (η); (b) *gauche*, G^+ (1); (c) *gauche*, G^- (τ)

sions of isotactic vinyl polymers^{18–24}. This approach may be also adapted, easily for iso-PVA (Figure 1) assuming fixed bond angles and bond lengths. Also, the set of rotational-isomeric states about single bonds in the skeleton and the corresponding conformation free energies must be specified for the calculation.

The usual set of the rotational isomeric states *trans*, *gauche* plus and *gauche* minus (T , G^+ , G^-), localized at the angles 0° , 120° , -120° were used. In view of the illustrative character of the calculations, we neglected the shift in the rotational isomeric states, which is usual in the case of vinyl polymers, owing to intramolecular steric interactions.

Following Flory¹⁸, the first order free energies depending on single rotational angle are referred to the G^+ state. Their representation and denotation are given in Figure 2 for iso-PVA. In general, it may be expected that the statistical weight τ is smaller than η , because of the coincident *syn* position of the groups with respect to the CH_3 as well as OH groups. The interactions of second order depend on the relative position of two bonds in skeleton and are denoted as ω , ω_1 and ω_2 ²⁵. Factor ω represents the interaction between the pairs of CH_2 or CH groups, ω_1 characterizes the interaction between CH_2 and OH groups. Statistical weight ω_2 , expresses the interaction between two OH groups and is, therefore, a function of the energy of the intramolecular hydrogen bond.

By means of statistical weights it is possible to specify two matrices which are necessary for the analysis of isotactic vinyl polymers^{18,25}:

$$U' = \begin{bmatrix} \eta & 1 & \tau \\ \eta & 1 & \tau\omega \\ \eta & \omega & \tau \end{bmatrix}; U''_m = \begin{bmatrix} \eta\omega_2 & \tau\omega_1 & 1 \\ \eta & \tau\omega_1 & \omega \\ \eta\omega_1 & \tau\omega_2\omega & \omega_1 \end{bmatrix}$$

Matrix U' is attributed to the bond of $\text{CHOH}-\text{CH}_2$ which belongs to an asymmetric centre and matrix U''_m corresponds to the bond of CH_2-CHOH in *meso*-*dd*-dyad. These statistical weights together with the geometrical parameters of the chain skeleton, enable us to calculate the configurational partition function and other conformation dependent properties as e.g. characteristic ratio for perfectly isotactic PVA. The characteristic ratio $C = \bar{r}_0^2/nl^2$ expresses the ratio of the mean square value of the distance between the unperturbed chain ends, to the analogous value valid for the model of freely connected chains.

By simulating the effect of solvent on unperturbed dimensions we shall examine the dependence of the charac-

teristic ratio C on the statistical weight ω_2 . We suppose that the quality of solvent affects the value of other statistical weights, only slightly. Thus it is possible to convert the study of an originally intermolecular effect, into the investigation of the dependence of this effect on intramolecular interaction free energy.

Estimation of the statistical weights for iso-PVA

The magnitude of individual statistical weights may be assessed for iso-PVA in two ways, i.e. from the literary data concerning structurally analogous polymers and n.m.r. results obtained for low molecular weight model compounds of PVA. In the study of configurational characteristics of poly(trimethylene oxide) $[(\text{CH}_2)_3-\text{O}]_n$, Mark^{26,27} assigned the statistical weight $\sigma' = 1.4 \pm 0.5$, at 25°C to one of the *gauche* positions occurring in the chain (Figure 3a). In the case of polymethylene (Figure 3b), Flory¹⁸ used the value $\sigma = 0.54$, at 140°C for the *gauche* position, which corresponds to $\sigma = 0.43$, at 25°C . These values of σ , referring to the unit statistical weight for *trans* conformation in the chain, corroborate the preferential occurrence of oxygen in *gauche* position¹⁸. Provided the statistical weight η is predominately determined by the interaction of neighbouring atomic groups, the comparison between the conformations represented in Figure 2 and Figure 3, gives $\eta = \sigma'/\sigma = 3.2 \pm 1.1$, at 25°C . This reasoning involves the assumption that the interactions $\text{O} \dots \text{CH}_2$ and $\text{OH} \dots \text{CH}$, are approximately equal.

Under analogous assumptions, analysis of the conformations of poly(tetramethylene oxide)^{26,27} gives the value 0.55 ± 0.3 for the statistical weight ω_1 at 25°C . The value $\omega = 0.034$ (25°C) is normally used for the statistical weight incident to the overlap of two groups. But the accuracy of the estimate of this value is probably over estimated. Reliable data available for the estimate of the statistical weight τ , are not abundant. From the earlier paper on the configurational statistics of vinyl polymers, it follows that the value of factor τ effected the characteristic ratio only slightly. The value of τ assessed, was found to be in the range $0.05-1$ ¹⁸.

Another independent way for the estimation of the statistical weights for iso-PVA is based on the experimental results of the n.m.r. measurements obtained by Fukurci *et al.*²⁸, for the model substance 2,4-pentanediol in different solvents as well as the theoretical analyses of these results performed by Moritani and Fujiwara²⁹. By using the set of the five statistical weights mentioned, it is possible to express the population of individual conformers in the *meso* as well as *racemic* isomer of 2,4-pentanediol. From the dependence on temperature of the vicinal spin-spin coupling constant, the values of statistical weights may be also determined. Moritani and Fujiwara present the following values: $\eta = 1.94$; $\tau = 0.5$; $\omega = 0.04$; and $\omega_1 = 0.24$. The value of the statistical weight ω_2 varied with the polarity of the solvent used from 0.28 for D_2O to 4.87 for CH_2Cl_2 .

Figure 3 Newman representation of *gauche* position and the corresponding statistical weights for (A) poly(trimethylene oxide), $\sigma' = 1.4 \pm 0.5$; (B) poly-methylene at 25°C , $\sigma = 0.43$

Figure 4 Dependence of the characteristic ratio C on the statistical weight ω_2 for iso-PVA. Two different values of the statistical weight η , $\tau = 1$, $\omega = 0.05$, $\omega_1 = 0.5$. Curve A, $\eta = 3.5$; B, $\eta = 2.5$

In conformity with the previous assumption for iso-PVA, Moritani and Fujiwara explained the observed solvent effect on the conformations of 2,4-pentanediol, merely by the variation of the statistical weight ω_2 , while other statistical weights did not change with solvent.

If both the methods of the estimation of statistical weights are compared, a difference appears especially in the case of the statistical weights η and ω_1 . This disagreement may be partly removed, if we modify the statistical weights estimation for 2,4-pentanediol²⁹ by the use of experimentally found relationship between η and ω_1 , (Figure 6e)²⁹. In this way, choosing $\omega_1 = 0.55$ it is possible to obtain a modified value of the statistical weight η of about 2.5. Then the agreement of both methods is sufficient, but it does not count to over estimate the accuracy of the estimation of individual statistical weights.

RESULTS AND DISCUSSION

Dependence of C on ω_2

Following Flory¹⁸, we used the value of 1.53 Å for the length of the C–C bond in the chain skeleton and the values of 112° for the bond angle $\angle CCC$. The dependence of the characteristic ratio C on ω_2 for two representative values of η (2.5 and 3.5), while $\tau = 1$, $\omega = 0.05$, and $\omega_1 = 0.5$, is presented in Figure 4. For comparison, some other values of C found by the variation of the individual statistical weights are listed in Table 1.

The calculated values of the characteristic ratio in Figure 4 and Table 1 correspond to an infinitely long chain. The matrix multiplication method¹⁸ was applied and the value of 0.02 was used as a convergence limit for the difference between two characteristic ratios in two successive cycles. The rate of convergence of C_n is represented in Figure 5 for different values of ω_2 . With increasing ω_2 , it is possible to obtain the limiting value of C_n for very long chains ($n \geq 100$), only.

For small values of ω_2 the value of C does not change necessarily with any statistical weight, but for $\omega_2 > 5$ the value of C depends strongly on all other statistical weights.

The final form of this relationship depends mainly on the reliability of the statistical weights used. It may be stated with certainty that $\eta > 1$, since oxygen atoms tend to stabilize the *gauche* position¹⁸. Contrary to expectation the form of relationship between C and ω_2 is sensitive also on the exact value of τ , e.g. approximately the same shape of curves as in Figure 4 may be obtained for $\tau = 1$ and $\tau = 0.3$ with $\eta = 2.5$, $\omega = 0.05$, $\omega_1 = 0.5$. As regards the second order interactions, Flory¹⁸ has already stressed that three kinds of ω must be distinguished in the case of PVA when $\omega_2 > 1$. Because of the illustrative character of our calculations we did not consider it necessary to analyse in more detail the effect of other statistical weights on the C versus ω_2 relationship. We assume that the used values of statistical weights, represent a reasonable estimate of the interactions in the chain. Another approach to the estimate of statistical weights is based on the semi-empirical methods of theoretical conformation analysis¹⁸. Though the method was also applied in the case of 2,4-pentanediol³⁰, the results cannot be used here since the contribution of the intra-

molecular hydrogen bond was not explicitly taken into consideration.

By varying individual statistical weights about their average value, it is also possible using Boltzmann's factors to estimate very approximately the temperature coefficient $\text{dln } \bar{r}_0^2/\text{dT}$ of the unperturbed chain dimensions. This procedure is equivalent to the assumption that the details of the rotational potential function do not change in a narrow temperature range. The calculated value depends on the estimate of statistical weights. For instance, a relatively high negative value of the temperature coefficient (about -9×10^{-3} degree $^{-1}$) is obtained for $\eta = 2.5$, $\tau = 1$, $\omega = 0.05$, $\omega_1 = 0.5$ and $\omega_2 = 10$ at 25°C.

Solvent effect on ω_2

As it was to be expected, the characteristic ratio increases with the statistical weight ω_2 , because the population of the segments with a zig-zag stretched *trans* conformation stabilized by an intramolecular hydrogen bond in the chain increases. Provided the statistical weight ω_2 decreases, the characteristic ratio falls to the value of about 6 according to the choice of other statistical weights. This decrease is connected with a disruption of the intramolecular hydrogen bond and with an increase in the population of *gauche* conformations in the chain. It is clear from Figure 4 that the condition $\omega_2 = 0$, is not sufficient to provide a preference of the conformations of the type $(TG^+)_n$ or $(G^-T)_n$, forming 3_1 helices, which are characteristic for vinyl polymers. This would be manifested by the increase in C in Figure 4. Conversely, the values of C calculated for small values of ω_2 indicate a considerable flexibility of the chain forming a random coil in solution. The value of ω_2 particularly small may be expected for the aqueous solutions of iso-PVA.

Since the formation of intramolecular hydrogen bond depends on the polarity of medium, it may be concluded from Figure 4 that the characteristic ratio for iso-PVA, decreases with increasing polarity of the solvent. The results obtained for the *meso*-isomer of 2,4-pentanediol, confirm the decrease in the population of *TT* isomer with increasing polarity of the solvent^{28,31}. If we use the values of ω_2 estimated for 2,4-pentanediol as representative values for the chains of iso-PVA, then according to Figure 4, an increase in the characteristic ratio of about 15 or more, follows for the change of solvent from D₂O ($\omega_2 = 0.28$) to CH₂Cl₂ ($\omega_2 = 4.87$). It is evident that the attainment of such changes is limited in real polymer systems by the insolubility of iso-PVA in non-polar solvents and the experimental verification of the predicted relationship between the characteristic ratio and the quality of solvent, will be limited to a much narrower region of the polarity of solvents.

The manner in which the competitive equilibrium between intramolecular and intermolecular bond depends on the polarity of solvent, ensues from the results of analysis for 1,3-propanol³². While only 4.6% of the molecules of 1,3-propanol form an intramolecular hydrogen and almost the whole remainder forms two intermolecular hydrogen bonds in pure dioxane, in a less polar mixed solvent (dioxane/CCl₄ = 1:2), no less than 11.7% of molecules form an intramolecular hydrogen bond. The preferential formation of intermolecular hydrogen bond may be attributed to the fact that the linear system of atoms OH . . . X thus formed, is more energetically advantageous than a similar bent system containing an intramolecular hydrogen bond. Besides the molecules of solvent, the OH groups on neigh-

bour chain can form intermolecular hydrogen bonds. So in non-polar solvents the formation of intermolecular hydrogen bonds of the type polymer-polymer may modify the value of ω_2 , which may also vary with polymer concentration.

We have not found in the literature any experimental data concerning the solvent effect with respect to perfectly isotactic PVA. This effect was, however, found experimentally in the case of atactic PVA dissolved in mixed solvents³³. The use of mixed solvents or thermodynamically good solvents, complicates the analysis of the solvent effect on unperturbed dimensions^{5,6}. An attempt was also made to estimate the solvent effect from the measurements of elastic properties of a swollen polymer network³⁴. However, it may be expected that only the use of the methods more sensitive to the change in the local conformation of chain, will provide more reliable data concerning the magnitude of the solvent effect on the unperturbed dimensions of polymers. For instance by using n.m.r. it was possible to establish the solvent effect on the preference of stable conformations in the case of such non-polar polymer as polyethylene^{35,36}.

Now we shall try to extrapolate some conclusions from the presented calculation. Similarly as for the characteristic ratio, the solvent effect can be also simulated for other conformation dependent quantities of iso-PVA, such as mean square of dipole moment $\bar{\mu}_0^2$. In analogy with the characteristic ratio, a conspicuous solvent effect may be expected in this case, also. It follows from the study of model substances for perfectly syndiotactic PVA^{38,31}, that the *G*⁻*T* conformations are stabilized in non-polar solvents by intramolecular hydrogen bond. Because of a higher population of other conformations (*TT*, *G*⁺*G*⁻, *TG*⁺) a less distinct solvent effect may be expected for this polymer in comparison with the results obtained for iso-PVA.

Characteristic features of the model calculation of solvent effect in the case of iso-PVA, may be extended to other types of the polymers in which the formation of intramolecular hydrogen bond affects the stable conformations in the skeleton of the chain in a decisive way. For the refinement of the theoretical approach to the configurational statistics of polymers it will be, therefore, necessary in some cases to do away with the approximation involving the assumption that the relative energies of individual rotational isomers in the chain are independent of the quality of solvent.

ACKNOWLEDGEMENTS

The authors would like to thank Professor P. J. Flory for helpful discussion. They are also grateful to Dr K. Dusek for his valuable comments.

Monoclinic macrolattice of quenched and cold-drawn sheets of isotactic polypropylene*

(Received 3 July 1975; revised 18 December 1975)

The small angle scattering (SAXS) of quenched and cold drawn sheets of isotactic polypropylene (PP), has been analysed two-dimensionally. The appearance of equatorial SAXS reflections enabled a more detailed analysis of the size and arrangement of the microparacrystallites (*mPC*) in PP. These results confirm our earlier conclusions concerning polyethylene and polybutene, which were obtained without equatorial SAXS. Microparacrystals 50 Å wide and 40 Å long, build up a monoclinic macrolattice. The appearance of SAXS on the equator is explained by broadened lateral grain boundaries between the microparacrystallites of one layer in the direction of the sheet surface. This effect originates from plane stress fields generated in the necking zone of the stretched sheet.

INTRODUCTION

Most high polymers consist of paracrystalline microdomains. These microparacrystallites (*mPC*) aggregate to lamellae if the sample is hot stretched. They build up a more or less nematic-like super-lattice in the cold stretched state. These superlattices (tertiary structures) can be described by the paracrystalline theory, also. Bundles of microparacrystallites build up macroparacrystals (*MPC*)¹. They can be investigated quantitatively by a two-dimensional analysis of small angle scattering. A rapidly quenched, molten film of isotactic polypropylene (PP) consists of *mPC* with large distortions and is therefore, very poorly crystalline²⁻⁴. The different descriptions of this structure, for instance, 'smectic', 'non-crystalline', 'mesomorphic' or 'modification II', demonstrate that this structure is still quite unknown. It is the aim of this work to analyse the mutual arrangements of the *mPC* in the quenched and drawn PP-film, with the help of the paracrystalline theory; in other words, to analyse the structure of the *MPC* two-dimensionally, using the method that was developed for linear polyethylene and isotactic polybutene⁵⁻⁷. In this case the two-dimensional analysis of the SAXS is enhanced by the inclusion of SAXS equatorial reflections, corresponding to the macrolattice. These reflections were first observed by Hermans and Weidinger⁸.

EXPERIMENTAL

The samples were prepared by quenching 1 mm thick sheets of isotactic PP in an ice-water bath, which had previously been heated to the polymer melting point (176°C). The sheets were then cold drawn at 21°C to a stretching ratio of 9. The samples were investigated using a small angle X-ray camera, with pinhole collimation. The sample to film distance was 260.5 mm with the primary beam both paral-

lel and orthogonal to the PP sheet. The X-ray intensities were resolved with a Dupont 310 curve resolver.

TWO-DIMENSIONAL ANALYSIS OF THE SAXS MERIDIONAL REFLECTION

The SAXS pattern of the PP sample we used is shown in *Figure 1*. The meridional intensities observed with the specimen both perpendicular and parallel to the primary beam have the same shape. In contrast to Hermans and Weidinger⁸, we see only one SAXS reflection on the equator when the beam is orthogonal to the sheet. In the parallel position it is split into two relatively sharp spots. The analysis of the meridional reflection is performed in the manner described earlier⁵⁻⁷. The microphotometer curves are shown as full lines in *Figure 2* along the b_3 -axis which is parallel to the stretching direction, in *Figure 3* along the radial direction, b_r , parallel to the equator and through the maximum of the meridional reflection. The calculated points come from the theory of paracrystals⁹, applied to

Figure 1 SAXS pattern of a foil of quenched and cold drawn isotactic PP. The drawing direction is vertical. X-ray beam parallel to platelet. On each side two discrete equatorial reflections can be seen

Figure 2 Intensity distribution $I(b_r, b_3)$ in meridional direction $b_3(b_r = 0)$. The microphotometer curve (—) is compared with calculated values (●) folded with the profile of the primary beam

Figure 3 Intensity distribution $I(b_r, b_3)$ orthogonal to the meridian ($b_3 = \text{constant}$) through its maximum in a $\ln I - b_r^2$ plot. —, Experimental values; ●, calculated from theory and folded with the profile of the primary beam

the macrolattice, which is build up of microparacrystallites (*mPC*). The theoretical intensity function $I(b_r, b_3)$, then is folded with the shape of the primary beam. The agreement with the experimental values is very good. In Figure 2 $I(0, b_3)$, is plotted against b_3 ; in Figure 3 $\ln I(b_r, b_3 = \text{constant})$, is plotted against b_r^2 . This intensity can be separated into two Gaussian terms. The outer tail of the intensity defines the Gaussian term with the smaller slope. It gives the so called brick factor $f^2(b_r)$, which is the Fourier-transform of the shape of a *mPC* (brick) in the radial direction. It has a diameter of 50 Å. From a similar analysis of the continuous equatorial scattering (Figure 4), one obtains similar diameters (see later) for the bricks. This shows that the outer part in Figure 3 ($b_r \geq 9.5 \times 10^{-3} \text{ Å}^{-1}$), is really generated by the shape factor of the *mPC*, which build up the paracrystalline macrolattice. The inner part of Figure 3 (●), can be explained by the product of this shape factor, with the paracrystalline superlattice factor $Z^2 Z_3(b)$ ⁵⁻⁷. From this, the value g_{r3} of the macrolattice can be calculated (see Table 1). g_{r3} defines the relative statistical fluctuation of the lateral vector a_r of the macrolattice in the stretching direction 3 divided by the vector a_3 of the macrolattice in fibre direction. The *mPC* are so much shifted against each other in a direction that no lamellar structure exists. On the contrary, its relatively large value (40%) proves that the

macrolattice possesses a partially nematic-like character and bears little relation to a smectic phase.

The intensity along the meridian (Figure 2) shows the well known feature of cold stretched synthetic fibres; namely one diffuse maximum. From this one can calculate the relative statistical fluctuation g_{33} of a_3 in the direction 3 (see Table 1). In the outer part ($b_3 \geq 14 \times 10^{-3} \text{ Å}^{-1}$), $Z^2 Z_3$ again has reached the value 1. This part is therefore proportional to the brick factor $f^2(b_3)$ and gives a mean height H of 40 Å for the microparacrystallites in fibre direction (Table 1).

P is the so-called long period calculated from the position of the maximum of the meridional reflection. This value is again about 20% larger than the real superlattice cell a_3 in the fibre direction. Similar effects have been previously observed^{5,6}. Since $a_3 = 100 \text{ Å}$, the packing density in the meridional direction is $H/a_3 = 0.4$. Moreover one learns from the two-dimensional analysis that the cold drawn PP is similar to polyethylene and polybutene with rough fold-surfaces and no sharply defined boundaries between the paracrystalline and amorphous layer. They have an anomalously large value of 10 Å compared with H . This thickness of the transition region (given by the value of β) is 25% of the paracrystallite height H and so is relatively, much greater than in polyethylene (4%) and in polybutene (15%). The polydispersity g_H of the paracrystallite height H in chain direction, is $g_H = 0.25$. The shape of the meridional reflection parallel to the equator (Figure 3) is determined between the inner and outer part, discussed above, by the relative fluctuation g_{3r} of the vector a_3 , in radial direction also. It can be obtained, as mentioned in earlier papers^{6,7}, only with a relative uncertainty and is very large (40%). It demonstrates the lack of ultra-fibrillar character in the alignment of the microparacrystallites

Figure 4 Intensity distribution $I(b_r, 0)$ along the equator, primary beam orthogonal to the PP sheet. The SAXS reflection (100) of the cell of the *MPC* is separated from the reflection (000) which gives rise to the so-called continuous SAXS

Table 1 Parameters of the paracrystalline superlattice (*MPC*) of cold drawn isotactic PP calculated from the meridian. $P = 120 \text{ Å}$	$D = 50 \text{ Å}$	$g_H = 0.25$
$a_3 = 100 \text{ Å}$	$a_r = 50 \text{ Å}$	$g_{33} = 0.25$
$H = 40 \text{ Å}$		$g_{rr} = 0.23$
$\beta = 10 \text{ Å}$		$g_{r3} = 0.40$
		$g_{3r} \sim 0.40$

Figure 5 As for Figure 4, but the primary beam parallel to the sheet

along the stretching direction. Thus, there is no reason to speak of a smectic macrostructure, (as discussed above). It is to the advantage of the paracrystalline theory, that structures, which are neither smectic nor nematic, can be explained quantitatively.

ANALYSIS OF THE EQUATORIAL SAXS PATTERN

This is the first time that the two-dimensional SAXS analysis has been applied to a substance which shows SAXS-reflections on the equator. It is not surprising therefore that one can now obtain information directly about the macrolattice cell in the lateral direction. We will see moreover that the results obtained from the meridional reflection fit well to those obtained in this section.

The shape of the whole equatorial scattering is different when observed with the primary beam orthogonal (Figure 4) or parallel to the sheet (Figure 5). Orthogonal to the sheet, only one maximum at 47 Å exists. When parallel, there are two maxima at 48 and 41 Å. The analysis of the maxima was carried out by the Dupont curve resolver, taking Lorentzian squared profiles for the shape of the reflections. The $\ln I - b_r^2$ plot in Figure 6 shows the separation of the continuous particle scattering in two Gaussian curves. From the broader maximum one obtains a particle diameter, parallel to the film of 47 Å and from the same plot of the intensity in Figure 5, a diameter of 52 Å orthogonal to the sheet. These values agree well with the lateral paracrystallite size $D = 50$, obtained from the two-dimensional analysis of the meridional reflection, as mentioned previously. It proves directly that this outer tail of the meridional reflection, parallel to the equator, is given by the shape factor of the microparacrystals. The existence of the equatorial reflections gives evidence that the diameter of the microparacrystals are not only very similar (as in PE and PB), but that the paracrystallites are not fully closely packed within the layers and have a larger amount of amorphous material between them.

The integral width δb_{rr} of the equatorial SAXS reflections in the direction r is determined by the lateral sizes of the coherently scattering clusters of mPC and the g_{rr} value of their macrolattice. From a pure particle effect, one would obtain clusters of ~ 100 Å diameter, hence consisting of ~ 4 mPC . From the analysis of the meridional reflection we know⁶, that the particle effect is negligible in the SAXS of synthetic fibres and therefore δb_{rr} depends

also solely on the paracrystalline distortions. Further proof of this is given in a later section. Hence one obtains, as a first approximation for δb_{rr} and δb_{r3} :

$$\delta b_{rr} = \frac{1}{2d} (\pi g_{rr})^2; \delta b_{r3} = \frac{1}{a_3} (\pi g_{3r})^2 \quad (1)$$

from the theory⁶, d is the netplane distance (48 Å and 41 Å respectively). One obtains from the reflection from Figure 4, $g_{rr} = 0.24$ and from the two reflections from Figure 5, $g_{rr} = 0.19$ and 0.18. These three g_{rr} values are in good agreement with the value obtained from the meridional reflection $g_{rr} = 0.23$ (Table 1).

Another important advance in the two-dimensional SAXS analysis is the fact that one can now also measure the integral widths δb_{r3} of the SAXS equatorial reflections in the fibre direction. From this one obtains direct information concerning the smectic-like distortion g_{3r} of the macrolattice. It leads to a value $g_{3r} = 0.16$, which is much smaller than the g_{3r} value obtained from the middle section of Figure 3. The reason for this discrepancy is clearly explained by the bimodal statistics, $H_3(x)$, of the vector a_3 in r -direction*. In the calculation we use the fact that the SAXS is proportional⁵⁻⁷ to:

$$I \sim Z_3 Z_r^2 (h_r, h_3)$$

$$Z_3 = Re \frac{1 + F_3}{1 - F_3}; F_3(b) = \mathcal{F} H_3; \mathcal{F} = \int \exp(2\pi i b x) dx \quad (2)$$

$$|F_3| = \exp -2\pi^2 [g_{33}^2 h_3^2 + g_{3r}^2 h_r^2]; g_{ik}^2 = \overline{a_{ik}^2} / \overline{a_k^2} - 1 \quad (3)$$

In Figure 7 the inner part I of $|F_3(h_r)|$ is plotted for the large g_{3r} value, g_{3r} of Table 1, obtained from the meridional reflections. For the outer tail II of F_3 , a slope is used according to the value $g_{3r} = 0.16$ from the equatorial analysis. Furthermore two Gaussian components III and IV are plotted, whose sum gives the correct slope for the inner and outer part of $|F_3|$. Their slopes and weights, define a bimodal H_3 statistic in r direction, with values g'_{3r} and g''_{3r} given in Table 2, and occurring with the probability of 20 resp. 80%.

* In our previous papers⁵⁻⁷, similar bimodal statistics were found for the statistics $H_r(x)$ of the lateral vector a_r in fibre direction 3.

Figure 6 $\ln I - b_r^2$ plot of the intensity from Figure 4

Figure 7 Modulus of the statistic factor $F_3(b)$ of the axial vector a_3 composed of two Gaussian terms III and IV. I and II, experimentally observed slopes

Table 2 Parameters of the paracrystalline macrolattice (MPC) of cold drawn isotactic PP calculated from the equator (see Figure 8)

$a_1 = 50,5 \text{ \AA}$	$d_a = 48 \text{ \AA}$	to the sheet
$a_2 = 59 \text{ \AA}$	$d_b = 41 \text{ \AA}$	
$\gamma = 54,2^\circ$	$D = \begin{cases} 47 \text{ \AA} & \text{parallel} \\ 52 \text{ \AA} & \text{orthogonal} \end{cases}$	to the sheet
	$g_{rr} = \begin{cases} 0.24 & \text{parallel} \\ 0.19 & \text{orthogonal} \end{cases}$	to the sheet
	$g'_{3r} = 0.11$ (20%)	
	$g''_{3r} = 0.47$ (80%)	

Now let us discuss the equatorial macrostructure. Since only the reflection at 48 \AA appears with the primary beam orthogonal to the sheet, a monoclinic deformed pseudo-hexagonal lattice with a certain degree of disorientation is indicated. The families of netplanes parallel to the surface are compressed somewhat orthogonally to these netplanes. Figure 8a gives the respective reciprocal lattice and Figure 8b a schematic drawing of the macrostructure. Both kinds of reflections of 48 \AA and 41 \AA appear in the pattern with the beam parallel to the sheet. This can be explained by a texture of MPC. The macrolattices of Figure 8b have only a finite size and show a variety of orientation, which give rise to the 'sickle' shaped reflection of Figure 8a. It corresponds to a change of the orientation of the MPC by rotation about an axis parallel to the stretching direction, of at least 60° . Thus one obtains parameters of the idealized macrolattice cell in the equatorial plane which is monoclinic (Figure 8b). In reality the single MPC are polydisperse and have a statistical fluctuation in their diameter, of the order of the value g_{rr} ($\approx 24\%$). In Figure 8b is plotted for convenience one MPC which is not tilted. All MPC are somewhat elongated, orthogonal to the sheet surface, according to results obtained from the continuous SAXS along the equator (Table 2).

The model in Figure 8b is also idealized from the point of view of order. In the real structure, the netplanes are wavy and the diameters of the MPC vary slightly from one to the other, thus generating paracrystalline distortions in the sense discussed before.

DISCUSSION

First, we calculate the packing density α of the paracrystallites in the macrolattice. From the two-dimensional analysis we obtained the meridional packing density (Table 1):

$$\alpha_3 = \frac{H}{a_3} = 0.40 \quad (4)$$

The packing density α_r in the equatorial plane can be calculated from the model from Figure 8b as the ratio of the ultrafibril cross-section $\pi(D/2)^2$ to the lattice cell area V_c . From the measured netplane distances d_a and d_b one obtains:

$$V_c = \frac{d_a d_b}{\left[1 - \left(\frac{d_a}{2d_b}\right)^2\right]^{1/2}} \quad (5)$$

The packing density then is given by:

$$\alpha = \alpha_3 \times \alpha_r = \frac{H}{a_3} \pi \frac{D^2}{2} \frac{\left[1 - \left(\frac{d_a}{2d_b}\right)^2\right]^{1/2}}{d_a d_b} \quad (6)$$

$$\alpha = 0.40 \times 0.81 = 0.32$$

Thus one can calculate the density of the amorphous phase. The density ρ_c of the 'crystalline phase', can be determined from the size of the molecular lattice cell ($\rho_c = 0.921 \text{ g/cm}^3$)¹⁰. The macroscopic density is $\bar{\rho} = 0.891 \text{ g/cm}^3$. Using the above calculated value of α for a two-phase model, one obtains a density for the amorphous parts: $\rho_a = 0.877 \text{ g/cm}^3$. This is larger than the density of atactic PP which is $\rho_a = 0.85 \text{ g/cm}^3$.

Figure 8 (a) Monoclinic reciprocal lattice cell in the equatorial plane with an angular fluctuation of at least 56° ; (b) idealized model of a monoclinic MPC of paracrystallites in a cross-section orthogonal to draw direction

Figure 9 A microphotometer trace orthogonal through the equator at $b_r = 1.25 \times 10^{-2} \text{ \AA}^{-1}$. The outer maxima (---) are generated by crossing the meridional reflection

The dimension of the *MPC* in the chain direction, can be calculated from the integral width of the continuous equatorial scattering in the fibre direction analysed at various b_r values parallel to the meridian up to $1.5 \times 10^{-2} \text{ \AA}^{-1}$ (Figure 9). We obtain $M \sim 420 \text{ \AA}$ after correction for the primary beam. This indicates that on average, four *mPC* scatter coherently in the fibre direction. This agrees very well with the bimodal character of the statistics of a_3 in lateral directions. According to Table 2 the probability is only 20%, that one finds the neighbouring paracrystal with $g'_{3r} = 0.11$, in the fibre direction. It therefore makes no sense to consider ultrafibrils in this stretched material.

Another interesting fact can be deduced for the superstructure in these polymers. For the lattices of *mPC* one finds a relation between g and the number N_{\max} of maximum possible netplanes¹¹:

$$N_{\max} = (\alpha^*/g)^2 \quad (7)$$

where α^* is in the order of 0.07–0.23, for all samples investigated, up to now. This relation was explained by the fact that in a *mPC*, the distance fluctuation between the first and N th netplanes is given by $\Delta_N = (N)^{1/2} \Delta_1$, where Δ_1 is the distance fluctuation between adjacent netplanes with the mean distance d and Δ_1/d , hence the g value. If Δ_N reaches a value α^*d , the lateral binding forces within one netplane are so distorted that this netplane breaks.

In the case of *MPC*, α^* can be much larger because the nature of the 'crystalline' layers of assemblies of *mPC* is quite different from the netplanes within one *mPC*. From $g_{33} = 0.25$ (Table 1) and $N_{\max} = M/a_3 = 4.2$, one obtains:

$$\alpha^* = 0.25 (4.2)^{1/2} = 0.51 \quad (8)$$

This agrees well with electron microscopic pictures of PP, where bundles of lamellae and *mPC* can be seen directly. Here, they are much larger than they can be with $\alpha^* = 0.2$. Thus one can deduce an interesting result from the interpretation of line profiles: According to equation (1), the line width of the first order reflection is proportional to $(\pi g)^2$. Introducing equation (7), it becomes proportional to $1/N(\pi \alpha^*)^2$, whilst the particle size effect is proportional to $1/N$. Both effects add to each other quadratically,

to a first approximation. For molecular lattices $(\pi \alpha^*)^4 \ll 1$, for macrolattices $(\pi \alpha^*)^4 > 1$. For this one finds that the width of the first order SAXS reflection according to equation (1) is largely determined by the paracrystalline distortion of the *MPC* and the first order WAXS reflection has a width largely determined by the particle size of the *mPC*.

Another point of interest is that the equatorial SAXS reflection appears only if a sheet is stretched. A stretched rod shows no such reflections. In both cases the material is deformed according to an affined transformation¹². In the necking zone, the three-dimensional network is deformed in such a way that micro-necks are generated¹³. This can be explained by the schematic drawing in Figure 10. Each microdomain consists of a series of *mPC*, which are plastically deformed, in the necking zone. This necking process is isotropic for a rod, but quite anisotropic for a sheet, because its thickness is diminished by a much smaller amount than the width of the sheet. It is of no surprise, that parallel to the sheets, where the *mPC* have to change their lateral positions greatly during affined transformation, micro-necks may remain between them as shown in Figure 8b.†

Another point of interest is that the cold stretched sheet of PP still remains transparent but shows a remarkable equatorial SAXS. In all other cases of stretched polymers either they can be transparent and have no equatorial SAXS or they can become opaque and exhibit an equatorial SAXS. This anomalous behaviour can be explained by electron density inhomogenities, which are small comparable to the wave length of light. A similar phenomenon was observed for PE prepared under controlled shear conditions from the melt¹⁴.

† This kind of deformation is called plane stress.

Figure 10 Necking process during stretching to the natural draw ratio. Before stretching the microdomains are schematically drawn by circles (above) with tie-molecules and transform affined into elongated domains (below). The three-dimensional network of tie-molecules is deformed within the neck which gives rise to micro-necks (MN)

ACKNOWLEDGEMENTS

The Deutsche Forschungsgemeinschaft kindly supported this work by a grant. We are grateful to Dr P. Bond for his careful review of the manuscript and to Miss Chr. Kunze for technical assistance.

(Received 3 July 1975)

This paper indicates that changes in chain mobility, heat capacity, WAXS crystallinity, SAXS long period, SAXS peak intensity, specific volume and morphology as a function of increasing temperature, occur in three fairly distinct annealing ranges (I, II and III) that are more or less the same for all crystallized polymers with a lamellar morphology. It is shown that none of the proposed molecular models to date, including the well-known fold surface premelting model, can satisfactorily account for all the experimental data. However, a new molecular interpretation, based primarily on electron microscopy and SAXS studies of changes such as lateral 'melting' from edges of microparacrystallites (*mPC*) within the lamellae seen at the annealing temperatures can account for the data. With our new molecular interpretation, the effect of temperature increase is established to result in a slight breakup of the laterally aligned *mPC* within the lamellae at low annealing temperatures in range I, and selective lateral 'melting' of the exposed *mPC* and recrystallization at higher annealing temperatures in ranges II and III, with the recrystallization being very limited in range III. Annealing effects seen in cold- or hot-drawn polymers with a fibrillar morphology can also be readily accounted for by this very general molecular mechanism occurring in the same annealing temperature ranges.

INTRODUCTION

The effects of annealing a semi-crystalline polymer with a lamellar morphology to near its melting point are fairly well known^{1-3,6}. Substantial changes can be detected in molecular mobility, morphology, physical and mechanical properties. These changes are not only important from a user's point of view, but also in determining optimum conditions under which solid state processing techniques can be applied to fabrication of polymer products. However, in spite of the numerous extensive studies on this very important and practical subject of annealing in the past 10-20 years, we are still not very clear about the underlying molecular mechanisms responsible for the various observed annealing effects. There have been several proposed molecular mechanisms, all apparently very different from one another², none of which is seen to be more satisfying in the explanation of annealing data than the other although all of them appear to have some degree of experimental justification.

One of the major difficulties in coming up with a better understanding of the annealing phenomena, is the dependency of observed changes on numerous factors such as annealing temperature, time and rate, prior thermal history and the physical state (drawn vs. undrawn or single crystal vs. bulk) of the sample, as well as its chemical structure and composition (molecular weight, degree of branching, etc.). These factors often contribute to a shifting and/or narrowing of the temperature ranges in which the changes may occur, to the degree of reversibility and to the magnitude of the observed changes which may lead to the various proposed molecular mechanisms. Another factor, which is less important but contributes to some degree of confusion,

lies in the choice of words in describing some of the changes occurring well below the melting point. For example, it was cautioned by Hoffman⁴ several years ago, that the word 'premelting' should be used with care in describing certain annealing phenomena allegedly associated with melting in polymers.

It is the purpose of this paper to show and discuss briefly, that most of the annealing changes occur in three more or less distinct temperature ranges, to examine more critically the three most popular proposed molecular mechanisms, to introduce and discuss the validity of some other annealing mechanisms based on direct morphological changes observed at the annealing temperature, and to see how they can be applied to the understanding of annealing phenomena which occur in cold or hot drawn systems.

Whenever possible, we shall discuss primarily the annealing changes measured on as-crystallized, well-equilibrated lamellar systems kept at the annealing temperatures. Discussions on measurements made on samples after quenching will be limited and pointed out in order to minimize sources of confusion. For the sake of clarity and brevity we shall restrict our present discussions to annealing phenomena which occur upon temperature increase. The many interesting effects which occur upon temperature decrease after annealing (at higher temperatures) will be discussed only for clarifying points raised.

SEPARATION OF ANNEALING CHANGES INTO THREE ANNEALING TEMPERATURE RANGES

As the annealing changes are very much dependent on a number of factors as pointed out in the introduction, it is difficult to make any precise separations of the changes

* Dedicated to Professor G. Manecke on the occasion of his 60th birthday

Figure 1 (a)–(d) are schematic drawings showing some well-known annealing effects in crystallized polymers upon heating to temperature ranges I, II and III. (a) n.m.r. line-width, LW (inversely proportional to molecular mobility) of the crystalline polymer component and specific heat, C_p ; (b) WAXS crystallinity, X , and SAXS long period, L ; (c) SAXS intensity, I ; (d) specific volume difference, ΔV

with annealing temperature. However, after examining numerous annealing data, we have come to the conclusion that there are certain distinct characteristics e.g. the magnitude of changes upon temperature increases or the degree of reversibility of changes upon temperature decrease, which allow us to assign the changes according to three annealing temperature ranges I, II and III.

Figures 1a–1d represent schematically the generally reported changes in chain mobility from n.m.r. linewidth (LW), specific heat (C_p), WAXS crystallinity (X), SAXS long period (L), SAXS intensity (I), and difference in specific volume (ΔV), and the three approximate temperature ranges in which the changes are observed to vary for most polymers when heated to near their melting points. The

lines (dotted) in Figures 1c and 1d are inserted to show the expected changes in SAXS intensity and specific volume, assuming no changes in the relative respective amounts of the two crystalline and non-crystalline components of the polymers, (see references 2 and 3).

The three approximate temperature ranges are: (I), from $\sim(T_m - 60)$ to $\sim(T_m - 30)$ (or to a temperature near the original crystallization temperature or to the first annealing temperature of a crystallized polymer); (II) from $\sim(T_m - 30)$ to $\sim(T_m - 10)$; and (III) from $\sim(T_m - 10)$ to $\sim T_m$ (the melting point). They are generally believed to be more or less the dividing temperature ranges in which the above mentioned annealing effects are characteristically seen to be changing in nearly all well-equilibrated, crystallized polymers with a lamellar morphology. For example, the range will be from $\sim 80^\circ$ to 110°C , $\sim 110^\circ$ to 130°C and $\sim 130^\circ$ to 140°C for polyethylene crystallized by slow cooling, and from $\sim -35^\circ$ to -5°C , $\sim -5^\circ$ to 15°C and $\sim 15^\circ$ to 25°C for natural rubber also when crystallized by slow cooling. The melting points are assumed to be 140°C and 25°C respectively for polyethylene and natural rubber crystallized under isotropic conditions.

In the annealing temperature range I as shown in Figures 1a–1d, practically no changes are observed in C_p , X or L while some small increases are already noticeable in degree of chain mobility as reflected in the decrease in LW from n.m.r. and in ΔV ; the specific volume increase¹ indicating an apparent decrease in volume crystallinity. There is also a noticeable increase in SAXS intensity over and above the expected increase due to the thermal expansions of the respective crystalline and amorphous components¹.

All the annealing effects including the morphological changes (to be discussed later) detected in range I, are generally found to be small and generally reversible with temperature, i.e. upon temperature decrease to the original starting temperature the changes disappear. This is quite different from the annealing phenomena seen in annealing temperature ranges II and III, where the degree of reversibility appears to be generally limited.

In annealing range II the higher temperatures generally bring about greater increases in the changes (LW , I and V_{sp}) started in range I. In addition, other very noticeable changes begin to show up in this temperature range, i.e. C_p and L (see Figures 1a and 1b). The crystallinity X as determined from WAXS, however, remains practically unaffected in this temperature range, after long annealing times. The effect of annealing time in this temperature range on X was first reported by Fischer and Schmidt on bulk and single crystals of polyethylene⁵. Their data showing a loss of WAXS peak intensities at early stages of annealing, indicated some type of melting, followed by some type of recrystallization, which resulted in the recovery of the WAXS peak intensities.

Similar interpretation of annealing time effects, noted above for WAXS peak intensity changes, has also often been made for density changes detected in bulk and single crystal samples of polyethylene after quenching to room temperature from annealing temperatures in range II. However, the interpretation of premelting and surface melting and recrystallization based on such density data alone, is less convincing than the X-ray results.

In annealing range III whatever partial (but real) melting process has started in range II, continues into the higher annealing temperature range. However, the 'recrystallization process', cannot be extended to too high a temperature because of the limited supercoolings (and therefore

smaller nucleation rate) at higher temperatures. Consequently, one can see in this temperature range, that there is a substantial change in molecular mobility as judged by the decrease seen in LW , increases in ΔV and L (due to recrystallization at smaller supercoolings), and decreases in WAXS crystallinity as well as SAXS intensity.

PRESENT STATUS CONCERNING UNDERLYING MOLECULAR MECHANISMS

The three most often cited molecular mechanisms to account for the annealing effects, in particular the lamellar thickness increase, are: A, refolding by 'solid state' diffusion; B, 'selective melting of thinner lamellae and recrystallization to thicker lamellae' and C, the fold surface 'premelting'. Their merits have been reviewed extensively by Fischer² and therefore will not be belaboured further here. Nevertheless, it is felt that a brief discussion of these three molecular models, in light of all the annealing effects cited above, is appropriate for any new concepts of annealing mechanisms to be introduced later.

'Solid state' diffusion

Refolding by a 'solid state' snaking type long chain diffusion process along the c -axis, was based mainly on the observation that the c -axis in thickened portions of polyethylene single crystals after annealing to 125°C, remains perpendicular to the lamellar surface when examined at room temperature⁶. As was originally proposed, this seemed a very probable process especially in the higher annealing temperature ranges, where molecular mobility may be sufficiently high and lattice sufficiently expanded, for such gliding movements. However, in light of the annealing time effects discussed earlier concerning WAXS intensity changes in annealing temperature range II for polyethylene single crystals or bulk polyethylene and the detectable changes in annealed morphology (to be discussed later), one questions the general validity and applicability, if one defines solid state diffusion as diffusion of atoms or molecular chain segments in a lattice which retains its 3-dimensional crystalline property. Some limited refolding by solid state diffusion, of course, can and probably does occur, e.g. in non-equilibrated systems, such as cold or hot drawn systems containing numerous highly stressed defective crystals. However, in such systems we may be dealing with numerous 'crystalline' regions, that can hardly be considered as solid to begin with and annealing of such systems even at temperatures below those in ranges II and III may lead to limited growth of crystallites by a pseudo-recrystallization process.

Selective melting of thinner lamellae

Since the lamellae in crystallized polymers generally consist of a distribution of thicknesses, the proposal that thinner lamellae melt first (and therefore selectively), within a stack of lamellae appears to be a reasonable one and is still considered by many, including Hoffman and Kilian⁴, together with some degree of recrystallization, to be the most reasonable explanation for the observed long period increase. Fischer's objection to this model centres entirely around the disagreement between experimental SAXS peak intensity measurements (see *Figure 1c*) and theoretically predicted values which should show a decrease rather than the observed increase, if melting of lamellae occurs selectively in a stack of lamellae that can scatter X-ray coherently. Al-

though this is a reasonable objection which will be amplified further later there is some indication that a modified form of selective melting, also to be discussed in later, may indeed be occurring in annealing temperature range III.

Fold surface 'premelting'

This model indicates that starting at some temperature, the fold surfaces 'premelting' gradually inwards towards the crystalline core along the chain axis, until the whole lamellar crystal is melted at the T_m . This premelting model appears to be able to account for nearly all the experimental evidences of annealing effects, in particular the evidence concerning the SAXS integrated and peak intensity increase with annealing temperatures as has been found in a number of polymeric systems⁵. However, even if it is a correct model, as was pointed out earlier by Luch and Yeh⁹, it can be applied to lamellar systems with only very little increase in lamellar thickness upon annealing, since the melting of fold surface does not directly lead to large increases in amorphous thicknesses, as have been observed in a number of cases in annealing temperature ranges II and III. Furthermore, for the model to apply, the polymers must have initial crystallinities of greater than 50%; otherwise, a predicted decrease in SAXS peak or integrated intensity will result. However, Luch and Yeh⁷ studied natural rubber which has a maximum crystallinity of well below 50% and showed the same kind of SAXS peak intensity changes (*Figure 1c*) with an initial increase followed by a decrease at annealing temperatures close to T_m .

It should be mentioned that the difficulty with the surface premelting model to explain large changes in lamellar thicknesses (in regions II and III), was not encountered when the model was originally conceived and applied⁸ to explain the SAXS intensity changes for polyethylene single crystals in annealing temperature range I where there is hardly any change in long period (*Figure 1b*). Therefore, it will be of interest in this respect to re-examine the experimental evidence that has led to the surface premelting model. The evidence is in the SAXS intensity change (*Figure 1c*). Nukushina, Itoh and Fischer⁸ using PE single crystal mats and Schultz, Robinson and Pound⁹ using bulk PE have noted reversible peak intensity changes up to four-fold with hardly any changes in long period L . Since this intensity increase was found to be much greater than could be accounted for by density changes owing to thermal coefficients of expansion of the two respective phases, (see lines (dotted) in *Figures 1c* and *1d*) it was, albeit incorrectly, suggested that the increase must be due to increase in the amorphous thickness (or in the decrease of volume fraction of crystals) and, therefore, melting from the lamellar fold surface inward at the expense of the crystalline core.

MOLECULAR MECHANISM(S) BASED ON MORPHOLOGICAL OBSERVATIONS

The above discussions, although brief, clearly indicate a degree of inadequacy existing in all the three proposed models, including surface 'premelting', to account for the various phenomena that appeared during annealing.

In addition to the shortcomings mentioned earlier, the premelting and the surface melting models, seldom discuss specifically whether and how a recrystallization process follows the 'melting' process in either range II or III. If a recrystallization process takes place, i.e. one to increase the crystal thickness of the remaining, unmelted lamellae

(or the unmelted crystalline cores in the case of Fischer's fold surface premelting model), one wonders how this crystal thickness increase comes about without greatly disturbing the crystalline lattice of the remaining, unmelted lamellae in a stack of well-packed lamellae. Any substantial disturbance will lead to melting of the whole stack of lamellae. Otherwise, one has to suggest some kind of 'solid state' diffusion process by which the molecules from the melt regions can participate in the thickening process of the previously unmelted crystalline core of the lamellae.

It seems that on the one hand we need to propose some sort of melting, albeit of a limited extent, to explain most of the observed phenomena; while on the other hand we seem to need also, some sort of 'solid state' diffusion process to explain how the crystal thickness increase takes place. As will be shown below, these problems quickly disappear when one finds that the suggested 'premelting' in annealing temperature range I, and the suggested partial melting/recrystallization process and the 'solid state' diffusion process in annealing temperature ranges II and III, may all appear to have taken place. Even though the underlying molecular mechanism(s) which gives rise to the annealing changes seen in ranges I, II and III, may be quite different from the proposed models.

The underlying molecular mechanism(s) to be discussed below is primarily based on direct observations of morphological changes in polymers annealed at the temperature. The starting polymer has the well-known lamellar texture, which is typical of well-equilibrated, well-crystallized systems, in either the oriented or unoriented state. Another point to be made here is that the basic crystalline units in crystallized polymers are not the lamellae, as had been gradually assumed over the years, but rather the smaller micro-paracrystallites (*mPC*) or nodules within the lamellae. This has been established independently by Hosemann¹⁰ using X-ray scattering techniques and Yeh using direct morphological observations¹¹. It is particularly useful to keep this fact in mind when one tries to evaluate the generality of the observations and the molecular mechanisms discussed below.

Direct morphological studies of unoriented polymers or single crystals after annealing in temperature range I and examined at room temperature, do not generally reveal any detectable changes. This can be due to a number of reasons, e.g. the problem with detecting changes from unoriented specimens or single crystals when examined from vertical positions perpendicular to the lamellar surface, or with recovered morphological changes when examined at room temperature, or with the degree of resolution due to proper examining techniques and specimen preparations, etc.

In our earlier studies^{12,13} of strain-crystallized natural rubber (*cis*-polyisoprene) and gutta percha (*trans*-polyisoprene), we were able to detect definite changes in morphology at the annealing temperature in range I by means of OsO₄ staining technique and examining the edges of stacks of well-oriented lamellae in a direction *perpendicular* to the *c*-axis. An example of the changes is reproduced here in *Figure 2b* for natural rubber when annealed to -15°C (in the annealing temperature range I) and OsO₄ stained at the annealing temperature. It shows a slight, but noticeable 'breakup' of the well-formed lamellae originally present in the sample (*Figure 2a*) into blocks of about 100 Å lateral size as deduced by the attained 'amorphous' boundaries in between the *mPC*. *Figures 3b* and *3c* show schematic representations of the *mPC* originally present within the lamellae and after their 'breakup'. We suggest

that the 'amorphous' boundaries arise from an increase in localized intrachain defects at the *mPC* grain boundaries upon reaching annealing temperature in range I. They could very well contribute to the α_1 type of molecular motions as detected and assigned by Takayanagi to be occurring within the mosaic block grain boundaries of polyethylene single crystals¹⁴ in the same annealing temperature range I. Since intrachain defects involve a contraction of chain segments at the mosaic crystal grain boundaries, the contraction will create vacancies at the lamellar fold surface. They contribute to a greater lowering of the density in the interfacial region, inbetween the crystalline lamellae than that of the crystalline lamellar cores, thereby leading to a larger difference in density ($\rho_c - \rho_a$ or $\Delta\rho$) between the two phases. Therefore over and above the values based on changes due only to thermal coefficients of expansion there exists an extra ΔV increase (*Figure 1d*). The SAXS intensity increase in this temperature range I (*Figure 1c*) is then the direct result of vacancies created at the fold surface boundary since intensity is proportional to $(\Delta\rho)^2$, somewhat similar to the origin of substantial SAXS intensity increase observed for *n*-paraffins upon annealing¹⁵.

This type of morphological change was observed to be reversible with temperature, i.e. upon cooling the lamellae were found to be coherent again, as long as the annealing temperature stays inside range I, which also explains why the changes in SAXS intensity and specific volume are also found to be reversible with temperature. Therefore, it is not necessary to have a surface 'premelting' type of molecular mechanism to explain either the SAXS intensity increase or its reversibility with temperature. Furthermore, one would not expect this kind of intrachain defect to cause any significant change in molecular mobility, specific heat, crystallinity or long period, as, indeed, is generally found to be the case (*Figures 1a* and *1b*).

Upon entering annealing temperature range II, an entirely different morphology arises. First, there is clear indication from direct observations^{12,13} that whole or parts of *mPC* or nodular crystallites melt *within* the lamellae. This is again deduced from careful examinations of stacks of well-oriented lamellae of natural rubber and *trans*-polyisoprene annealed and OsO₄ stained at the annealing temperatures. When held at the annealing temperatures for a sufficient length of time, the true melting process within the lamellae is followed by a recrystallization process, resulting in more stable, thicker (along the *c*-axis) *mPC* which then repack and realign with one another to form apparently smooth and filled* lamellae, at long annealing times. The lamellae now have thicker crystalline as well as thicker amorphous regions, as for example, shown in *Figure 4* for *trans*-polyisoprene. The relatively constant WAXS crystallinity (*Figure 1b*) can now be explained by nearly the same percentage increase of the crystal (l_c) and the amorphous (l_a) thicknesses. In an ideal two phase lamellar structure, the WAXS crystallinity should be the same as the linear crystallinity $l_c/(l_a + l_c)$ directly measured from the electron micrographs, if the lamellae are present throughout the volume as recently demonstrated by Yeh¹⁶. The true melting process (which continues in range III) also causes substantial molecular motion and increase in specific heat (*Figure 1a*), while the increase in SAXS long period is due

* Polyethylene single crystals when annealed to this temperature range, often showed holes within single lamellae after annealing and cooling to room temperature⁶. This is due to unavailability of neighbouring crystallites, above or below the lamella, for space filling.

Figure 2 (a) Typical bundles of 'lamellae', seen edgewise in strain-crystallized natural rubber after OsO₄ staining at -28°C¹²; (b) Individual *mPC* seen within lamellae after annealing and OsO₄ staining at -15°C in range I¹²

to an increase in both l_a and l_c (Figure 4). If the melting involves melting of smaller or thinner *mPC* within the lamellae, as we believe it does, then a slightly modified selective *mPC*, rather than lamellar, melting model will apply very well here. This will be shown later. Nevertheless, one can safely eliminate the fold surface 'premelting' model involving longitudinal melting from the lamellar fold

surface inward, or the selective melting of the thinner lamellae within a stack of lamellae, since neither are observed^{12,13}. The basis for the objection to the fold surface premelting model in annealing temperature ranges II (and III) is therefore quite different from that in range I, where no substantial 'premelting' of the lamellae (either laterally or longitudinally) is observed.

Figure 3 Structure of the *mPC* in the three temperature ranges. Schematically 10 columns of *mPC* extend over the whole picture. The numbers at the bottom give the number of *mPC* along the vertical direction. (a) Below range I in non-equilibrated drawn systems; the *mPC* are nematic-like; some of them can be very thin (circled). (b) Beginning of range I. The *mPC* are laterally aligned to form a smectic-like layer structure (originally present in well-equilibrated lamellae systems). Thin *mPC* are partially melted upon reaching range I in non-equilibrated drawn systems. (c) In range I the chain segments in lateral boundaries of *mPC* have higher mobilities, will begin to melt and contract to produce vacancies at the fold surface and unprotected lateral boundaries (circled). (d) In range II lateral melting of *mPC* may start at the unprotected lateral boundaries with simultaneous recrystallization to thicker *mPC*, resulting in the increase of long period. (e) At end of range II, after long annealing times, most of the melted regions have recrystallized epitaxially onto the more stable thicker *mPC*, which are now realigned to form smoother lamellae. (Only a few regions may still remain molten). (f) In range III, only thicker *mPC* can resist the melting process, while many other regions remain molten. The volume fraction γ of bundles and hence l , the crystallinity X and n.m.r. line-width LW decrease drastically; whereas the long period L may still keep on increasing

In annealing range III, the partial melting process of *mPC* which started in region II occurs with a much greater intensity at higher temperatures. However, the recrystallization process cannot be expected to extend to too high a temperature, since nucleation rate is a strong function of supercooling. Consequently, some of the melted regions remain selectively and permanently molten, contributing to substantial increases in molecular mobility (as judged by a substantial decrease in LW) and specific volume, and decreases in WAXS crystallinity, while other molten regions may still recrystallize into lamellae of greater thicknesses and therefore larger SAXS long periods consisting of substantially greater crystalline and amorphous thicknesses (Figure 4). An example is given in Figure 5 showing the presence of permanently molten regions as well as shorter segments of lamellae. A similar possibility of permanent melting and thickening of portions of lamellae, is seen from recrystallized morphology of polyethylene single crystals, observed at room temperature after annealing to higher temperatures in region III¹. The deduction of permanent melting in polyethylene single crystals occurring at the

annealing temperature was based on the observed disoriented fibrillar crystallites present within the lamellae at room temperature.

The permanently melted regions directly detected in Figure 5 can also explain the much lower volume crystallinity measured at annealing temperatures in region III, as reported earlier by Fatou and Mandelkern¹⁷ for polyethylene of various molecular weights.

Melting and recrystallization process

We believe that the melting starts at the grain boundaries between the *mPC* where the intrachain defects have become substantially increased upon heating to annealing temperature range I (Figure 3c). Because of their small size ($\sim 100 \times 100 \times 100 \text{ \AA}^3$), the much weakened exposed boundaries can be sources of instability and initial melting (Figure 3d). Eventually the melted region can recrystallize epitaxially onto the more stable, thicker *mPC* which had remained unmelted, with a greater lamellar thickness corresponding to a particular smaller supercooling (Figure 3e). The new crystals will have the same *c*-axis orientation as the old crystals upon which the new crystallites have nucleated. One can easily show that the melting and recrystallization can lead to a substantial reduction in total surface free energy. For example, an increase in lamellar thickness to 120 \AA from a 100 \AA thick cube, will result in a reduction in total surface free energy of about 12% owing to reduction of high energy fold surface area from $100 \times 100 \text{ \AA}^2$ to about $91 \times 91 \text{ \AA}^2$, assuming a reported¹⁸ end fold surface

Figure 4 E.m. long period, L , plotted against annealing temperature for a strain-crystallized *trans*-polyisoprene¹³ (---). Variation in crystal thickness, l_c , (---) and variation in amorphous thickness, l_a (—)

Figure 5 Typical bundles of lamellae seen edgewise in strain-crystallized *trans*-polyisoprene after annealing and OsO_4 staining at 70°C in range III¹³

free energy of about 80 ergs/cm^2 and a reasonable lateral side surface free energy of about 10 ergs/cm^2 . The new *mPC* can further reduce their total surface free energy through lateral alignment to form new lamellae consisting of some old and some new *mPC*.

Figures 3c and 3d schematically give an example of this melting and recrystallization process. Along columns 2, 3, 4 and 7 six *mPC* with unprotected lateral surfaces show up (circled) in Figure 3c upon annealing to range I. (Prior to reaching temperature I, the lamellae have the smooth fold surface as shown in Figure 3b.) Upon reaching temperature range II (Figure 3d), the *mPC* (circled) become molten in either column 2, 3, 4 or 7. Therefore the number of long periods in these columns has decreased in range II; column 3, 4 or 7 by one and column 2 by 3, from 7 to 4. The average number of long periods in the 10 columns has diminished from 70/10 or 7.0 in Figure 3c to 64/10 or 6.4 in Figure 3d. The average long period is therefore 9% larger in Figure 3d than in Figure 3c. Lateral alignment of the new and old *mPC* in further reduction of total surface free energy, is shown in Figures 3e and 3f.

With the type of lateral melting of *mPC* similar to the lateral melting proposed by Hosemann in 1962¹⁹, recrystallization and repacking, one can readily explain how the formation of new lamellae comes about, without resorting to nearly complete melting, as well as all the other annealing effects observed in annealing ranges II and III, including SAXS intensity and substantial long period increases, while the X-ray crystallinity remains relatively constant at long annealing times (Figure 1). Unlike the cause of SAXS intensity change in annealing range I which is due to greater differences of densities caused mainly by the vacancies introduced at the fold surface, the increase in SAXS peak intensity in annealing temperature ranges II and III, is

caused primarily by increases of the thickness of lamellae (due to increases in l_d and l_c) which is not discussed in the various idealized two-phase lamellar models in an earlier section. This process continues into annealing temperature range III. However, because of the limited driving force at higher temperature (smaller supercooling) substantial permanent melting will set in and lead to a reduction of the number of bundles (Figure 5), resulting in a substantial loss of crystallinity X and in the observed drop of SAXS intensity (Figures 1b and 1c). The following formulae give the quantitative expressions.

Peak intensity of SAXS

The formulae of SAXS for an idealized lamellar two-phase model, do not take into account the lateral boundaries existing between the adjacent *mPC* within a given lamella. Therefore they cannot adequately describe the changes in peak intensity I_p for many of the observed structures that may differ appreciably from an ideal lamellar two-phase model. However, it can be shown (see below), that with a slight modification of the basic formulae from the paracrystalline theory¹⁹ the changes in peak intensity for an oriented polymer can be readily accounted for by the changes in structure as a function of temperature. For example it has been demonstrated that a two-dimensional analysis of the SAXS of oriented samples can also give information about the shape of the *mPC* and their mutual positions²⁰⁻²², but this generally requires the use of a pin-hole-camera. But even with the use of a camera with a slit orthogonal to the fibre axis some information can still be obtained of the two phases whether or not unbounded lamellae exist.

Let $f(b)$ be the scattering amplitude of one *mPC* and $Z(b)$ the macroparacrystalline (*MPC*) lattice factor of an

unbounded assembly of *mPC* (if they are all pointlike). If $|S^2(b)|$ is the shape factor of the volume of a bounded assembly of *mPC*, the SAXS is given by:

$$I(b) = n[\bar{f}^2(b) - \bar{f}^{-2}(b)] + \frac{1}{v} \bar{f}^{-2}(b) \widehat{Z(b)} |S^2(b)| \quad (1)$$

n is the number of *mPC* in the assembly, which occupies the volume V and $v = V/n$ that of one *mPC*.

In the case of polymers having a lamellar structure there exist M bundles, each containing N lamellae in the average. If b_3 is the axis of one of these bundles in the reciprocal space, then $Z_3(b)$ is the intensity function of the centres of lamellae of an unbounded bundle:

$$Z_3(b) = R \exp \frac{1 + F_3(b)}{1 - F_3(b)}; F_3(b) = \mathcal{F}H_3(x) \quad (2)$$

$H_3(x)$ is the frequency distribution of a vector x between the centres of gravity of adjacent lamellae and $\mathcal{F} = [\int \exp - (2\pi i b x) dx]$ the symbol of Fourier-transform. The vector x expands the physical and b the reciprocal space. If l_c is the mean thickness of the lamellar crystalline cores and l_a that of the amorphous interlayer, the intensity of one bundle along the b_3 -axis of the reciprocal b -space is proportional to equation (1) with:

$$b \rightarrow b_3; v \rightarrow l_c + l_a; \widehat{Z(b)} |S^2(b)| \rightarrow \widehat{Z_3(b_3)} |S_3^2(b_3)|; \quad (3)$$

$$f(b) \rightarrow f_3(b_3) = \frac{\sin \pi l_c b_3}{\pi b_3}.$$

$f_3(b_3)$ is proportional to the scattering amplitude of one lamellae which consists of many *mPC* packed next to each other in the lateral direction. The symbol $\widehat{}$ stands for a convolution product. In equation (1) there is a three-dimensional convolution product of the three-dimensionally defined function Z and $|S^2|$; in equation (3) there is a one-dimensional convolution product of the one-dimensionally defined function Z_3 and $|S_3^2|$.

If all the lamellae are cylindrical discs with a diameter D and if $\Delta\rho$ is the electron density difference between the 'crystalline' and the 'amorphous' phase of a lamella one obtains for the integral intensity of the SAXS along a line, at a constant distance b_3 , parallel to the equator:

$$I(b_3) = \iint I(b_1, b_2, b_3) db_1 db_2 = (\Delta\rho)^2 \frac{\pi D^2}{4} \left(\frac{\sin \pi l_c b_3}{\pi b_3} \right)^2 \times \frac{1}{l_c + l_a} \widehat{Z_3} |S_3^2|. \quad (4)$$

For convenience the first term of equation (1) is neglected here, because it does not affect the final results very much²¹. The application of the paracrystalline theory to the macro-paracrystalline lattice of the lamellae will now be introduced. (It should be pointed out here that the exact one-dimensional solution of Hermans²³, often used by Tsvankin et al.²⁴ in avoiding statistical overlapping of adjacent lamellae cannot be generalized to a three-dimensional bundle of lamellae²⁵.)

Equation (2) shows that Z_3 has its first peak at $b_3 = 1/(l_a + l_c)$ with a maximum value:

$$Z_{3 \max} = \frac{1 + |F_3(b_{3m})|}{1 - |F_3(b_{3m})|}; b_{3m} = (l_c + l_a)^{-1} \quad (5)$$

Z_3 has an integral width δb_Z given by²⁵:

$$\delta b_Z = \frac{1}{2(l_c + l_a)} (1 - |F_3(b_{3m})|) \quad (6)$$

$|S_3^2|$ on the other hand has an integral width given by:

$$\delta b_s = \frac{1}{(l_a + l_c)N} \quad (7)$$

The peak intensity depends on the relative contributions of these two quantities and has extreme values as follows:

$$\frac{1}{l_a + l_c} \widehat{Z_3} |S_3^2| = \begin{cases} N^2 & \text{if } \delta b_Z < \delta b_s \\ NZ_3(b_{3m}) & \text{if } \delta b_Z > \delta b_s \end{cases} \quad (8a)$$

$$(8b)$$

Since the modulus of $F_3(b)$ in equation (5) can be approximated as:

$$|F_3(b_3)| \sim \exp(-2\pi^2 g^2 h^2) \quad (9)$$

where $g^2 = \frac{(l_c + l_a)^2}{(l_c + l_a)^2} - 1$; $h = b_3/(l_c + l_a)$

introducing this into equation (6) one obtains for the integral width of the first peak at $h = 1$ of Z_3 :

$$\delta b_Z = \pi^2 g^2 / (l_a + l_c) \quad (10)$$

g generally lies in the order of $\sim 20\%$ from a two-dimensional SAXS analysis of high oriented polymers²⁰⁻²². The product, $(l_a + l_c)\delta b_Z$, is therefore in the order of 0.4. From electron microscopy^{12,13} the number of lamellae in one bundle is generally found to be larger than 10. Therefore $\delta b_Z \gg \delta b_s$ and in all these cases equation (8b) should hold.

Now, to obtain the peak intensity $\iint I db_2 db_3$ of the bundle one must subtract the background of the SAXS. Part of the background is given by the first term of equation (1). The rest comes from $Z_3(b)$ and is given by:

$$Z_{3 \min} \cong \frac{1 - |F_3(b_{3m})|}{1 + |F_3(b_{3m})|} \quad (11)$$

The difference between equations (5) and (9) then gives the contribution of Z_3 to the peak intensity of the bundle:

$$Z_{3p} = \frac{4|F_3(b_{3m})|}{1 - |F_3(b_{3m})|^2} \quad (12)$$

The peak intensity of the first meridian reflection of an oriented sample in a microdensitometer with a slit parallel to the equator is therefore given by equation (4). If one introduces equations (8b) and (12) the result is:

$$\bar{I}_p = (\Delta\rho)^2 \frac{\pi D^2}{4} \left(\frac{\sin \pi l_c b_{3m}}{\pi b_{3m}} \right)^2 NZ_{3p} \quad (13)$$

Its position is approximately given in most cases by $h = 0.9$ since the peak of $Z_3(b_3)$ at $h = 1$ is multiplied with $\sin \pi l_c b_{3m} / \pi b_{3m}$, which in most cases decreases drastically with increasing b_3 in the region of this peak²². $|F_3(b_{3m})|$ is, according to the above mentioned value of g ($\sim 20\%$), in

Figure 6 Density, ρ , of hot-drawn polyethylene (linear polyethylene LUPOLEN 6001H stretched) plotted against the reciprocal of long period for various annealing temperatures ($^{\circ}\text{C}$): A, 129; B, 126; C, 120; D, 110; E, 100; F, 95 and times²⁷ in the three temperature ranges and the respective SAXS pattern. P (long period) reaches a finite value after some days according to Figure 3b and grows unbounded in range III according to Figure 3f. Stretching temperature T_1 , 80°C , draw ratio 9.6x

the order of $1/2$, hence $4F_3(b_{3m})/1 - |F_3(b_{3m})|^2$ is in the order of 3.

If V is the irradiated volume of the sample, M the number of bundles and γ the volume fraction of bundles, then the volume occupied by the bundles is given by:

$$\gamma V = MN(l_a + l_c)\pi D^2/4 \quad (14)$$

Introducing this in equation (13) we finally obtain for the SAXS peak intensity:

$$\bar{I}_p = (\Delta\rho)^2 \gamma V \left(\frac{\sin\pi l_c b_{3m}}{\pi b_{3m}} \right)^2 \frac{l_c + l_a}{\pi} Z_{3p} \quad (15)$$

Equation (15) shows that \bar{I}_p is proportional to the square of the electron density difference (as seen in annealing range I), to the volume fraction of bundles (as seen in range III) and to Z_{3p} as defined by equation (12), or in the order of 3. At a given long period ($l_a + l_c$) it has a maximum for $l_a = l_c$, which is well-known. The next interesting result is the proportionality to $(l_a + l_c)$. Even if the volume fraction γ , l_a/l_c , g and $\Delta\rho$ are constant, \bar{I}_p increases if the thickness of the lamellae ($l_a + l_c$) increases uniformly as in annealing range II.

APPLICATION TO ANNEALING EFFECTS OBSERVED IN DRAWN SYSTEMS

In the case of cold or hot drawn systems, the lamellar morphology is often replaced by a typical fibrillar morphology at sufficiently high extensions (Figure 3a). When the highly drawn fibrillar systems is annealed in the different temperature ranges I, II and III and studied by means of electron microscopy (e.m.) at room temperatures²⁶, results suggest little or no morphological changes taking place at the annealing temperature in range I, but that a transformation from a fibrillar to a lamellar morphology must have taken place starting at some temperature in annealing temperature range I (Figure 3b). The generally accepted ex-

planation is that at high enough temperature additional molecular mobility allows the lateral alignment of crystallites in neighbouring fibrils as well as the additional growth of lamellar thickness by means of a solid state refolding process.

However, additional information can be obtained about the transformation process from two-dimensional analysis of SAXS patterns obtained at room temperatures of such systems after annealing at various temperatures for various times. Since the details of the SAXS studies have already been reported elsewhere²⁷, it is our purpose here to show how the annealing mechanisms described earlier can also be of direct application to the understanding of the annealing effects detected in such non-equilibrated drawn systems that are often encountered during normal fibre or film processings or any future applications of solid state forming processes.

Figure 6 shows a plot of density vs. the inverse of SAXS long period for an annealed hot drawn polyethylene. Both the density and the long period were measured at room temperature after quenching from the various annealing temperatures at the end of various annealing times. There are various interesting characteristics to the curves. When annealed to temperatures below 110°C (which we shall refer to as range I'), the observed changes are quite different from those seen after annealing between $\sim 110^{\circ}\text{C}$ and $\sim 130^{\circ}\text{C}$ (range II'). In range I, after 10^2 min, the SAXS long period stays nearly constant while ρ increases and finally reaches a limiting value. The voids originally present between the microfibrils as a result of the stretching process are now partially removed after the annealing step, which contributes to the observed increase in density to a limiting value. The limited mobility of the chain segments in range I (Figure 1a) explains the limited increase of long period as well as the lack of lateral alignment of mPC in neighbouring fibrils, from information provided by the SAXS patterns, which showed an mPC packing to be nearly the same as the one depicted in Figure 3b.

In range II', both the long period and density increase with time except for a small plateau, where density stays nearly constant and only long period increases. The extent of this plateau becomes shorter, but it takes place earlier with increasing annealing temperature. Two-dimensional analysis of the SAXS patterns indicates that in temperature range II', the morphology begins to change with annealing time going from a fibrillar to a lamellar structure. This is in complete agreement with similar electron microscopy studies²⁶, which not only showed the transformation but that it takes less and less time with increasing temperature after annealing between 110° and 130°C . The results from density measurements and SAXS and e.m. studies indicate that the fibrillar-to-lamellar morphological transformation can take place by a similar melting of the exposed small mPC (Figures 3a, 3c and 3d), and recrystallization process described earlier. However, because the recrystallization on crystallization from an oriented melt occurs at a much faster rate than recrystallization from an unoriented melt, the solidification process is most likely to have been completed within the annealing times or during quenching to room temperatures after annealing. This explains the differences seen in density changes with time for unoriented and oriented systems; the density for oriented systems generally increases with time whereas for unoriented systems it may show a drop initially before it proceeds to increase with time⁵. We suggest that if the density for our annealed oriented systems is measured fast enough at the

annealing temperature, we should be able to detect a decrease due to initial melting.

Phosphonitrilic chloride: 33. Cyclomatrixphosphazene polymers formed from hexachlorocyclotriphosphazene and metal acetates

M. Kajiwara and H. Saito

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

(Received 18 November 1975)

Cross-linked polymers of the metaphosphomic type structure were prepared by the reaction of hexachlorocyclotriphosphazene with various divalent metal acetates in aqueous solution at 30°C. The poorly crystalline insoluble products swell in water and most organic solvents. The product containing barium was the most stable toward heat. The products were easily decomposed by dilute hydrogen chloride at 80°C.

INTRODUCTION

This paper describes cyclomatrixphosphazene polymers formed from the reaction of hexachlorocyclotriphosphazene (NPCl₂)₃ with metal acetates (CH₃COO)₂M in aqueous solution.

EXPERIMENTAL

Hexachlorocyclotriphosphazene, (NPCl₂)₃, was prepared by the modified method of Kajiwara¹. The pure trimer was obtained by repeated fractional recrystallization from light petroleum ether.

The reaction of (NPCl₂)₃ (3.4 g, 0.01 mol) of 28 mesh grain size added to a 200 ml aqueous solution containing

0.09 mol metal acetates, was carried out at 30°C with vigorous stirring. The extent of the reaction was measured by the amount of metal chloride formed. The reaction mixture was filtered, and the residue extracted with petroleum ether, acetone and after washing with water, was dried in air at 105°C for 24 h. Metal salts used were calcium, magnesium, barium, zinc, lead, nickel, cobalt, copper and tin acetate, respectively.

The infra-red spectra were recorded on a Shimadzu Model-450 type spectrometer in the region of 4000 cm⁻¹ to 200 cm⁻¹ using the pressed KBr disc technique. X-ray diffraction photographs were measured using a Shimadzu Co. VDF-1 type instrument and powder diffraction method. The thermal analysis was recorded on a Shimadzu Model-20B in air at 5°C/min.

Table 1 Yield of the products and the variations of pH in aqueous solution

(NPCl ₂) ₃ (g)	(CH ₃ COO) ₂ M		pH		Yield (g)	Appearance

Figure 1 Amount of formed chlorine as a function of the reaction time. A, Mg; B, Ba; C, Ca; D, Zn; E, Ni; F, Co; G, Pb; H, Cu

RESULTS AND DISCUSSION

The reaction rate determined by the amount of metal chloride is shown in Figure 1.

The yield of the products and pH values of the reaction solution are summarized in Table 1. The acidity is due to HCl formed. Water soluble products were formed with cobalt or nickel acetates. The insoluble products which were highly crosslinked, swell in water, benzene and other organic solvents.

X-ray diffraction analysis showed that the products formed from barium, zinc and copper acetates gave well defined diffraction lines but showed no polarization under the polarizing microscope owing to poor lattice fit.

Infra-red absorption spectra of the products showed the NH frequency in the region of 3200 cm⁻¹ and P-N fre-

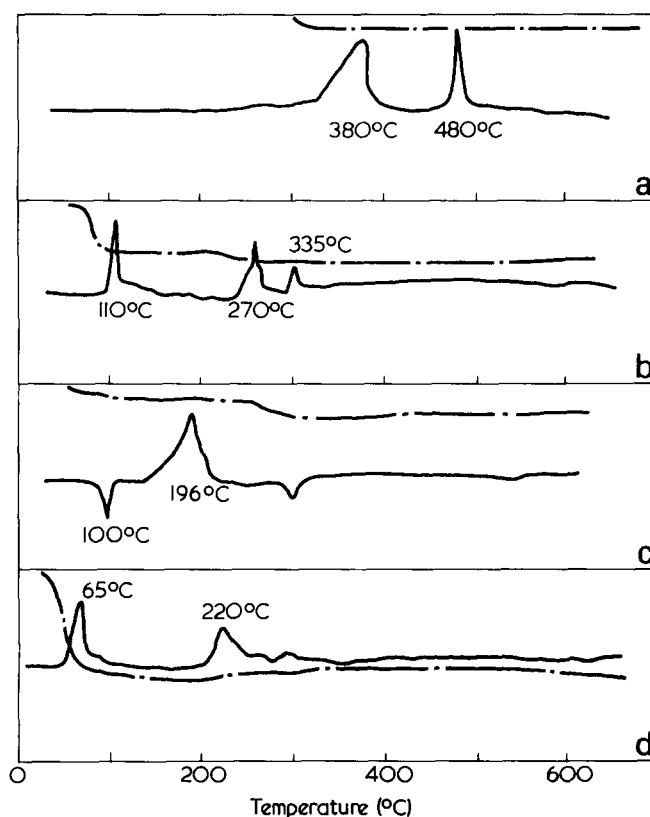

Figure 2 Thermal gravimetric (---) and differential thermal analysis (—) of the products formed by reaction between dichlorocyclophosphazene and metal acetate. (a), Ba; (b), Ca; (c), Cu; (d), Mg

quency in the region of 1200 cm⁻¹ and 1050 cm⁻¹, respectively.

Chemical analyses (Table 2) were in fair agreement with the calculated values for the metaphosphomic structure shown below.

Thermal decomposition temperatures as measured by differential thermal analysis and thermogravimetric analysis (Figure 2) show that the barium acetate product is very stable to heating. The products formed by heating were shown by gas chromatography to contain NH₃, H₂O or a trace of CH₃COOH. Ammonium and phosphate ions were detected as the products treated with dilute hydrogen chloride at 80°C for a few minutes.

New photoinitiating systems and photoactive polymers and their applications*

C. H. Bamford

Department of Inorganic, Physical and Industrial Chemistry, University of Liverpool, Liverpool, L69 3BX, UK

(Received 30 October 1975)

Two new types of photoinitiating systems based on transition metal carbonyls [mainly $\text{Mn}_2(\text{CO})_{10}$ and $\text{Re}_2(\text{CO})_{10}$] and free from abstractable halogen atoms are described. The first consists of a low concentration (typically $\sim 0.1 \text{ mol l}^{-1}$) of a fluoro-olefin, together with the metal carbonyl. Quantum yield data for photoinitiation by a number of these systems are presented; $\text{Re}_2(\text{CO})_{10}$ is generally more active than $\text{Mn}_2(\text{CO})_{10}$ and quantum yields near unity are obtainable. Polymers prepared with the aid of these initiators carry terminal groups in which the metal atom is covalently bound to the polymer chain through a fluoro-olefin unit. In the second type no halogen is present. The additive employed with the metal carbonyl is (a) acetylene or an acetylene derivative (e.g. acetylene dicarboxylic acid); or (b) an olefinic derivative carrying electron-attracting groups (e.g. diethyl fumarate). Mechanistically these photoinitiators resemble those based on fluoro-olefins; high quantum yields of initiation may be obtained and terminal groups containing covalently bound metal atoms are present in the polymers. Polymers prepared with either type of photoinitiator behave as macromolecular thermal initiators at higher temperatures (e.g. 100°C) and furnish a convenient route to block copolymers. A third type of photoinitiator, based on a vanadium (V) chelate, is also discussed. Chelates such as $\text{V}^{\text{V}}\text{OQ}_2$ or, where Q represents 8-quinolyloxo, have been shown to photolyse by scission of (OR)'. If R is a side chain attached to a polymer molecule, photolysis yields a macroradical capable of initiating grafting reactions. The behaviour and applications of these photoactive polymers are described.

INTRODUCTION

The photochemistry and photophysics of systems based on monomers and/or polymers currently attract much attention. In this lecture we shall be concerned mainly with photochemistry, but we may note that photophysical studies provide information about a number of processes of interest to the chemist, such as the migration of energy along polymer chains and the effects of polymer chain conformation on interactions of electronically excited chromophores with ground state species¹.

Interest in the photochemistry of these systems stems from a number of origins. A study of photoinitiation yields data about the nature and reactivities of intermediates and the mechanism of polymerization. Of great importance are the many practical applications of photoactive polymer-based systems, for example, in image and data storage and retrieval, and in the manufacture of printing plates and printed circuits. Increasing environmental pressures demand the development of systems free from organic solvents, so that there is a rapidly developing interest in all types of photocuring processes. Further, it is conceivable that such processes may displace some conventional fabrication technologies.

Since photoinitiation and photocuring are processes which are closely related there is an obvious incentive for work on photoinitiation. Some years ago we embarked on a study of photoinitiation of free-radical polymerization by transition metal complexes². After a very brief reference to early work (following section), our more recent results will be described.

SYSTEMS CONTAINING ABSTRACTABLE HALOGEN ATOMS²

Many transition metal complex/organic halide combinations are photoactive. Among the transition metal carbonyls which have been investigated in detail from this point of view are $\text{Mn}_2(\text{CO})_{10}$, $\text{Re}_2(\text{CO})_{10}$ and $\text{ArCr}(\text{CO})_3$. In all systems of this type, an active species produced photochemically enters into a redox reaction with the halide; as a result the metal atom (M) in the former acquires a higher oxidation state while the halide is converted into a free radical, e.g.

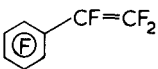

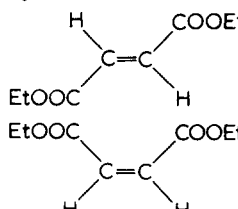

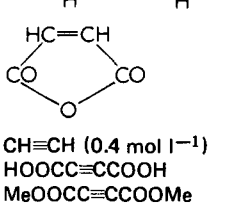

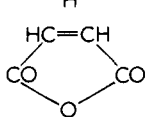

By replacing the simple halide by a preformed polyhalide, a wide variety of graft block and network copolymers have been synthesized and highly efficient photocrosslinking systems may be developed²⁻⁴.

SYSTEMS WITHOUT ABSTRACTABLE HALOGEN ATOMS

In 1972 we observed^{5,6} that manganese and rhenium carbonyls are very active photoinitiators for the polymerization of liquid tetrafluoroethylene at -92°C . Some other carbonyls [e.g. $\text{Os}_3(\text{CO})_{12}$ and $\text{Ru}_3(\text{CO})_{12}$] also photoinitiate, but are less active. Further, one of these carbonyls in the presence of a low concentration of C_2F_4 (e.g. 0.1 mol l^{-1}) was found to photoinitiate free-radical polymerization of common vinyl monomers at 25°C . In other words, C_2F_4 appeared able to function as halide component of systems such as those described². However, it

$\text{HOCC}=\text{CCOOH}$	0.98	0.42
$\text{MeOCC}=\text{CCOOMe}$	0.98	0.61

seemed very unlikely that the fluorine atoms in C_2F_4 are abstractable under the experimental conditions, so that a mechanism different from that of equation (1) was indicated. In support of this, saturated fluorocarbons such as perfluorocyclohexane were found to be completely inactive. Two additional observations clarified the nature of the initiation process: (a) Analysis⁶ of the polymers obtained from the system methyl methacrylate + $\text{Mn}_2(\text{CO})_{10}$ + C_2F_4 revealed that the polymers carry covalently bound manganese atoms, the mean number per polymer chain being 1.23. This is close to the number expected (1.21) if each initiating radical contains one Mn atom, with combination of poly(methyl methacrylate) radicals constituting 34% of the total termination; (b) The polymers show infra-red absorption near 2000 cm^{-1} , very similar to that of model compounds such as $(\text{CO})_5\text{MnC}_2\text{F}_5$ ⁷. It therefore seems clear that the initiating radicals have the structure:

More recently⁷ a number of different fluoro-olefins have been shown to behave similarly to C_2F_4 . Detailed observations have been extended⁸ to $\text{Re}_2(\text{CO})_{10}$, which photoinitiates by the same type of mechanism as $\text{Mn}_2(\text{CO})_{10}$, but is more active. The quantum yields of initiation obtainable in these systems are presented in Table 1.

The rate of consumption of $\text{Mn}_2(\text{CO})_{10}$ has been measured spectrophotometrically and found to follow simple first-order kinetics^{6,7}. Comparison with the rate of initiation deduced from polymerization kinetics shows that for the photoinitiators $\text{Mn}_2(\text{CO})_{10}/\text{C}_2\text{F}_4$ and $\text{Mn}_2(\text{CO})_{10}/\text{C}_2\text{F}_3\text{Cl}$, each molecule of $\text{Mn}_2(\text{CO})_{10}$ consumed gives rise

to one initiating radical. Unfortunately, similar observations with $\text{Re}_2(\text{CO})_{10}$ are not feasible⁸ since the formation of a product with strong light absorption obscures the decreasing absorption attributable to the decay of $\text{Re}_2(\text{CO})_{10}$.

The results we have described demonstrate the great difference in behaviour between fluoro-olefins and 'conventional' monomers (e.g. methyl methacrylate) in these systems. We attribute the high activity of the former to the ability of the fluoroderivatives to form relatively strong metal-carbon bonds⁶. In fluoroalkyl-, compared to alkyl-, derivatives of transition metals, the metal-carbon bonds are relatively short, probably on account of back-donation from d_π metal orbitals to σ^* levels of fluoroalkyl⁹. The resulting increase in bond energy would play a decisive role in the formation of radicals such as structure (I).

SYSTEMS WITHOUT HALIDES

The observations on fluoro-olefins reported above suggested that other classes of additives which readily form ligands with transition metals might be active components of photoinitiating systems containing a Group VII metal carbonyl. Very recently¹⁰ we have demonstrated that this is the case. The additives studied include: (a) olefinic derivatives carrying electron-attracting groups e.g. diethyl fumarate, diethyl maleate, maleic anhydride; (b) acetylene and its derivatives acetylene dicarboxylic acid and the dimethyl ester of the latter. Thus, a new class of photoinitiators, free from halogen atoms, becomes available.

Mechanistically, these photoinitiators resemble systems based on fluoro-olefins. The kinetics indicate uncomplicated free-radical polymerization; Figure 1 presents the dependence of the rate of polymerization on additive concentration for selected systems. Quantum yields of initiation under 'plateau' conditions are given in Table 1; evidently with acetylene and its derivatives values close to unity are obtainable with $\text{Re}_2(\text{CO})_{10}$. The lower activity of $\text{Mn}_2(\text{CO})_{10}$, relative to $\text{Re}_2(\text{CO})_{10}$, is also clear from Table 1. Further, with $\text{Mn}_2(\text{CO})_{10}$ /acetylene dicarboxylic acid dimethyl ester systems, it has been shown that one initiating radical arises from each $\text{Mn}_2(\text{CO})_{10}$ consumed¹⁰

Figure 1 Dependence of rate of polymerization of methyl methacrylate at 25°C (ω) on [additive]. $[\text{Re}_2(\text{CO})_{10}] = 5.11 \times 10^{-4} \text{ mol l}^{-1}$, $\lambda = 365 \text{ nm}$. $10^8 I_{\text{abs}}$ (einstein $\text{l}^{-1} \text{ s}^{-1}$): X, 2.51 (acetylene); O, 2.72 (acetylene dicarboxylic acid); □, 2.72 (acetylene dicarboxylic acid dimethyl ester); ●, 2.03 (diethyl fumarate); △, 2.03 (diethyl maleate)

Figure 2 Infrared absorption of poly(methyl methacrylate) prepared by photoinitiation with $\text{Re}_2(\text{CO})_{10}$ + additive. A, additive: acetylene dicarboxylic acid dimethyl ester. B, additive: acetylene

Analysis of purified polymers obtained from methyl methacrylate with the aid of these initiators reveals the presence of Mn or Re atoms and the polymers show infra-red absorption near 2000 cm^{-1} , characteristic of end-groups such as $(\text{CO})_5\text{ReCH}=\text{CH}-$ and $(\text{CO})_5\text{Re}(\text{MeOOC})\text{C}=\text{C}(\text{COOMe})-$ (Figure 2).

In the light of these results we believe that the mechanism of initiation is substantially the same as with the fluoro-olefins. In our opinion these reactions may provide a useful method of introducing functional terminal groups into polymer chains. Acetylene derivatives, $\text{CX}\equiv\text{CH}$ or $\text{CX}\equiv\text{CY}$, where X or Y are functional groups, appear most appropriate for this purpose, in view of the reluctance of these derivatives to polymerize readily by free-radical reactions.

It is of interest that the polymers obtained with the aid of the photoinitiating systems described in this and the preceding section behave as thermal initiators at higher temperatures. As an example we may refer to the polymer obtained from methyl methacrylate with photoinitiation by $\text{Mn}_2(\text{CO})_{10}$ /acetylene dicarboxylic methyl ester, which we may designate as $(\text{CO})_5\text{MnA}\sim\sim$, where A is equivalent to $-(\text{MeOOC})\text{C}=\text{C}(\text{COOMe})-$. At 100°C in solution in a vinyl monomer, this polymer forms macroradicals by reaction (2):

Propagation from $\sim\text{A}\cdot$ leads to the formation of a block copolymer. We have demonstrated the occurrence of this process and are examining its potential value as a general synthetic route to block copolymers¹⁷.

PHOTOCHEMISTRY OF V^{V} DERIVATIVES

In earlier papers^{11,12} we have reported investigations of the photochemistry of $\text{V}^{\text{V}}\text{O}(\text{acac})_2\text{Cl}$ and derivatives of the type $[\text{V}^{\text{V}}\text{O}(\text{acac})_2\text{D}]^+\text{Cl}^-$ obtained from $\text{VO}(\text{acac})_2\text{Cl}$ in the presence of an electron-donor D. More recently¹³, we have described studies of the vanadium chelate

$\text{V}^{\text{V}}\text{OQ}_2\text{OCH}_3$ where Q represents 8-quinolyloxo

On irradiation with light of wavelength 365 nm, photolysis occurs according to equation (3).

The radical product of equation (3) can initiate free-radical polymerization giving an overall quantum yield 2×10^{-3} . Comparison of the rates of chelate decomposition and initiation of polymerization shows that each chelate molecule photolysed yields one initiating radical. Spin-trapping experiments with benzylidene-(*t*-butyl) amine *N*-oxide in benzene solution reveal the rapid isomerization of the primary $\text{CH}_3\dot{\text{O}}$ radical to CH_2OH . This isomerization is therefore not dependent on the presence of methanol, as some earlier workers suggested¹⁴ (see also ref.15). Photolysis of the chelate VOQ_2OR is a useful general method of producing (OR) radicals in non-aqueous solution.

For present purposes the main interest in these derivatives lies in their incorporation into polymer chains to yield photoactive polymers. Copolymers of methyl methacrylate and hydroxyethyl methacrylate with units (II) containing vanadium have been synthesized.

Photolysis of (II) ($\lambda = 365\text{ nm}$) proceeds by the mechanism described for VOQ_2OCH_3 (equation 4), with formation of a V^{IV} chelate and the macroradical (III) (which may be isomerized). Irradiation in a vinyl monomer therefore leads to graft polymerization and ultimate gelation. As a synthetic route to grafts and networks this technique has the advantage of not producing unwanted homopolymer; further, after reaction, excess vanadium may be removed by treatment with methanol.

The kinetics of photolysis of these photoactive polymers show unexpected complexities¹⁶. The possible dependence of the kinetic behaviour on chain conformation is being examined.

Chemorheology of irradiation-cured natural rubbers: 2. Stress relaxation mechanisms of sulphur-containing cured systems in air

Saburo Tamura and Kenkichi Murakami

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai, Japan
(Received 4 November 1975)

Stress relaxation mechanisms in air were investigated for irradiation-cured natural rubbers (NR) containing the various levels of sulphur, in relation to the crosslinked structure. All the stress relaxation curves of these vulcanizates except the sulphur-free sample were the sum of two exponential terms. The relaxation rate in the long time region increased with increasing sulphur contents, in spite of having the same initial chain density. This behaviour could be explained by introducing the assumption, that this system has two independent networks, i.e. one ($N_p(O)$) based on the polysulphide crosslinkages and another ($N_{c,m}(O)$) based on the mono- and di-sulphide linkages and the carbon-carbon bonds. $N_p(O)$ increased with increasing sulphur contents and $N_{c,m}(O)$ decreased with increasing sulphur contents. The $q_{m,c}(t)$ (the number of moles of main chain scission) were in agreement with each other, independent of the sulphur contents. However, this value was larger than that of the sulphur-free sample. This was similar to irradiation-cured tetramethylthiuram disulphide NR, in which the crosslinking sites consisted of mono- and di-sulphides and carbon-carbon bonds.

INTRODUCTION

In part 1¹, stress relaxation mechanisms were investigated for various curing systems of natural rubber in air, specially the complex crosslinking irradiation-cure systems containing tetramethylthiuram disulphide (TMTD) or sulphur (S) at high temperature. In the case of irradiation-TMTD cures, the stress decay was based on the oxidative scission of the main chain. The number of moles of main chain scission was independent of the ratio, ρ , of initial chain density $N_c(O)$, based on the carbon-carbon crosslinkages, to $N_m(O)$ based on the mono- and di-sulphide linkages. The stress relaxation curve (the relative stress) of irradiation-sulphur cures in air was expressed by the sum of two exponential terms, i.e.:

$$f(t)/f(O) = A \exp(-k_A t) + B \exp(-k_B t) \quad (1)$$

where, $f(O)$ is the initial stress and $f(t)$ is the stress at time t . We suggested that the stress relaxation of these curing systems could be explained by both the interchange reaction of polysulphide linkages (rate constant k_B) and the random scission on the main chain (k_A). However, we did not carry out the quantitative discussion of the relaxation mechanism of these curing systems.

In the present paper, we will attempt to investigate quantitatively, the chemical relaxation of irradiation cured natural rubbers, with varying sulphur contents, in air.

EXPERIMENTAL

Thin sheets (~0.5 mm) of non-crosslinked natural rubber (RSS No 1), were made by cold milling with 0.0, 0.1, 0.25, 0.5, 0.75, 1.0, 2.0, and 3.0 phr of sulphur, and pressing at 145°C. The sheets were cured by exposure to γ -rays from ⁶⁰Co. Total dose of γ -irradiation was 28.8 Mrad. All the samples were extracted with hot acetone for 48 h, in order to eliminate the impurities and the residual sulphur, and were dried *in vacuo*.

Details of stress relaxation methods have been described in a previous paper¹. Stress relaxation was measured (in most cases) at 100°C in air.

RESULT AND DISCUSSION

Crosslinking structure of sulphur irradiation-cured NR

The initial chain density, $N(O)$ (mol/ml) of samples used in this study, was estimated by the statistical theory of rubber-like elasticity. The relation of $N(O)$ and sulphur content (from 0.0 to 2.0 phr) is shown in Figure 1. It can

Figure 1 Relation between initial chain density $N(O)$ and sulphur content. ●, $N(O)$; ○, $N_{c,m}(O)$; △, $N_p(O)$

Figure 2 Stress relaxation of irradiation-cured NR containing various levels of sulphur in air at 100°C: ●, free; △, 0.1 phr; ■, 0.25 phr; ⊕, 0.5 phr; ⊙, 0.75 phr; ▲, 1.0 phr; □, 2.0 phr

be seen from this Figure that, as the sulphur level is increased to 0.75 phr, the $N(O)$ value gradually decreases and the value for samples containing 0.75 phr sulphur or more is almost independent of sulphur content. In this Figure, the $N(O)$ value of the sample containing 3.0 phr sulphur (mark X in Figure 1) obtained in the previous paper, is also represented and is slightly larger than others. In the case of γ -irradiation curing, if the sample was prepared at different times, even though the sulphur content was the same and the curing condition the same; good reproducibility of $N(O)$ could not be obtained. Therefore, the comparison between 3.0 phr sample and others is not correct.

The crosslinking site, in these samples, except for the sample not containing sulphur, will consist of carbon-carbon bonds, and mono-, di- and polysulphide linkages.

Figure 2 shows the stress relaxation curves [the logarithm of relative stress $\log f(t)/f(O)$ versus time t (h)] of these samples in air at 100°C. The relaxation curve of the sulphur-free sample ($S = 0$) is represented by a straight line over the range of observation time and is based on the random scission of the main chain, as is well-known¹⁻³. However, the others, i.e. the stress relaxation of sulphur-containing samples, decay rapidly in a short time and then become linear after a longer time. All these curves can be expressed by equation (1). The rapid relaxation at the initial stage increases with increasing sulphur content. This relaxation was discussed in connection with the interchange reaction of polysulphide linkages at length elsewhere^{1,4-6}. On the other hand, the rate of relaxation at a later stage, also increases with increasing sulphur content, despite having the same value of $N(O)$ at 0.75 phr sulphur or more. This behaviour cannot be explained by Tobolsky's theory², related with $N(O)$ only.

The investigation of the relaxation mechanism of these curing systems in the longer time region, will be attempted in some detail. For the discussion, it is necessary to have quantitative information of the crosslinking structures. The carbon-carbon bonds, and mono- and di-sulphide linkages of crosslinkages as mentioned above, seem to be stable for thermal oxidation at this temperature^{1,7}. Now, we define the initial chain density based on these crosslinkages as $N_{c,m}(O)$ and that based on the polysulphide crosslinkages, which are thermally unstable, as $N_p(O)$. Therefore, $N(O)$ is expressed by equation (2):

$$N(O) = N_{c,m}(O) + N_p(O) \quad (2)$$

The initial stress, $f(O)$ and that at time t , $f(t)$, are related to $N(O)$ and to the chain density at time t , $N(t)$, respectively by the following equations²:

$$f(O) = N(O)RT(\alpha - \alpha^{-2}) \quad (3)$$

$$f(t) = N(t)RT(\alpha - \alpha^{-2}) \quad (4)$$

Where, R is the gas constant, T the absolute temperature and α the extension ratio. From equations (2), (3) and (4) we obtain:

$$f(t)/f(O) = N(t)/N(O) = N_{c,m}(t)/N(O) + N_p(t)/N(O) \quad (5)$$

If the stresses associated with $N_{c,m}$ and N_p are $f_{c,m}$ and f_p , respectively, then:

$$\begin{aligned} f(t)/f(O) &= N_{c,m}(t)/N(O) + N_p(t)/N(O) \\ &= f_{c,m}(t)/f(O) + f_p(t)/f(O) \end{aligned} \quad (6)$$

Also, from equations (1) and (6), if $N_{c,m}$ and N_p are presumed to be independent of each other and can be separated into two networks, the following two relations will be valid:

$$f_{c,m}(t)/f(O) = A \exp(-k_A t) \quad (7)$$

$$f_p(t)/f(O) = B \exp(-k_P t) \quad (8)$$

When $t = 0$:

$$f_{c,m}(O)/f(O) = N_{c,m}(O)/N(O) = A \quad (9)$$

The A value can be estimated directly by extrapolation of $\log f(t)/f(O)$ versus t plot. Therefore, the initial chain density $N_{c,m}(O)$ based on carbon-carbon crosslinkages, mono- and di-sulphide linkages can be calculated from equation (9), and the $N_p(O)$ based on polysulphide linkages is also obtained from equation (2).

For the irradiation-sulphur curing systems, the results estimated by the above method are shown in Figure 1. The value of $N(O)$ of samples containing 0.75 phr sulphur or more, is almost independent of sulphur content, while the $N_{c,m}(O)$ gradually decreases with sulphur content until 2 phr. The question may be raised, whether the above treatment, in particular, the assumption that $N_{c,m}$ and N_p are independent of each other, is correct. As described in the previous paper¹, the value of A [i.e. $N_{c,m}(O)$] estimated from the stress relaxation in air, is in good agreement with that in nitrogen. Therefore, this treatment appears probably, to be correct. If it is not correct, as each relaxation at the later stage is based on the distinct chemical actions (in air as compared with in nitrogen), the A value should be different. In order to confirm the above theory further, we carried out the following experiment. Moore and Trego⁸ reported that poly- and di-sulphide crosslinkages were cleaved in a benzene solution of sodium di-*n*-butyl phosphite, as follows:

Figure 3 Stress relaxation of irradiation-cured NR, containing 3.0 phr of sulphur having different initial chain density and relation between the number of moles of main chain scission $q_{c,m}(t)$ and time t : \circ , irradiation dose 28.8 Mrad, $N(O) = 0.84 \times 10^{-4}$ mol/ml, and $N_{c,m}(O) = 0.54 \times 10^{-4}$ mol/ml; \times , 43.2 Mrad, $N(O) = 1.13 \times 10^{-4}$ mol/ml, and $N_{c,m}(O) = 0.71 \times 10^{-4}$ mol/ml

The sample containing 3 phr of sulphur, was placed into 0.14 mol/l benzene solution of sodium di-n-butyl phosphite. After nitrogen was passed through the solution for about 10 min, the mixture was sealed *in vacuo*. The reaction was carried out by heating for 24 h at 25°C and then for 4 h at 80°C. After that, the sample was extracted with benzene for 24 h and was dried *in vacuo*. The effective chain density $N'_{c,m}(O)$ of this sample, was estimated by stress-strain measurement, to result in 0.36×10^{-4} mol/ml. The difference between $N'_{c,m}(O)$ and $N_{c,m}(O)$ (0.53×10^{-4} mol/ml) is somewhat large; however if one considers that $N_{c,m}(O)$ is the effective chain density due to carbon-carbon crosslinkages, and mono- and di-sulphide linkages as defined above, it seems to be comparable. Therefore, the above mentioned assumption seems to be correct. In order to confirm our treatment, further, it is necessary to have a detailed knowledge of crosslinking structure in this system.

Chemical stress relaxation of sulphur-irradiation-cured NR

Initially, it is necessary to investigate the stress relaxation of samples having the same sulphur content and having different initial chain density. Though the stress relaxation of such samples, containing 3 phr of sulphur was reported in the previous paper, quantitative results were not concluded. Figure 3 shows some of the results of the previous work. The samples having different initial chain density $N(O)$, were prepared by the alternation of irradiation dose. In that curing system, since the rate of relaxation at a later stage was dependent on $N(O)$, the stress decay was probably based on the oxidative scission of the main chain. The value of $N_{c,m}(O)$ estimated by the above method, was 0.54 mol/ml for 28.8 Mrad irradiation-sample and 0.72 mol/ml for 43.2 Mrad irradiation-sample, respectively. Now, if this sample was assumed to have carbon-carbon, mono- and di-sulphide crosslinkages but not polysulphide linkages, then the stress relaxation will be expressed by:

$$f_{c,m}(t)/f_{c,m}(O) = A' \exp(-k'_A t) \quad (10)$$

In the case of undergoing the random scission on the main chains in the system, the number of moles of main chain scission, $q_{c,m}(t)$, is represented by equation (11), which was proposed by Tobolsky²:

$$q_{c,m}(t) = -N_{c,m}(O) \ln f_{c,m}(t)/f_{c,m}(O) \quad (11)$$

Hence, $q_{c,m}(t)$ can be obtained directly from a stress relaxation measurement. The relation between $q_{c,m}(t)$ and t is also shown in Figure 3. The $q_{c,m}(t)$ is almost independent of $N_{c,m}(O)$. This suggests that the stress decay at the later stage of this sample, is based on the random scission of only the main chain.

Next, we investigate the effect of sulphur content on $q_{c,m}(t)$, which is obtained from Figure 2. The result is shown in Figure 4. It can be seen that the $q_{c,m}(t)$ are almost equivalent, regardless of the sulphur contents, except for the 0.1 phr and the sulphur free samples. This is independent of the ρ values which were defined, in Part 1, as the ratio of the effective chain density $N_c(O)$ based on the carbon-carbon bonds, to $N_m(O)$ based on mono- and di-sulphide linkages and probably varies with sulphur content. Further, this supports the validity of our assumption in Part 1, relating to the result of tetramethylthiuram disulphide (TMTD)-irradiation cured NR having carbon-carbon, mono- and di-sulphide crosslinkages. Both results, however, are not in agreement, i.e. the $q_{c,m}(t)$ estimated from the relaxation of TMTD-irradiation cured NR is significantly larger than that of the sulphur-irradiation cure (Figure 4). Though we are unable to explain the difference definitely, the following two reasons can be considered: (a) in the case of the latter, the gloval network was considered as two independently separated networks (giving rise to $N_{c,m}(O)$ and $N_p(O)$). Consequently, the number of moles of main chain scission which occurred in the $N_p(O)$ network was not estimated. On the other hand, the former case exhibited only the scission of main chain; (b) there is a distinction of stress relaxation mechanisms between both curing systems, i.e. the latter follows the interchange reaction of polysulphide, resulting in the mono- and/or di-sulphide linkages, and the formation of these crosslinkages probably affects somewhat the continuous stress relaxation⁹, while during the former, little crosslinking reaction is considered to occur.

Temperature dependence of the chemical stress relaxation

The temperature dependence of the rate of chemical stress relaxation in air, for all the samples used here, was investigated. The measurements were carried out at 100°, 110° and 120°C. The rate constants of the main chain scission K_A can be obtained from the gradients of stress relaxation at the later stage, and is expressed by the Arrhenius equation:

$$K_A = A \exp(-E_a/RT) \quad (12)$$

Figure 4 Relation between $q_{c,m}(t)$ and t of irradiation sulphur-cured NR and irradiation-TMTD-cured NR (---); Sulphur: \circ , free; \triangle , 0.1 phr; \square , 0.25 phr; \oplus , 0.5 phr; \odot , 0.75 phr; \blacktriangle , 1.0 phr; \blacksquare , 2.0 phr

Figure 5 Plot of $\log K$ versus $1/T$ for each sample containing various sulphur levels: ●, free; △, 0.1 phr; □, 0.25 phr; ⊕, 0.5 phr; ○, 0.75 phr; ■, 1.0 phr; ▲, 2.0 phr

where E_a is the apparent activation energy (kcal/mol) for main chain scission reaction. The relation of $\log K_A$ (h^{-1}) and $1/T$ (K) is shown in Figure 5. From the Figure, we find that the value of K_A in this system becomes larger as the sulphur content increases. This result is different from the one related to EPDM¹⁰ or EPR¹¹. In the case of EPDM, the relaxation rate in the longer time region decreases with increasing the sulphur content. The value of E_a for all the samples used here was estimated to be ~ 21 kcal/mol. This value also differs from the one for TMTD-irradiation-cured NR, which was 27 kcal/mol as mentioned in Part 1.

Time dependent effects of pressure on the shear modulus of polypropylene

R. A. Duckett and S. H. Joseph

Department of Physics, University of Leeds, Leeds LS2 9JT, UK

(Received 15 September 1975)

The time dependent changes in the shear modulus of polypropylene have been followed subsequent to both step and ramp changes in pressure for pressures up to 400 MN/m². Although the changes in pressure (*P*-jumps) are accompanied by transient heating effects which complicate the interpretation of the results; large changes in modulus can be seen at times of up to three hours after the pressure change. At these times the effects of temperature changes would be expected to be negligible. The results are consistent with the expected changes of free volume occurring during the dilatational creep under pressure, and lend no support to the 'microstress' theory recently proposed.

INTRODUCTION

It is now well established that hydrostatic pressure can have a considerable effect on the physical properties of polymers. This has stimulated interest in relating the effects of pressure to those of temperature and time or frequency. Considerably less effort has so far been invested in studying the transient response of the polymer to changes in pressure, although this is also of considerable significance. There have recently been suggestions regarding the possible forms of the response to changes in pressure. One proposal¹⁻³ is that a change in pressure, the same as a change in temperature, induces a volume change which is accompanied by the generation of microstresses around structural heterogeneities such as crystallites. These microstresses combined with the usual type of non-linear behaviour produce an anomalously low value of the modulus. As the microstresses decay with time the modulus rises steadily towards the linear value appropriate to the new conditions, regardless of whether the change in temperature or pressure is positive or negative. A completely different approach suggests that changes in pressure cause changes in the free volume in the polymer, as the dilatational creep progresses. These free volume changes will also affect most physical properties of the material and furthermore the 'sense' of the changes would be expected to depend on whether the pressure is increased or decreased.

There are thus distinct qualitative differences between these two approaches. In an attempt to discern which of these applies to polypropylene we have investigated the time dependence of the large changes in the shear modulus following positive and negative changes in hydrostatic pressure (*P*-jumps) by performing torsion tests at constant twist rate, at different elapsed times from the *P*-jump. It turns out that the results of these experiments are complicated by the concomitant changes in temperature induced by the changes in pressure, in both the pressure transmitting fluid and in the polymer. In order to investigate the contribution to this temperature rise by the polymer itself, temperature changes due to adiabatic compression of polypropylene were studied using a constrained uniaxial compression cell. An alternative approach to the investigation of the time dependent shear modulus, involving the use of hydrostatic pressure increasing at constant ramp rates, was also used. This results in a closer approximation to iso-

thermal conditions, and provides more accurate temperature control.

Although little previous work has been carried out directly on time dependent modulus changes following changes in pressure or temperature¹⁻³, the changes in modulus on the free volume scheme are expected to relate to total volume changes under such conditions. Such time dependent volume measurements have been made following small changes in temperature and pressure⁴ and following large changes in temperature⁵ in amorphous polymers near their dilatational glass transition temperature (*T_g*). Volume creep in several polymers has also been investigated at high pressures^{6,7}. There are more data available on the static effects of hydrostatic pressure on both shear and bulk moduli; such data have been reviewed⁸ and we refer especially here to torsion pendulum data for polypropylene⁹.

EXPERIMENTAL

Torsion tests

Full details of the apparatus and specimens will be presented elsewhere¹⁰ so here we give only a brief description. The apparatus is a modified version of that previously described¹¹. Right solid cylindrical specimens of isotropic isotactic polypropylene (PP), density 909.5 ± 0.1 kg/m³, are subjected to a constant rate of twist whilst under hydrostatic pressure applied via Plexol 201 lubricant (diethyl dihexyl sebacate). The specimen design minimizes the magnitude of end effects, thus enabling the strain in the specimen to be deduced accurately from the angle of twist of the grips, which can be monitored outside the pressure vessel. Torque is also continuously monitored via an angular transducer mounted on the torque tube, and the torque-twist curve for the specimen for small angles of twist is recorded on an X-Y recorder. From this curve the stress-strain curve for small strains under constant strain rate conditions may be deduced¹⁰. The vessel temperature is governed by a water bath controlled to ±0.3°C surrounding the vessel.

The first two testing programmes followed the pressure schedule shown in *Figure 1*. Each step in pressure corresponded to 30 MN/m² in the first programme and to 100 MN/m² in the second. The specimen was loaded into the vessel and allowed to come to equilibrium at the testing

Figure 1 Pressure schedule for the first two testing programmes (I) and (II). In each case step length, approximately 3600 sec. Pressure 'step-height' (I) 30 MN/m²; (II) 100 MN/m²

Figure 2 Shear modulus vs. time under pressure (logarithmic scale) according to testing programme (I), (see Figure 1). Pressures: A, 30 MN/m²; B, 60 MN/m²; C, 90 MN/m²; D, 120 MN/m². ●, pressure increasing; ○, pressure decreasing

Figure 3 Shear modulus vs. time under pressure (logarithmic scale) according to testing programme (II), (see Figure 1). Pressures: A, 100 MN/m²; B, 200 MN/m²; C, 300 MN/m²; D, 400 MN/m². ●, pressure increasing; ○, pressure decreasing

temperature for at least 12 h at atmospheric pressure. A torsion test was then performed at a rate equivalent to a strain rate of 1.1×10^{-3} /sec, up to a maximum strain of 2.5×10^{-2} . The specimen was immediately unloaded to zero torque and allowed to recover for 300 sec. The pressure was then changed to the first in the schedule (30 MN/m² for the first programme), at a rate of 5 MN/m² sec and a sequence of the above torsion tests performed at convenient logarithmically spaced times, i.e. at about 30 sec, 300 sec, 1000 sec, 3000 sec after the achievement of the new pressure. Then, after a further recovery period of 300 sec from the final test in the sequence, the pressure was changed to the next on the schedule, and the same sequence of torsion tests performed again, under the new constant

pressure. In this way the whole of the pressure schedule is completed. The results, 2% secant modulus values against elapsed time, at 58°C, are plotted in Figures 2 and 3.

In the second pair of testing programmes the effects of starting at atmospheric pressure and increasing directly to constant pressures of 100, 200, 300 and 400 MN/m² were examined (see Figure 4) at 39°C and 58°C. After application of the hydrostatic pressure the above time sequence of tests was performed; graphs of the modulus vs. elapsed time are shown in Figures 5 and 6.

Figure 4 Second pressure schedule, showing the pressure increased rapidly from atmospheric to each of 100, 200, 300 and 400 MN/m² in turn. The time at atmospheric pressure between tests was approximately 3600 sec

Figure 5 Shear modulus vs. time under pressure (logarithmic scale) according to second pressure schedule (see Figure 4). Pressures: A, 100 MN/m²; B, 200 MN/m²; C, 300 MN/m²; D, 400 MN/m². Nominal temperature 58°C

Figure 6 Shear modulus vs. time under pressure according to second pressure schedule. Pressures as in Figure 5. Nominal temperature 21°C

Figure 7 Temperature changes due to P -jumps. The temperature was measured at the surface of the specimen using copper resistance thermometry. Pressure changes involved are: A, -100 MN/m^2 ; B, -30 MN/m^2 ; C, $+30 \text{ MN/m}^2$; D, $+100 \text{ MN/m}^2$

Temperature effects

In the hydrostatic fluid system. Findley, Reed and Stern⁶ have pointed out the need to consider temperature changes caused by adiabatic compression of hydrostatic pressure fluid. The temperature changes in our system are shown in Figure 7 for changes in pressure of $\pm 100 \text{ MN/m}^2$ and $\pm 30 \text{ MN/m}^2$. The temperature was found to rise at the rate of $0.09^\circ\text{C} (\text{MN/m}^2)^{-1}$ at pressures of up to 100 MN/m^2 , the rate dropping slightly to about $0.06^\circ\text{C} (\text{MN/m}^2)^{-1}$ for pressures above 200 MN/m^2 . This resulted in temperature changes of up to 25°C for a 400 MN/m^2 change in pressure. At all pressures, the temperature rise decayed with a time constant of approximately 340 sec as the centre of the vessel came into equilibrium with the bath.

The temperatures above were measured using the change in resistance in a copper coil of resistance approximately 20 ohms wound in a single layer on a PP former. Thus the temperature measured was at the PP-fluid surface. In order to check that a significant amount of the polymer also experienced these temperatures, the temperature measurement was repeated after coating the coil with latex to a thickness of 1.5 mm. Similar temperature-time profiles were found as before, but delayed in time by about 40 sec. The resistance thermometry was checked against mercury-in-glass thermometers at atmospheric pressure, and had absolute accuracy better than $\pm 0.5^\circ\text{C}$. The pressure coefficient of resistance of copper¹² is such that the error in temperature measurement due to pressure changes with this method is less than $0.005^\circ\text{C} (\text{MN/m}^2)^{-1}$. Thus with this method we are able to find the temperature changes that have occurred within the specimen after the P -jump experiments.

Within the polymer. In the case of PP, as with polymers in a rubbery state, the bulk modulus and density are of the same magnitude to those of oils, and there is a considerable temperature change on the application of pressure. It is readily shown¹³ that for a reversible adiabatic change:

$$\left(\frac{\partial T}{\partial P}\right)_s = \frac{\alpha VT}{C_p} \quad (1)$$

where α , V and C_p are the coefficient of cubical expansion, specific volume and specific heat at constant pressure respectively.

Using appropriate engineering data values* for PP we get:

$$\left(\frac{\partial T}{\partial P}\right)_s = 0.06^\circ\text{C} (\text{MN/m}^2)^{-1} \text{ at } 20^\circ\text{C}$$

To examine this for PP we constructed, to fit an Instron compression/tension test machine, a simple pressure cell in which the specimen is restrained from lateral expansion during axial compression (see Figure 8). The highest pressure used was 150 MN/m^2 . The specimens were 13 mm diameter \times 15 mm long and had a 34 swg chromel-alumel thermocouple inserted into a 0.9 mm diameter axial hole filled with grease, so that the junction was centrally placed within the specimen.

In this mode of deformation the effective modulus of the specimen M can be shown to be:

$$M = K + \frac{4}{3}G \quad (2)$$

where K is the bulk modulus and G the shear modulus. To check the operation of the cell, load deflection curves were plotted at low strain rate ($6.4 \times 10^{-5}/\text{sec}$) to ensure isothermal conditions, and the experimental value of M found for pressures less than 45 MN/m^2 was in good agreement with estimates based on published values of K and G at atmospheric pressure^{7,10}. Above this pressure, M was seen to rise, an effect we attribute to an increase in K and G at high pressures offset by the slight decrease in G at high shear strains. (For very low loads, corresponding to pressures less than 15 MN/m^2 , there is a region of low modulus where the specimen is effectively under unconstrained uniaxial compression before play is taken up and lateral strain is eliminated).

To investigate the adiabatic heating effect intrinsic to the polymer, the following sequence of tests was performed: a nearly static load was applied to the specimen, and load cell and thermocouple outputs continuously recorded.

* $\alpha = 3.3 \times 10^{-4} (\text{C}^\circ)^{-1}$ at 20°C and $C_p = 1.8 \text{ kJ/kg}$

Loading was achieved through a nominal strain rate of 6×10^{-3} /sec corresponding to a maximum loading time of 10 sec. When the temperature once again became static (after approximately 1000 sec) the load was rapidly removed (unloading time ~ 0.1 sec). In Figure 9 the peak temperature change is plotted against the pressure change for both unloading and loading. We see a region at low stress corresponding to unconstrained uniaxial compression. Then for pressures greater than 15 MN/m² the temperature changes are linearly dependent on pressure, and equal and opposite for compression and decompression, with a temperature coefficient of $0.04^\circ\text{C}(\text{MN}/\text{m}^2)^{-1}$. There is a discrepancy between the temperature coefficient found here and that calculated above using standard engineering data values for C_p and α . This may be merely due to differences between samples of polypropylene, but may also reflect the shorter times involved in this experiment compared with those usually involved in measurements of α and C_p .

Using the measured value of $(\partial T/\partial P)_s = 0.04^\circ\text{C}(\text{MN}/\text{m}^2)^{-1}$ the low stress region of Figure 9 has also been analysed and the measured temperature changes are consistent with the interpretation of unconstrained uniaxial deformation.

At stresses greater than 50 MN/m² the temperature changes for compression, $|\Delta T_+|$, exceed those observed for decompression, $|\Delta T_-|$. Further tests indicate that the values approach each other at low strain rates, extending the pressure range for which $|\Delta T_+| \sim |\Delta T_-|$.

To assess the possibility that the divergence between $|\Delta T_+|$ and $|\Delta T_-|$ is due to temperature changes arising from viscous work done, which being positive in sign, will increase $|\Delta T_+|$ but decrease $|\Delta T_-|$, we have calculated the temperature change ΔT_v expected for a standard linear solid. Assuming that K is elastic, that the shear modulus G has an unrelaxed value $G_u = 2100 \text{ MN}/\text{m}^2$ and a relaxed value $G_r = 450 \text{ MN}/\text{m}^2$, and that the load is changed in a time very much smaller than the creep relaxation time, we find that $\Delta T_v = 3.5 \times 10^{-5} (\Delta P)^2 (\text{C})$, where ΔP is the pressure change in MN/m². Values of $|\Delta T_-| + |\Delta T_v|$ are plotted in Figure 9 and are seen to lie approximately midway between the two curves for $|\Delta T_+|$ and $|\Delta T_-|$. Although the excellent agreement obtained may be somewhat fortuitous in view of the simplicity of the model assumed, it does seem to indicate that the difference between $|\Delta T_+|$ and $|\Delta T_-|$ is due to viscous heating.

If we write $|\Delta T_{\pm}| = |\pm\Delta T_p + \Delta T_v|$, then it can be seen from Figure 9 that $\Delta T_p/\Delta P$ decreases at higher pressures. This is as expected from the changes in α and C_p as pressure increases and the β transition is approached.

Pressure ramp experiments

We have shown that the rapid changes in pressure involved in the P -jump experiment necessarily implies transient heating effects of up to 25°C for P -jumps of $400 \text{ MN}/\text{m}^2$. In the next section we discuss the additional complexities of interpretation arising from this temperature change. To observe changes in modulus under more nearly isothermal conditions we have performed tests in which the pressure is increased at a constant rate and the modulus is measured at convenient intervals of pressure. (We refer to these as a pressure ramp experiments). In these experiments an initial rise in temperature of the vessel is seen, but the constant heat input due to the ramp results in an equilibrium temperature being obtained within 500 sec, at which temperature losses from the fluid to the surrounding water bath are equal to the heat input. Thus by presetting the bath temperature slightly below the desired experimental temperature by an amount calculable from the thermal characteristics of the vessel, we can achieve a well defined temperature which is effectively constant throughout the pressure ramp.

With this pressure ramp experiment we have attempted to detect the effects of varying ramp rate within the range 67 and $1200 \text{ MN}/\text{m}^2 \text{ h}$. At the higher rates it is possible that the pressure can be applied in times less than the volumetric creep relaxation time, whereas at low rates the polymer might be able to creep sufficiently fast to remain in equilibrium with the pressure at all times. In Figure 10 the results of such ramp experiments are shown, at tem-

peratures of 58°C and 21°C. (Where necessary small corrections for errors in temperature setting have been made.) It can be seen that at both temperatures the modulus increases with increasing pressure, and that there is a qualitative similarity to the effects of increasing frequency. Also, to within experimental accuracy, the only detectable effect of ramp rate has been at 58°C and below 400 MN/m² pressure, although the rate effects might have been expected to be more apparent in the glass transition region, say at 30°C, 200 MN/m².

DISCUSSION

Modulus changes on pressurization

The data in Figures 2, 4, 5, 6 and 10 show clearly the development in time of the changes in shear modulus of PP subsequent to changes in pressure. The curves indicate that the hydrostatic pressure is taking the polymer through its glass (β) transition. The data show that the changes in modulus are quantitatively consistent with the idea that the modulus is closely related to the volume of the specimen during loading and unloading; i.e. the application of pressure reduces free volume, and hence lengthens the relaxation times in the polymer.

For $P\uparrow$ steps the fraction of the modulus change that occurs in the time interval 30 to 3000 sec increases with pressure, as one would expect on the basis that the higher pressures cause slowing down of the bulk creep process and hence the modulus change. The $P\downarrow$ steps show marked asymmetry compared to the $P\uparrow$ steps in that the process appears slower for pressure release than for pressure increase.

However, the temperature changes resulting from the P -jump complicates any interpretation of the results. For times less than 1000 sec from the pressure change some sort of temperature correction is required. Findley *et al.*⁵ corrected their hydrostatic creep data for temperature effects using the instantaneous temperatures and the coefficient of volume expansion. The efficacy of such a correction in our case is doubtful, both because of the increased theoretical complexity involved in dealing with dynamic pressure and temperature changes and their effects on modulus in the transition region, and also because of their

findings of its inability to describe the results from partial release of pressure experiments.

Hutchinson and McCrum¹ proposed an alternative mechanism for time dependent changes in modulus in crystalline polymers following jumps in temperature or pressure. They proposed that the relaxation of microstresses generated by P -jumps would lead to a time dependent hardening as shown in Figure 11, curve A. However if we allow for the appropriate temperature changes we would expect curves B and C for $P\uparrow$ and $P\downarrow$ respectively. Comparison with Figure 2 indicates no support for the microstress hypothesis. It should be pointed out that PP does not show microstress effects in T -jump experiments either, unlike the polyethylene used by Hutchinson and McCrum^{1,3}.

A more helpful way of interpreting the P -jump results is to consider the temperature rise as partially negating the compression effects for a period up to 1000 sec. We can therefore attempt to interpret the data on the basis of an isothermal experiment in which the pressure is applied fairly gradually, and look to see if there are any changes in the modulus at times long compared with the effective rise time of the pressure. The data in Figures 2 and 3 show that as pressure increases, there is an increase both in the rate of change of modulus with pressure, and in the fraction of modulus change that takes place in the observed time interval, independent of the sign of the pressure change. This is consistent with the onset of the β transition as pressure increases. In Figures 5 and 6 we see the large modulus changes involved in the transition region, and also definite evidence of time dependence of modulus not only at times greater than 1000 sec but even at a time of 3 h, thus showing the need for working at a consistent time under pressure when investigating the dependence of modulus on pressure. A more quantitative analysis of these data is difficult in view of the temperature changes, not only as they instantaneously affect the modulus but also because temperature history can affect the modulus at a later time¹. However, the results here qualitatively agree with the ideas of temperature dependent bulk-viscosity as applied by Kovacs^{5,14} to his data on volume changes following a temperature change. As a transition temperature is approached (in the case of Kovacs, T_g for PVAC) the bulk processes slow down, as do shear processes, until bulk relaxation times are of the order of experimental times. If we further assume that the free volume affects the relaxation time and hence the modulus as in the WLF approach, then changes in modulus following P -jumps will become larger and slower with increasing pressure, as found in the present investigation.

However, when we look at the pressure ramp experiments in this light, we would expect to find that as pressure rises the bulk relaxation time should increase until at a pressure P_1 it becomes greater than the time allowed by the ramp rate. At pressures greater than P_1 the volume and hence the modulus should depend on the ramp rate, modulus being higher for lower ramp rate due to the greater degree of bulk contraction allowed by the longer times involved. Thus a bulk dispersion region should be revealed by these modulus measurements. Despite the slight dispersion seen at 58°C (Figure 10) there is none in the measurements at 21°C for which one would expect to see a higher dispersion as the transition region is swept through. Thus we conclude that at the rates we are able to employ, the shear dispersion region occurs at a lower pressure than the bulk dispersion region. This agrees with available evidence on bulk and shear relaxation times in glass forming liquids¹⁵ and poly(vinyl

acetate) (PVAC)^{16,17} which show that shear relaxation times are greater than bulk relaxation times. That is, in terms of the pressure ramp experiment, the bulk processes are relaxed throughout the shear β transition region.

Adiabatic heating

The adiabatic heating effect is of much greater experimental importance in studying modulus changes following a pressure jump than it is in studying volume changes. The adiabatic heating has been correctly ignored in volume measurements⁴. This is justified for PP as follows: equal changes in volume are produced by $\sim 1 \text{ MN/m}^2$ pressure change and 1°C temperature change at 20°C . However, the adiabatic heating effect produces only 0.04°C temperature change for 1 MN/m^2 pressure change. If the change in volume due to change in temperature following a P -jump is ΔV_θ , and the total change in volume consequent on the jump is ΔV , then $\Delta V_\theta \simeq 0.04\Delta V$. In volume change experiments⁴ the volume seen to relax in the experimental time scale is greater than $0.4 \times \Delta V$, i.e. an order of magnitude larger than ΔV_θ . However, in the case of modulus measurements the situation is different: equal changes of modulus are produced by 10 MN/m^2 and 1°C ⁸, and the adiabatic heating produces a temperature change of 0.4°C for 10 MN/m^2 pressure change. Thus the difference between shear modulus changes resulting from adiabatic or isothermal pressure changes is much more significant than the difference between adiabatic and isothermal bulk moduli.

The experimental precision achieved here in studying the adiabatic heating phenomenon could be much improved by the use of a pure hydrostatic pressure apparatus^{6,7}. This would enable the bulk processes in transition regions to be investigated via the temperature changes produced by application of pressure. Such investigations would hope to reveal both thermodynamic effects of changes in specific heat and thermal expansion coefficient as included in equation (1) on passing through the transition, and also viscous heating effects associated with the bulk compression.

CONCLUSIONS

Considerable changes in the shear modulus of isotropic polypropylene have been observed subsequent to changes in

hydrostatic pressure. In qualitative terms the effects on the shear modulus of increasing pressure are similar to those of decreasing temperature and take the polymer through its glass transition. The increases in modulus, which can occur over periods up to three hours after the pressure change, are consistent with a relaxation of free volume during the period of hydrostatic creep. The data lend no support to the 'microstress' hypothesis recently proposed.

Subsidiary experiments have revealed that the pressure changes are also accompanied by significant temperature changes; no reliable method of correcting the data for these temperature changes can be proposed.

Craze growth and crack growth in poly(vinyl chloride) under monotonic and fatigue loading

N. J. Mills and N. Walker

Department of Physical Metallurgy and Science of Materials, University of Birmingham, Birmingham, B15 2TT, UK

(Received 9 October 1975; revised 10 December 1975)

Cracks in poly(vinyl chloride) sheet were loaded to known stress intensity factors and the craze length measured. These measurements, and the craze thickness profile, were compared with the Dugdale model of crack tip yielding. The fracture toughness of poly(vinyl chloride) was measured, and an analysis made of circular 'advance fractures' that occur on the fracture surface. Fatigue crack growth studies confirmed that crack growth occurs discontinuously once every few hundred cycles, and showed that the craze fracture mechanism is quite different from the monotonic loading failure mechanism.

INTRODUCTION

This research forms part of a fracture mechanics programme on glassy polymers. By studying the brittle fracture processes, and analysing them using fracture mechanics, it is hoped both to produce design data, and to aid the analysis of more complex situations, such as notched impact tests.

In an early investigation¹ of fracture surfaces of poly(vinyl chloride) (PVC), no evidence for crazing was found. However subsequent research has shown that PVC under tensile stress will craze from the surface^{2,3}. It has also been found that the process of notching PVC can produce a bundle of crazes at the notch tip⁴. Therefore any treatment of crack tip plasticity in PVC should take into account the possibility of crazing.

Elinck *et al.*⁵, in their study of fatigue crack growth in PVC, observed regular striations on the fracture surface. They used the Dugdale model⁶ of plasticity at a crack tip, to relate the striation spacing to the ratio of maximum applied stress to the yield stress. They were unable to observe crack tip events since they used red pigmented PVC, but they established that the number of striations was approximately one two hundredth of the number of cycles of loading. A subsequent investigation with transparent PVC⁷ showed that craze growth at the crack tip was continuous during fatigue, and that the crack tip advanced discontinuously. The fatigue crack growth tests^{5,7} covered only a limited range of the stress intensity range ΔK , and did not investigate the effect of the mean stress intensity K_m on the growth rate. It was felt that a more comprehensive investigation was justified, in view of the deviation from the usual rule of one cycle per striation.

Kambour⁸ observed the thickness profiles of crazes that grew at a crack tip under monotonic loading, and Cotterell⁹ subsequently applied the Dugdale model to these data. More recently¹⁰, the complete shape of a craze at a crack tip in poly(methyl methacrylate) has been shown to fit the Dugdale model. If this can also be shown to be true for PVC it would give further support for the use of the Dugdale model to interpret fatigue crack growth. Since Rice¹¹, has extended the model to deal with loading/unloading situations, it should be possible to relate the observed reverse plastic zone size to the stress-strain behaviour of the craze.

THEORY

Application of the Dugdale model of yielding at a crack to crazing

Dugdale⁶ considered the problem of a central slit in a thin sheet of material, with an applied tensile stress σ perpendicular to the slit (*Figure 1*). He assumed that: (a) the plastic zone is confined to the line of the slit; (b) the stress in the yielded zone has a constant value σ_0 ; (c) at the extremity of the yielded zone there is no stress singularity. He applied the elastic stress field methods of Muskhelishvili¹² and found that the plastic zone length R is related to the crack half length a , and to the applied stress by:

$$R/a = \sec(\pi\sigma/2\sigma_0) - 1 \quad (1)$$

$$\simeq \frac{1}{2}(\pi\sigma/2\sigma_0)^2 \text{ for } \sigma < 0.3 \sigma_0$$

The conditions when this last approximation can be used are usually referred to as small scale yielding. Under these conditions, Rice¹¹ used Westergaard stress functions to calculate the plastic zone face separation δ as a function of the distance x from the crack tip:

$$\delta = \frac{(\kappa + 1) \sigma_0 R}{\pi G} \left[\xi - \frac{x}{2R} \log \left(\frac{1 + \xi}{1 - \xi} \right) \right] \quad (2)$$

where $\kappa = (3 - \nu)/(1 + \nu)$ for plane stress deformation or $(3 - 4\nu)$ for plane strain and ν is Poisson's ratio, G is the shear modulus, and $\xi = (1 - x/R)^{1/2}$. The variation of the normalized separation δ/δ_0 with distance is shown in *Figure 2*. Crazing at a crack tip can be considered as a plane strain

Figure 1 Dugdale model of crack tip plasticity

Figure 2 Separation of the plastic zone faces versus distance from the crack tip for the loaded Dugdale model — equation (2); and the unloaded model - - - - equation (4)

process, if there is no yielding outside the craze. The craze thickness is far smaller than the usual sheet thickness, and no significant through thickness plastic strain occurs.

Although the Dugdale model does not consider the criterion for fracture, it can be combined with the suggestion of Wells¹³ that fracture occurs when a critical crack opening displacement (COD) is exceeded. The COD can be identified with the value of δ_0 at the crack tip. Recently a critical COD criterion has been suggested for crack growth in drawn poly(ethylene terephthalate) film¹⁴ and toughened polystyrene¹⁵. In both these polymers the plastic zone size is large compared with the crack length at fracture. If however the only form of yielding before fracture is a single craze at the crack tip, the craze length is usually much smaller than either the crack length or any specimen dimension, and the elastic stress field around the crack can still be adequately described by Irwin's stress intensity factor K ^{16,17}. In these cases either a critical stress intensity K_c or a critical COD fracture criterion can be used. The two quantities are related, as can be seen by combining equations (1) and (2) in the case of small scale plane stress yielding, and using the Young's modulus E instead of shear modulus G :

$$\delta_0 = \sigma^2 \pi a / E \sigma_0$$

$$\text{then } \delta_{0c} = K_c^2 / E \sigma_0 \quad (3)$$

Existing knowledge of the conditions for craze initiation, and of the stresses in crazes, should be considered before applying the Dugdale model indiscriminately. Experiments on craze initiation in unnotched polymers have used biaxial stress fields. It has been shown that crazing occurs when the largest principal stress in poly(methyl methacrylate)¹⁸ or the largest principal strain in polystyrene¹⁹ reaches a critical value, which is dependent on the hydrostatic tension component of the total stress. There has been very little research with notched polymers, where a triaxial stress can occur ahead of the notch. Recent work with polycarbonate²⁰, showed that both a tensile stress greater than the conventional yield stress, and a hydrostatic ten-

sion are required to initiate internal crazes. There has been no similar experimental analysis of crack tip conditions, but recent theoretical results²¹ confirm the Prandtl slip line field solution for the stresses in a plane strain plastic zone at a crack tip. Thus conventional plane strain yielding will lead to a high triaxial tension ahead of a crack tip, which should be able to nucleate a craze in most glassy polymers. Once the craze has formed, the question remains as to whether the stresses at its boundaries are of the same nature as those in the Dugdale model. In the model, if the applied stress at infinity is a uniaxial stress $\sigma_{yy} = \sigma$, then the stresses at the yielded zone boundary are $\sigma_{yy} = \sigma_0$, $\sigma_{xx} = \sigma_0 - \sigma$. For materials with a Tresca or Von Mises type of yield criterion, conventional yielding will then occur under plane stress conditions, i.e. with $\sigma_{zz} = 0$. If crazing occurs, then the yielding is plane strain, but some doubt remains over the stress conditions at the craze/bulk boundary. It is possible that the void formation in crazing largely relaxes the hydrostatic tension component of stress, and hence also the through thickness stress. We have assumed this in some later calculations. Another problem may be that the stresses vary with position in the craze. If this is the case, the thickness profile of equation (2) will differ from the craze thickness profile.

Dugdale model and fatigue crazes

Rice¹¹ has calculated the yielded zone thickness for the strip yield model on complete unloading, on the assumption that the compressive yield stress in the zone is $-\sigma_0$. The length of the reverse yielded zone is one quarter of the original yielded zone, and within it the thickness varies according to:

$$\delta = \frac{(\kappa + 1) \sigma_0 R}{\pi G} \left[\xi - \frac{x}{2R} \log \left(\frac{1 + \xi}{1 - \xi} \right) - \frac{\phi}{2} + \frac{x}{R} \times \log \left(\frac{1 + \phi}{1 - \phi} \right) \right] \quad (4)$$

where the symbols are as in equation (2) and $\phi = (1 - 4x/R)^{1/2}$. Figure 2 shows that on unloading, the major changes in δ occur very close to the crack tip, and the value of δ_0 is halved.

If however the yielded zone had a zero yield stress for compression back to zero plastic strain, then the Dugdale model would predict $\delta = 0$ for the whole zone i.e. the reverse yielded zone would be the same length as the original plastic zone, and there would be no residual elastic stresses on unloading. Kambour²² has shown that crazes in polycarbonate, grown in a solvent environment to extend right across a tensile specimen, exhibit considerable hysteresis in a loading-unloading cycle, and that the foam-like craze structure does not collapse back to the original density on unloading. Hence, although during the initial unloading we can approximate the craze behaviour by a zero compressive yield stress, there is a stable craze strain beyond which a very large compressive stress is required for further contraction. This stable unloaded craze will exist on both crack faces, and will lead to compressive stresses across the crack faces in an unloaded specimen. Such crack closure stresses have been observed after fatigue crack growth in polycarbonate²³, which is a more sensitive photoelastic material than PVC. Thus we expect the whole craze to be cyclically strained in low frequency fatigue, with however

Figure 3 Ratio of craze to crack length versus applied tensile stress for 6 mm thick PVC sheet. +, $a = 19.68$ mm; □, $a = 3.14$ mm

a residual δ_0 even if the load reduces to zero, because of crack face closure.

In high frequency fatigue it is possible that the craze resists compression, and the stress must fall by an amount $\Delta\sigma$ before reverse yielding starts. If this is the case Rice¹¹ shows that the reverse yielded zone length R' is related to the fall in the stress intensity factor ΔK by:

$$R' = \frac{\pi}{8} \left(\frac{\Delta K}{\Delta\sigma} \right)^2 \quad (5)$$

for small scale yielding.

EXPERIMENTAL

Sample preparation

The rigid PVC used was ICI Darvic 025 in 1, 2, 3 and 6 mm sheets. No information on the molecular weight was available. It is assumed that the stabilizer/lubricant system is of the liquid type since the polymer does not stress whiten when it yields in a tensile test. Other PVC samples which incorporate insoluble stabilizers do stress whiten, and differ in their fracture toughness from Darvic 025. 8 in \times 3 in specimens were milled from the sheet and double edge notched (*DEN*). The machined V-notch was then sharpened by inserting a new razor blade, and then the PVC given a thermal history of either: (a) 1 h at 65°C, 5 h at 50°C and 16 h at 40°C; (b) 30 min at 90°C, then 15 min at 0°C. Treatment (a) was intended, by annealing below the glass transition temperature of about 65°C, to obtain a material with the highest possible yield stress. Treatment (b), of rapidly cooling through the glass transition was intended to effectively remove the yield stress maximum in a tensile test. Further discussion of how these thermal treatments affect plane stress yielding from a crack is given in ref 24. The treated PVC was stored at 23°C and 50% relative humidity before monotonic loading with an Instron tensile testing machine.

For fatigue crack growth tests single edge notched (*SEN*) specimens, and compact tension specimens were cut from 6 mm Darvic sheet. The former were used with a 0.4 ton

Amsler Vibrophore testing machine to obtain fatigue crack growth data at a frequency of about 67 cycles/sec. The latter were fatigue loaded on a small electromagnetic shaker driven machine to obtain sharp fatigue cracks, and then used for fracture toughness tests. Critical stress intensity factors (K_c) were obtained from fracture loads at low Instron crosshead speeds (0.05 cm/min) using corrections for the finite specimen width²⁵, for single edge notched and for compact tension specimens²⁶.

Craze growth during monotonic loading of cracks

First, the craze length was observed at known stress intensities. *DEN* samples machined from 6 mm thick Darvic 025 sheet were annealed (thermal history a). They were then loaded at an overall strain rate of $5 \times 10^{-5} \text{ sec}^{-1}$, in a temperature (23°C) and relative humidity (50%) controlled room. The craze growth was observed with a low power binocular microscope, using obliquely transmitted light. This method was devised by Kambour²⁷ who found that with the correct choice of the angle of incidence, total internal reflection occurs at the crack surface but not at the polymer/craze interface. Figure 3 shows the variation of craze length with applied stress. The data has been normalized, and using equation (1) the slope of the fitted straight line through the origin gives a value $\sigma_0 = 46 \text{ MN/m}^2$.

Secondly the craze thickness profile was investigated, although in this case the stress field intensity was unknown. *SEN* specimens of 6 mm thick Darvic 025 sheet were fatigued in a Amsler Vibrophore at 67 cycles/sec until several mm of crack growth had occurred. The specimens were then cut and polished parallel to the crack plane to give a specimen 6 mm deep containing the crack. The crack in the resulting slice was opened by driving a metal wedge into the machined part of the crack, using a hand operated compression cage on the stage of an optical microscope. The craze that formed was viewed by normal incidence using approximately monochromatic green light (maximum intensity at 0.54 nm and half width of 0.04 nm). The growth of a particular craze is shown in Figure 4. After each wedging open of the crack, the craze grew rapidly in length at first, but tended to an equilibrium length after about a minute. The effect of unloading on the fringe pattern was investigated, and in some cases, when the crack propagated and the craze wedge was left intact on one fracture surface, the fringe pattern of a craze on a free surface recorded. For unbroken crazes the thickness δ is related to the fringe number f (counting dark fringes from the zeroth fringe at the craze tip), the refractive index of the craze n_c , and the wavelength λ by:

$$\delta = f\lambda/2n_c \quad (6)$$

If equation (6) is to be used for crazes viewed on fracture surfaces, the fringes should be numbered $\frac{1}{2}$, $1\frac{1}{2}$ etc, since there is a phase change of π , only when light is reflected into a medium of lower refractive index. The shape of crazes in unloaded PVC and on fracture surfaces is shown in Figure 5. The craze tip is cusp-like, but the main portion of the craze is a uniform wedge, in contrast to the unloaded Dugdale model of Figure 2.

The refractive index of an unloaded craze was determined by Kambour's method of determining the critical angle for total internal reflection at the craze/matrix interface²⁷. The critical angle of incidence i at the sheet surface

Figure 4 Sequence of optical micrographs of a craze taken at time intervals of a, 30 sec; b, 90 sec; c, 300 sec of loading a crack; d, unloaded. The equally spaced lines on the left are the fatigue crack growth striations

was found to be $59 \pm 5^\circ$. Use of the relationship:

$$n_c^2 = n_m^2 - \sin^2 i$$

together with a matrix refractive index of $n_m = 1.56 \pm 0.01$, lead to a value for the unloaded craze refractive index of $n_c = 1.30 \pm 0.03$.

In order to convert the fringe pattern of a loaded PVC craze into a thickness profile, the refractive index of the loaded craze n_L , must be found. This is carried out by assuming that very little birefringence occurs in the craze, so that the Lorentz-Lorenz relationship applies before and after loading.

$$\frac{n^2 - 1}{n^2 + 2} = p\rho; \quad \frac{n_c^2 - 1}{n_c^2 + 2} = p\rho_c \quad (7)$$

where p is a material constant and ρ is the density. The craze deformation is a plane strain process, so if the polymer content of the craze is constant the product of craze thickness and density also remains constant. Denoting the

ratio of the loaded thickness to the unloaded thickness by r , we have from equation (6):

$$r = \frac{fn_c}{f_0n} \quad (8)$$

where f_0 is the unloaded and f the loaded fringe number. Eliminating n between equations (8) and (7) leads to the cubic in r :

$$r^3 + 2Ar^2 - Br + AB = 0 \quad (9)$$

where $A = (n_c^2 - 1)/(n_c^2 + 2)$ and $B = (n_c f/f_0)^2$. The one solution of this cubic with value >1 is used. The ratio of f/f_0 was plotted versus the distance from the craze tip in Figure 6. The ratio falls in the range 1.43 ± 0.03 , except at the very tip of the craze. Substituting this value in equation (9) gives $r = 1.57$. Further application of the above analysis to the observed values of refractive index for the original PVC and the unloaded craze leads to the result that the unloaded craze has an extension ratio of 1.72 compared

Figure 5 Thickness profiles of unloaded crazes. □, an unbroken sample; +, on a fracture surface. The thickness in fringes is plotted against the distance from the craze tip

Figure 6 Ratio of the fringe number for a loaded craze to the unloaded value versus the distance from the craze tip

with the original polymer. Both these values are independent of the position in the craze, excluding the craze tip. Since the craze was observed to grow in length with a constant wedge angle, it can be concluded that it does so by drawing in more polymer, rather than by further straining material already in the craze. On the other hand, on unloading this new material does not revert to the uncrazed state.

The maximum thickness of unloaded crazes at the crack tip was estimated by linearly extrapolating craze thicknesses to the observed position of the crack tip (the thickness fringes are obscured near the crack tip). Values of 4.0 to 5.7 μm were obtained. Using the calculated value of r , we can calculate the crack tip thickness of loaded crazes to have a maximum value of 6.3 to 8.9 μm .

Fracture toughness measurements

Two main sets of fracture toughness measurements were made. In the first the effect of sheet thickness on the validity of the plane strain K_C test was investigated. It is recommended²⁵ that the sheet thickness should exceed $2.5 (K_C/\sigma_0)^2$ for a valid test. In this set DEN samples were used and the machined notches were sharpened by a cut of ~ 0.05 mm with a new razor blade, before heat treatment. Table 1 shows the results.

R_C is the length on the fracture surface from the original crack tip to the end of the flat craze region (see next section). σ_0 is the plane strain tension lower engineering yield stress; this has been shown to be the yield stress relevant to the Dugdale model (a localized neck forms in the plane of the crack if very thin sheet is tested) and the values are taken from ref.24. Finally in the last column a plain strain fracture toughness of $K_C = 2.0 \text{ MN/m}^{3/2}$ is used to calculate the recommended sample thickness.

From Table 1 it can be seen that the recommended thickness requirements are somewhat conservative. For 'valid' fracture toughness tests the thermal history has no significant effect on the K_C values observed.

The second set of tests were made in view of the results of Marshall *et al.*²⁸, who found that the method of notching in polystyrene strongly affected the observed K_C values, in particular slow razor notching produced a craze bunch at the notch tip and a high K_C value, whereas cracks grown by fatigue at 30 cycles/sec, had a single craze at their tip and gave a low K_C value. Even though we did not observe craze bunches with razor notched specimens, there was a chance that fatigued specimens would give a smaller K_C value. Table 2 shows the fracture toughness values obtained on loading compact tension (CT) specimens at a crosshead speed of 0.05 cm/min. The two typical fatigue crack surface appearances have been described for polycarbonate²⁹. The conventional fatigue striations parallel to the crack tip occur if the crack grows in the plane perpendicular to the applied load. However, in some cases, the crack twisted about its growth direction by about 12° . In this case, the

Figure 7 Scanning electron micrograph of a PVC fracture surface. AA is the boundary of the fatigue crack growth, and BB of the craze grown in monotonic loading

crack front splits up into a large number of small crack fronts on slightly different layers, and where these fronts overlap and intersect cylindrical pieces of polymer are detached. It is suspected that this latter type of fatigue crack growth, is a result of a slight misalignment of the load points, and that the greater effective crack front leads to a higher K_c value. It can be noted that the K_c values for the conventional fatigue surface appearance are not significantly different to those for the *DEN* tests, so craze bunch formation in the type of PVC used cannot be a problem.

Having obtained a fracture toughness value, it is instructive to use the Dugdale model and equation (3) to calculate a critical crack opening displacement. Using $K_c = 1.84 \text{ MN/m}^{3/2}$, $\sigma_0 = 46 \text{ MN/m}^2$, and literature values of 100 sec for the creep modulus at 20°C and 1% strain of 3.0 GN/m^2 ³⁰, and Poisson's ratio of for other glassy plastics of 0.42³¹, we obtain $\delta_{0c} = 20 \text{ }\mu\text{m}$, which is approximately double the observed maximum craze thickness.

Fracture surface appearance

The fracture surface of 6 mm thick Darvic fracture toughness specimens shows no evidence of slow crack growth, rather there is a flat region about 0.5 mm wide where a craze had developed on loading, followed by a rough fast fracture region (Figure 7). If the flat region is observed by normally incident light, it will be found that one fracture surface has interference bands parallel to the end of the craze, and the other has no bands. Since the craze thickness fringes are identical to those for unloaded crazes in an unbroken specimen, it follows that the craze has broken on one of its interfaces with the uncrazed material. Circular holes are visible in the craze in Figure 7, and on another fracture surface where the craze has detached, some circular remnants remain (Figure 8). This suggests that 'penny' shaped cracks have developed in the craze be-

fore the craze/bulk interface has fractured. Close to the crack tip, the density of these $\sim 10 \text{ }\mu\text{m}$ radius 'penny' shaped cracks, may be so great that they coalesce (Figure 8) into a larger crack, which would appear to be the fracture source. With the razor notched specimens the crack usually propagates rapidly from this source either above or below the craze, so the flat craze areas only appear at the sides of the fracture surface. With the fatigue cracked specimens the fracture usually follows the initial craze. The craze/bulk interface must split much more rapidly than the penny shaped cracks are growing, otherwise the latter would have non-circular outlines.

Mechanism of fatigue crack growth

Fatigue crack growth was observed both as a function of the stress field intensity range ΔK , and the *R* ratio of $K_{\text{max}}/K_{\text{min}}$. Whereas previous workers^{5,7} had used *R* ratios of 0.1 or smaller, this greater range of experiments enabled the following observations to be made:

(a) It is confirmed that the crack grows discontinuously. The number of cycles of loading at the natural frequency of the Amsler of about 67 cycles/sec being about 1400 at ΔK values of $0.5 \text{ MN m}^{-1.5}$, decreasing to about 200 cycles at $\Delta K = 1.2 \text{ MN m}^{-1.5}$ for each fatigue striation.

(b) It is confirmed that craze growth occurs continuously⁷ at the crack tip. This is a single craze, and not a double craze as inferred⁷, where the surface of the sheet was examined. It is suggested that the two parallel markings on the sheet surface are a result of the shear lip that occurs at the surface.

(c) Except at very low *R* ratios, the crack does not jump the full length of the existing craze when it grows. Figure 9 shows clearly that the crack only advances a fraction of the craze length. The previous observation⁷ that for *R* = 0.1, the crack jumped approximately the full craze length is consistent with this.

Figure 8 As Figure 7, but for a razor notched specimen, showing more detail of the coalescence of 'penny' shaped cracks

Figure 9 Series of photographs of the crack tip during fatigue at 67 cycles/sec

(d) If the striation spacing s is plotted against ΔK , the results of many experiments can be correlated well (see Figure 10). If however K_{\max} is used, the correlation is much poorer.

(e) The fatigue crack growth rate also correlates well with ΔK (Figure 11), but not with K_{\max} .

Observations (c) and (d) strongly suggest that the crack jumps the length of the reversed plastic zone, which should be proportional to ΔK^2 on Rice's strip yield model (equation 5), rather than the full length of the craze, which might be expected to vary with either the maximum or the mean value of K . Since static loading experiments have shown that craze growth is time dependent for at least 1 min, it is not surprising that an equilibrium craze length is not reached in the 2 to 20 sec between crack jumps. The slope of the log striation spacing versus log ΔK (Figure 10) is only 1.35. On the strip yield model of a rigid-plastic material, whatever the ratio of the reverse to the forward yield stress, the reverse yielded zone should be proportional to ΔK^2 . The discrepancy may be due either to a further viscoelastic effect or to a change in the stress-strain behaviour of the craze as its size increases.

Examination of the fatigue surfaces showed that the craze structure is visible inbetween the striation bands (Figure 12). The cellular holes in the craze, just ahead of the crack arrest band, are only about $0.2 \mu\text{m}$ in diameter. There is no obvious change in the size of these holes between one arrest band and the next ($20 \mu\text{m}$ apart in this case). This conflicts with observations of fatigue surface replicas⁷ which suggest that 'equiaxed dimples' on the surface decrease in size from about $2 \mu\text{m}$ in front of one arrest band to about $0.2 \mu\text{m}$ behind the next band. It may reasonably be concluded that the craze fails near its mid-section rather than near the craze bulk interface, and that it is a fast 'brittle' failure; hence the audible clicks when growth occurs.

DISCUSSION

The first area of discussion is the usefulness of the Dugdale model in describing craze formation at a loaded crack in PVC. The form of the craze is far closer to the Dugdale's assumed plastic zone shape than is the equivalent plane stress plastic zone in thin sheets. Time dependent craze growth is a problem, but an equilibrium length is reached either after several minutes at each load, or on very slow continuous loading. Brown and Ward¹⁰, found that the

Figure 11 Fatigue crack growth rate versus stress intensity range for *R* ratios of □, 0.05; ○, 0.2; ◇, 0.33; △, 0.5

Figure 12 Scanning electron micrograph of a fatigue fracture surface. AA is a crack arrest line

thickness profile of loaded crazes in poly(methyl methacrylate) (PMMA) was in good agreement with the Dugdale model, but in PVC the profile has been found to be much closer to a uniform wedge. This may be related to the much greater length of crazes in PVC than in PMMA (see Table 3).

It is useful to see whether information obtained by applying the Dugdale model to crazes in PVC, is in accord with independent information on the crazing and fracture behaviour. By observing the craze length versus the applied stress (Figure 3), a value of $\sigma_0 = 46 \text{ MN/m}^2$ for the stress at the boundary of the yielded zone was obtained. This stress is slightly lower than the estimated lower plane strain tension yield stress of 55 MN/m^2 for annealed PVC. As the

density of a loaded craze is only 37% of that of the bulk polymer, the true stress in the highly oriented craze fibrils, must be about 124 MN/m^2 . It must be supposed that the orientation hardening in the craze fibrils is such that, rather than the fibrils yielding further, the craze thickens by advancing the craze-bulk boundary. The observation that the craze grows with a constant wedge angle (Figures 4 and 5), shows that the ratio of crack opening displacement to craze length δ_0/R remains constant. From the Dugdale model equations (1) and (3) we have:

$$\delta_0/R = 8\sigma_0/\pi E \tag{10}$$

At the boundary of the plastic zone the stresses are $\sigma_{xx} = \sigma_{yy} = \sigma_0$ and $\sigma_{zz} = 0$ (the model assumes uniform biaxial loading at infinity, which is not too different from the actual small uniaxial tension), so the elastic strains are $e_{xx} = e_{yy} = \sigma_0(1 - \nu)/E$; $e_{zz} = -2\nu\sigma_0/E$.

Substituting in equation (10) we then have:

$$\delta_0/R = 8e_{yy}/\pi(1 - \nu) \tag{11}$$

Equation (11) has been used to calculate the tensile strain e_{yy} at the boundary of the craze from our δ_0/R values, and from literature values for other glassy polymers, using $\nu = 0.42$. These are compared in Table 3 with e_{cr} , the critical strain below which crazing does not appear in long time ($\sim 24 \text{ h}$) tensile creep tests on unnotched glassy polymers.

If it is assumed that flaws on the surface of tensile creep specimens initiate craze growth if the tensile strain is great enough, then the correspondence between this strain and the value deduced from the Dugdale model is reasonable. In the case of PVC where σ_0 is known independently (Brown and Ward only calculated a value for PMMA by measuring the specimen compliance, and hence effective Young's modulus E^*), we can calculate $\sigma_0(1 - \nu)/e_{yy}$ to get a value of 6.5 GN/m^2 for the Young's modulus. This is about twice the experimental creep modulus³⁰. The discrepancy may be due to some yielding occurring above and below the craze. σ_0 is of the same order as the conventional yield stress, and if this additional yielding occurs, the craze would not need to be so thick, and e_{yy} would be underestimated by equation (11). It would also explain why the earlier calculation of a critical crack opening displacement of $20 \mu\text{m}$, from the Dugdale model and the measured K_{Ic} value, is greater than the observed value in Table 3.

The second area of discussion is the mechanism of craze failure in monotonic loading. We can start with the comment³² that the occurrence of circular 'advance fractures' in polystyrene shows that it is incorrect to use Griffith's approach to fracture (or the modification by Orowan³⁴ to include the plastic deformation of a surface layer) for polystyrene. We have observed for PVC both similar craze dimensions to those in polystyrene, and circular 'advance fractures'. Since we have suggested that the Dugdale model is more suitable for the crack/craze situation than the purely elastic situation investigated by Griffiths, we must

Table 3 Maximum craze dimensions, and strains

Polymer	δ_0 (μm)	<i>R</i> (μm)	e_{yy}	e_{cr}
PMMA ³³	1.73	24.2	0.016	0.008 ³²
Polystyrene ⁸	6*	550	—	0.0035 ³³
PVC	9	500	0.0041	0.007 ²

* For an unloaded craze

Figure 13 Model of the energy transfer in the formation of an advance fracture in a craze

investigate whether it is consistent with the formation of 'advance fractures'. In the model, the stresses in the yielded zone are uniform, whereas 'advance fractures' are observed to occur in the thickest part of the craze nearest the crack. We now estimate the amount of energy released when an 'advance fracture' forms. This consists of contributions from both within the craze, and from the surrounding uncrazed polymer (Figure 13). If the craze material is sufficiently anisotropic for the oriented strands bridging the craze to be able to break without load transfer to the neighbouring strands, then the energy released when a circular feature of radius c appears in the craze of thickness δ is the relaxed volume $\pi c^2 \delta$ multiplied by the elastic energy density released on unloading the craze. Such data are only available for specially thick crazes in polycarbonate²², so we assume that the craze unloads linearly from a stress of 46 MN/m² to 0.65 of its loaded thickness. Thus the recoverable energy density in the loaded craze is 8 MJ/m³. If a crack of radius 10 μm appears in a 8 μm thick craze, the energy released is 2×10^{-8} J. A second contribution from the uncrazed material is estimated as follows: we assume that a 'penny' shaped crack of radius C appears in a material that initially had a uniform stress $\sigma_0 = 46$ MN/m² normal to the plane of the crack. Sneddon³⁵ has shown that the reduction in the stored elastic energy of the solid is given by $8(1 - \nu^2) \sigma_0^2 C^3 / 3E$, which for $C = 10 \mu\text{m}$, $\nu = 0.42$ and $E = 3.0$ GN/m² gives a value of 0.15×10^{-8} J. The actual amount will be rather less because the stresses in the Dugdale model decrease away from the yielded zone rather than remaining constant. Even though the effect of the craze plane on the result is unknown, this suggests that energy release from within the craze is an order of magnitude greater than that from the surrounding uncrazed material for $C = 10 \mu\text{m}$. Since the former term is proportional to the craze thickness, we have provided a necessary explanation of the advance fracture appearing in the thickest part of the craze. However it is not sufficient, since the mechanism of the fracture initiation is unknown.

It has been common practice to quote 'surface energies' for the fracture of polymers, using Orowan's modification of Griffith's approach. If this is carried out for PVC we obtain a critical strain energy release rate ($2 \times$ the surface energy) of $G_c = K_c^2/E$ or 1300 J/m². The danger of presenting the fracture information in this way is that, it implies that PVC behaves in accord with the Griffiths model i.e. that if a testpiece of the correct geometry is used (so that the strain energy release rate is constant as the crack grows) then stable slow crack growth is possible for a value of G just exceeding G_c , with a uniformly thick craze layer being left on the crack surfaces. However the real situation is quite different. If our analysis of advance fracture forma-

tion is correct, this is a low surface energy process with a G_c of $8 \text{ MJ/m}^3 \times 8 \mu\text{m} = 64 \text{ J/m}^2$. When a number of these fractures have coalesced, cleavage at the craze boundary occurs, which again should be a low surface energy process. The crack immediately accelerates to about 500 m/sec⁴, at which speed crack bifurcation and other processes occur and absorb the 1300 J/m² of strain energy release. The difficulties of using G_c can be avoided entirely by using the critical stress intensity factor K_c , since this represents the critical elastic stress field, outside the yielded zone, that is necessary to initiate crack growth. Green and Pratt⁴ have shown that a stress intensity factor K of 2 MN/m^{3/2} is sufficient to maintain crack speeds of 500 m/sec in a similar PVC. Thus this PVC grade differs from PMMA, where it has been shown that K is an increasing function of crack speed for crack speeds less than 0.025 m/sec³⁶. Since advance fracture formation does not occur ahead of a slowly moving crack in PMMA, it seems likely that this low surface energy process is responsible for the absence of slow crack propagation in PVC.

Turning finally to the fatigue crack growth results, it is evident that the Dugdale model is less successful here than for the static craze growth experiments. Although Elinck *et al.*⁵ calculated values of σ_0 in the Dugdale model from their observed striation spacings, their experiments only covered a limit range of stress intensities. It is apparent that the striation spacing does not have a ΔK^2 dependence for our more extensive tests, so it is impossible to calculate σ_0 . The continuous craze growth during high frequency fatigue is most likely to be a viscoelastic process, with the craze having insufficient time to reach its equilibrium length before further crack growth occurs. If this is the case it is not very helpful to apply crack growth theories developed for metals which behave as elastic-plastic solids. Investigation of the cyclic stress strain behaviour of PVC crazes to see if they work harden or soften would be necessary before any further analysis of the crack growth process could be made. Observation of the fatigue fracture surfaces showed no 'advance fractures'. This is not surprising if the mechanism proposed for their formation is valid; the crazes fracture in fatigue when they are only 20–80 μm long, and if they have the same wedge angle as static crazes they will be too thin to contain sufficient elastic energy. In the fatigue fracture the craze appears to fail near its centre plane with relatively little damage to the open celled craze structure. The key to the fatigue growth rate probably lies in the material at the crack tip during each crack arrest. This material is left on the fracture surface as a distinctive band. The material survives a decreasing number of cycles as the stress intensity range increases, but at present the reasons for its eventual failure are unknown.

Determination of chain branching in low density polyethylene by ^{13}C nuclear magnetic resonance and infra-red spectroscopy

M. E. A. Cudby and A. Bunn

ICI Plastics Division, Welwyn Garden City, Hertfordshire, UK
(Received 27 August 1975, revised 5 December 1975)

Pulsed Fourier transform ^{13}C n.m.r. studies clearly demonstrate the presence of ethyl, butyl and longer chain branches in commercial low density polyethylene. The most suitable conditions for the measurement of the relative intensities of the resonance in the ^{13}C spectrum, were determined using a standard linear long chain hydrocarbon. The ^{13}C spectra of polyethylenes obtained using these parameters, in conjunction with a total methyl content by infra-red spectroscopy allow a quantitative measurement of the number of each branch type to be made.

INTRODUCTION

It is now well established¹⁻⁸ that many physical properties of low density polyethylene are dependent upon the nature and number of both short and long chain branches. As a result the study of branching in polyethylene has received considerable attention⁹⁻¹⁷. The early work on this problem by Willbourn⁹ made use of infra-red spectroscopic examination of model compounds such as branched polymethylenes and of the mass spectroscopic analysis of the products of irradiation of deuterated branched polymethylene. He found that low density polyethylene contained ethyl and butyl short chain branches, and the measurements which he reported, gave a ratio of 2:1 in favour of the ethyl branch.

Other authors¹⁸ then produced results which in general agreed, that ethyl and butyl branches were present in low density polyethylene but offered small variations on the ethyl to butyl ratio. This general picture was accepted until Bovey¹⁹ produced his ^{13}C n.m.r. data, and stated 'that for all practical purposes only n-butyl branches are present in commercial high pressure polyethylene'.

The work reported in this paper demonstrates the validity of the original claim that both ethyl and butyl branches are present in low density polyethylene and we have shown that quantitative determination of the number of these branches by ^{13}C n.m.r. is feasible under controlled experimental conditions. However, we also show that the ratio of ethyl to butyl branches can vary over a wide range and we believe this to depend on the reactor conditions used during the manufacture of the polymer being studied. Nevertheless, the present measurements generally indicate much lower ethyl/butyl ratios than those reported by Willbourn. A re-examination of the data in Willbourn's paper, in the light of subsequent work, suggests that the absolute values of the ethyl/butyl ratios may well be in error. Owing to the relatively small number of samples then available with known branching characteristics, assumptions had to be made both in relation to extinction coefficients and band overlap. The effect of these assumptions was to introduce a systematic error in the measurement of ethyl/butyl ratio. We also show furthermore, that the presence of longer chain branches is revealed by the ^{13}C n.m.r. examination and that the concentration of these branches may be determined also.

INSTRUMENTATION AND EXPERIMENTAL CONDITIONS

The ^{13}C n.m.r. spectra were obtained on a Varian XL-100-15 pulsed Fourier transform spectrometer controlled by a Varian 620i 16K computer. Concentrated solutions (~50% w/v) of polymers and eicosane were prepared in *o*-dichlorobenzene and the spectra obtained at ~140°C. A deuterium field/frequency lock is required for the operation of the XL-100-15 spectrometer and 1,1,2,2-tetraethoxyethylene glycol proved satisfactory at elevated temperatures. The D_4 ethylene glycol was contained in a 5 mm o.d. n.m.r. tube held centrally in a 12 mm o.d. n.m.r. tube containing the polymer solution. The chemical shifts were initially related to tetramethylsilane (TMS) but consistency was obtained by internal reference to the $-(\text{CH}_2)_n$ resonance in polyethylene at 29.9 ppm.

In order to achieve a signal to noise ratio adequate to determine the type and extent of branching in low density polyethylene, it is necessary to use the pulsed Fourier transform (*FT*) technique. This will result in a signal enhancement due to the Nuclear Overhauser Effect (*NOE*)²⁰⁻²². However, it is known that small differences in the *NOE* factor may be observed between for example methyl and methylene carbons²³. Thus, in the experiments described comparisons are only made between like ^{13}C species where the *NOE* factor is assumed to be constant. Further difficulties in quantitative analysis are experienced with *FT* experiments because of differences in the relaxation times of ^{13}C nuclei in different chemical environments. Therefore a series of experiments were devised using a pure sample of the linear hydrocarbon eicosane as a standard in which the instrumental parameters pulse width, pulse delay and acquisition time were varied. The best conditions were determined by measurement of the peak heights of the resonances due to the various carbon atoms of eicosane obtained with different instrument parameters. The instrumental conditions which produced the optimum relationship between the methylene carbon atoms were then used in the subsequent experiments with low density branched polyethylenes. All polyethylene spectra were therefore run with a pulse width of 40 μsec equivalent to a 30° tip angle, pulse delay of 3.0 sec and an acquisition time of 1.0 sec.

Figure 1 ^{13}C n.m.r. spectra obtained from low density commercial polymers (a) polymer A; (b) polymer B

Figure 2 ^{13}C n.m.r. spectra obtained from low density commercial polymers C and D. (a) polymer C; (b) polymer D

Representative spectra of the commercial low density polyethylene samples which are the subject of this paper are shown in Figures 1 and 2. The total methyl group contents of these materials were determined by the standard infra-red method²⁴ and the results are shown in Table 1.

It can be seen from the spectra of the low density polymers used, that resonances are clearly observed at 11.2 and 14.0 ppm from TMS. These correspond respectively to the methyl carbons in ethyl branches and butyl plus greater

length branches²⁵. In addition it is expected from observation of the spectra published by Randall²⁵ that the α -methylene carbon, i.e. that carbon adjacent to the terminal methyl group, will have a recognizably different chemical shift for n-butyl branches and for branches of longer linear methylene sequences. We find these resonances to occur at 23.3 and 22.7 ppm from TMS, respectively, in the spectra of the low density polyethylenes examined. Whilst we do not question the appearance of resonances at 32.02 and 32.58 ppm (Randall shifts) in the spectrum of low density polyethylene, we are not convinced that the assignment of the 32.58 ppm resonance to amyl branches is consistent with the data presented. For example, from the data listed for copolymers, the methyl carbon for amyl branches at 14.72 ppm should be observably different from the methyl carbon of longer branches at 14.29 ppm; a difference of 0.43 ppm. However, these are not observed as separate resonances in Randall's spectrum of low density polyethylene in which he claims to recognise the presence of both amyl and longer chain branches. The 3 methylene carbons (Randall) show a much smaller chemical shift difference in the same copolymers, 0.08 ppm. This is now apparently observed in the spectrum of polyethylene with a 0.56 ppm difference. Unlike Randall therefore, we cannot claim to be able to recognise separately the presence of the amyl branch.

In his paper, Bovey¹⁸ draws particular attention to the absence of a resonance in his spectra due to the β -methylene carbon, β to the terminal methyl of a long chain branch. However, it is possible to observe a resonance at 32.0 ppm in low density polyethylene under our specified experimental conditions which we attribute to the β -methylene carbon in question found in long chain branches. Thus, it is possible to distinguish resonances due separately to the presence of ethyl, n-butyl and longer chain branches in low density polyethylene.

The concentrations of ethyl, n-butyl and longer chain branches in the tabulated low density polymers were determined using the specific parameters indicated and the total methyl content per 1000 C atoms were determined by infra-red spectroscopy. The ratio of ethyl to butyl, plus longer branches is determined from area measurements of the resonances due to the end methyl carbons. This is justified since the measurement involves only carbon atoms where the NOE is similar. The ratio of butyl to longer branches is determined from the respective methylene carbons and are therefore also comparable in this analysis. The results are given in Table 1.

Because of the low molecular weight of polymer C the value for branches longer than n-butyl will be enhanced because of a significant contribution from the end group methyl. In the original paper by Willbourn⁹ on the branch-

Table 1

Figure 3 ^{13}C n.m.r. spectrum of an ethylene/butene-1 copolymer containing approximately 30 mol% butene-1

ing in polyethylene by infra-red spectroscopy a ratio of ethyl to n-butyl branches was given as 2:1 for a number of commercially available polymers. It is apparent from our ^{13}C n.m.r. data, that the ratio of n-butyl to ethyl branches can vary considerably in low density polyethylenes. The activation energy for formation is much higher for ethyl branches than for butyl branches and thus depending upon reactor conditions polymers produced will have different ethyl to butyl branch ratios. However, it would seem from the present examination that the number of n-butyl branches generally exceeds the number of ethyl branches in low density polyethylene.

Nevertheless, contrary to Bovey *et al.*¹⁸ it is clear that certain commercially available low density polyethylenes do contain a marked proportion of ethyl branches. The ratio of ethyl to n-butyl branches now observed, although different to that proposed by Willbourn, does not invalidate his comments on the branching mechanism. The new ratios indicate that there is less bunching of short chain branches than was originally thought to be the case. It may be noted that the resonance due to the methyl carbon of the ethyl branch is considerably more broad than the methyl carbon resonance of the n-butyl branch. Figure 3 is the spectrum of an ethylene/butene-1 copolymer containing approximately 30 mol% butene-1. The methyl carbon of the ethyl branch is now seen as three separate resonances arising from ethyl branches in different environments. These, we believe will be associated with (a) isolated butene units, giving rise to a resonance at 11.2 ppm; (b) adjacent butene-1 units as *meso* and *racemic* dyads, giving rise to resonances at 10.8 and 10.4 ppm respectively. Such variations may also be possible in the environment of ethyl branches in polyethylene, in combination with other structural possibilities such as the 2-ethyl hexyl branch. Thus, it would be reasonable to expect sufficient variations in the chemical shift of the terminal methyl carbon which could contribute to the observed broadening of the resonance. Although it is possible that n-butyl and longer branches also exist as *m* and *r* dyads it is unlikely that the methyl carbon resonance will show similar broadening since there is a greater distance and therefore less interaction between the methyl carbon and the main chain carbons than is the case for the ethyl branch.

CONCLUSION

There is no doubt that the ^{13}C n.m.r. spectrum demonstrates the presence of ethyl, n-butyl and longer branches in a number of unfractionated commercially available low density polyethylenes. Furthermore, the quantitative estimation of the number of branches of each type may be achieved provided the correct conditions for the Fourier transform experiment pertain.

Notes to the Editor

Glass transition temperature determination of poly(ethylene sulphide), poly(isobutylene sulphide) and their random copolymers

E. Sorta and A. De Chirico

*Snamprogetti SpA., Direzione Ricerca e Sviluppo, 20097 San Donato Milanese, Milano, Italy
(Received 20 October 1975)*

INTRODUCTION

In the course of further physicochemical characterization of copolymers made from ethylene sulphide (ES) and isobutylene sulphide (IBS) having very high crystallization rates, a method of very fast quenching was developed, following a suggestion reported in Wrasidlo's review¹.

This fact allowed us to obtain homopolymers and copolymers sufficiently amorphous to allow their glass transition temperature (T_g) to be determined. For poly(ethylene sulphide), it was not possible to find a direct measurement of T_g in the literature.

An attempt was made² to obtain the T_g of poly(ethylene sulphide) as a result of extrapolation from the T_g values of amorphous copolymers ethylene sulphide-propylene sulphide. The results, in this respect, were not sufficiently reliable and a direct experimental confirmation is required. The same techniques were used to determine the T_g of ES-IBS copolymers, obtained by means of polymerization with a low degree of conversion, which previously gave uncertain experimental values owing to the high degree of conversion. Hence every examined copolymer shows a T_g , which may be correlated, following existing theories, to its composition and to the homopolymer T_g .

EXPERIMENTAL

Materials

Homo- and co-polysulphides were prepared by methods described elsewhere⁶.

Besides poly(ethylene sulphide) (PES), and poly(isobutylene sulphide) (PIBS), four completely random copolymers with different comonomer ratio were prepared and then the random character tested by means of nuclear magnetic resonance⁴. The compositions are reported in Table 1.

Table 1 Copolymer compositions and glass transition temperatures

Sample	ES content (mol %)	T_g (°C)
IBS	0	-14
ES-IBS 18	17.7	-24
ES-IBS 32	32.0	-31
ES-IBS 40	40.0	-35
ES-IBS 58	58.0	-42
ES	100	-50

Figure 1 Glass transition temperatures vs. ethylene sulphide content (mol %) in the copolymer ethylene sulphide-isobutylene sulphide

Differential thermal analysis

Differential thermal analyses measurements were carried out using a model 900 Du Pont instrument in the d.s.c. version with a heating rate of 10°C/min.

The samples were heated at 30°C above their melting temperature for 10 min and then quenched between two metallic plates previously cooled at -190°C. The thermograms showed a typical glass transition, followed by a sharp cold crystallization peak. The glass transition temperatures were measured by the initial departure of the base line⁵.

RESULTS AND DISCUSSION

The experimental T_g values of the homopolymers (PES, PIBS) and copolymers (PES-PIBS) are reported in Table 1.

Figure 1 shows the relationship between T_g and the content of ethylene sulphide expressed in mol %. The behaviour is typical for random copolymers. This fact enables us to analyse the results following the theory of

Figure 2 Glass transition temperatures vs. $M_2 n_2 / M_1 n_1 (T_{g2} - T_g)$ and $M_1 n_1 / M_2 n_2 (T_{g1} - T_g)$ according to the Gordon-Taylor representation

Gordon-Taylor shown by Wood³. According to these authors, the glass transition temperature, T_g of the copolymer, can be represented by a function of the glass transition of the homopolymers T_{g1} and T_{g2} made from the respective constituents PES(1) and PIBS(2), in the following manner:

$$T_g = KX(T_{g2} - T_g) + T_{g1} \text{ or } T_g = \frac{1}{K} \frac{1}{X} (T_g - T_{g1}) + T_{g2} \quad (1)$$

where $T_{g2} > T_g > T_{g1}$; K is a constant of the materials and $X = n_2 M_2 / n_1 M_1$ with n_1, n_2 molar fractions of the comonomers having molecular weight M_1 and M_2 .

We obtain two straight lines which satisfy with good approximation, equation (1) as shown in Figure 2. The straight lines were drawn with the mean square method, without taking into consideration the homopolymers' experimental T_g values. Experimentally, the glass transition temperature of PIBS and PES were found to be -14° and -50° C, respectively. These values are in accordance with those extrapolated from copolymers and differ slightly from those predicted earlier².

Configuration of low molecular weight polystyrene in deuterated cyclohexane

D. G. H. Ballard and M. G. Rayner

Imperial Chemical Industries Limited, Corporate Laboratory, Runcorn, Cheshire, UK

and J. Schelten

Institut für Festkörperforschung, KFA, Jülich, West Germany
(Received 15 August 1975; revised 1 December 1975)

The radius of gyration of low molecular weight polystyrene in cyclohexane has been measured using the small-angle scattering facility at Jülich. The purpose of these measurements was to investigate how the molecular weight dependence of $\langle s_0^2 \rangle^{1/2}$ deviates from the $M^{0.5}$ law which holds for high molecular weights. The solvent was deuterated to provide the dissolved molecules with a larger scattering amplitude in a scattering experiment with slow neutrons. In a small-angle X-ray scattering experiment, the small difference between the electron density along the dissolved molecules and that of the solvent provides a low contrast. Hence, it would become extremely difficult to measure the coherent scattering from the low molecular weight polystyrene in the presence of a large background. Solutions with 5% and 1% narrow distribution polystyrene of 4000, 2100 and 600 molecular weight have been prepared and measured with neutrons of 7 \AA wavelength with

a sample-to-detector distance of 1 and 2 m. The measurements were performed at the θ -temperature, $T = 38^\circ$ C, in order to avoid long range interaction effects.

The coherent scattering from the solution of 1% polystyrene of the highest molecular weight, $M = 4000$, was, at zero scattering angle, about the same as the background scattering caused by the incoherent scattering cross-section of deuterium in the solvent and of hydrogen in the solute. This demonstrates that the background corrections had to be handled carefully, especially for the lowest molecular weight $M = 600$, where for background reasons experiments with a 1% solution were not feasible. A typical result of the coherent scattering from the dissolved polystyrene is shown in Figure 1 as a plot I_0/I versus K^2 .

The radii of gyration $\langle s_0^2 \rangle_2^{1/2}$ and $\langle s_0^2 \rangle_1^{1/2}$ obtained from the 2 m and 1 m runs, respectively, for the 5% and 1% solutions and their mean values, (giving the 2 m runs

Figure 2 Glass transition temperatures vs. $M_2 n_2 / M_1 n_1 (T_{g2} - T_g)$ and $M_1 n_1 / M_2 n_2 (T_{g1} - T_g)$ according to the Gordon-Taylor representation

Gordon-Taylor shown by Wood³. According to these authors, the glass transition temperature, T_g of the copolymer, can be represented by a function of the glass transition of the homopolymers T_{g1} and T_{g2} made from the respective constituents PES(1) and PIBS(2), in the following manner:

$$T_g = KX(T_{g2} - T_g) + T_{g1} \text{ or } T_g = \frac{1}{K} \frac{1}{X} (T_g - T_{g1}) + T_{g2} \quad (1)$$

where $T_{g2} > T_g > T_{g1}$; K is a constant of the materials and $X = n_2 M_2 / n_1 M_1$ with n_1, n_2 molar fractions of the comonomers having molecular weight M_1 and M_2 .

We obtain two straight lines which satisfy with good approximation, equation (1) as shown in Figure 2. The straight lines were drawn with the mean square method, without taking into consideration the homopolymers' experimental T_g values. Experimentally, the glass transition temperature of PIBS and PES were found to be -14° and -50°C , respectively. These values are in accordance with those extrapolated from copolymers and differ slightly from those predicted earlier².

Configuration of low molecular weight polystyrene in deuterated cyclohexane

D. G. H. Ballard and M. G. Rayner

Imperial Chemical Industries Limited, Corporate Laboratory, Runcorn, Cheshire, UK

and J. Schelten

Institut für Festkörperforschung, KFA, Jülich, West Germany

(Received 15 August 1975; revised 1 December 1975)

The radius of gyration of low molecular weight polystyrene in cyclohexane has been measured using the small-angle scattering facility at Jülich. The purpose of these measurements was to investigate how the molecular weight dependence of $\langle s_0^2 \rangle^{1/2}$ deviates from the $M^{0.5}$ law which holds for high molecular weights. The solvent was deuterated to provide the dissolved molecules with a larger scattering amplitude in a scattering experiment with slow neutrons. In a small-angle X-ray scattering experiment, the small difference between the electron density along the dissolved molecules and that of the solvent provides a low contrast. Hence, it would become extremely difficult to measure the coherent scattering from the low molecular weight polystyrene in the presence of a large background. Solutions with 5% and 1% narrow distribution polystyrene of 4000, 2100 and 600 molecular weight have been prepared and measured with neutrons of 7 \AA wavelength with

a sample-to-detector distance of 1 and 2 m. The measurements were performed at the θ -temperature, $T = 38^\circ\text{C}$, in order to avoid long range interaction effects.

The coherent scattering from the solution of 1% polystyrene of the highest molecular weight, $M = 4000$, was, at zero scattering angle, about the same as the background scattering caused by the incoherent scattering cross-section of deuterium in the solvent and of hydrogen in the solute. This demonstrates that the background corrections had to be handled carefully, especially for the lowest molecular weight $M = 600$, where for background reasons experiments with a 1% solution were not feasible. A typical result of the coherent scattering from the dissolved polystyrene is shown in Figure 1 as a plot I_0/I versus K^2 .

The radii of gyration $\langle s_0^2 \rangle_2^{1/2}$ and $\langle s_0^2 \rangle_1^{1/2}$ obtained from the 2 m and 1 m runs, respectively, for the 5% and 1% solutions and their mean values, (giving the 2 m runs

Figure 1 The reciprocal of the coherent neutron scattering I from the 5% polystyrene molecules of $M = 2100$ in deuterated cyclohexane, normalized to its forward scattering value I_0 as a function of the square of the scattering vector K^2

Table 1 Radii of gyration obtained with 5% and 1% solutions

M	$\langle s_0^2 \rangle_2^{1/2}$		$\langle s_0^2 \rangle_1^{1/2}$		Mean $\langle s_0^2 \rangle^{1/2}$
	5%	1%	5%	1%	
4000	15.6	15.4	16.5	16.0	15.7 ± 1
2100	10.2	10.0	12.1	12.2	10.8 ± 1
600	4.0	—			4.0 ± 0.5

twice the statistical weight of the 1 m runs), are given in Table 1. Within experimental errors, both the forward scattering normalized to the same concentration and the radius of gyration were found to be concentration independent.

The tabulated mean $\langle s_0^2 \rangle^{1/2}$ values are plotted versus the molecular weight in Figure 2 in order to compare the experimental results with various models. The uncertainties in measurement at different molecular weights are shown by error bars.

For high molecular weight polystyrene in a θ -solvent, it has been established that the unperturbed radius of gyration is related to molecular weight by the following expression¹:

$$\langle s_0^2 \rangle^{1/2} = \beta M^{0.5} \quad (1)$$

where $\beta = 0.272 \text{ \AA}$. This relationship is plotted in Figure 2 (solid line). As expected the measured $\langle s_0^2 \rangle^{1/2}$ are considerably below this line but they approach it asymptotically at higher molecular weights.

At very low molecular weights it is anticipated that a rigid-rod model should apply. The radius of gyration for such a model is determined by the total length L of the molecule:

$$\langle s_0^2 \rangle^{1/2} = L/(12)^{1/2} \quad (2)$$

where $L = l_b M/M_b$ and l_b and M_b are the length and the molecular weight of the repeat unit C_8H_8 . Using $l_b = 2.6 \text{ \AA}$ we find:

$$\langle s_0^2 \rangle^{1/2} = \gamma M \quad (3)$$

where $\gamma = 0.0072 \text{ \AA}$. This relationship is also plotted in Figure 2 for comparison with the experimental results. In this case the measured $\langle s_0^2 \rangle^{1/2}$ are below the line drawn for this model but they approach it asymptotically at low molecular weights.

A possible model for chain molecule configurations should yield an expression for $\langle s_0^2 \rangle^{1/2}$ which approaches equation (3) for very small M and equation (1) for very large M . Such a model has been proposed by Porod and Kratky and is frequently referred to as the worm-like chain^{3,4}. The expression for the radius of gyration is:

$$\langle s_0^2 \rangle = \frac{aL}{3} \left\{ 1 + \frac{3a}{L} + 6 \left(\frac{a}{L} \right)^2 - 6 \left(\frac{a}{L} \right)^3 \times [1 - \exp(-L/a)] \right\} \quad (4)$$

The persistence length, a , is determined from the requirement that for large L , equation (4) should approach equation (1) i.e.

$$\frac{aL}{3} = \beta^2 M \quad (5)$$

which yields $a = 8.8 \text{ \AA}$.

The molecular weight dependence of $\langle s_0^2 \rangle^{1/2}$ from equation (4) is shown in Figure 2. The experimental values are close to this line. Taking into account that the $\langle s_0^2 \rangle^{1/2}$ are z -averages which have to be lowered by less than 4% according to the equation⁵:

$$\langle s_0^2 \rangle_w^{1/2} = \langle s_0^2 \rangle_z^{1/2} \left(\frac{1+U}{1+2U} \right)^{1/2} \quad (6)$$

where $U = (\bar{M}_w/\bar{M}_n) - 1 \leq 0.1$ for these polymers, the result of this experiment is that the molecular weight dependence of $\langle s_0^2 \rangle^{1/2}$ is satisfactorily described by the Porod-Kratky model.

These results may be compared with those described in Figure 1 of Kirste's paper⁶, obtained for low molecular weight poly(methyl methacrylate) in acetone, by small-

Figure 2 Radius of gyration $\langle s_0^2 \rangle^{1/2}$, as a function of molecular weight on a log-log scale. Neutron scattering results, I ; (—), $\langle s_0^2 \rangle^{1/2} = \beta M^{0.5}$; (- - -), $\langle s_0^2 \rangle^{1/2} = \gamma M$; (- · - · -), Porod-Kratky model $\langle s_0^2 \rangle^{1/2} = f(a, L)$

angle X-ray scattering. In contrast with the present data, Kirste reported serious deviations between his experimental data and those predicted by equation (4). He attempted to explain these deviations in terms of the finite cross-section of the chain but concluded that deviations from the Porod-Kratky model were responsible for the differences. The contribution of the finite cross-section of the chains is in the case of neutron scattering, about 15% of the smallest measured $(s_0^2)^{1/2}$ value and less than 2% for the others. It would seem from our data that in the critical region equation (4) is correct for polystyrene.

Reaction between lithium polystyryl and iodinated polystyrene

J. Pannell

Research Department, ICI Plastics Division, Welwyn Garden City, Herts, UK
(Received 3 November 1975; revised 1 December 1975)

INTRODUCTION

The successful preparation of comb-type branched polystyrenes has been reported by several authors¹⁻⁵. In all cases 'living' polystyrene (the branch precursor) was allowed to react with appropriate functional groups incorporated in another polystyrene chain (the backbone). The most commonly used functional group was the chloromethyl group substituted in the aromatic rings *para* to the carbon chain¹⁻⁴, although the ester group has also been used⁵, incorporated into the backbone by copolymerizing methyl methacrylate with styrene. In this method of preparation the branched polymer forms part of a mixture also containing linear polymer, which is produced by termination of the living polymer by impurities in the system. A study of the properties of these branched polymers therefore necessitates either a fractionation to remove this linear homopolymer^{2a,3} or some way of making allowance for it^{2b}. An alternative method of preparing branched polymers, and one that can in principle be used to prepare graft copolymers also, is the addition of a monomer to a multifunctional polymeric initiator. However, this type of initiator has not so far been prepared free of a monofunctional species, which competes for the monomer to give linear homopolymer.

In considering alternative methods for preparing branched polymers and graft copolymers, a study was made of the reaction between low molecular weight lithium polystyryl* and iodinated polystyrene. The preparation of the latter⁶ was found to be easily controlled and reproducible and not accompanied by undesirable side reactions, factors which make it preferable to the introduction of chloromethyl groups into polystyrene by classical chloromethylation. The results of this study are reported here.

rene ($\bar{M}_n = 1.14 \times 10^5$), was partially iodinated in nitrobenzene solution at 90°C using a procedure described by Braun⁶. After 12 h the solution was cooled and the polymer precipitated by adding to a large volume of methanol. The pale yellow polymer was re-precipitated from tetrahydrofuran (THF) into methanol and dried. The iodine content, determined by the oxygen flask combustion method, was 28.9% by weight. This result, together with the infra-red spectrum of the product, shows that one in three of the aromatic rings contain iodine substituted exclusively *para* to the carbon chain of the polymer.

Preparation of lithium polystyryl

Low molecular weight lithium polystyryl was prepared using n-butyl lithium as initiator, employing techniques described elsewhere² and was used in the reaction with partially iodinated polystyrene shortly after its preparation. A small portion was terminated with methanol and characterized. The solvent used in the preparation of lithium polystyryl was either benzene or a mixture of THF and benzene (80:20 v/v).

Reactions

The reaction between lithium polystyryl and the iodinated polystyrene was carried out at room temperature in an inert atmosphere of argon using techniques similar to those described previously². Three experiments were performed.

(i) A solution containing 3 g iodinated polystyrene in 150 cm³ THF was added slowly to a stirred solution of lithium polystyryl in THF/benzene mixture. A slightly yellow granular precipitate formed immediately and the addition of the iodinated polystyrene was continued until no more precipitate formed. At this stage the solution was amber-coloured but became colourless immediately on the addition of methanol.

(ii) A solution of 18.5 g lithium polystyryl in 80 cm³ benzene was added slowly to a stirred solution of 1 g iodinated polystyrene in 150 cm³ THF. A turbidity developed during the addition of about two-thirds of the living poly-

angle X-ray scattering. In contrast with the present data, Kirste reported serious deviations between his experimental data and those predicted by equation (4). He attempted to explain these deviations in terms of the finite cross-section of the chain but concluded that deviations from the Porod-Kratky model were responsible for the differences. The contribution of the finite cross-section of the chains is in the case of neutron scattering, about 15% of the smallest measured $(s_0^2)^{1/2}$ value and less than 2% for the others. It would seem from our data that in the critical region equation (4) is correct for polystyrene.

Reaction between lithium polystyryl and iodinated polystyrene

INTRODUCTION

The successful preparation of comb-type branched polystyrenes has been reported by several authors¹⁻⁵. In all cases 'living' polystyrene (the branch precursor) was allowed to react with appropriate functional groups incorporated in another polystyrene chain (the backbone). The most commonly used functional group was the chloromethyl group substituted in the aromatic rings *para* to the carbon chain¹⁻⁴, although the ester group has also been used⁵, incorporated into the backbone by copolymerizing methyl methacrylate with styrene. In this method of preparation the branched polymer forms part of a mixture also containing linear polymer, which is produced by termination of the living polymer by impurities in the system. A study of the properties of these branched polymers therefore necessitates either a fractionation to remove this linear homopolymer^{2a,3} or some way of making allowance for it^{2b}. An alternative method of preparing branched polymers, and one that can in principle be used to prepare graft copolymers also, is the addition of a monomer to a multifunctional polymeric initiator. However, this type of initiator has not so far been prepared free of a monofunctional species, which competes for the monomer to give linear homopolymer.

In considering alternative methods for preparing branched polymers and graft copolymers, a study was made of the reaction between low molecular weight lithium polystyryl* and iodinated polystyrene. The preparation of the latter⁶ was found to be easily controlled and reproducible and not accompanied by undesirable side reactions, factors which make it preferable to the introduction of chloromethyl groups into polystyrene by classical chloromethylation. The results of this study are reported here.

Preparation of lithium polystyryl

Low molecular weight lithium polystyryl was prepared using n-butyl lithium as initiator, employing techniques described elsewhere² and was used in the reaction with partially iodinated polystyrene shortly after its preparation. A small portion was terminated with methanol and characterized. The solvent used in the preparation of lithium polystyryl was either benzene or a mixture of THF and benzene (80:20 v/v).

Reactions

The reaction between lithium polystyryl and the iodinated polystyrene was carried out at room temperature in an inert atmosphere of argon using techniques similar to those described previously². Three experiments were performed.

(i) A solution containing 3 g iodinated polystyrene in 150 cm³ THF was added slowly to a stirred solution of lithium polystyryl in THF/benzene mixture. A slightly yellow granular precipitate formed immediately and the addition of the iodinated polystyrene was continued until no more precipitate formed. At this stage the solution was amber-coloured but became colourless immediately on the addition of methanol.

(ii) A solution of 18.5 g lithium polystyryl in 80 cm³ benzene was added slowly to a stirred solution of 1 g iodinated polystyrene in 150 cm³ THF. A turbidity developed during the addition of about two-thirds of the living poly-

mer solution but beyond this, a slightly yellow granular precipitate settled out. The addition of lithium polystyryl was continued until a definite orange colouration persisted and then a few drops of methanol were added, giving a colourless solution.

(iii) Experiment (ii) was repeated, except that the iodinated polystyrene was in solution in benzene. A slight turbidity formed during the reaction but no precipitate separated.

The precipitate which formed in experiments (i) and (ii), was separated by centrifuging and was washed repeatedly with THF until the washings were colourless. The soluble polymer in all three experiments was recovered by precipitation into methanol, followed by re-precipitations into water and methanol.

RESULTS AND DISCUSSION

Characterization of the soluble polymer recovered after the reaction between lithium polystyryl and partially iodinated polystyrene shows that its molecular weight is nearly double that of the lithium polystyryl (see Table 1).

G.p.c. also shows that the molecular weight of the soluble polymer recovered after the reaction, although still low compared with that of the polystyrene used for iodination, is higher than that of the lithium polystyryl precursor. Furthermore the chromatograms show that the molecular weight distribution of the soluble product is less skewed than that of the precursor. (Figure 1).

These results suggest that during the title reaction the lithium polystyryl was involved in a chain extension reaction rather than a coupling reaction with the iodinated polystyrene. (During the reaction some of the living polymer is terminated by impurities and it is this which makes the apparent molecular weight of the soluble product somewhat less than twice that of the precursor). The simplest mechanism which can explain these results involves two distinct steps. In the first step the lithium polystyryl and the partially iodinated polystyrene undergo lithium-halogen exchange:

The iodo-capped polymer (II) then couples with lithium polystyryl to give the soluble product polymer with a head-to-head linkage:

The lithium-halogen exchange reaction is known to occur between both poly(*p*-bromostyrene) and poly(*p*-iodostyrene) and *n*-butyl lithium⁶⁻⁸ and evidence has been presented (Altares *et al.*¹) which suggests that the more ionic lithium polystyryl can also take part in an exchange reaction (with chlorine in 1, 2, 4, 5-tetrachloromethylbenzene), although this occurs to a lesser extent than the coupling or displacement reaction. If lithium polystyryl

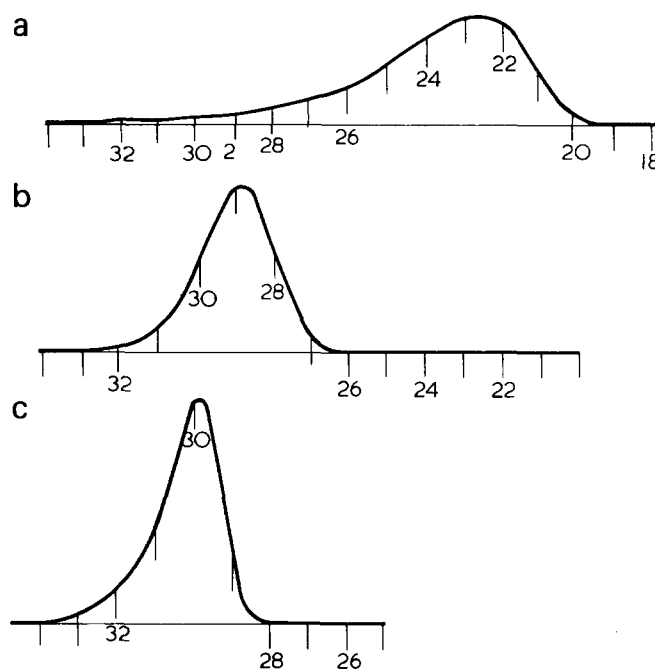

Figure 1 The g.p.c. chromatograms: (a) polystyrene used for iodination; (b) soluble product polymer from reaction (2); (c) proton-terminated lithium polystyryl used in reaction (2). The samples were injected into a Waters Associates chromatograph at 308 K using chloroform as solvent; their concentration was 1/4% by wt. Four columns (each 122 cm long and 0.95 cm in diameter) containing 'Styragel' were used in series (10^6 , 10^5 , 10^4 , and 10^3 Å respectively)

is capable of participating in lithium-halogen exchange with an organic chloride, then it is more likely to do so with an organic iodide e.g. poly(*p*-iodostyrene).

The chain extension reaction shown in equation (2), also occurs in the reaction of the disodium salts of the dianions of both polystyrene and the α -methyl styrene tetramer with iodine^{9,10} and in the reaction between potassium polystyryl and bromine¹¹.

The polymer that was recovered from the reaction carried out in benzene, was largely the chain-extended polymer, but a turbidimetric titration confirmed the presence of a small proportion of a high molecular weight component which before protonation was the lithiated polystyrene (I).

Additional evidence in support of the proposed mechanism was sought by looking for differences in the accumulated ¹³C n.m.r. spectra of the proton-terminated precursor and the chain extended polymer(III). The spectra of both polymers (Figure 2) show weak resonances at 13.8, 22.2, 26.9 and 31.7 ppm (relative to the resonance from the internal standard tetramethylsilane) not present in the spectrum of free radical polystyrene¹²; they are assigned to the carbon

Figure 2 Part of the accumulated ^{13}C n.m.r. spectra of (a) proton-terminated lithium polystyryl and (b) the soluble product polymer from the reaction of lithium polystyryl with iodinated polystyrene. The spectra were recorded on a Varian XL100 spectrometer at 25.2 MHz with the polymers dissolved in CDCl_3

atoms in the *n*-butyl end groups derived from the initiator. However, an additional weak resonance at 33.7 ppm appears in the spectrum of the proton-terminated living polymer and this is thought to be due to the $-\text{CH}_2-$ carbon in the terminal $-\text{CH}_2-(\text{Ph})$ group, a group not present in the chain-extended polymer (III). The resonance from the corresponding methylene carbon in some model compounds (ethyl-, *n*-butyl-, dodecyl- and *n*-propyl benzene) appears at 29.3, 35.9, 36.2 and 38.3 ppm respectively¹³.

A resonance attributable solely to the methine carbons of the head-to-head linkage $-\text{CH}(\text{Ph})-\text{CH}(\text{Ph})-$ in the chain extended polymer was not observed, probably because of overlap with the much stronger resonance at 40.5 ppm from the methine carbons of the repeat units in the chain.

The lithiated polystyrene (I) which formed as a result of the lithium-iodine exchange reaction (1), and which precipitated from the mixed benzene/THF system, became protonated on the addition of methanol but remained insoluble thereafter. The infra-red spectrum of this insoluble polymer shows that not all the iodine in the original iodinated polystyrene had exchanged with lithium; about one in nine of the aromatic rings of the repeat units still contained iodine *para* to the carbon chain. This is about one third of the iodine content of the original iodinated polystyrene.

One of the consequences of the lithium-iodine exchange reaction in the system described here is that species are

present which might conceivably crosslink and this could be the reason for the formation of an insoluble polymer from the THF/benzene mixture used in two of the experiments. However, the granular form of the original precipitate was unlike that of a typical crosslinked polystyrene and an insoluble polymer did not form when the reaction was carried out in benzene. It seems more likely, therefore, that differences in solubility of the lithiated polystyrene, either alone or as a complex with lithium iodide, accounts for the formation of a precipitate from THF/benzene but not from benzene alone. If this is so then the reason why the precipitate that formed in the THF/benzene system remained insoluble on protonation, is that crosslinking occurred subsequently i.e. during isolation of the polymer.

CONCLUSION

When low molecular weight lithium polystyryl reacts with iodinated polystyrene, lithium-iodine exchange occurs to give a lithiated polystyrene and a chain extended polymer derived from the lithium polystyryl. The lithiated polystyrene precipitates from a THF/benzene mixture when approximately 22% of the aromatic rings are lithiated, i.e. before all the iodine has exchanged. When the reaction is carried out in benzene by the addition of lithium polystyryl to the iodinated polystyrene the lithiated polymer remains in solution and can be prepared free of excess living polymer. Thus a multifunctional anionic initiator may be made for the preparation of branched polymers or graft copolymers free of an excess of a monofunctional species which can cause homopolymerization of the added monomer. This method of preparing lithiated polystyrene therefore appears to have a distinct advantage over that which uses (a) *n*-butyl lithium in a similar lithium-halogen exchange reaction^{6,7} or (b) the *n*-butyl lithium/TMEDA* complex for direct metalation of polystyrene¹⁴. Further experimental work will be necessary to confirm this.

ACKNOWLEDGEMENTS

The author is grateful to Mr A. Titterton for experimental assistance and to Mr A. Bunn for recording the n.m.r. spectra.

Raman scattering from the longitudinal acoustic mode in crystalline poly(ethylene oxide)

Low-frequency Raman bands have been observed in solid n-paraffins. These bands which have fundamental frequencies inversely proportional to chain length¹ have been assigned as the longitudinal acoustic (LA) accordion-like vibration of the chain. If the chain is treated as a continuum the fundamental frequency ν (cm^{-1}) is given by:

$$\nu = \frac{1}{2lc} \left(\frac{E}{\rho} \right)^{1/2} \quad (1)$$

where E is the Young's modulus of the chain, l is the chain length and ρ the density. Analogous LA modes in single crystals of polyethylene^{2,3} and in bulk melt-crystallized polyethylene⁴⁻⁶ have also been reported. Here, we report the first observation of the LA mode in well-characterized α,ω -hydroxy-poly(ethylene oxide) fractions of molecular weights from 1000 to 20 000 and in a series of α,ω -alkoxy-poly(ethylene oxide) fractions.

Poly(ethylene oxide) samples, obtained from the sources listed in Table 1, were precipitated from benzene solution by addition of iso-octane and dried. These fractions, with very narrow molecular weight distributions (see Table 1), were melt-crystallized at the temperatures indicated in Table 1. Raman spectra from 6 cm^{-1} to 100 cm^{-1} were obtained using a Cary 82 spectrometer and an argon ion laser operating at 5145 \AA with 600 mW power. A typical spectrum is shown in Figure 1. Three distinct peaks were obtained for the crystalline polymers, two of which are illustrated in Figure 1. None of these peaks are present in the spectrum of the melt. Lamella spacings were determined by small-angle X-ray scattering by means of a Rigaku-Denki camera as described elsewhere⁷.

The lowest peak frequencies (ν) and the lamellar spacings (l_x) are listed in Table 1. For samples of $\bar{M}_n < 3000$, which are known⁷ to crystallize in chain-extended form when melt-crystallized at 25°C , the frequencies show a smooth shift to lower values corresponding to the gradual increase in lamellar thickness. Therefore, we assign these peaks to the fundamental LA accordion-like modes in

Figure 1 Low-frequency Raman spectrum for crystalline poly(ethylene oxide) of $\bar{M}_n = 2000$. The Rayleigh scattered peak is recorded on reduced scale

poly(ethylene oxide). The second peaks, which are broader and of lower intensity, have frequencies greater than those of the fundamentals by a factor of approximately 2.3, rather than 3.0 as would be expected of a third overtone. The third peak centered at 84 cm^{-1} , is very broad and does not change with lamellar thickness.

On the basis of the Raman and X-ray evidence it can be concluded that for a crystallization temperature of 25°C , poly(ethylene oxide) of $\bar{M}_n = 2000$ or less crystallizes in the chain-extended form and that of $\bar{M}_n = 4000$ or higher in the chain-folded form. Fraction 3000 contains both types of crystal. Its low-angle X-ray diffraction pattern shows two maxima of similar intensities corresponding to repeat distances of 19.3 and 9.9 nm. The Raman peak at 12.0 cm^{-1} , which is close to that of fraction 1500, is indicative of the presence of the once-folded crystal in fraction 3000. Unfortunately, the LA mode frequency for the chain-extended crystal is too low to be observable by the present technique. Fraction 3000 crystallized at 35°C was found to give a weak Raman peak at 12.0 cm^{-1} , reflecting a decrease in the proportion of the once-folded material. These findings are in accordance with previous conclusions derived from crystallization rate and melting point data^{7,8}.

A simple stacked lamella model with alternating crystalline and non-crystalline layers can be used to describe the crystalline state of poly(ethylene oxide)⁹. There is evi-

dence⁹ that the crystalline lamella thickness (l_c) is proportional to the lamella spacing (l_x) obtained from X-ray scattering. The constant of proportionality for chain-extended crystals of poly(ethylene oxide) fractions has been estimated⁹ to be about 0.67. A value of $\nu l_x = 121 \times 10^{-7}$ (see Table 1) leads to a value of νl_c of 81×10^{-7} and so, taking the density of perfectly crystalline poly(ethylene oxide) to be 1.12 g/cm^3 , to a value of the elastic modulus of the crystalline helical poly(ethylene oxide) chain of $E = 2.7 \times 10^{10} \text{ N/m}^2$ as compared with the value of $1.0 \times 10^{10} \text{ N/m}^2$ found from lattice extension measurements¹⁰. However, we must be cautious in this interpretation since it is not clear from our present data whether the Raman peak is associated with l_c or l_x .

We have also studied the Raman spectra of a series of fractions with a constant central poly(ethylene oxide) block of $\bar{M}_n = 2000$ and with symmetrical alkoxy-end-groups ranging in chain lengths from 1 (methoxy-) to 18 (octadecoxy-) carbon atoms. The samples were prepared from α,ω -hydroxy-poly(ethylene oxide) by a modified Williamson ether synthesis recommended by Dr D. R. Cooper. The LA mode frequencies for these fractions melt-crystallized at 25°C , are plotted against the numbers of carbon atoms in the alkoxy-end-group in Figure 2. These results indicate that the lower members of the series crystallize in chain-extended form whereas the higher members crystallize in chain-folded form; the sample with heptoxy-end-groups (C7) forms both types of crystals. These findings are confirmed by small-angle X-ray scattering and melting point measurements¹¹. A further feature of interest in these data is a slight decrease in the product νl_x as the alkane chain length is increased. Various diblocks, triblocks and mixtures of poly(ethylene oxide) are currently under investigation.

Intermolecular forces and the Raman spectrum of crystalline PVC

In a recent paper¹, Moore and Krimm have presented the results of a vibrational analysis of crystalline syndiotactic poly(vinyl chloride). The calculation was based on a general valence force field derived from an analysis of the spectra of small secondary chloride molecules and it included an intermolecular force field chosen to reproduce correctly the infra-red band observed at 64 cm^{-1} in both secondary chlorides and highly syndiotactic PVC. This band has been assigned previously^{2,3} to a vibration whose potential energy is distributed between an intramolecular torsional vibration and an intermolecular motion and the intermolecular interaction is taken to be hydrogen-bonding of the form C—H...Cl—C.

The results of the calculation are compared with the i.r. results of Krimm *et al.*⁴ and the Raman results of Koenig and Druedow⁵ and the overall agreement appears to be good. In particular, the calculation predicts that the A_1 and B_1 C—Cl stretching modes, observed in the infra-red at 640 and 604 cm^{-1} , should each be split, because of correlations between the motions of the two chains in the unit cell, into two components with significant separation. The four predicted frequencies are shown in Table 1, together with their spectral activity and the frequencies observed by Krimm *et al.* and by Koenig and Druedow.

We are at present involved in a detailed study of the vibrational spectra (more particularly the Raman spectra) of various samples of PVC with a view to characterizing their tacticity, conformational distribution and molecular orientation distribution. We are studying the C—Cl stretching region in great detail because of its sensitivity to these structural parameters and the frequency that we observe for the B_{3g} Raman-active mode of highly syndiotactic urea-canal complex PVC does not agree very well with that of Koenig and Druedow, as is shown in the last column of Table 1. Also shown in this column are our values for the frequencies of the A_g Raman active mode and the B_{1u} and B_{2u} infra-red active modes, which agree quite well with the earlier results.

The Raman spectra were obtained from powder samples of urea-canal complex PVC held in the open ends of capillary tubes. The laser beam was focused into the open end and the Raman light was collected at 90° to the direc-

Intermolecular forces and the Raman spectrum of crystalline PVC

In a recent paper¹, Moore and Krimm have presented the results of a vibrational analysis of crystalline syndiotactic poly(vinyl chloride). The calculation was based on a general valence force field derived from an analysis of the spectra of small secondary chloride molecules and it included an intermolecular force field chosen to reproduce correctly the infra-red band observed at 64 cm^{-1} in both secondary chlorides and highly syndiotactic PVC. This band has been assigned previously^{2,3} to a vibration whose potential energy is distributed between an intramolecular torsional vibration and an intermolecular motion and the intermolecular interaction is taken to be hydrogen-bonding of the form C—H...Cl—C.

The results of the calculation are compared with the i.r. results of Krimm *et al.*⁴ and the Raman results of Koenig and Druedow⁵ and the overall agreement appears to be good. In particular, the calculation predicts that the A_1 and B_1 C—Cl stretching modes, observed in the infra-red at 640 and 604 cm^{-1} , should each be split, because of correlations between the motions of the two chains in the unit cell, into two components with significant separation. The four predicted frequencies are shown in Table 1, together with their spectral activity and the frequencies observed by Krimm *et al.* and by Koenig and Druedow.

We are at present involved in a detailed study of the vibrational spectra (more particularly the Raman spectra) of various samples of PVC with a view to characterizing their tacticity, conformational distribution and molecular orientation distribution. We are studying the C—Cl stretching region in great detail because of its sensitivity to these structural parameters and the frequency that we observe for the B_{3g} Raman-active mode of highly syndiotactic urea-canal complex PVC does not agree very well with that of Koenig and Druedow, as is shown in the last column of Table 1. Also shown in this column are our values for the frequencies of the A_g Raman active mode and the B_{1u} and B_{2u} infra-red active modes, which agree quite well with the earlier results.

The Raman spectra were obtained from powder samples of urea-canal complex PVC held in the open ends of capillary tubes. The laser beam was focused into the open end and the Raman light was collected at 90° to the direc-

tion of the incident beam and analysed by means of a Coderg PHO Raman spectrometer. The spectrometer was calibrated by means of a neon discharge-tube and the frequencies are believed to be accurate to ± 1 cm⁻¹.

Figure 1 shows the C-Cl stretching modes which are much more clearly resolved in our spectrum than in that of Koenig and Druedow. As part of our detailed study of the C-Cl stretching region, the spectra of the various samples in the range 550 cm⁻¹ to 750 cm⁻¹ have been recorded digitally on paper tape and analysed into a set of overlapping Lorentzians and a linear background. It is necessary to use at least four Lorentzians to fit this region of the urea-canal complex PVC spectrum, the two most intense of which correspond to the observed peaks at 608 and 639 cm⁻¹. A broad weak peak centred at 695 cm⁻¹ is to be interpreted as being due to vibrations of non-crystalline bent syndiotactic conformations and possibly isotactic structures. This region of the i.r. spectrum has been discussed in detail by Krimm and his coworkers⁶. The fourth Lorentzian corresponds to a small peak centred near 645 cm⁻¹ and this feature cannot be interpreted, as far as we can see, as a C-Cl stretching mode. It appears to be present in all our samples of PVC and further study of its intensity relative to the other peaks in the C-Cl region is being undertaken with a view to understanding its origin.

The present results suggest that the predicted correlation splitting of the B₁ species is too small and that the predict-

ed order in frequency of the components is wrong. This in turn suggests that the interchain force field used may not be entirely satisfactory, although both the observed and predicted splittings are quite small, so that the test is not very sensitive. Similar but larger correlation splittings are predicted for the A₁ and B₁ C-C-Cl bending vibrations. The calculated and observed frequencies for the C-C-Cl bending vibrations between 300 and 400 cm⁻¹ are given in Table 2 and the Raman spectrum is shown in Figure 2. For the A₁ and B₁ vibrations the observed Raman and infra-red frequencies show splittings of only 1 or 2 cm⁻¹, whereas the predicted splittings of the A₁ and B₁ species are 16 and 6 cm⁻¹ respectively. We do not observe any Raman peak at 330 or 345 cm⁻¹.

A more direct test of the force-field would be provided by the observation of the predicted low-frequency modes which depend more directly on the intermolecular force field and we therefore attempted to obtain good spectra in the region of the Raman spectrum below 200 cm⁻¹, which was not reported by Koenig and Druedow. Spectra were obtained down to ~ 50 cm⁻¹ on the Coderg double spectrometer and down to ~ 7 cm⁻¹, on a Carey 82 triple spectrometer. Both Stokes and anti-Stokes spectra were run on the Carey 82 and Figure 3 shows the results from 15 cm⁻¹ to 200 cm⁻¹.

A very strong peak is observed at 88 ± 1 cm⁻¹, which

clearly corresponds to the peak observed² at 89 cm^{-1} in the infra-red and predicted at 86 cm^{-1} in the Raman. Peaks of moderate strength are observed at 170 and 185 cm^{-1} and a very weak peak at 60 cm^{-1} . There are no predicted Raman-active modes within 10 cm^{-1} of any of these, the nearest possible assignment being that of the 60 cm^{-1} peak to the predicted B_{3g} mode at 45 cm^{-1} . There is no sign of peaks in the predicted positions 39 , 45 , 80 and 134 cm^{-1} , the first three of which would be particularly sensitive to the intermolecular potential. It is possible that the modes predicted at 39 and 134 cm^{-1} are too weak to be observed, and that the two modes predicted at 80 cm^{-1} are of low intensity and are lost beneath the peak at 88 cm^{-1} , which has a half width of $\sim 13\text{ cm}^{-1}$.

The two peaks observed at 170 and 185 cm^{-1} are not easily accounted for. Tasumi and Shimanouchi⁷ have observed an absorption in the infra-red spectrum of an oriented highly syndiotactic sample at 180 cm^{-1} which shows parallel polarization and a weaker shoulder at about 160 cm^{-1} . They were unable to predict vibrations in this frequency region from their single-chain analysis and suggested that it was likely that the absorption at 180 cm^{-1} arises from a mode in which internal rotation is coupled with a lattice vibration, whereas Moore and Krimm⁸ have subsequently suggested that vibrations in the vicinity of 180 cm^{-1} should be assigned to conformations other than the planar zig-zag. The weakness of the observed Raman peaks for the urea-canal complex polymer does not allow us to deny the possibility that they may originate from disordered chains, but we have observed that in the Raman spectrum from a less ordered sample (Montecatini-Edison fibre-forming grade PVC) there is only what appears to be a single peak about 40 cm^{-1} wide centred near 160 cm^{-1} , which is somewhat more intense relative to the peak at 88 cm^{-1} than the 170 and 185 cm^{-1} peaks are for the urea-canal complex sample. This observation suggests that the vibrations due to disordered conformations may occur predominantly at lower frequencies than 170 and 185 cm^{-1} . Another possibility for the origin of these two peaks is that they are due to overtones or combinations of the four modes predicted by Moore and Krimm¹ at 80 , 80 and 86 cm^{-1} in the Raman and 90 cm^{-1} in the infra-red, but bands due to overtones and combinations are usually too weak to be observed in the Raman spectrum.

Polarization studies might be expected to help in the interpretation of the spectrum, since the only bands due to the crystalline material that should not be totally depolarized are those corresponding to A_g symmetry. One of the modes predicted at 80 cm^{-1} has this symmetry, and so do any first overtone bands. The only other predicted A_g mode in the low frequency region is that at 39 cm^{-1} . Unfortunately, we have only very small quantities of the urea-canal complex polymer in powder form so that we have been unable to make polarization studies on it. We have, however, looked for variations in the depolarization of bands in the low frequency Raman spectrum of sheets pressed from Montecatini-Edison fibre-forming grade PVC (which is more syndiotactic than the usual commercial PVCs but less syndiotactic than urea-canal PVC) but without success. All bands appeared to be depolarized to approximately the same degree.

We conclude that the observed low frequency Raman spectrum offers no confirmation of the intermolecular force-field used by Moore and Krimm¹. The only observed frequency which coincides closely with a predicted frequency is that at 88 cm^{-1} , which corresponds directly to that at 86 cm^{-1} in the infra-red. The internal torsional force constant was based essentially on the corresponding frequencies for secondary chlorides. None of the frequencies predicted for the lattice modes have been observed, unless the peak observed at 60 cm^{-1} corresponds to the B_{3g} mode predicted at 45 cm^{-1} , and peaks observed at 170 and 185 cm^{-1} are not satisfactorily accounted for. The low frequency region would thus repay further study, particularly if larger quantities of highly syndiotactic polymer were available.

Acknowledgements

We should like to thank the Department of Chemistry at the University of Manchester, for allowing us to use the Carey 82 spectrometer, Montecatini-Edison SpA., for supplying us with a sample of their fibre-forming grade of PVC and B. F. Goodrich Co. for providing the sample of urea-canal complex PVC. We are grateful to the SRC for granting a CASE studentship to M.E.R.R.

On the structure of 3,4-/*cis*-1,4-polyisoprene by ^{13}C n.m.r.

Introduction

^1H n.m.r. and infra-red spectroscopic studies on polyisoprenes with different microstructure have given information only on the content but not on the arrangement of isomeric units¹. Although ^{13}C n.m.r. spectroscopy has been proven to be a powerful tool for the elucidation of the sequence structure of polybutadienes^{2,3}, only a little work has been carried out on polyisoprene by this method since the pioneering ^{13}C n.m.r. study of Duch and Grant⁴. A recent study on *cis-trans* isomerized 1,4-polyisoprene⁵ showed that the distribution of *cis-cis*, *cis-trans* and *trans-trans* linkages can be determined by ^{13}C n.m.r. The purpose of this communication is to report that ^{13}C n.m.r. spectroscopy gives detailed information on the sequence structure of a binary polyisoprene with 3,4- and *cis*-1,4 structural units.

Experimental

The polymer was prepared with $\text{Ti}(\text{O}-n\text{-C}_3\text{H}_7)_4$ $\text{Al}(\text{C}_2\text{H}_5)_3$ catalyst⁶ in toluene at 0°C . The conversion was low. The sample contained 64% 3,4- and 36% *cis*-1,4-units as determined by ^{13}C and ^1H n.m.r.

Results and Discussion

In order to label the position of a particular carbon atom in a given sequence the i 'th C-atom of 3,4-units (v) and *cis*-1,4-units (c), is marked by v_i and c_i respectively ($i = 1, 2, 3, 4, 5$) where the carbon atoms are numbered according to the following scheme:

Throughout head-to-tail enchainment of the structural units is assumed. In a sequence of symbols the enchainment of the corresponding units is head-to-tail from right-to-left. Thus the notation v_3c_4 , for instance, means the tertiary C-atom, C^x , of the central v -unit in the following chain segment:

Figure 1 shows the ^{13}C n.m.r. spectrum of 3,4-/*cis*-1,4-polyisoprene. In the olefinic region (a), particularly the resonances of olefinic α -C-atoms, v_2 , of 3,4-units and olefinic β -C-atoms, c_3 , of *cis*-1,4-units show fine structure due to different isomeric structure of neighbouring units. Of the methyl groups in the aliphatic part of the spectrum (b), only the resonance of the methyl carbon v_5 in the vinyl side group of 3,4-units is split into several signals. The highest informational content, however, is contained in the region between 26 and 50 ppm which contains 12

Figure 1 ^{13}C n.m.r. spectrum (22.63 MHz) of 3,4-/*cis*-1,4-polyisoprene; (a), olefinic region; and (b) aliphatic region

resonances of methylene C-atoms c_1 and c_4 of *cis*-1,4-units, of methylene C-atoms v_4 of 3,4-units and of methine C-atoms v_3 of 3,4-units. The analysis of the present communication is restricted to this region.

By comparison with the spectrum of pure *cis*-1,4 polyisoprene, the signals of methylene C-atoms c_1 and c_4 in *cis*-1,4-block sequences can be localized at once at 26.2 ppm (1) and at 32.4 ppm (7). Although the ^{13}C n.m.r. spectrum of pure 3,4-polyisoprene is not available at present it will be shown that the resonances of secondary C-atoms v_4 and tertiary C-atoms v_3 in 3,4-block sequences must be assigned to signal 9 at 37.8 ppm and to signal 10 at 42.1 ppm.

For linear saturated hydrocarbons the chemical shift δ_k of the k 'th C-atom can be expressed by the following relation

$$\delta_k = B + \sum_l A_l n_{kl} \quad (1)$$

The constant B is almost equal to the chemical shift of methane, -2.6 ppm⁷, n_{kl} is the number of carbons in the l 'th position relative to the k 'th carbon and A_l is the chemical shift parameter assigned to the l 'th C-atom. The five A_l values: α , β , γ , δ and ϵ found by regression analysis of the chemical shifts of linear alkanes, are given in Table 1. The chemical shifts of polyisoprene evaluated on the basis of these parameters by means of relation (1) are far from being in agreement with the experimental values. The calculated set, however, has two important features. First, the calculated values can be classified into 12 groups of closely

Table 1 Chemical shift parameters (ppm) for the calculation of chemical shifts in 3,4-*cis*-1,4-polyisoprene

Values for linear alkanes ⁷		Correction parameters ^a	
α	9.1	$c_1(\alpha)$	-7.5
β	9.4	$c_4(\alpha)$	1.0
γ	-2.5	$3 \times (2^\circ)$	-6.2
δ	0.3	$2^\circ (3 \times)$	-1.1
ϵ	0.1		

^a symbols as explained in the text

spaced signals corresponding to the observed signals 1–12. Secondly, the three highest predicted shifts are obtained for the tertiary C-atoms of 3,4-units in the central position of triads. The differences between these values are essentially due to the γ -shift induced by the tertiary centre of the flanking v-units in these triads. The observed shift differences of the 3 low field signals of the aliphatic spectrum (b) in *Figure 1* are of similar magnitude indicating corresponding structural differences. The best absolute agreement of predicted and observed shifts of these signals is obtained by using an improved parameter set for tertiary C-atoms in branched alkanes⁸. With this set one finds 39.5 ppm (vv_{3v}), 44.2 ppm (vv_{3c}, cv_{3v}) and 46.3 ppm (cv_{3c}) as compared with the experimental positions of 42.1 ppm (10), 44.7 ppm (11) and 47.9 (12).

Even with the best available parameter sets for branched alkanes⁸, it is not possible to obtain perfect agreement either between predicted and postulated signal positions of tertiary C-atoms v₃ in 3,4-block sequences or between predicted and known positions of the methylene C-atoms c₁ and c₄ in the *cis*-1,4-homopolymer. Therefore we use the 5 shift parameters for linear alkanes only and determine new experimental correction parameters for polyisoprene from the differences of observed and evaluated signal positions of the block sequences. From the difference of the experimental shift 32.4 ppm and the predicted value 39.9 ppm of the signal cc_{1c} the parameter c₁(α) is obtained, which means the correction for methylene C-atoms with 1,1 disubstituted olefinic C-atom in α -position. From the difference of 26.2 ppm and 25.2 ppm for experimental and calculated positions of the c_{4c} signal the parameter c₄(α) is determined, which means a correction for methylene C-atoms with a monosubstituted olefinic C-atom in α -position. For the signal of tertiary C-atoms vv_{3v} in 3,4-block sequences the difference of the postulated position at 42.1 ppm and the predicted position at 54.5 ppm yields the parameter $3 \times (2^\circ)$, which means the correction for tertiary C-atoms with an olefinic vinyl C-atom in α -position bound to a secondary C-atom. The values of c₁(α), c₄(α) and $3 \times (2^\circ)$ are contained in *Table 1*. Now the shifts of all C-atoms c₁ and v₃ in other than block sequences are calculated by means of relation (1) and the experimentally determined correction terms. The corresponding sequences are assigned to the spectral positions (2), (6) and (11), (12) as shown in *Table 2*. One is left with the secondary C-atoms v₄ of 3,4-units and secondary C-atoms c_{4v} of *cis*-1,4-units adjacent to the tertiary centre of a neighbouring 3,4-unit. The maximum predicted shift, 40 ppm, of these signals is evaluated for the methylene C-atoms in 3,4-block sequences. Therefore, of the remaining signals, the signal 9 at lowest field at 37.8 ppm is assigned to these C-atoms. From the difference of the postulated and calculated positions a further parameter $2^\circ (3 \times)$ is determined, which means a correction for secondary C-atoms adjacent to tertiary centres, with olefinic vinyl C-atoms in α -position. By means

of the complete set of correction parameters of *Table 1*, the chemical shifts of the remaining carbon resonances are recalculated and assigned to the spectral positions 3, 4, 5 and 6. Considering the complete assignment given in *Table 2* one notices that the predicted shifts assigned to the positions 2–6 exceed the experimental values by 0.2–0.4 ppm, which is the order of separation between the observed signals in this region. Actually, an almost perfect coincidence between experimental and calculated shifts could be achieved if the assignment of the positions 3–6 is displaced by one position towards lower field and the empty position at (3) is filled by some of the calculated signals assigned to position (2). This would, however, not be in agreement with the observed relative signal intensities.

The probability $P(v)$ of finding a 3,4-unit in the polymer can be estimated according to the relation:

$$\frac{1}{2} P(v) = I_{10} + I_{11} + I_{12} \quad (2)$$

where I_{10} , I_{11} , I_{12} are the relative intensities of the signals 10, 11 and 12 normalized with respect to the total intensity of the signals 1–12. The factor 1/2 on the left hand side of equation (2) arises because the total intensity is proportional to twice the total number of structural units. From equation (2) and the experimental intensities the value $P(v) = 0.64$ is obtained. The conditional probability of finding a v-unit, given an adjacent c-unit, can be estimated from:

$$\frac{1}{2} [1 - P(v)] P_{cv} = \frac{1}{2} I_{11} + I_{12} \quad (3)$$

The correspondingly defined conditional probability P_{vc} is determined from the equation:

$$\frac{1}{2} P(v) [1 - P_{vc}] = I_{10} + \frac{1}{2} I_{11} \quad (4)$$

Table 2 Chemical shift data and relative intensities in 3,4-*cis*-1,4-polyisoprene

^a Symbols as explained in the text; ^bcalculated for a Bernoullian distribution; ^ccalculated for first order Markov statistics.

From (3) and (4) the values $P_{CV} = 0.86$ and $P_{VC} = 0.49$ are obtained. These values indicate that the distribution of structural units does not follow Bernoullian chain statistics but statistics with a tendency towards alternation of structural units. This can also be seen qualitatively by comparing the relatively strong intensity of the signal cv_3c (12) of triads with alternating structure with the intensity of the signal vv_3v (10) of block triads.

By means of the statistical parameters determined from the spectrum the relative intensities of all signals were evaluated assuming first order Markov statistics as well as Bernoullian chain statistics. Table 2 shows that for all signal groups, the intensity of which can be measured with sufficient accuracy, the best agreement between predicted and experimental intensities is found for the Markov model. To explain these results further investigations are being carried out on this system.

Book Reviews

The Physics of Rubber Elasticity (third edition)

L. R. G. Treloar

Clarendon Press, Oxford, 1975, pp 310, £14.00

The first edition of this book was published some twenty five years ago. It deservedly won respect from physicists and chemists of the time for its lucid exposition of a subject which was widely regarded until then as being unamenable to scientific discipline. The second edition appeared in 1958. It maintained the same high standard but in order to allow an adequate updating of the major themes some peripheral topics were curtailed. This process is continued in the third edition to the point where the chapters on the dynamic mechanical properties and on crystallization have been dropped completely. The book is still about the same length as of previous editions, but it is now devoted entirely to the equilibrium properties of rubbers and to the rubbery state of matter. The treatment of this narrower field is refined and very much up-to-date. It sets a standard of presentation rarely equalled in monographs of this kind.

The first nine chapters deal with general phenomena, statistics of a single chain, network statistics and the experimental examination of the predictions of theory which includes the thermodynamics of dry and swollen rubbers and photoelasticity. Extraneous information has been carefully pruned from the earlier texts and the main arguments are clarified and amplified. The author is at pains to point out where opinions differ and where he stands with respect to these opinions.

The remainder of the book deals with recent developments in the phenomenology of general strain, the theory of large deformations and thermoelastic studies. These chapters are new and two at least – 'alternative forms of the strain-energy function' and 'thermoelastic analysis of the Gaussian network' – are gems.

Treloar's personal qualities include a clear mind and a facility for designing simple pertinent experiments. These qualities shine through the book. It will be enjoyed by research workers, teachers and students whether or not they are familiar with the subject.

One sad comment: The elasticity of caoutchouc is exceeded only by the elasticity shown by the publishers in stretching the price of the third edition. In 1960, the second edition cost £2-5-0.

Mechanics of Polymers

R. G. C. Arridge

Clarendon Press, Oxford, 1975, £6.50

A wide coverage of topics make this book suitable as a course book on mechanics of polymers. It may also be useful to researchers requiring information on aspects of polymer mechanics related to their work. Chapter 1 provides a good general introduction to polymers and plastics. Viscoelasticity is outlined in some detail in Chapter 3. The relationships between the relaxation and retardation spectra and between the stress relaxation, creep and dynamic moduli and compliances have also been discussed. However the useful approximate conversion equations are dealt with rather briefly (p 75), although reference is made to a good source. Perhaps some examples of their use and graphical representation of typical data could have been given following the descriptions of lab methods in Chapter 4. Here, although the torsion pendulum is described in adequate detail, creep and stress relaxation testing is described very briefly. A brief discussion of the tensile test would be here appropriate. Values of frequencies used in Figures 4.2, 4.5, 4.8 should be quoted and discussed in relation to the investigated temperature range.

The subject of secondary transitions is also dealt with rather briefly considering the important effects these have upon polymer properties. On the other hand stress and strain are dealt with at length and this is available in many books on strength of materials.

The subject of anisotropy is well treated and is of practical importance. Also yield, cold drawing, work hardening and softening is treated thoroughly and had a close relationship to fracture. The reviewer finds the subject of fracture being dealt with rather briefly. The compliance method of measuring fracture toughness should have been described in detail. Some of the more widely used fracture toughness specimen types with their K calibration formulae could have been included so that non specialists could carry out fracture toughness measurements without further information. Alternatively reference could have been made to suitable texts (such as ASTM) on this extensive and important subject. Apart from some basic references on fracture mechanics, a few more important papers on fracture toughness of specific plastics (e.g. Ehrlich, Knaus, Wnuk, Retting) could be quoted. Similarly, a brief description of the modern approach to fatigue (Hirschberg, Manson) and stress corrosion (Scully) would be useful in providing a simple link between physics and engineering.

The effort made in the book to compare and contrast polymer behaviour with that of metals and ceramics is useful. Similarly the treatment of properties on an atomic (or molecular), micro and macro scale is valuable. However students might find that there was a lack of practical examples compared to the theoretical content while the book's usefulness to other users e.g. researchers, would be much improved if the book had a much higher content of up-to-date data on the properties of the more important polymers (e.g. see McCrum-Read-Williams book).

J. C. Radon

From (3) and (4) the values $P_{CV} = 0.86$ and $P_{VC} = 0.49$ are obtained. These values indicate that the distribution of structural units does not follow Bernoullian chain statistics but statistics with a tendency towards alternation of structural units. This can also be seen qualitatively by comparing the relatively strong intensity of the signal cv_3c (12) of triads with alternating structure with the intensity of the signal vv_3v (10) of block triads.

By means of the statistical parameters determined from the spectrum the relative intensities of all signals were evaluated assuming first order Markov statistics as well as Bernoullian chain statistics. Table 2 shows that for all signal groups, the intensity of which can be measured with sufficient accuracy, the best agreement between predicted and experimental intensities is found for the Markov model. To explain these results further investigations are being carried out on this system.

Book Reviews

The Physics of Rubber Elasticity (third edition)
L. R. G. Treloar
Clarendon Press, Oxford, 1975, pp 310, £14.00

The first edition of this book was published some twenty five years ago. It deservedly won respect from physicists and chemists of the time for its lucid exposition of a subject which was widely regarded until then as being unamenable to scientific discipline. The second edition appeared in 1958. It maintained the same high standard but in order to allow an adequate updating of the major themes some peripheral topics were curtailed. This process is continued in the third edition to the point where the chapters on the dynamic mechanical properties and on crystallization have been dropped completely. The book is still about the same length as of previous editions, but it is now devoted entirely to the equilibrium properties of rubbers and to the rubbery state of matter. The treatment of this narrower field is refined and very much up-to-date. It sets a standard of presentation rarely equalled in monographs of this kind.

The first nine chapters deal with general phenomena, statistics of a single chain, network statistics and the experimental examination of the predictions of theory which includes the thermodynamics of dry and swollen rubbers and photoelasticity. Extraneous information has been carefully pruned from the earlier texts and the main arguments are clarified and amplified. The author is at pains to point out where opinions differ and where he stands with respect to these opinions.

The remainder of the book deals with recent developments in the phenomenology of general strain, the theory of large deformations and thermoelastic studies. These chapters are new and two at least – 'alternative forms of the strain-energy function' and 'thermoelastic analysis of the Gaussian network' – are gems.

Treloar's personal qualities include a clear mind and a facility for designing simple pertinent experiments. These qualities shine through the book. It will be enjoyed by research workers, teachers and students whether or not they are familiar with the subject.

One sad comment: The elasticity of caoutchouc is exceeded only by the elasticity shown by the publishers in stretching the price of the third edition. In 1960, the second edition cost £2-5-0.

Persistence length of cellulose tricarbaniolate by small-angle neutron scattering

A. K. Gupta, J. P. Cotton*, E. Marchal, W. Burchard† and H. Benoit

Centre de Recherches sur les Macromolécules CNRS, 6, rue Boussingault, 67083 Strasbourg Cedex, France

(Received 12 December 1975)

Small-angle neutron scattering measurements were made on cellulose tricarbaniolate in dioxane at different temperatures. The persistence length evaluated from the Kratky plot was found to be 110 Å at room temperature. A decrease in persistence length with increasing temperature was observed.

INTRODUCTION

Cellulose tricarbaniolate (CC) has been shown to have a rather rigid conformation in dioxane solution. Its conformation is usually described by the Kratky–Porod model¹ for which the rigidity is characterized by a quantity, a , called ‘persistence length’. A variation of persistence length with temperature was noticed^{2,3} for CC and was shown to be related to a change from one conformational state to another². Usually, persistence lengths are determined by studying one quantity as function of molecular weight. If the conformation, and thus a , depends on molecular weight, which is the case for CC², these methods cannot be used in a straightforward manner. Thus, those investigations which allow the determination of a on a single sample are of utmost interest.

Small-angle neutron scattering (SANS) or X-ray scattering provide such methods. The X-ray technique has been applied with success to CC in acetone at 20°C⁴. It is interesting to compare the two techniques. We report SANS results on CC in dioxane at various temperatures. The previous two studies^{5,6} on the application of this technique for the determination of a were made on systems in which independent determinations of a had not been carried out. For the present system, the values of a determined from various techniques have been reviewed in a recent publication².

Two sets of experiments were performed in order to cover a wide range of wave vectors, using different wavelengths of incident neutron beams and different sample-detector separations. Identical results were obtained from both sets of experiments. However, at the larger sample-detector separation an important scatter of experimental points was found at higher scattering angles (due to a smaller difference between signal and background). The extrapolations carried out on these data were ascertained by comparison with theoretical scattering curves. The persistence length was evaluated using the Kratky procedure⁷, which is described below in brief.

It is well known that the scattering envelope can be divided into different domains depending on the relative values of the wavevector q [$q = (4\pi/\lambda) \sin \theta/2$, λ being the wavelength and θ the scattering angle] and the dimensions of the coil:

(1) If $q \leq 1/R$, R being molecular radius of gyration, we are in the Guinier domain and a plot of I^{-1} or $\log I$ (I being scattered intensity) as a function of q^2 allows the determination of R .

(2) When q increases, the scattering envelope can be described by the Debye formula⁸:

$$I = \frac{2KcM}{(q^2R^2)^2} [q^2R^2 - 1 + \exp(-q^2R^2)] \quad (1)$$

if the chain is Gaussian. Here K is the optical constant of the system, c the concentration in g/ml. This formula is valid as long as $q < 1/a$. If $(R^2)^{1/2}$ is much longer than a there is a domain of q :

$$\frac{1}{R} \leq q \leq \frac{1}{a}$$

where the asymptotic law $I \sim q^{-2}$ is valid.

(3) If $1/a < q < 1/r$, r being the radius of gyration of a cross-section of the chain or a characteristic distance of the repeating unit of the polymer, the chain behaves like a rod of length L and the asymptotic expression:

$$I = Kc \frac{M}{L} \pi q^{-1} \quad (2)$$

can be used⁹.

It is usual to represent the results using the Kratky procedure, i.e. plotting Iq^2 versus q . If the three quantities R , a and r are very different, one should obtain a graph similar to that plotted in Figure 1. Part 1 is the Guinier range; part 2 the Debye domain, where Iq^2 reaches an asymptotic value; part 3 the rod-like behaviour domain, where Iq^2 is proportional to q and part 4 the domain where the internal structure of the monomeric units has to be taken into account.

The most interesting feature in this representation is the transition between domains 2 and 3. Under favourable circumstances there is a sharp transition between the horizontal domain (part 2) and the sloping straight line (part 3) at a value q^* of q related to the persistence length by:

$$a = A/q^* \quad (3)$$

The constant A is easily calculated by equating the limiting

† Institut für Makromolekulare Chemie, Universität Freiburg, Freiburg i-Br, West Germany.

Figure 1 Schematic representation of a Kratky plot showing the four parts of the scattering pattern for stiff chains

intensity in equation (1) at high q and that of equation (2). Using the expression for radius of gyration of worm-like chain in the limiting case $L \gg a$ ($R^2 = aL/3$), this value is $A = 6/\pi \sim 1.91$.

This ideal situation is not often encountered and various authors^{4,10} have made calculations to see the exact shape of the scattering curve in the regions 2 and 3 when the above equations are not fulfilled. More specifically, if R is not very large compared to a , the Debye branch (part 2) is no longer horizontal in the Iq^2 vs. q plot and q^* lies in the region where the curvature goes through a maximum. The value of the constant A may differ from the ideal value 1.91; in fact values of $A = 2.23$ ¹⁰ and $A = 2.87$ ⁴ have been reported as upper limits. A lower value of $A = 1.7$ is obtained from des Cloizeaux's¹¹ treatment of an infinite Kratky–Porod chain. The approximation used by some authors⁵, which consists in using $A = 1$, seems to be an over-simplification. In the case of an infinitely large Gaussian coil the horizontal line would lie below the curve obtained for real chains.

EXPERIMENTAL

Apparatus

Neutron scattering experiments were made on the small-angle apparatus of the Leon Brillouin Laboratory using the neutron flux produced by the reactor EL3 (CEN, Saclay). The detector used is the multidetector of (ρ, θ) type¹². The principle of the set up is very similar to that described elsewhere¹³. Here the incident beam is collimated by two holes (3 mm diameter) separated by a distance of 1.20 m. The effects of the large incident wavelength distribution ($\Delta\lambda/\lambda \sim 30\%$) are corrected for by taking for the mean wavelength¹³:

$$\langle \lambda \rangle = \frac{1}{I_0} \int \lambda i(\lambda) d\lambda$$

which is valid in the range of q where equation (2) holds. The mean wavelength of neutron beam 7.05 Å and sample detector distance of 3.75 m provided measurements in the range $0.007 < q < 0.07 \text{ Å}^{-1}$ for the first set of experiment (experiment I). For the second set of experiments (experiment II) a range of q values $0.004 < q < 0.04 \text{ Å}^{-1}$ was obtained by using a neutron beam of wavelength 8.72 Å and a sample-detector distance of 5 m. A 5 mm thick quartz cell was employed for holding the sample. The tempera-

ture of the sample was kept constant to within $\pm 0.1^\circ\text{C}$ by enclosing the sample in a thermostatically controlled chamber.

Materials

The CC sample of weight-average molecular weight 130 000 was used in this study. Details of its preparation and characterization are given elsewhere². Deuterated dioxane (from Carl Roth OHG Karlsruhe) was used without redistillation, to obtain better contrast between intensity scattered from solvent and solute. Concentration of the solution was maintained at $\sim 8 \times 10^{-3} \text{ g/ml}$, which was within the range where no intermolecular effects are observed².

RESULTS AND DISCUSSION

Experiment I

The scattering data of experiment I are shown in Figure 2 in the form of Iq^2 vs. q plots at different temperatures. Because of the finite molecular weight of the sample, the horizontal straight line corresponding to the Debye branch (of ideal case) is not observed. However, there are inflection points in the expected regions on these experimental curves. They are very similar to the theoretical curves described⁴ for finite chains. They allow a rather precise determination of q^* and thus of the persistence length. These values are recorded in Table 1.

Values of persistence length obtained from this experiment are in agreement with those reported in previous studies. For CC in dioxane at 25°C its value as obtained from dielectric measurements² is 108 Å. Some other known values for the same system are: 136 Å at 20°C from light scattering¹⁴; 80 Å at 25°C from translational diffusion coefficient measurements¹⁵; and 129 Å at 25°C from stress–optical coefficient measurements³. In other solvents the values reported are: 77 Å in benzophenone at 55°C ¹⁶; 108 Å* in acetone at 20°C from low-angle X-ray scattering

* This value was obtained with $A = 2.87$; when using $A = 1.91$, a smaller persistence length of $a = 72 \text{ Å}$ is found for CC in acetone.

measurements⁴. Slight disagreement of these values, except for the last one, has been attributed to the molecular weight range studied or the incomplete degree of substitution of the samples used.

The variation with temperature of persistence length is, however, less reliable in this set of experiments. This is due to low precision in locating the inflection point which lies near the boundary of the experimental range.

Experiment II

The scattering data of experiment II are shown in Figure 3 in the form of Iq^2 vs. q plots at different temperatures. Even though a dispersion of the data occurs in both experiments the inflection points are again apparent around the same q -values. Values of the wavevector, q^* , corresponding to the characteristic inflection points as well as the persistence lengths deduced from these, are recorded in Table 2.

The q^* values in experiment II are relatively more precise since the domain of experimental q values is more favourable. Variation of persistence length with temperature also becomes well apparent in this case. The agreement of temperature variation of persistence length obtained in this experiment is better in comparison to that obtained from stress-optical coefficient data³ than to that from dielectric data² (also shown in Table 2).

In order to check the self consistency of these results and thus to ascertain the extrapolations for different branches of the scattering curve we proceed in the following way. From the slope of the ascending straight line branch and the mass per unit length one can obtain the

value of optical constant K from equation (2). In this calculation we have used for monomer length the value 5.15 Å determined from X-ray crystallographic data on cellulose¹⁷ and found $K = 1.55 \times 10^{-3}$. Further, we tried to fit the results at smaller angles with the Debye scattering function (equation 1) using this value of K . One such calculated Debye curve along with the experimental data is shown in Figure 3 (by the broken line), where the agreement is good upto $q \sim 0.01 \text{ \AA}^{-1}$. Above this q range the tendency of deviation from ideal horizontal Debye curve becomes apparent. It is clear that in this range neither of the ideal expressions hold, as already mentioned.

At this stage we wish to point out that all calculations for the persistence lengths from SANS were made with an A -constant of 1.91 which refers to the idealized model discussed above. The persistence lengths so calculated, may be considered as lower limits. By the use of $A = 2.87$, which was found from the Daniels approximation, one would obtain persistence lengths 1.5 times larger than reported here. These values would agree with an interpretation of light scattering data¹⁴. Since the question of the correct A -value does not seem to be fully settled in theory, we confine ourselves to reporting these two limits (it is probable that A depends on the chain stiffness, i.e. the number of repeating units per persistence length, and on the ratio L/a of the contour length to the persistence length).

The relatively good internal fit makes the determination of persistence length more reliable. Furthermore, the value $a = 110 \text{ \AA}$ found by SANS at room temperature agrees with those found by other methods. These measurements thus justify the applicability of SANS technique for the determination of characteristic parameters of the Kratky-Porod chain. Because of the large contrast which can be obtained by the use of deuterated solvents and the large domain of q -values obtainable if besides the Saclay apparatus one uses the one at ILL Grenoble, it is clear that experiments are much faster and much easier with neutrons than with X-rays, if one does not take into account the price of the equipment.

Note added in proof

A recent re-examination of previous light scattering measurements¹⁴, assuming $l = 5.15 \text{ \AA}$ and taking into account the chain length dependence of persistence length leads to $a = 113 \text{ \AA}$ for the sample in concern, which is in very satisfactory agreement with SANS and dielectric relaxation measurements.

Some morphological aspects of AB crosslinked polymers

G. C. Eastmond and E. G. Smith*

*Department of Inorganic, Physical and Industrial Chemistry, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK
(Received 28 November 1975)*

The structures of multicomponent species present in AB crosslinked polymers (ABCPs) formed by the random introduction of crosslinks of polymer B into an assembly of chains of polymer A are described for different extents of crosslinking. Microphase separation has been observed in solvent cast samples of ABCPs prepared by crosslinking poly(vinyl trichloroacetate) and a styrene copolymer (A-components) with polychloroprene (B-component). The morphologies of the polymers at low and high degrees of crosslinking are presented. Polychloroprene domain sizes have been determined for various crosslink lengths and crosslink densities. Domain sizes and their variation with molecular weight of the B-chains are discussed in terms of the structures of the multicomponent species present in the ABCPs and with theoretically predicted domain sizes in linear block copolymers. Distributions of domain sizes have been determined and compared with the molecular weight distributions of the B-chains.

INTRODUCTION

The term AB crosslinked polymers (ABCPs) refers to polymers in which chains of polymer A are connected by long crosslinks of a chemically different polymer B. This terminology can be used to describe materials ranging from simple structures with low degrees of crosslinking to infinite network structures with high degrees of crosslinking.

Previous papers¹⁻⁴ described a general method of preparing ABCPs of known structure by reacting a preformed polymer (the A-component) having reactive halogen in side chains with a metal carbonyl in the presence of a monomer. The metal carbonyl specifically removes halogen atoms (at a predetermined rate in a thermal or photochemical reaction) from the preformed polymer to produce radical sites on the side groups of the A-chains. These macroradicals initiate polymerization of the monomer to produce growing chains of polymer B attached to the A-chains. Combination termination of the propagating grafts produces B-crosslinks, while disproportionation termination generates B-branches on A-chains. The specificity of the initiating system ensures that, in the absence of chain transfer, no homopolymer of B is formed. However, as prepared, ABCPs always contain some unreacted A homopolymer in addition to the multi-component species. By careful control of the reaction kinetics it is possible to achieve random crosslinking, (thus avoiding excessive intramolecular crosslinking of A-chains) and to control number average degrees of polymerization of the crosslinks. Conditions for achieving random crosslinking in these systems have been presented elsewhere¹.

The normal incompatibility of chemically different polymers leads to phase separation in most polyblends and to microphase separation in block and graft copolymers. In both cases, molecular reorganization occurs readily in solution or in the melt allowing like chains to aggregate and to exclude unlike chains from their vicinity. At low crosslink densities ABCPs contain, in addition to homopolymer

A, only simple crosslinked structures (e.g. two A-chains crosslinked by one B-chain) and it might be anticipated that they could readily undergo microphase separation. However, at high crosslink densities ABCPs contain infinite network structures and, although the ABCPs are normally prepared in dilute solution, it is not immediately apparent that microphase separation will be observed in the solid polymer since molecular reorganization could be restricted by the comparative immobility of junction points in the network structures.

Preliminary electron microscope studies of thin cast films demonstrated that microphase separation can occur in ABCPs of poly(vinyl trichloroacetate) (PVTCA) crosslinked with polychloroprene (PCP), designated PVTCA/PCP⁵. Indirect evidence for microphase separation in highly crosslinked ABCPs of PVTCA crosslinked with polystyrene (PS) or with poly(methyl methacrylate) (PMMA) has been obtained from dilatometric studies of the solid polymers⁶.

In this paper we report the results of an electron microscope study of thin sections of some ABCPs, providing information on the morphological features of the bulk polymers. The ABCPs used were PVTCA/PCP and a copolymer of styrene and *p*-vinyl benzyl-trichloroacetate (PS*) crosslinked with PCP (designated PS*/PCP). In both cases the crosslinks were the minor component. The morphological features of these materials are discussed in terms of the structures and compositions of the ABCPs.

EXPERIMENTAL

Materials

Methyl methacrylate and manganese carbonyl were purified as described previously⁷. Chloroprene was washed free of inhibitor with aqueous sodium hydroxide, dried, prepolymerized and vacuum distilled before use. PVTCA (\bar{P}_w of trichloroacetate residues was 4140) was prepared by trichloroacetylation of poly(vinyl alcohol) (\bar{M}_n 124 000) as described previously¹. The polystyrene copolymer PS* (\bar{M}_n 130 000) incorporating 7% (mol/mol) *p*-vinylbenzyl-

* Present address: Unilever Research Port Sunlight Laboratory Port Sunlight, Wirral, Merseyside, L62 4XN.

trichloroacetate, was prepared from polystyrene homopolymer⁸.

ABCs were prepared by reacting preformed polymer in chloroprene solution using photoinitiation with manganese carbonyl ($\lambda = 436 \text{ nm}$) at 25°C . Small concentrations of benzene, as cosolvent, were used to ensure dissolution of the preformed polymer. Degrees of polymerization of crosslinks were determined by the manganese carbonyl concentration and light intensity employed. Crosslinking indices of the ABCs were controlled by the reaction time; reaction times required for gelation were ascertained in separate experiments performed under the same conditions.

PVTCA/PCP ABCs of low crosslink density (reaction stopped prior to gelation) were precipitated into petroleum ether. Samples of higher crosslink density were isolated by removing excess monomer under high vacuum. PS*/PCP ABCs were initially isolated by evaporation of volatiles under high vacuum.

Electron microscopy

Samples of ABCs of low crosslink density were cast as films (0.5–1 mm thick) from dilute solutions in appropriate solvents. Samples of higher crosslink density were prepared by drying pieces of polymer swollen by solvent. Pieces of the dry ABCs were mounted on epoxy-resin blocks. PVTCA/PCP and PS*/PCP ABCs were stained and hardened for ~ 4 days in an aqueous solution of osmic acid [$\sim 1\%$ solution (w/v)]. Ultra-thin sections ($\sim 100 \text{ nm}$ thick) were cut on an ultramicrotome (LKB Mk III) and examined using a JEM 7 transmission electron microscope.

NATURE OF MULTICOMPONENT SPECIES IN ABCs

In the preparation of an ABC the initial reaction mixture contains an assembly of homopolymer A-chains with a distribution of molecular weights. Crosslinks of polymer B are then introduced randomly. Because of their higher functionality, high molecular weight A-chains are preferentially incorporated into multicomponent species in the early stages of reaction. If the propagating B-chains terminate exclusively by combination (e.g. when chloroprene is used to form the crosslinks) the first multicomponent species to be formed have structure (I), reminiscent of an ABA block copolymer but with two terminal blocks at each end of the

central block, i.e. an A_2BA_2 block copolymer. Continued reaction generates more species with structure (I), the reaction gradually involving a larger proportion of the shorter A-chains. Simultaneously, A-chains already incorporated into multicomponent species react further to produce species such as (II)

and even more complex species; again reaction preferentially involves long A-chains. Eventually the reaction mixture gels as infinite network structures are formed; the reaction mixture then contains a gel fraction comprised of

attached A- and B-chains and a sol fraction consisting of simpler multicomponent species together with unreacted A-chains. Further reaction then incorporates more B-chains and species from the sol fraction into the infinite structure.

If propagating B-chains could terminate exclusively by disproportionation, only B-branches would be formed on A-chains. In the early stages of reaction, species such as (III)

would be formed (an A_2B block copolymer) and subsequently more complex branched structures would be produced. In cases where termination proceeds by both combination and disproportionation (e.g. when using methyl methacrylate to form crosslinks) a mixture of branches and crosslinks of polymer B will be incorporated into multicomponent species, their relative proportions depending on the relative rates of the two termination reactions.

For random crosslinking in an assembly of monodispersed polymer chains, Flory calculated⁹ the weight fractions of crosslinked species of different complexity as a function of crosslink density. Stockmayer¹⁰ considered random crosslinking of a polydispersed polymer but to the best of our knowledge the relative proportions of crosslinked species of different complexity and molecular weight have not been determined quantitatively. Exactly the same principles as used by Flory and Stockmayer apply to the formation of ABCs but with the complication that the crosslinks themselves have a distribution of degrees of polymerization determined by the kinetics of the crosslinking polymerization. Prior to gelation, the crosslinks formed have a molecular weight distribution characterized by $\bar{M}_w/\bar{M}_n = 1.5$; branches have a most probable distribution. Following gelation, the rate of polymerization of certain monomers accelerates (at constant rate of initiation) owing to an increase in chain length; the molecular weight distribution of crosslinks formed under such conditions is not known at present but the average degree of polymerization can be calculated from kinetic data. At the present time, therefore, we are unable to give a quantitative description of the numbers of multicomponent species of different complexity in ABCs but we calculate the number of crosslinks and the crosslinking index in these materials. (We define the relative crosslinking index γ_r as the ratio of the true crosslinking index to that at the gel point; γ_r is the number of crosslinking units per weight-average A-chain and is proportional to the number of crosslinks in the system.) Following the arguments of earlier workers we may predict that prior to gelation the population of multicomponent species with different numbers of A-chains decreases with increasing numbers of A-chains. Also, as reaction proceeds the average length of unreacted A-chains and of A-blocks in multicomponent species decreases.

In the present study no attempt has been made to separate multicomponent species from unreacted A-chains. Consequently the morphologies reported are those of blends of AB crosslinked species and unreacted A-chains.

RESULTS AND DISCUSSION

General morphological features

Table 1 presents structural parameters for ABCs having polychloroprene crosslinks as the minor component.

Table 1 Structural parameters of some ABCPs

ABCP	Polychloroprene (% w/w)	\bar{P}_n of PCP crosslinks	γ_r
PVTCA/PCP 1	4	900	0.4
PVTCA/PCP 2	6	900	0.8
PVTCA/PCP 3	8	900	1.2
PVTCA/PCP 4	25	3720	8-9
PS*/PCP 1	~5	1064-2800	0.67
PS*/PCP 2	15	5900	0.83

Figure 1 is a representative selection of electron micrographs of the above samples cast from various solvents illustrating the occurrence of microphase separation. Samples with low crosslinking index ($\gamma_r \leq 1.2$) exhibit well-defined spherical PCP domains randomly distributed within the matrix of the A-component. ABCP, PVTCA/PCP4 (Figure 1c), with high crosslinking index ($\gamma_r \sim 8$), contains highly-crosslinked network structures and exhibits a more confused morphology of very small domains; some aggregates of small domains are apparent in the micrograph.

Low crosslink density. For $\gamma_r \ll 1$ the volume fraction of crosslinks is very small, the predominant multicomponent species have structure (I) and a large proportion of A-chains remain unreacted. Assuming complete microphase separation with a narrow interface, the PCP chains which aggregate to form the domains will have both ends located at the domain-matrix interface with the attached A-chains in the matrix, as schematically represented in Figure 2a. While we shall show later that domain diameters may be related to the degree of polymerization of the B-chains, the average inter-domain distance will be determined by the overall composition and not by the structural parameters of the A-chains; the domains are distributed randomly in a matrix of A-chains. Any species such as (II), or more complex species, which are present will have both B-chains in the same domain (Figure 2b) with the central A-chain forming a loop on the domain surface (this A-chain will normally be too short to traverse the distance between neighbouring domains). Thus, inter-domain linkages (Figure 2c) will be infrequent.

Magnification 60 000 X

Figure 2 Schematic representation of microphase separation in ABCPs for species with structures (I) and (II), as discussed in text. —, A; ---, B component, broken circles represent the domain-matrix interface

As γ_r increases ($\gamma_r < 1$) the volume fraction of B-chains and the proportion of A-chains in multicomponent species (and to some extent the complexity of those species) increases. Consequently the inter-domain separation must decrease and it might be anticipated that some increase in long-range order would be observed under appropriate conditions. However, at higher degrees of crosslinking this latter event may be overtaken by the increasing complexity of the system. A reduction in inter-domain separation will also allow an increase in inter-domain connections (Figure 2c).

High crosslink density. Under conditions $\gamma_r > 1$ the ABCPs contain infinite network structures which must restrict molecular reorganization and may affect microphase separation. For γ_r slightly in excess of unity, the ABCPs contain a large sol fraction capable of diffusing through the swollen gel and minimizing constraints on microphase separation as the swollen gel collapses during sample preparation; Figure 1b is an electron micrograph of PVTCA/PCP 3 with $\gamma_r = 1.2$, which exhibits the same morphological features as more lightly crosslinked samples. At high values of γ_r (Figure 1c is a micrograph of PVTCA/PCP 4, $\gamma_r \sim 8$) the sol fraction is negligible. Aggregation requires the relative movement of network junctions and may be restricted. Additionally, most A-chains will have multiple junctions, so that the average block length of A-chains between the junctions will be short and inter-domain separations must be small. This view is consistent with the relatively small PCP domains in Figure 1c (ABCPs PVTCA/PCP 3 and 4; \bar{P}_n for crosslinks are 900 and 3720, respectively) and a more confused morphology.

Domain size analysis

In this section we consider domain sizes in ABCPs where γ_r is small and the morphology is not dominated by network constraints. Electron micrographs of ABCPs PVTCA/PCP 1–3 and PS*/PCP 1 and 2, show distributions of domain sizes which are wide compared with those obtained from linear block copolymers with narrow molecular weight distributions. Any natural distribution of domain sizes in the sample is complicated by the sectioning process since domains with centres outside the section, but within one domain radius of the section surface, will be cut during sectioning leaving an apparently small domain in the sec-

tion (assuming domains are not torn out during sectioning). This effect, which apparently enhances the number of small domains, increases with decreasing section thickness.

In analysing size distributions we measured the diameters of between 200 and 340 domains for each sample and corrected observed distributions for effects of sectioning assuming a section thickness of 100 nm (microtome settings were 80–100 nm). Figures 3a and 3b show, respectively, the uncorrected and corrected distributions for PS*/PCP 2 cast from chloroform. [For comparative purposes all corrected distributions have been normalized to a count of 250 domains (positive)]. The negative portion of the corrected distribution probably reflects errors in counting small domains which may be slightly underestimated as a result of domain overlap or lack of contrast (some domains show relatively poor contrast for their diameters probably because they are fragments of domains left on sectioning). We shall assume the positive portions of the distributions provide adequate descriptions of the true distributions.

Casting solvent. Figures 3b and 3c are the corrected distributions for PS*/PCP 2 cast from chloroform and benzene, respectively; the mean radii and their standard deviations are very similar (Table 2). Corrected distributions for PS*/PCP 1 cast from various solvents are shown in Figure 4 and their mean radii and standard deviations are given in Table 2. Again, the distributions are very similar. For both ABCPs, domain radii for samples cast from

Figure 3 Domain size distributions in ABCP, PS*/PCP 2. (a), (b) are uncorrected and corrected distributions, respectively, for a sample cast from chloroform solution, (c) corrected distribution for a sample cast from benzene solution

Table 2 Domain size analysis for some ABCPs

ABCP	Casting solvent	Mean domain radius (nm)	Standard deviation (nm)
PVTCA/PCP 1	Benzene	18.38	3.25
PVTCA/PCP 2	Benzene	19.99	5.06
PVTCA/PCP 3	Benzene	19.50	4.71
PS*/PCP 1	Benzene	15.25	2.83
PS*/PCP 1	Chloroform	16.42	3.67
PS*/PCP 1	Chloroprene/ benzene (4:1 v/v)	13.53	2.38
PS*/PCP 1	Compression moulded	15.1	3.20
PS*/PCP 2	Benzene	38.17	4.56
PS*/PCP 2	Chloroform	40.24	4.93

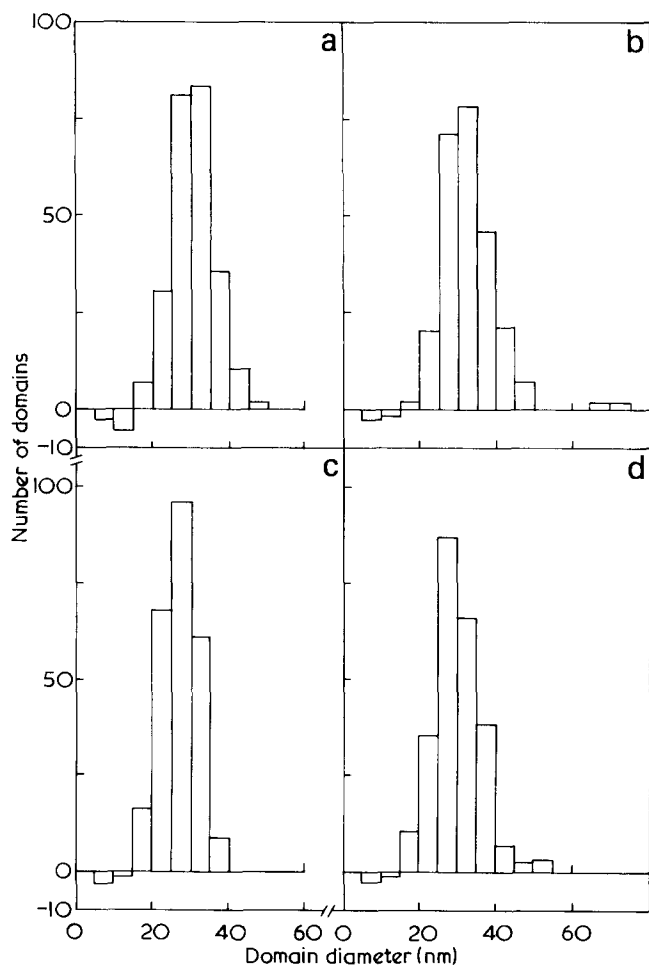

Figure 4 Corrected domain size distributions for ABCP, PS*/PCP 1. Samples cast from: (a) benzene; (b) chloroform; (c) chloroprene benzene (4:1 v/v); (d) refers to a compression moulded sample

chloroform are slightly greater than for those cast from benzene. Whether or not the minor variations observed reflect true changes with casting solvent cannot be ascertained from the limited data available.

Crosslink density. Variations in domain size distribution with crosslinking index (at constant crosslink length) were examined using ABCPs PVTCA/PCP 1–3 cast from benzene solution; corrected distributions are shown in Figure 5. Small differences in domain diameter and standard deviations are observed. Perhaps the most significant differences are the changes in shape of the distributions and the increase in proportion of small domains in PVTCA/

PCP 3 ($\gamma_r = 1.2$) which possibly reflects a tendency for highly crosslinked structures to produce large numbers of very small domains (Figure 1c).

Influence of crosslink molecular weight. We now consider domain sizes in relation to the molecular weights of the domain-forming chains. Using a space-filling model aimed at achieving uniform segment densities within the domains and within the matrix, Meier considered the morphologies of AB block copolymers^{11,12} and predicted that characteristic morphological features would be given by equations of the type:

$$r = k\alpha CM^{1/2} \quad (1)$$

For spherical domains, r is the domain radius, k is a constant characteristic of the morphology (1.33 for spheres), C is the constant relating unperturbed root mean square end-to-end chain dimensions to the molecular weight M of the domain forming chains and α is a perturbation parameter equal to the ratio of the perturbed to unperturbed chain dimensions. The calculations assumed that the sizes of statistical segments of A- and B- components were equal, that the chains conformed with random flight statistics and that the blocks were monodispersed with respect to molecular weight.

The mean diameters \bar{r} of the PCP domains in ABCPs: PVTCA/PCP 1–3 and PS*/PCP 2 are consistent with an equation of the same type as equation (1), viz.:

$$\bar{r} \approx 0.06\bar{M}_n^{1/2} \quad (2)$$

Unfortunately, the number-average molecular weight of the PCP chains in PS*/PCP 1 is uncertain but if it is at the lower end of the possible range, domain sizes in this sample are consistent with equation (2) which is also substantiated by data¹³ from recent micrographs of other samples of PS*/PCP.

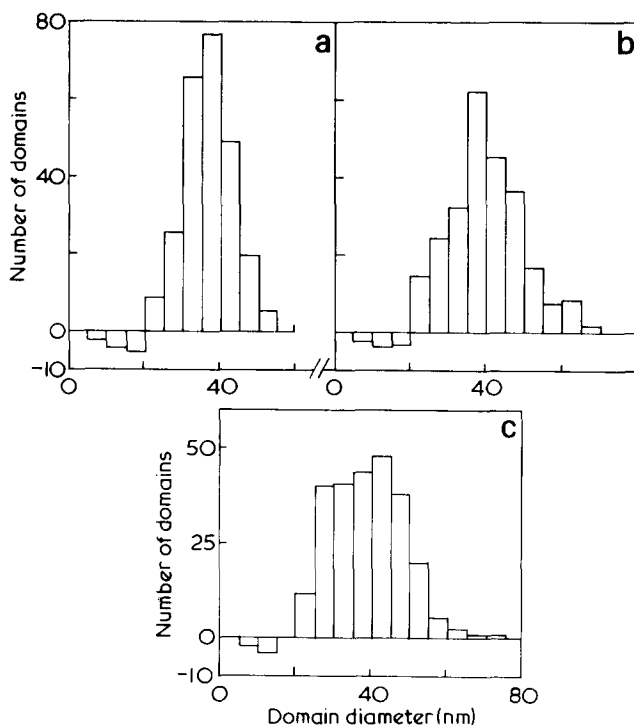

Figure 5 Corrected domain size distributions for ABCPs: (a) PVTCA/PCP 1; (b) PVTCA/PCP 2; (c) PVTCA/PCP 3

Figure 6 Variation in the total relative volumes of domains $[N_i(r_i/10)^3]$ of radius r_i with r_i^2 (—) and the variation in weight fraction w_x with degree of polymerization P_x for a polymer with $\bar{P}_n = 5900$ and $\bar{M}_w/\bar{M}_n = 1.5$ (---). Curves normalized as described in text

To compare relations (1) and (2), we assume a value of $C = 0.08$ nm, a reasonable value for polydienes¹⁴. Appropriate values of α for PCP domains in a PVTCA or PS* matrix are unknown, but Meier estimated¹¹ a value between 1.3 and 2.6 for polystyrene in a polydiene matrix (molecular weights $\sim 10^5$) and predicted that for spherical domains values of α relating to domain and matrix components should be approximately equal¹². We assume a value of $\alpha = 2$ when relation (1) becomes:

$$r = 0.21M^{1/2} \quad (3)$$

which predicts domain sizes considerably in excess of those observed for ABCPs.

A basic structural difference between ABCPs and AB block copolymers is that in the former both ends of the B-chains are attached to A-chains. For B-chains in domains, in an AB block copolymer only one end of the B-chain is restricted to the domain-matrix interface and the other end is free to occupy any point within the domain. In ABCPs both ends of the B-chains are restricted to points on the interface. Consequently, for equal chain lengths, B-chains in ABCPs cannot occupy sites as far removed from the interface as in AB block copolymers and smaller domains must ensue. To estimate the magnitude of this effect we may assume that structures such as (I) behave as two $A_2B_{1/2}$ copolymers; i.e. B-chains behave as if they were half their true length, reducing the predicted domain diameter by a factor of $(2)^{1/2}$. This estimate compares favourably with Meier's predicted value of $k = 1.0$ for ABA block copolymers with B-domains¹⁵ for which similar considerations apply.

ABCPs and ABA block copolymers differ structurally

in that in the former case two A-chains are attached to each end of the B-chains but only one in the latter. In ABCPs two A-chains occupy area at the surface of the domains for each junction point and it is to be expected that the surface area occupied by the two A-chains will be greater than if they were a single chain of the same total degree of polymerization. Meier's prediction that, for AB block copolymers with spherical domains, the values of α for both components are approximately equal and independent of chain lengths, was based on the assumption that the number of A- and B-chains per unit area of the interface are equal¹². This assumption is not true for ABCPs for which there are two A-chains attached to one B-chain at each junction point. By analogy with arguments presented by Meier for calculating α_A/α_B for lamellar morphologies in AB block copolymers¹⁵ we may expect that for spherical domains in ABCPs, $\alpha_B = \alpha_A/2$. Unless α_A (the perturbation factor for the matrix component) is increased by 2, α_B will be smaller in ABCPs than in AB block copolymers and this effect will also contribute to a reduction in domain size.

ABCPs as prepared and examined here contain homopolymer A. Although it is now known that the amount of homopolymer A present can influence the gross morphology of the ABCPs¹⁶, it is not yet known if the sizes of B-domains are influenced by homopolymer A.

Molecular weight distribution of crosslinks. Hoffmann *et al.*¹⁷ reported that mixtures of two AB block copolymers, differing only in molecular weights of the blocks, produced domains of two different sizes, i.e. fractionation according to molecular weight occurred during microphase separation. It might be anticipated that domain-size distributions in ABCPs arise as a result of fractionation of the B-chains. Figure 6 contains a plot of the relative volumes of domains $[N_i(r_i/10)^3]$, where N_i is the number of domains of radius r_i of different sizes as a function of the square of the domain radii for ABCP, PS*/PCP 2; i.e. effectively as a function of degree of polymerization assuming $r \propto P^{1/2}$. Also presented in Figure 6 is a plot of the weight fraction distribution for a polymer with \bar{P}_n 5900 prepared by free-radical polymerization with combination termination. The abscissae have been normalized by calculating a degree of polymerization corresponding to r assuming Meier's formula for ABA block copolymers (B domains) applies with $\alpha = 1$ and making \bar{r}^2 coincident with this value of P on the weight fraction distribution. Obviously the volume fraction distribution of domain sizes is much narrower than the weight fraction distribution (similar distributions are obtained with other ABCPs). From these data there is no evidence of fractionation in the ABCPs. It can also be concluded that high molecular weight crosslinks are incorporated into smaller domains than if they were in linear block copolymers with a narrow molecular weight distribution; α for these chains must be small.

Theoretical calculations of domain sizes for multicomponent polymers with distributions of block lengths have not been reported and it is uncertain as to which average of the molecular weight distribution should be used in attempting to employ relations developed for simple systems to more complex materials. A large proportion of the weight fraction of the polymer is in chains with molecular weights greater than \bar{M}_n and the tendency for such chains to adopt random flight statistics would tend to expand the domains. On the other hand, short chains introduce a relatively large number of junction points into the interface and such chains will have a disproportionately large effect on the surface energy of the domains.

CONCLUSIONS

ABCPs prepared by crosslinking PVTCA or PS* with PCP (the crosslinks being the minor component) have been shown to exhibit microphase separation in the bulk polymer at both low and high degrees of crosslinking. While highly crosslinked polymers show a somewhat confused morphology of very small domains because of network constraints hindering the development of domains, lightly crosslinked materials contain well-defined spherical domains of PCP crosslinks.

For lightly crosslinked polymers, and within the limited range of conditions employed in these experiments, no significant variations in domain diameters were observed with changes in the casting solvent or crosslink density. Domain diameters appear to be proportional to the square root of the degree of polymerization of the domain-forming chains.

Diameters of domains of the B-component in ABCPs are smaller than those predicted for AB and ABA block copolymers with B-chains of the same degree of polymerization. It is proposed that the relatively small sizes of the domains arise since both ends of the B-chains are located at the domain-matrix interface and since each end of such a chain is attached to two chains of the A-component.

Although ABCPs exhibit a distribution of diameters of B-domains those distributions are narrow compared with the molecular weight distributions of the domain-forming chains and no evidence for fractionation with respect to the molecular weights of the B-chains was observed.

ACKNOWLEDGEMENTS

The authors wish to thank the Department of Metallurgy and Materials Science for providing the electron micro-

scope facility, Dr J. Ashworth for the provision of the PS*/PCP ABCPs, British Petroleum Limited for a gift of chloroprene, Unilever Research for financial assistance to E.G.S. and Science Research Council for funds to purchase the ultramicrotome.

Thermodynamics of α,ω -methoxy-poly(ethylene oxide)/*n*-alkane systems by gas – liquid chromatography

Yu-Kwan Leung

Department of Chemistry, University of Manchester, Manchester M13 9PL, UK

(Received 16 October 1975; revised 29 December 1975)

The gas–liquid chromatographic method has been used to measure the thermodynamic parameters of low molecular weight α,ω -methoxy-poly(ethylene oxide) with C_5 – C_{12} *n*-alkanes. High positive values of the solution interaction parameters and reduced residual enthalpies are obtained. The signs of the reduced residual entropies at infinite dilution of solvent can be predicted by the Flory–Orwoll–Vrij theory.

INTRODUCTION

The morphology and melting behaviour of α,ω -alkoxy-poly(ethylene oxide) samples are currently being investigated in this laboratory. In order to assess the effect of mixing of end and mid-chain segments on the process of melting, it is desirable to investigate the thermodynamics of mixing of the corresponding pure substances, i.e. PEO and *n*-alkanes. To avoid complications due to specific interaction of the hydroxy-end-groups of commercially available samples of poly(ethylene oxide) it is necessary to substitute less polar groups. In this work a Williamson synthesis, as modified by Dr D. R. Cooper, has been used to substitute methoxy end-groups. Since *n*-alkanes are in fact very poor solvents for PEO, conventional methods of experimental solution thermodynamics are not applicable. Recently the technique of gas–liquid chromatography (g.l.c.) has been developed and shown to be reliable in obtaining thermodynamic information on concentrated polymer solutions^{1–5}. In this paper, we report the results of g.l.c. measurements of several *n*-alkanes in two α,ω -methoxy-poly(ethylene oxide) fractions of molecular weight 2000 and 1000.

EXPERIMENTAL

Preparation

Hydroxy-ended poly(ethylene oxide) of MW 1000 and 2000 were obtained from Shell Chemical Company Ltd and Hoechst Chemical Ltd respectively. The Williamson ether synthesis was used for the transformation of the terminal hydroxy-groups of PEO to methoxy-groups:

Details of the method will be published elsewhere⁶. Two samples, designated PEO-1000M and PEO-2000M, were prepared.

Laboratory reagent (BDH) *n*-pentane, *n*-heptane, *n*-octane, *n*-decane and *n*-dodecane or Spectrosol reagent *n*-hexane were used as received.

Characterization

The degree of methoxylation of PEO was estimated by comparison of the intensities of the hydroxyl stretching

band at $\sim 3500\text{ cm}^{-1}$ for the starting polymer and the product. The C–H stretching peak at $\sim 2900\text{ cm}^{-1}$ was taken as reference to account for variation of film thickness. At least 95% replacement of hydroxy- by methoxy-groups was achieved.

Number-average molecular weights of the samples, determined by vapour pressure osmometry (Mechrolab, benzene at 25°C), were close to the nominal *MW* of their parent polymers and therefore the nominal values were adopted for subsequent calculation. Gel permeation chromatography was used to monitor the molecular weight distribution of the polymers⁷. The PEO did not exhibit detectable degradation during the preparation and the value of M_w/M_n was near to 1.06.

Specific volumes (v_{sp}) and thermal expansion coefficients (α) of the polymers were determined by pycnometry. The pycnometers have been described elsewhere⁸. For PEO-2000M, $v_{sp} = 0.9196\text{ cm}^3/\text{g}$ (55.8°C) and $\alpha = 7.2 \times 10^{-4}/\text{K}$ (55° – 70°C); for PEO-1000M, $v_{sp} = 0.9100\text{ cm}^3/\text{g}$ (46.1°C) and $\alpha = 7.4 \times 10^{-4}/\text{K}$ (40° – 55°C). Melting points, measured by hot-stage microscopy, were found to be 52.6°C and 36.8°C for PEO-2000M and PEO-1000M respectively.

Gas–liquid chromatography

The experimental procedures of g.l.c. and column preparation have been described fully elsewhere³. The stationary phase was coated onto Chromosorb W(45/60) from solution in benzene. The % weight of polymer on the solid support was determined by Soxhlet extraction with benzene for duplicate samples. The coated particles were packed into a stainless-steel tube, 1 m long and 4 mm i.d. Two columns were prepared, one with 1.302 g PEO-2000M (24.2% by wt) and the other with 0.768 g PEO-1000M (17.9% by wt).

The apparatus used was a Perkin-Elmer Model 452 Gas Chromatograph with a thermal-conductivity detector. Column temperatures were controlled to $\pm 0.05\text{ K}$. Hydrogen was chosen as carrier gas. A soap-bubble flowmeter located at the outlet of the instrument was used to measure flow rate with an accuracy of $\pm 1\%$. Flow rates, commonly in the range of 15 – $30\text{ cm}^3/\text{min}$, were controlled by adjusting an upstream pressure regulator. Inlet pressures of $\sim 17 \times 6984.76\text{ N/m}^2$ were measured by a pressure gauge.

Table 1 Experimental thermodynamic quantities of interaction in α,ω -methoxy-poly(ethylene oxide) of *MW* 2000

	57.0°C			66.7°C			κ	$\bar{S}_1^R/R\phi_2^2$
	χ_v	χ_s	ν_{1b}	χ_v	χ_s	ν_{1b}		
n-C ₅	1.90	2.06	0.085	1.82	2.00	0.096	2.0	-0.0 ₃
n-C ₆	2.02	2.16	0.074	1.94	2.09	0.083	2.4	+0.2 ₇
n-C ₇	2.15	2.26	0.063	2.06	2.18	0.071	2.8	+0.5 ₈
n-C ₈	2.30	2.39	0.053	2.19	2.29	0.062	3.7	+1.3
n-C ₁₀	2.67	2.74	0.035	2.51	2.59	0.042	5.3	+2.6
n-C ₁₂	3.04	3.09	0.023	2.84	2.90	0.029	6.4	+3.4

The outlet pressure was atmospheric pressure. Liquid *n*-alkanes (C₅–C₈, C₁₀, C₁₂) mixed with air were injected into the carrier gas stream. The retention time for the solvent was taken to be the difference between the elution times of the solvent and the air. Retention volumes of n-C₅ to n-C₈ did not alter with the injected amount over the range 0.01–0.3 mm³ while that of n-C₁₀ and n-C₁₂ increased considerably. Therefore the retention volume was extrapolated (approximately linearly) to zero concentration for n-C₁₀ and n-C₁₂. For the rest, retention volumes corresponding to sample size of 0.02 mm³ were measured. For this sample size, a rough estimation of the peak area places the volume fraction of solvent near 10⁻⁴. Also, variation of retention volume with the flow rate in the stated range was insignificant.

RESULTS AND DISCUSSION

The Flory–Huggins solution parameter χ_v using volume fraction (ν) as composition variable is related to the net retention volume V_N as follows³:

$$\chi_v = \ln(RTV^L/V_1^0 p_1^0 V_N) - (B_{11} - V_1^0) p_1^0 / RT - 1 + 1/r + (2B_{13} - \bar{V}_1^\infty) p_o J_3^4 / RT \quad (1)$$

where V^L is the volume of the polymer (designated as 2), V_1^0 , p_1^0 and B_{11} are the molar volume, the vapour pressure and the gas-phase second virial coefficient of pure solvent (designated as 1) at the column temperature T (K), \bar{V}_1^∞ is the partial molar volume of solvent at infinite dilution, B_{13} is gas-phase mixed second virial coefficient for solvent vapour and carrier gas, r is the ratio of molar volumes of polymer and solvent. The J_3^4 pressure factor is defined as $(3/4)[(p_i/p_o)^4 - 1]/[(p_i/p_o)^3 - 1]$ where p_i and p_o are inlet and outlet pressures across the column respectively. The last term in equation (1) is included to correct for the effect of the finite column pressure upon the retention volumes⁹ and its magnitude is ~ 0.006 for hydrogen carrier gas and *n*-alkane solvents.

The Flory–Huggins theory is based upon a quasi-lattice model of the liquid mixture. More satisfactory approaches^{10–12} take account of the differing properties of the component liquids. The Flory, Orwoll and Vrij theory^{10,11}, which has been widely applied to a number of polymer/solvent systems, leads to an interaction parameter based on segment fraction (ϕ) given by:

$$\chi_s = \chi_v + \ln(\bar{\nu}_1/\bar{\nu}_2) \quad (2)$$

where $\bar{\nu}_i$ is the reduced volume of component i . The reduced partial molar residual enthalpy ($\kappa = \bar{H}_1^R/RT\phi_2^2$) is obtained from the temperature dependence of χ , viz.:

$$\kappa = -(\partial\chi_s/\partial\ln T)_{\phi_1=0} = -(\partial\chi_v/\partial\ln T)_{\phi_1=0} + T(\alpha_2 - \alpha_1) \quad (3)$$

Consequently, the reduced partial molar residual entropy is:

$$\bar{S}_1^R/R\phi_2^2 = \kappa - \chi_s \quad (4)$$

in the limit $\phi_1 = 0$. Experimental values of χ , κ and $\bar{S}_1^R/R\phi_2^2$ are recorded in *Tables 1* and *2* for PEO-2000M and PEO-1000M respectively. The estimated uncertainties of χ , κ and $\bar{S}_1^R/R\phi_2^2$ are 1%, 25% and 25% respectively. Constants of *n*-alkanes used for calculation have been reported earlier¹³. Temperature variations of κ are omitted because of limited data.

In order to verify that the solution formed during the elution of alkane vapour is homogeneous, it is necessary to investigate the miscibility gaps of the mixtures. If a system containing a polymer and a very poor solvent separates into two phases, then each of the phases contains one of the components virtually in its standard state. The condition for equilibrium of the solvent is:

$$\ln\nu_{1b} + (1 - 1/r)\nu_{2b} + \chi_v\nu_{2b}^2 = 0 \quad (5)$$

where subscript b denotes the binodial compositions. Volume fractions ν_{1b} in the highly concentrated polymer phase were obtained by numerical solution of equation (5) using the experimental χ_v values (assuming χ_v to be independent of concentration). These values are also entered in *Tables 1* and *2*. They indicate that the concentration range ($\nu_1 \approx 10^{-4}$) studied by g.l.c. is orders of magnitude smaller than the solubility limit. Therefore homogeneity of solutions is assured.

Several features of the data are noteworthy. The systems investigated show high positive values of the interaction parameters (χ_v , χ_s) as expected for polymer/poor solvent systems. Secondly, despite the larger combinatory entropy gain for the lower *MW* polymer during the mixing process, it can be seen, by comparing ν_{1b} values in *Tables 1* and *2*, that a given alkane molecule appears to be a better solvent for the higher *MW* polymer. Thirdly, the residual entropies change sign and become increasingly positive as the solvents increase in chain length from *n*-pentane to its higher analogues.

These features can be further analysed in terms of the Flory, Orwoll and Vrij (FOV) theory. According to the FOV theory, the contact interaction parameter X_{12} denoting the energy change for the formation of contacts between unlike species at the expense of contacts between like species is evaluated from the experimental χ_s data, as follows:

$$X_{12} = RT(\bar{\nu}_2/V_1^*)\chi_s - P_1^* \bar{\nu}_2 \{3\bar{T}_1 \ln[(\bar{\nu}_1^{1/3} - 1)/(\bar{\nu}_2^{1/3} - 1)] + (\bar{\nu}_1^{-1} - \bar{\nu}_2^{-1})\} \quad (6)$$

n-C ₁₂	12.6	12.1	+0.50			

where V_1^* is the characteristic molar volume. (Characteristic quantities are denoted by an asterisk.) The reduced partial molar residual entropy can then be calculated from:

$$\begin{aligned} \bar{S}_1^R/R\phi_2^2 = & - (P_1^*V_1^*/R) \{3(T_1^*)^{-1} \ln[(\bar{v}_1^{1/3} - 1)/ \\ & (\bar{v}_2^{1/3} - 1)] - \alpha_2\bar{v}_2^{-1}(T_2^*/T_1^* - 1) + \alpha_2V_1^*X_{12}/R\bar{v}_2 \} \end{aligned} \quad (7)$$

by employing the corresponding X_{12} values. Predicted values of $\bar{S}_1^R/R\phi_2^2$ are recorded in Table 3, together with the values found for X_{12} .

Comparison of contact parameters between different polymer fractions indicates that the interaction of a given solvent molecule with terminal segments of PEO-M is more repulsive than that with mid-chain segments. This is consistent with the molecular geometry of the α,ω -methoxy-poly(ethylene oxide) chain: the fraction of the surface area attributable to sp^2 oxygen is greater in the methoxy end-group than in the mid-chain segment.

The trend of the residual entropies is reproduced by the theory. Examination of equation (7) reveals that the sign of the residual entropy is determined by the balance between the negative contribution from the equation-of-state terms and the positive contribution from the contact energy term. The magnitude of the latter are, in most cases, larger than those of the former because of the large positive exchange energy term. Quantitative agreement between theory and experiment is unsatisfactory. There is some

difficulty in making the comparison because of the experimental problems of measuring small changes in χ with T . However, overall it seems that theory underestimates \bar{S}_1^R by a factor of about 5.

As pointed out previously⁴, the residual entropy of mixing in the concentration range near pure polymer might yield valuable information concerning the conformation of polymers in the amorphous state. The poly(ethylene oxide) mixtures with n-pentane exhibit a negative \bar{S}_1^R , whereas the observed positive residual entropies for higher n-alkanes are the direct consequence of their large positive contact interaction parameters. Therefore no dissipation of order with dilution of low MW α,ω -methoxy-poly(ethylene oxide) is discernable in the present data.

ACKNOWLEDGEMENTS

The author wishes to thank Dr C. Booth for many helpful discussions and for a critical reading of the manuscript and Dr D. R. Cooper for recommending the procedure of sample preparation.

Melt rheology of some aliphatic polyamides

P. Parrini, D. Romanini and G. P. Righi

Montedison SpA, Centro Ricerche Ferrara, 44100 Ferrara, Italy

(Received 13 October 1975; revised 16 January 1976)

The melt rheology of nylon-6, nylon-6,6, nylon-6,10 and nylon-11, has been investigated by different techniques. It has been found that their behaviour is quite similar and almost Newtonian regarding both the flow curves and the elastic and instability properties. The samples show rather different viscous flow activation energies, although their values approach each other at high shear rate. The critical shear stresses of such materials are compared with those of other known polymers.

INTRODUCTION

The rheological properties of polyamides in the molten state have received little study, although these polymers are among the best known and most extensively used, especially as synthetic fibres.

The literature gives very little information on polycaprolactam (nylon-6). Publications are of a general type¹, or concern the processes of transformation². Pezzin and Gechele³ studied the behaviour of such a polymer by capillary rheometer, over a wide range of molecular weights and shear stresses.

On the other hand, no literature exists on other polyamides, such as poly(hexamethylene adipamide) (nylon-6,6) and poly(ω -undecanamide) (nylon-11) and poly(hexamethylene sebacamide) (nylon-6,10), which are used on an industrial scale.

Therefore, the purpose of this paper is to investigate the rheology of nylon-6 using both capillary rheometers of different types and cone and plate rotational viscometers to obtain information on normal stresses, and to study the behaviour of the other nylons. It is thus possible to obtain a general picture of the properties of an entire class of polymers, especially regarding the influence of the temperature and the elastic properties of the materials.

EXPERIMENTAL

Polymers

Measurements were made on commercial polymers. Poly(hexamethylene adipamide) (nylon-6,6), polycaprolactam (nylon-6) and poly(hexamethylene sebacamide) (nylon-6,10) were produced by Montedison; poly(ω -undecanamide) (nylon-11) was produced by Organico and sold under the trade name of Rilsan. Table 1 shows the characteristics of the investigated samples. Melting temperatures and corresponding enthalpies, ΔH , (cal/g) were detected by differential calorimetry using a Perkin-Elmer DSC-IB apparatus. Densities (g/cm³) were measured using a gradient column (ASTM-D-1505/68).

Intrinsic viscosities in *m*-cresol at 30°C were measured and molecular weights were calculated from the $[\eta] - M$ relationships given in the literature⁴. The melt indices were determined according to the ASTM 1238/71 standard, condition *K* for nylon-6,6 and condition *Q* for the other samples. Before measurement, all the polymers were carefully

dried at 110°C for 8 h under a nitrogen stream to give a water content of not more than 100 ppm.

Rheological measurements

Capillary rheometer under constant pressure. Using a viscometer (obtained from Ceast, Turin) the amount of extruded material in the unit of time was measured. Shear stress τ and shear rate $\dot{\gamma}$ at the wall are calculated from the known relations:

$$\tau = \frac{PR}{2L} \text{ (dyne/cm}^2\text{)} \quad (1)$$

$$\dot{\gamma} = \frac{4Q}{\pi R^3} \text{ (sec}^{-1}\text{)} \quad (2)$$

where P is the applied pressure (dyne/cm²); Q is the amount of extruded polymer (cm³/sec); R is the capillary radius (cm), L its length (cm).

With this type of viscometer, were determined: the flow constancy in the time, the existence or the absence of wall slipping and the end correction. An interchangeable series of capillaries having the geometrical properties shown in Table 2 were used. Capillary diameters are given with an error of about 1%, lengths with an error lower than 1%.

By using spinnerets with a different L/D ratio, possible inlet phenomena were investigated, whereas by using capillaries with the same L/D ratio but with different diameters, the existence of wall slipping was sought. By this device, a shear rate range from 10 to 2×10^4 sec⁻¹ was considered. Temperatures to within $\pm 1^\circ$ were maintained. Melt densities of the polymers at the different temperatures were measured via dilatometry⁵.

6	0.5	2.5	5.0
7	1.0	1.0	1.0
8	1.0	5.0	5.0

Capillary rheometer at constant rate (MCR). Using an Instron capillary rheometer the applied stress was measured by a load cell placed at the top of the piston pushing the molten polymer into the capillary. The shear stress and shear rate at the wall are again given by relations (1) and (2).

The apparent viscosity η may be calculated, with a good approximation, by the Poiseuille equation, since the flow curves do not considerably differ from those corrected according to the Rabinowitsch law⁶, for these materials.

With this rheometer the flow curves of nylons at different temperatures and the activation energies of viscous flow were determined, using one capillary having a diameter of 0.734 mm and length of 25.56 mm ($L/D = 34.82$).

A shear rate range from 20 to $2 \times 10^4 \text{ sec}^{-1}$ was employed. By using this capillary, the corrections due to entrance effect are eliminated. Using a capillary having a diameter of 0.25 mm and length of 5 mm ($L/D = 20$), the flow instability conditions have been investigated.

Cone and plate rotational viscometer (WRG). By this rheometer, (Weissenberg rheogoniometer model R-18 of Sangamo Control Ltd) the shear rate is given by:

$$\dot{\gamma} = \frac{\omega}{\alpha} \quad (3)$$

where ω is the rotational velocity of the bottom plate and α is the cone-angle.

The shear stress at any point of the fluid is given by:

$$\tau = \frac{3M}{2\pi r^3} \quad (4)$$

where M is the torque transmitted from the material to the top plate and r is the plate and cone radius.

The apparent viscosity η is again obtained from the relation:

$$\eta = \frac{\tau}{\dot{\gamma}} \quad (5)$$

Because of the considerable fluidity of the polymers, the experimental studies by rheogoniometer have been carried out at temperatures slightly above the melting point, by using a plate and cone having a diameter of 5 cm and an angle $\approx 4^\circ$. The range of shear rates explored was between 10^{-1} and 10^2 sec^{-1} . By this apparatus, also the first normal stress difference $P_{11} - P_{22}$ (indicated by σ) has been measured as a function of $\dot{\gamma}$. Temperatures within $\pm 2^\circ\text{C}$ were kept constant.

Outline of measurements. The test temperatures have been selected on the basis of the apparatus used and the melting point of materials examined (see Table 3).

Determination of the rheological parameters at very low shear rates require quite long measurement times; therefore, knowledge of thermal stability material is required in order to avoid possible decomposition effects and consequent variation in molecular weight and molecular weight distribution. By volumetric flow measurements at different residence times (using constant-pressure rheometer), the polymers should remain stable at least for 30 min, a necessary condition for this investigation.

RESULTS AND DISCUSSION

By using the constant-pressure rheometer and interchanging the capillaries (see Table 2), flow curves ($\tau-\dot{\gamma}$) have been determined. The curves obtained are practically coincident with values contained over a very narrow range, although the capillaries used have very low L/D ratios. Therefore, it can be stated that the nylons studied do not give rise to any entrance and wall slipping effects.

Typical flow curves

Using the apparatus described we determined the flow curves of the four nylons so as to acquire a greater knowledge of the rheological behaviour of such materials and to study their optimum use in the transformation processes.

Figures 1-4 give $\eta-\dot{\gamma}$ curves of the samples examined at different temperatures in a very wide range of shear stresses or shear rates. As it may be seen, nylons exhibit a Newtonian behaviour up to $\sim 10^2 \text{ sec}^{-1}$ depending on the test temperature. To obtain a direct comparison among the samples examined, the rheological parameters must be expressed as a function of reduced variable normalizing the temperature effect. For this purpose, we record in Figure 5 the values of shear stress obtained using the MCR and the WRG rheometers, at different temperatures as a function of the product $\eta_0\dot{\gamma}$ for all the four nylons. η_0 is the Newtonian viscosity of the material at the test temperature.

Similarly, Figure 6 shows the behaviour of the η/η_0 ratio as a function of the product $\eta_0\dot{\gamma}$. On examining the two Figures, it appears to be evident that all the polyamides investigated exhibit essentially the same rheological behaviour, independent of the temperature effect. They are Newtonian up to values greater than 10^5 dyne/cm². In order to represent the rheological behaviour of the polymers investigated by single relation we may write with a good approximation:

$$\log \tau = -2.88 + 2.18 \log \eta_0 \dot{\gamma} - 0.121 (\log \eta_0 \dot{\gamma})^2 \quad (6)$$

which is valid between 10^2 and 10^8 dyne/cm². Equation (6) has been calculated by regression analysis.

Viscous flow activation energy

From flow curves at different temperatures, we obtain $(E - \log \tau)$ and the $(E - \log \dot{\gamma})$ relations; the viscous flow activation energies E of investigated polymers are markedly different. In the examined shear stress field, the values of E are constant and are shown in Table 4, whereas the curves $(E - \log \dot{\gamma})$ are shown in Figure 7.

Table 4 Activation energies E for the nylons in the shear stresses field between 1×10^5 and 1×10^7 dyne/cm²

	Nylon-6	Nylon-6,6	Nylon-6,10	Nylon-11
E (kcal/mol)	11.3	23.9	13.7	17.3

Figure 7 Activation energy E at constant shear rate versus shear rate $\dot{\gamma}$ for the samples examined: ●, nylon-6; ■, nylon-6,6; ▲, nylon-6,10; ▽, nylon-11

This plot shows the activation energy considerably decreasing with increasing $\dot{\gamma}$ for nylon-6 and nylon-11, whereas far less markedly for the other samples. All curves are converging at fairly close energy values. The differences observed do not considerably influence processing of such polyamides, since both spinning and extrusion moulding shear rates are fairly high, of the order of $10^4 - 10^5 \text{ sec}^{-1}$.

Elastic properties

The first normal stress difference σ (dyne/cm²) on varying the shear rate for the different test temperatures, was determined using WRG. Figure 8 shows the values of σ as a function of the reduced variable $\eta_0 \dot{\gamma}$ for the different polymers; as may be seen, all the experimental points fall on the same curve within the experimental error.

This means that, the shear stress being the same (the product $\eta_0 \dot{\gamma}$ has the dimensions of dyne/cm²), by excluding the temperature effect, the four nylons examined have almost the same values of the first normal stress difference. With good approximation, the following relation (obtained by regression analysis) may be given:

$$\log \sigma = -2.706 + 1.43 \log \eta_0 \dot{\gamma} \quad (7)$$

which is valid in a $\eta_0 \dot{\gamma}$ range between 10^3 and 10^6 dyne/cm². The σ/τ ratio, obtained at the same shear rate (sec^{-1}), is directly connected to the elastic recovery and hence to the material swelling. For the examined samples, σ/τ ratio keeps at extremely low values, within the shear field investigated, as shown in Figure 9 where σ/τ is reported as a function of the reduced variable $\eta_0 \dot{\gamma}$. Polyolefins, in the same measurement range, assume σ/τ values of 2–3 units.

Because of the extreme fluidity of the polyamides under examination, the extrudate swelling could not be determined.

Flow instability

The flow instability of the four nylons, by use of the Instron rheometer, has been investigated up to fairly high extrusion rates ($\sim 7 \times 10^4 \text{ cm/min}$). The flow instability parameters of such materials are reported in Table 5.

This Table shows the excellent performance of the nylons examined at high deformation rates; the flow instability appears at very high shear rates for all the samples, excluding the nylon-11 which has been extruded at quite low temperatures. Therefore the $\dot{\gamma}_c \eta_0$ product takes it into the values field of the other samples.

The τ_c (critical shear stress) $\times \bar{M}$ (molecular weight) products of the four investigated nylons, assume fairly close results, within $1.1 - 1.5 \times 10^{11}$ range. (The \bar{M} values have been taken from Table 1.)

The above products have been obtained excluding the test temperature effect on the τ_c determination. Such effect, in the temperature field employed, has little influence on the $\tau_c \times \bar{M}$ product.

A comparison between the critical flow conditions of some of the best known polymers and the nylons is made in Table 6, where the critical shear stress values determined by the authors⁷ and drawn from the literature⁸⁻¹² are reported.

Even by taking into account the approximation of such measurements, it appears that the excellent rheological behaviour of the polyamides, is quite favourable in processes involving high shear rates.

Figure 8 First normal stress difference σ versus reduced variable $\eta_0 \dot{\gamma}$, measured by rheogoniometer: ●, nylon-6 at 230°C; ■, nylon-6,6 at 270°C; ▲, nylon-6,10 at 240°C; ▽, nylon-11 at 210°C

Table 6 Critical shear stresses of different polymers

Sample	Temperature (°C)	Critical stress (dyne/cm ²)
Nylon-6	240	9.0×10^6
Nylon-6,6	280	8.6×10^6
Nylon-6,10	240	9.0×10^6
Nylon-11	210	7.0×10^6
Polyacetals (copolymers)	190	$7-8 \times 10^6$
Poly(methyl methacrylate) ([η] = 0.46)	170	5.0×10^6
Poly(ethylene terephthalate) ([η] = 0.67)	270	$1-1.6 \times 10^7$
HDPE ($M_l = 2.1$)	150-240	$1.5-2 \times 10^6$
LDPE	130-230	$0.8-1.3 \times 10^6$
Polypropylene ([η] = 1/3)	200-300	$0.8-1.4 \times 10^6$
Polystyrene	200-250	$1.2-1.4 \times 10^6$
Polytetrafluoroethylene	360	$1-2 \times 10^6$

CONCLUSIONS

Nylons exhibit quite negligible inlet and wall slipping effects in the capillaries and have essentially the same rheological behaviour. Their pseudo-plastic behaviour is very small. Activation energies of viscous flow are rather different depending on the type of polymer; however this does not seem to influence processing since a flattening of the curves is observed at the shear rates used. Melt elastic recovery of such polymers is quite low, much lower than that of the polyolefins, but the polyamides examined show an unstable flow onset at very high shear stresses.

The work indicates that the rheological behaviour of these materials make them very suitable for transformation techniques requiring high output rates and high precision geometries.

ACKNOWLEDGEMENTS

We wish to express our appreciation for the help given with the experimental work by Mrs B. Barboni and Mr L. Ceron.

Ion-clustering and viscoelastic properties in poly(butadiene–styrene–4-vinylpyridine) crosslinked by nickel chloride

C. T. Meyer* and M. Pineri

Centre d'Études Nucléaires de Grenoble, Département de Recherche Fondamentale, Section de Physique du Solide, BP 85, 38041 Grenoble Cedex, France

(Received 20 October 1975; revised 12 January 1976)

A butadiene–styrene–4-vinylpyridine terpolymer was crosslinked by coordination of the pyridine side-groups with nickel chloride. Previous studies have shown that the complexes cluster together, although some complexes remain isolated, especially at low metal concentration. Thermoreversibility of the crosslinking is studied by stress relaxation and internal friction. Superposition of two relaxation mechanisms occurs; up to a temperature $T \approx 20^\circ\text{C}$ the shift factor follows the usual WLF equation. For higher temperatures $\log a_T$ obeys an Arrhenius equation with an activation energy of 28 kcal. This secondary relaxation mechanism is attributed to exchange reactions between complexes of the clusters. This behaviour is similar to that of other polymers with microphase separation. Influence of the concentration is studied by internal friction. At low concentration breakdown of the modulus takes place in two steps corresponding to the onset of intermolecular bonding lability, first in isolated complexes and then in clustered complexes. At higher concentration clustered complexes are sufficiently numerous to prevent the first flow.

INTRODUCTION

Ion-containing polymers have been intensively studied during the past decade¹. Particular attention was given to ionomers, statistical copolymers containing a small percentage of salt groups such as neutralized carboxylic acid². Microphase separation occurs by clustering of the ionic groups as a result of the electrostatic interactions between them. These clusters may be considered as crosslinks, which contrary to usual covalent crosslinks, are thermoreversible.

Polymers crosslinked by coordination complexes may be considered as very similar to ionomers. Crosslinking is achieved by complexing pyridine side-groups, statistically distributed along the polymer chain, by a transition metal chloride. The first experiments on these polymers have shown that they have the same properties as ionomers: microphase separation and thermoreversibility of the crosslinking.

Clustering of these complexes has been shown by electron microscopy³, small-angle X-ray (SAXS) or small angle neutron scattering (SANS)⁴, and Mössbauer effect⁵. The size distribution is very broad but most of the clusters are less than 100 Å in diameter. The clusters still exist at very high temperatures because no change in the SAXS curve is found up to 200°C.

Salt concentration has been shown to play an important role; at low concentration, (less than one metal for two pyridine) the complexes are predominantly isolated but at high concentration most of the complexes are in clusters. However, the two kinds of complexes are present whatever the concentration. The exact nature of the crosslinks is not clear. In particular complexes involving only one pyridine, i.e. only one polymer chain, may possibly exist⁴. They cannot be crosslinks in the true sense of the word. We must thus consider that crosslinking is due to the clustering of complexes. However, it does not exclude

that the isolated complexes, if involving more than one pyridine, can constitute true chemical crosslinks.

The mechanical properties of these polymers are characterized by the thermoreversibility of the crosslinking⁶, indicating some lability of the intermolecular bonding.

A study of their mechanical properties was undertaken here by stress relaxation and dynamic mechanical measurements, to explain the mechanism of the thermoreversibility and to determine what is the influence of microphase separation on the viscoelastic response. In these polymers there is the same problem as in ionomers, i.e. the validity of the time–temperature superposition principle. Inapplicability of time–temperature superposition in the treatment of viscoelastic data has been reported for many amorphous polymers, thus defined as thermorheologically complex. This behaviour can be attributed to the existence of a secondary relaxation mechanism operating simultaneously with the usual diffusional process⁷. This secondary relaxation mechanism may be for example, side chain motion as in poly(alkyl methacrylate)⁸, bond interchange as in polymeric sulphur⁹.

Ionomers have been reported as thermorheologically complex. Eisenberg *et al.*¹⁰ have shown that in styrene–sodium methacrylate copolymers the viscoelastic response is characterized by two relaxation mechanisms. A breakdown in time–temperature superposition has been observed. The shift factors corresponding to the short time superposition obeyed the WLF equation¹¹ with some increase in the C_1 and C_2 values due to the increased cohesion introduced by the electrostatic interactions. The shift factors corresponding to the secondary master curve, fit an Arrhenius type equation from which an activation energy of 25 kcal has been obtained. This secondary mechanism exists only for concentrations in ionic groups higher than 6 mol %, when clustering occurs. For lower concentration superposition is possible and the shift factors fit a WLF equation.

* Present address: Laboratoire d'Électrostatique, CNRS, 38042 Grenoble Cedex, France.

However, other thermorheologically complex systems, where microphase separation occurs, show good superposition, although two relaxation processes are operating. This behaviour is observed for example in triblock copolymers such as styrene–butadiene–styrene. The shift factors have been shown to obey a WLF equation for temperatures near the glass transition of the butadiene phase. For higher temperatures an Arrhenius dependence is found¹². This good time–temperature superposition has been shown to be only apparent¹³ and could be explained by the large separation in temperature or frequency of the two relaxation mechanisms.

In this paper we shall attempt to answer the following questions: (a) is time–temperature superposition possible that is to say how does the presence of complexes affect the usual diffusional process, in particular does it introduce a secondary relaxation mechanism? (b) what is the influence of concentration, do the isolated complexes play the same role as the clustered complexes do?

EXPERIMENTAL

Samples

The polymer used in this study is an amorphous terpolymer, butadiene–styrene–4-vinylpyridine. The percentage of monomer units are respectively 85, 10 and 5%.

This polymer has been synthesized by free radical polymerization in emulsion by ATO*. Addition of the vinyl pyridine monomer during the reaction was progressive to take into account the different reactivity factors of the monomers. Nitrogen concentration of the latex during polymerization remains constant. Thus due to polymerization conditions, this polymer may be considered as statistical.

The number-average molecular weight is of the order of 80 000, the polydispersity being 4. In order to prevent any degradation a small amount (1%) of antioxidant (*N*-phenyl-*N'*-cyclohexyl-*p*-phenylenediamine) is added. A careful purification has been performed so as to eliminate impurities coming from polymerization.

The transition metal salt used for coordination is NiCl₂·6H₂O. Coordination is achieved in solution: a concentrated methanolic solution of nickel chloride is added slowly to a 3% polymer solution in benzene under vigorous stirring. No precipitation takes place. The solvents are then taken off by vacuum pumping to constant weight. Samples are designated by *x*, the number of nickel ions per pyridine side-group.

Stress relaxation

The experiments were performed with type IFC relaxometers¹⁴.

Two different relaxometers were used, depending on the temperature range (–33°C to room temperature and 30°C to 140°C), the temperature being correct to ±0.2°C. The samples have a cross-section of 1 × 2 mm² and are 18 mm long. They have been taken from films obtained by compression at 150°C.

The deformation in length is 10% and achieved very quickly (some 1/10 sec) with an oleopneumatic jack.

In order to keep measurable stress values, the experiments have been limited to 1 h (3.5 decades of time in seconds) and a temperature of 90°C.

Internal friction

The experiments were performed by using a free oscillation torsion pendulum in a frequency range around 1 Hz¹⁵. The shear modulus is calculated by:

$$G(T) = \frac{K}{P^2}$$

where *P* is the period of the oscillations; *K* is a constant depending on the geometry¹⁷. The relative energy loss $\Delta W/W$ during one period was obtained from:

$$\Delta W/W = 1 - \exp \left(-\frac{2}{n} \log \frac{\theta_1}{\theta_{n+1}} \right)$$

where θ_1 is the amplitude for the first oscillation and θ_{n+1} that of the (*n* + 1) oscillation.

The samples (25 mm long × 3 mm wide) used were taken from films obtained by compression moulding at 150°C. A thickness of 2 mm has been chosen so that the period above *T_g* remains between 1 and 10 sec. So experiments of temperatures lower than *T_g* are impossible because of the very small value of the period.

STRESS RELAXATION

Results

Relaxation experiments have been realized with the sample *x* = 1.23. This high concentration was chosen in order to have the best conditions to see the influence of clusters: at this concentration complexes are mostly clustered.

Figure 1 represents the log $E(\rho_0 T_0 / \rho T)$ values plotted against log *t* for different temperatures. The values of the modulus have been corrected from the variations of density, ρ , when changing the temperature. The reference temperature *T₀* has been chosen as –31.4°C, which is the lowest temperature at which the experiments have been carried out.

We can see that some of the curves intersect. This fact may be due to the systematic error introduced when calculating the modulus from the stress as a result of ill-defined parameters. If we suppose an error of 2% in the section, 0.2% in the strain, then the systematic error in the modulus value is 6% i.e. 0.03 in log *E*. Because of this error in the log *E* values, a vertical shift is necessary to obtain a good fit when operating superposition of the curves. The best vertical shift factor is calculated with a computation program derived from that employed by King¹⁶ for the determination of the horizontal shift factor. The superposition of two curves is achieved for different values of the vertical shift factor log *f*. For each value the horizontal shift factor is calculated:

$$A = \frac{\sum \alpha_i}{N}$$

where α_i are the different distances between the two curves and *N* the number of values. The accuracy of the fit is

Figure 1 Stress relaxation curves (sample $x = 1.23$). Temperatures ($^{\circ}\text{C}$): A, -31.4; B, -20; C, -10; D, 0.2; E, 7.5; F, 8.6; G, 16; H, 19.4; I, 25.7; J, 30; K, 40; L, 50; M, 60; N, 75; O, 90

Table 1 Vertical shift factors $\log f$ and horizontal shift factors $\log a_T$, used for master curve construction

$T(^{\circ}\text{C})$	$\log f$	$\log a_T$	$\chi^2 \times 10^4$
-31.4		0	
-20	0.01	-1.385	6
-10	-0.025	-2.454	2
0.2	0.005	-3.055	3
7.5	-0.025	-3.631	6
8.6	-0.02	-3.737	3
16	0.01	-4.196	3
19.4	-0.02	-4.309	3
25.7	0.015	-5.103	1
30	0	-5.640	0
40	0	-6.314	2
50	0	-6.829	2
60	0	-7.528	2
75	0	-8.222	3
90	0	-9.118	1

characterized by:

$$\chi^2 = \frac{\sum(\alpha_i - A)^2}{N}$$

The best vertical shift factor corresponds to the lowest χ^2 values. Table 1 gives the horizontal and vertical shift factors and χ^2 values. The vertical shift factors vary at random

with temperature and are smaller than the possible error in $\log E$.

Figure 2 gives the master curve obtained by this procedure. Its shape shows clearly that the complexes do not give stable crosslinking; a breakdown of the modulus is observed, contrary to covalent crosslinking, with which a constant modulus is obtained.

Figure 3 represents the variation of the experimental shift factors $\log a_T$ with temperature. $T = 20^{\circ}\text{C}$ appears as a critical temperature. For temperatures lower than 20°C , $\log a_T$ fits a WLF equation:

$$\log a_T = \frac{-C_1(T - T_0)}{C_2 + T - T_0}$$

with constants $C_1 = 11.3$ and $C_2 = 82.3$. If $T_g = 217\text{ K}$, as determined by internal friction, is chosen as reference temperature, C_1 and C_2 are found to be 16 and 59.3, i.e. very similar to the usual constants⁷.

Figure 2 Master curve (sample $x = 1.23$), $T_0 = 31.4^{\circ}\text{C}$

Figure 3 Shift factors $\log a_T$ versus temperature and WLF curve corresponding to the low temperature experimental points

Figure 4 Shift factors $\log a_T$ versus $1/T$ with the corresponding WLF curve (●) for low temperatures and Arrhenius curve (▲, $\Delta H = 28$ kcal/mol) for high temperatures

For temperatures above 20°C the experimental shift factors deviate clearly from the WLF curve which best fits the experimental shift factors below 20°C . Therefore an additional relaxation mechanism takes place and must be related to the breakdown of the temporary crosslinks formed by the complexes.

Figure 4 gives the curve of $\log a_T$ versus $1/T$. Above 20°C this curve is a straight line, indicating a constant activation energy for the process. Thus this secondary relaxation mechanism obeys an Arrhenius equation:

$$a_T = a_0 \exp \left(-\frac{\Delta H}{RT} \right)$$

with an activation energy ΔH of 28 kcal.

The distribution of relaxation time is plotted in Figure 5. $H_1(\tau)$ is calculated with the first approximation of Alfrey:

$$H_1(\tau) = E(t) \left[\frac{d \log E(t)}{d \log t} \right]_{t=\tau}$$

A broad maximum related to the second mechanism of relaxation is observed.

Discussion

The first fact to note is that the relaxation operates by two processes. The first one is predominant at temperatures below 20°C . Because of the WLF dependence on the shift factor, this process must be related to the usual diffusional process above the glass transition. In the distribution of relaxation times, it corresponds to the initial decrease with a slope of the order of $-1/2^7$.

At higher temperatures the relaxation is completely dominated by the breaking of high energy crosslinks, this

process follows an Arrhenius law. Owing to the previously shown existence of clusters with high density of complexes, it is logical to relate this relaxation process to this phase. An exchange reaction, breaking and reforming of crosslinks must be supposed because the clusters are stable up to very high temperatures, as it has been shown in SAXS⁴.

The observed superposition agreement must be only apparent. The relaxation times having a WLF and an Arrhenius dependence must be affected to a different degree by a change in temperature. Failure of the time-temperature superposition would be observed if the measurements were realized during more than 3.5 decades. In our thermorheologically complex polymer, the relaxation behaviour is completely dominated by one phase (with a WLF dependence) or by the other (with an Arrhenius dependence).

INTERNAL FRICTION

Results

Figure 6 represents $\log G$ and $\Delta W/W$ plotted against temperature for samples with different nickel concentration. For increasing nickel concentration, we note for the modulus: an increase in the values of the modulus associated with the rubbery plateau, and an increase in the temperature amplitude of this rubbery plateau.

For the $\Delta W/W$ against temperature curves, we note a decrease in the minimum value of $\Delta W/W$ related to the rubbery plateau for the modulus and the disappearance in samples $x = 0.645$ and $x = 1.25$ of a peak located around 280 K in samples $x = 0.296$ and $x = 0.176$.

Modulus and damping curves in the transition zone give the same transition temperature for all samples i.e. 217 ± 3 K. This result is in agreement with that of differential enthalpic analysis³. The fact that glass transition does not shift after coordination has been attributed to microphase separation; the observed glass transition concerns a phase containing no or few crosslinks.

Discussion

The modulus and $\Delta W/W$ curves can be explained by the presence of temporary crosslinks. The same behaviour has been observed in non-crosslinked polymers when changing the molecular weight¹⁷. The increase of the number of entanglements gives an increase of the modulus associated to the rubbery plateau, wider temperature range of this plateau, a decrease in the damping minimum value.

In samples $x = 0.176$ and $x = 0.296$ simultaneous presence of two kinds of temporary crosslinks are clearly

Figure 5 Relaxation time distribution, $T_0 = 30^\circ\text{C}$

Figure 6 Modulus G and damping $\Delta W/W$ versus temperature curves for various nickel concentrations: $x = 0.176$ (- · - · - ·); $x = 0.296$ (·····); $x = 0.645$ (---); $x = 1.25$ (—)

shown. A first $\Delta W/W$ maximum associated with the beginning of the decrease of the modulus, is observed around 280 K and must be related to breakdown of temporary crosslinks. These crosslinks slow down the polymer chains diffusion much more than entanglements do; for the uncoordinated polymer the beginning of the flow is already observed at 245 K.

The existence of another maximum in $\Delta W/W$ against temperature curve after the beginning of viscous flow reveals the presence of other, higher energy, temporary crosslinks. The number of these crosslinks is not large enough to prevent the beginning of the flow at a lower temperature.

In samples $x = 0.645$ and $x = 1.25$ the high energy crosslinking density is large enough to avoid an initial flow. The plateau region covers a wider temperature range and the decrease of modulus is associated with breaking and

reforming of high energy crosslinks. A maximum in the damping curves is associated with the fall of the modulus.

Thus the first crosslinks to break must be the isolated complexes, predominant for low concentrations. The crosslinks which break at higher temperature are constituted by the clustered complexes predominant at high concentration.

CONCLUSION

These experiments of stress relaxation and internal friction give some answer to the questions. Relaxation of the polymer chains operate by two mechanisms: the usual diffusional process and a secondary mechanism obeying an Arrhenius equation with an activation energy of 28 kcal. This mechanism corresponds to exchange between complexes and is related to the second phase constituted by the clusters.

Isolated complexes enable relaxation before clustered complexes but their role is only seen at low concentrations.

Dissolution of polypropylene in organic solvents: 1. Partial dissolution

D. A. Blackadder and G. J. Le Poidevin*

Department of Chemical Engineering, University of Cambridge, Cambridge CB2 3RA, UK

(Received 8 January 1976)

The dissolution of polypropylene in organic solvents has been investigated in detail. The complete study will provide an interesting comparison with the literature concerning the dissolution of amorphous polymers. Under appropriate conditions polypropylene dissolves at a steady rate, but there is a preliminary induction period. The results reported here concern this period, and provide the foundation for later parts of the work. It was necessary to study solvent sorption by polymer as well as the partial or fractional dissolution characteristic of the induction period. The Hildebrand solubility parameter proved useful in understanding the behaviour of polypropylene soaked in various solvents over a range of temperatures. Factors controlling the partial dissolution have been identified and analysed.

INTRODUCTION

In a series of papers¹⁻⁷ Ueberreiter and his collaborators have provided a detailed description of the dissolution of polystyrene, a typical amorphous polymer, in organic solvents. Among the factors identified as having a bearing on the rate of dissolution were: the nature and molecular weight of the polymer; the viscosity and size of the solvent molecules; the compatibility of polymer and solvent; and the temperature and conditions of agitation in the system. Hitherto, relatively little has been reported concerning the dissolution of semi-crystalline polymers where one would expect the crystallinity to have some effect and, less obviously perhaps, where some material and some regions are more soluble than the remainder under given conditions. The dissolution of polypropylene has now been studied in detail.

The present paper, Part 1 of a series, describes the effect of soaking polypropylene film in organic solvents at various temperatures up to 110°C. It will be shown in a later paper that bulk specimens of this polymer can be made to dissolve at a constant rate at temperatures from 110°C upwards, once an induction period has been completed. This induction period arises because the penetration of polymer by solvent is a prerequisite for dissolution and it takes time to establish a situation in which characteristic events are occurring at different depths of penetration. Clearly there will be a gradation in composition and properties between dry bulk polymer to which no solvent has penetrated and the boundary layer of liquid adjacent to the swollen surface of the solid.

In order to understand the induction period it is necessary to investigate the general effects of solvents on the polymer under conditions where total dissolution does not occur. This involves measurement of the amount of polymer dissolved and the amount of solvent imbibed under various conditions, and the interpretation of the results in the light of thermodynamics and kinetics. It is already known that fractional dissolution of polyethylene can occur at temperatures well below the melting point⁸ and the material dissolved is of low molecular weight. When steric fac-

tors are of importance, as for polypropylene, the extracted material may consist mainly of low molecular weight isotactic chains and also of atactic chains, not necessarily of low molecular weight⁹⁻¹¹.

At temperatures well below their melting points, semi-crystalline polymers do not dissolve wholly in organic solvents. This is because the positive entropy changes associated with fusion and mixing do not sufficiently offset the large heat of fusion and the overall free energy change for crystallite dissolution is therefore positive. However, even at low temperatures, *most* solvents can penetrate the non-crystalline regions to some degree, resulting in the solvation of individual segments of polymer chains and overall swelling of the specimen. At the equilibrium swollen state, the osmotic pressure associated with the mixing of solvent and polymer is just balanced by the elastic retractive forces supplied by a network of interlamellar tie-molecules.

EXPERIMENTAL

Materials

Polymer. The polypropylene used was a homopolymer, GXM 43, kindly supplied by ICI Plastics Division. The amount of atactic material present was estimated to be about 2 wt %, and the polymer contained the usual small amounts of antioxidant and stabilizer. In view of the relatively high temperatures used in some of the present experiments these additives were welcome and no attempt was made to remove them. The polymer was quoted as having a melt flow index of 2.16 and a melt viscosity of 5.0×10^3 Nsec/m at 190°C.

Solvents. The *p*-xylene was a 99% product obtained from ICI. The other organic solvents, of SR or AR grade, were used as received.

Procedures

Preparation of film specimens. To investigate the effect of soaking polymer in solvent it is convenient to use film rather than thicker specimens. Polypropylene chips were compression moulded between platens at 220°C for 4 min.

* Now at the Electricity Council Research Centre, Capenhurst, Chester, UK.

Figure 1 Relationship between solubility parameter and equilibrium solvent uptake by polypropylene at 25°C: □, chlorinated solvents; ○, aromatic and naphthenic solvents; △, n-alkanes

The resulting films were quench cooled by immersion in cold water. The thickness was about 0.3 mm, and rectangular pieces measuring 50 mm by 16 mm were cut as required. The average thickness of each strip was determined from ten micrometer measurements spaced along both of the long sides. The density of strips was adjusted when necessary by annealing for 2 h in a vacuum oven at an appropriate temperature.

Solvent sorption. Several dry strips of film were weighed to 0.05 mg and then transferred simultaneously to tubes of solvent held in a thermostat controlled to $\pm 0.05^\circ\text{C}$. After a suitable immersion time a strip was removed from the liquid, lightly pressed between tissues, and hung from one arm of a balance. A second stopwatch was started as the strip was removed from the liquid and the total mass of polymer and imbibed solvent was noted at 30 sec intervals over a period of 3 min. A graph of mass against time permitted extrapolation to the moment of removal, thus giving the true mass of solvent imbibed per unit mass of dry polymer after a known period of immersion¹². The time for attainment of equilibrium at 25°C varied from a few hours to several days but all equilibrium values were based on the uptake after 7 days, using the original mass of dry polymer as a basis, irrespective of the amount of polymer dissolved while solvent was imbibed. At higher temperatures it is quite possible that equilibrium was not always attained, but the results were instructive nevertheless. The error in measuring the uptake was estimated to be only $\sim 1\%$ at 25°C, rising to at least 5% at 100°C. It was often convenient to convert the measured uptake into units of volume sorbed per unit mass of polymer.

Soluble fraction. Strips of film, as described above, were vacuum dried at 80°C for 12 h before weighing. For initial densities between 908 and 918 kg/m³, this treatment was shown to cause no detectable change in density. Strips were soaked for 7 days in solvents at chosen temperatures, with a solvent: polymer ratio of 250:1 to avoid any possibility of saturating the solvent with soluble species. After removal from solvent, specimens were wiped dry and left in air for 24 h. A period of 12 h in a vacuum oven at 60°C

completed the drying process by removing residual solvent. The final mass of the specimen was used to calculate the percentage of the original material which had been dissolved out.

Density and crystallinity. Densities were measured in a density gradient column at 25°C using *p*-xylene and chlorobenzene as column liquids. Fragments of polymer film were cut so as to have a specific surface of less than 10 m²/kg, as recommended by Blackadder and Keniry¹³. In general they reached equilibrium in the column in less than 24 h. It can be shown that loss of soluble material to the column liquids requires a small correction to the observed density, which would otherwise be overestimated. With the correction, values are reliable to 0.2 kg/m³. When required, crystallinities were calculated from densities using Natta's formula¹⁴:

$$(1 - \lambda) = \frac{983 + 0.90(T - 93) - (10^6/d)}{0.48(T - 93)} \quad (1)$$

where $(1 - \lambda)$ is the weight fraction of crystalline material, commonly written as w_c , and d is the density (kg/m³) at T (K).

RESULTS AND DISCUSSION

Solubility of polypropylene in various solvents

In order to interpret polymer solubility in thermodynamic terms, it is natural to turn to well-tried parameters which have enjoyed some success in characterizing simpler systems. The strength of the non-valence or secondary bonding in a liquid system is related to the cohesive energy density, $\Delta E_v/V$, where ΔE_v is the molar energy of vaporization and V is the molar volume. It is better to predict and interpret solubilities in terms of the square root of the cohesive energy density, known as the Hildebrand solubility parameter¹⁵ given by:

$$\delta = \left(\frac{\Delta E_v}{V} \right)^{1/2} \quad (2)$$

Liquids with like values of δ tend to be equally good solvents for a given solute and to be mutually compatible. This leads to indirect methods of measuring δ for a polymer where $\Delta E_v/V$ cannot be evaluated. Michaels *et al.*¹⁶ have measured the equilibrium sorption of various solvent vapours by polypropylene at 25°C, and found that the equilibrium sorption (mass of solvent vapour sorbed by unit mass of dry polymer) reached a maximum for cyclohexane which had a solubility parameter of 16.8 (MJ/m³)^{1/2}. Since the thermodynamic dissolution temperature of the polymer, T_s , was a minimum in the same solvent, it was suggested that polypropylene had a solubility parameter of ~ 16.8 (MJ/m³)^{1/2}. Other authors¹⁷ have pointed out that the viscosity of solutions of a polymer in various solvents at a given temperature and concentration shows a maximum when the polymer and solvent have most nearly the same δ value. The maximum arises because the polymer chains are most uncoiled in solvents of high compatibility.

Figure 1 shows Q , the equilibrium volume of solvent imbibed per unit mass of dry polypropylene at 25°C, plotted against literature values^{15,18} of the solubility parameters of the various solvents, calculated from the heats of vaporization and the molar volumes. The density of the poly-

Table 1 Effect of solubility parameter, δ , on the equilibrium swelling, Q , of polypropylene at 25°C

Solvent	Solvent type	$Q \times 10^4$ (m ³ /kg)	δ (MJ/m ³) ^{1/2}
Benzene	Aromatic	1.16	18.7
Toluene	Aromatic	1.24	18.2
<i>p</i> -Xylene	Aromatic	1.30	17.9
Cumene	Aromatic	1.06	17.7
Cyclohexane	Hydroaromatic	2.20	16.8
Methylcyclohexane	Hydroaromatic	1.80	16.1
Tetrahydro-naphthalene	Naphthenic	1.04	19.5
Decahydro-naphthalene	Naphthenic	1.91	17.2
α -Chloro-naphthalene	Chlorinated naphthenic	0.74	21.1
Chlorobenzene	Chlorinated hydrocarbon	1.22	19.9
Carbon tetrachloride	Chlorinated hydrocarbon	2.08	17.6
<i>n</i> -Dodecane	<i>n</i> -Alkane	1.06	16.1
<i>n</i> -Decane	<i>n</i> -Alkane	1.10	15.8
<i>n</i> -Octane	<i>n</i> -Alkane	1.21	15.5
<i>n</i> -Heptane	<i>n</i> -Alkane	1.66	15.1
<i>n</i> -Hexane	<i>n</i> -Alkane	1.48	14.7

propylene used was 907.7 kg/m³ at 25°C. In good agreement with Michaels *et al.*¹⁶ the maximum uptake of solvent for the naphthenic and aromatic solvents occurs at a value of δ between 16.5 and 16.8 (MJ/m³)^{1/2}. There is a separate curve for *n*-alkanes, and signs of yet another for chlorinated hydrocarbons. The swelling data appear in Table 1. It is significant that for alkanes the maximum occurs at a lower δ value than for the naphthenics and aromatics; Hildebrand¹⁹ and other workers have noted anomalies in binary solutions where one component is a paraffin. In particular Hildebrand²⁰ evaluated δ values by means of regular solution theory and showed that they were consistently higher than values obtained from equation (2). He quoted isooctane and *n*-heptane as having δ values 2.0 and 1.2 (MJ/m³)^{1/2} higher, respectively, than those determined from ΔE_v and V , whereas the value for cyclohexane was much the same for both methods of evaluation. This reinforces the argument that δ for polypropylene is indeed very close to 16.8 (MJ/m³)^{1/2}, and there is a case for correcting alkane values by ~ 1.7 (MJ/m³)^{1/2}, an amount which would make the maximum of the alkane curve on Figure 1 coincide with that of the other curve.

It is noteworthy that cumene falls between the aromatic–naphthenic curve and the *n*-alkane curve. This may be because cumene has a fairly bulky aliphatic side chain, which confers some alkane character without being large enough to overshadow the effect of the benzene ring. If the abscissa of the point for cumene is indeed too small it would account for the observed displacement.

Repeating the above experiments at 50°C gave the results shown on Figure 2, which includes data discussed in the following section.

Soluble fraction

It was mentioned in the introduction that atactic and some low molecular weight isotactic material might be expected to dissolve at temperatures substantially lower than the dissolution temperature of the bulk polymer. An attempt was made to correlate the densities of 3 distinct polypropylene specimens with the weight losses recorded after soaking in 4 different solvents for 7 days at 25°C. No

correlation could be established, though shorter soak times might have shown up some dependence on crystallinity¹². At least the results suggest that the material soluble at 25°C is essentially non-crystalline. The lowest recorded weight loss was 0.11% in 1-chloronaphthalene and even this was probably more than mere antioxidant removal. Further experiments were devised to test the hypothesis that the 1.1% or so dissolved by *p*-xylene, the best solvent used, was polymeric and mostly atactic.

Figure 4 Loss of soluble material (wt%) plotted against density of polypropylene after treatment with various solvents (initial density 908 kg/m^3): \circ , measured values; —, calculated values assuming soluble material is leached only from non-crystalline regions of the bulk polymer

Figure 3 shows one consequence of soaking polypropylene film in *p*-xylene at 25°C . Several selected strips of uniform thickness ($0.300 \pm 0.010 \text{ mm}$) and density 907.7 kg/m^3 were weighed and separately immersed in *p*-xylene. Samples were removed after appropriate times and dried as described earlier, so that the soluble fraction might be calculated at various intervals over a period of 7 days. After a steep initial rise the curve flattened off to become effectively horizontal after about 90 h. It is possible to test directly whether the soluble material being removed had about the same density as amorphous polypropylene. Suppose that a specimen is soaked as above for 7 days, dried, and a fragment released into the density gradient column at the same time as an unsoaked fragment of identical shape and size. The pre-soaked specimen will settle fairly quickly to its final density since there is no more material to be dissolved, but the other will behave differently. According to Figure 3 about 0.68 wt% will go into solution in the first 7 h, assuming that the mixture of column liquids behaves like pure *p*-xylene. (This is a reasonable assumption on two counts: the column liquid adjacent to the specimen after 7 h is 83% *p*-xylene by volume, and separate experiments have shown that the weight loss after 7 days is the same in pure chlorobenzene as in pure *p*-xylene.) In the period between 7 h and 7 days after insertion of the test fragments into the column, the unsoaked piece will still be losing atactic or low crystallinity isotactic material and will continue to fall as its density increases.

The above argument was tested by cutting 4 samples, 2 mm square, from film previously soaked in *p*-xylene at 25°C for 7 days, then dried, and 4 similar samples were cut from unsoaked film. Figure 3 predicts that unsoaked specimens should lose about 0.44% in weight between 7 h and 7 days, and equation (1) permits the calculation of the corresponding increase in overall crystallinity. A crystallinity change of 0.30% corresponds to a displacement of 3.7 mm in the density gradient column, which compares well with the observed value of $3.9 \pm 0.5 \text{ mm}$. The implication is that

the dissolved material had an *in situ* density of between 848 and 860 kg/m^3 , limits which enclose Natta's value¹⁴ of 857 kg/m^3 for the density of wholly amorphous polypropylene at 25°C . Since the atactic content of the polymer is $\sim 2\%$, it seems that the 1.12% lost to *p*-xylene in 7 days is very probably wholly atactic.

Having demonstrated that at 25°C the overall density of a polypropylene specimen increased as soluble material was leached from the non-crystalline regions, it was appropriate to investigate higher temperatures and other solvents, always with a view to understanding the induction period preceding steady total dissolution at higher temperatures still. Figure 2 shows that at 50°C there is a rather close correspondence between solvent uptake and weight loss in the same period, and the solubility parameter correlates both properties effectively, bearing in mind the possible corrections to the δ values for some solvents. Figure 4 gives the measured weight loss for various temperatures and solvents plotted against the appropriate density after soaking for the usual 7 days. The intercept corresponds to unsoaked film and the solid curve is the relationship expected if: (a) all the material dissolved had the density of amorphous polypropylene; and (b) the soaking treatment left the remainder totally unaffected. The curve was obtained as follows. Equation (1) relates $(1 - \lambda)_u$ to d_u as well as $(1 - \lambda)_s$ to d_s , where the subscripts *u* and *s* denote unsoaked and soaked specimens. If the mass of crystalline material is indeed unaffected by any soaking treatment then it follows that:

$$\frac{(1 - \lambda)_u \times 100}{100 - m} = (1 - \lambda)_s \quad (3)$$

Evidently the percentage loss in weight, *m*, can be calculated from this expression if d_s and d_u can be measured. It is clear from Figure 4 that there are marked deviations from the theoretical curve, and these deviations prove to be very informative.

Comparison of columns 4 and 5 in Table 2 will show that for all solvents the significant deviations arise for soak temperatures in excess of 50°C . It appears that up to ~ 4 wt% of the soluble material has a density like that of amorphous polypropylene, as required by the theoretical curve. Some of the 4% is evidently isotactic yet non-crystalline. For weight losses between 4 and 12% the points lie to the right of the curve, which is evidence for a structural reorganization process during the soaking, the result being a density increase over and above that caused by dissolution of low density material. At very high temperatures and when the weight loss exceeds 12%, the points start to fall above the curve and another new feature requires explanation.

To interpret Figure 4 it is necessary to recall certain morphological features of semi-crystalline polymers. During the crystallization of polyethylene from the melt there is some segregation of low molecular weight material^{21,22} and this tends to persist in part in uncrystallized form located within and between the spherulites. Hofmann and Lauritzen²³ have shown that the disappearance of crystallinity at temperatures well below the melting point²⁴⁻²⁶ may be attributed to the early melting of the smallest crystallites. Baddour *et al.*²⁷ have pointed out that such effects are accentuated by the presence of solvent acting as a diluent to reduce the melting points of crystallites of any size below their 'dry' value. If the smaller crystallites also tend to contain more of the lower molecular weight

Table 2 Effect of soak temperature on the density of polypropylene

material, then the deviations from the curve in Figure 4 may be interpreted in terms of three parallel processes: (a) removal of amorphous material having the same density as amorphous polypropylene; (b) melting out and dissolution of small crystallites or crystallites containing notable amounts of low molecular weight polymer; (c) inclusion of material described in (a) and (b) into existing crystallites with a consequent increase in overall density, or possibly the creation of new crystallites large enough to resist solvent.

Process (a), on which the theoretical curve in Figure 4 is exclusively based, evidently covers the lower temperatures of soaking and weight losses up to ~4%. Suppose that at temperatures of 75°C upwards, the consequences of soaking were covered by processes (a) and (b) only. Although m would continue to rise with d_s , the points would lie above the curve, because the dissolved material would include some polymer from the crystalline regions. The density of the soaked polymer would therefore be lower than if all the soluble material had come from non-crystalline regions. (Indeed if a high enough proportion were leached from the crystalline regions it would even be possible for d_s to fall with increasing m , though this was not observed.) Figure 4 shows that the points concerned actually lie below the curve, and this positively requires the operation of process (c) in addition to (a) and (b) for values of m from 4 to 12%. The process is presumably similar to that induced in pure bulk crystallized polymer on dry annealing at elevated temperatures, but with solvent present, the reorganization occurs at much lower temperatures. At temperatures in excess of 100°C it can be seen that the experimental points lie well above the curve on Figure 4, and this may be interpreted in terms of the increasing dominance of process (b). It does not mean that

process (c) becomes less important in absolute terms, as the following observations confirm.

Consider a polypropylene specimen which had been soaked at 100°C in decahydronaphthalene (well above the curve in Figure 4) and another soaked in *p*-xylene at the same temperature (below the curve). After removing all the imbibed solvents these dried specimens were re-immersed in separate tubes containing fresh *p*-xylene at 25°C. The results are shown in Table 3. The sample pre-treated in *p*-xylene is seen to have absorbed more than twice as much of this same solvent at 25°C as the sample pre-treated in decahydronaphthalene. Even on the basis of C^* (volume of liquid sorbed per unit volume amorphous polymer) the uptake at 25°C is much higher for the sample pre-treated in *p*-xylene. This is the opposite of what is generally found for specimens not subjected to pre-treatment, as it will be shown later that C^* normally increases with the density of dry but annealed specimens. The decrease in C^* with increased density cannot be explained in terms of void formation caused by the loss of soluble polymer, since the percentage loss is considerably higher for decahydronaphthalene pre-treatment, yet the amount of *p*-xylene finally imbibed at 25°C is lower.

A possible explanation is that the interlamellar tie-lengths in the two specimens are different after pre-treatment, and these lengths determine the extent to which re-swelling can occur. The specimen pre-treated in decahydronaphthalene would have to have the shorter tie-molecules and this could arise if some of the inter-lamellar chains originally present were incorporated into the crystalline lattice structure as a result of soaking in this good solvent. Re-swelling at 25°C would then give a low result.

Blackadder and Keniry⁸ have shown that if polyethylene film is soaked in liquid *p*-xylene at 50°C then dried, it absorbs a greater amount of *p*-xylene vapour at 30°C than

Table 3 Effect of solvent pretreatment at high temperatures on subsequent reswelling at 25°C in *p*-xylene

Temperature (°C)	Solvent pre-treatment			Reswelling in <i>p</i> -xylene at 25°C		
	Solvent	Equilibrium swelling $\times 10^4$ (m ³ /kg)	Percentage weight loss	d_s † (kg/m ³)	Equilibrium swelling $\times 10^4$ (m ³ /kg)	C^*

Figure 5 Reduced sorption curves for polypropylene and liquid *p*-xylene at 25°C. Initial densities: □, 907.7; ○, 914.1; ×, 917.9 kg/m³

does untreated film, whatever the vapour activity. Indeed by extrapolating the relevant isotherms to unit activity it emerged that the increased volumetric uptake exactly compensated for the volumetric loss of soluble material in the pre-treatment. Experiments along similar lines would appear to offer another method of establishing when the dissolution of soluble material from polypropylene is accompanied by reorganization of the crystalline and non-crystalline regions.

For this work liquid uptakes were measured rather than vapour isotherms. Specimens of polypropylene film of density 908.0 kg/m³ were immersed in *p*-xylene (at 75° or 100°C) or decahydronaphthalene (at 100°C). After 7 days the specimens were removed from their respective liquids, dried, reweighed and the losses determined. They were then re-immersed in separate 50 cm³ quantities of *p*-xylene at 25°C. Unsoaked control specimens were also treated in this way. After 24 h the equilibrium uptakes were determined and, without exception, samples which had been pre-treated at temperatures above 25°C imbibed more solvent than did untreated specimens. The increased liquid uptake was used to estimate the equivalent weight lost during the pre-treatment on the assumption that the soluble material had a density of about 860 kg/m³ at 25°C. The results appear in Table 4, together with the true weight losses and values calculated from d_s .

For the samples pre-treated in *p*-xylene at 75°C it is noteworthy that the weight losses arrived at by all three methods are much more comparable than for the other pre-treatment procedures. This suggests that for this 75°C treatment the material removed is largely from non-crystalline regions and any induced reorganization is small. The wide spread in the loss values for treatment at 100°C in

p-xylene, can be explained as follows. The fact that the true weight loss is less than the value calculated from d_s points to some incorporation of previously non-crystalline material into crystallites, while the much larger loss calculated from the swelling data points to a considerable lengthening of the average interlamellar tie length above the untreated value. Blackadder and Keniry⁸ showed that sorption of vapour at quite low activity and temperature by polyethylene film resulted in a permanent increase in the average length of interlamellar ties. This can arise because bulk crystallized polymer has a wide distribution of tie-lengths. On the way to sorption equilibrium some of the shorter ties might be pulled out or even fractured, and this process can hardly be reversed on removing the solvent, thus resulting in a permanent increase in the average length of the interlamellar ties. The sorption of liquid *p*-xylene by polypropylene at 100°C has a more drastic effect, as seen by the very large difference between the measured weight loss and that calculated from swelling data.

The situation when polypropylene is pre-treated in decahydronaphthalene at 100°C is quite different. The much lower percentage loss calculated from swelling measurements is presumably the result of some recrystallization, yet at 100°C untreated polymer absorbs almost twice as much decahydronaphthalene as *p*-xylene. This fits perfectly with the expectation that the former solvent would penetrate the polymer to a greater extent than the latter and recrystallization would be easier under the conditions of the pre-treatment.

Sorption kinetics

Studies of sorption kinetics are likely to be relevant to polymer dissolution. Unlike microcrystalline substances, amorphous polymers swell prior to dissolution²⁸, and it will be shown in Part 2 that polypropylene also swells. One of the factors determining the rate of dissolution might thus be the rate of movement of the diffusing solvent front as it penetrates the non-crystalline material before affecting the crystallites.

For a plane sheet of polymer, thickness l , immersed in a liquid, it is a standard result that:

$$D = \frac{0.0419}{(t_{1/2}/l^2)} \quad (4)$$

where D is a diffusion coefficient and $t_{1/2}$ is the time required for the amount of liquid imbibed to reach half of its equilibrium value. The intrinsic error in this approximate formula is negligible, but a more serious objection is that it assumes a constant diffusion coefficient. In fact D will depend on concentration (among other things) and the use of equation (3) will generate some sort of average value for the range of concentrations present in the film during the measurements.

Reduced plots for the sorption of liquid *p*-xylene into polypropylene films of different densities are presented in Figure 5, which refers to 25°C. M_t/M_∞ is expressed as a function of t/l^2 , M_t being the uptake at time t , and M_∞ is the final equilibrium uptake. The curves have sigmoid shapes as observed by Rogers *et al.*²⁹ for the sorption of organic vapour into polyethylene at high vapour activities. Figure 5 shows that liquid is imbibed more rapidly for the higher densities, and Table 5 indicates that there is a reduced equilibrium uptake at the higher densities. Note that appropriate film densities were obtained by annealing, and

Table 5 Effect of density on diffusion coefficient and equilibrium uptake of *p*-xylene at 25°C

Anneal temperature (°C)	Density (kg/m ³)	$D \times 10^{12}$ (m ² /sec)	Equilibrium uptake (w/w%)
120	907.7	0.75	10.70
150	914.1	1.08	9.57
163	918.1	1.28	9.05

the temperatures concerned appear in Table 5. It has been shown by McCrum³⁰, Michaels *et al.*³¹ and by Keniry³² that for bulk polymer, D increases with annealing temperature for experiments with low activity solvent vapours and polyethylene. In the present work on polypropylene and where the solvent activity is unity (pure liquid), it is again evident that the value of D increases with the annealing temperature.

Michaels *et al.*^{31,33} have expressed the diffusion coefficient of a penetrant in a semi-crystalline polymer in the form:

$$D = D^*/\tau\beta$$

where D^* refers to the same penetrant in wholly amorphous polymer, τ is a tortuosity factor to allow for the increased path length when diffusion occurs round crystallites, and β is a chain immobilization factor to account for the restraining effect of crystallites on segmental mobility. It is known that annealing leads to an increase in fold length which, in turn, causes a decrease in the width to thickness ratio of crystalline lamellae and hence a decrease in tortuosity (for a given volume fraction of obstructive material tortuosity is increased least by spheres and most by rods). This would appear to explain the increase in D with annealing temperatures noted here.

Figure 6 shows the sorption data plotted on the basis of C^* , the volume of liquid sorbed per unit volume of non-crystalline polymer (assuming the two phase model), rather than M_t/M_∞ , and it can be seen that C^* increases with density. The explanation of this interesting observation lies in a comparison of the morphology of semi-crystalline polymer with that of crosslinked amorphous polymer. The latter swells much less than the unlinked form of the same polymer because the links restrain the uncoiling of chains which accompanies sorption. In polypropylene the non-crystalline regions might thereby be expected to have a lower sorptive capacity than wholly amorphous polypropylene, volume for volume. Ochiai *et al.*³⁴ measured the equilibrium uptake of two liquids by polypropylene film and found that C^* increased with density as in the present work. Their explanation virtually constituted a denial of the simple two-phase model, and the suggestion made by Keniry in the context of polyethylene³² appears more convincing. It hinges on the observation that mats of agglomerated single crystals swell more than bulk crystallized polymer, the obvious inference being that tie-molecules inhibit the swelling of the latter and are absent in single crystal agglomerates. Furthermore, the sorptive capacity of unit volume of non-crystalline material was highest for single crystals, and bulk polymer tended towards this only as the density was increased by annealing. An increase in the fraction of non-crystalline material in the form of chain folds rather than miscellaneous tangle would appear to favour high absorption.

CONCLUSIONS

(1) The Hildebrand solubility parameter for polypropylene is $16.7 \text{ (MJ/m}^3)^{1/2}$. This quantity is obtainable by plotting the swelling caused by various solvents against calculated values of the parameter for these solvents and noting the position of the maximum. A correction must be applied to values for *n*-alkanes obtained from the cohesive energy density. When suitably corrected the solubility parameters correlate well with the amount of polypropylene dissolved by each solvent at 50°C and with the amount of solvent imbibed by the polymer.

(2) At 25°C the density of polypropylene films cannot be correlated with the amount of polymer dissolved by soaking at that temperature. This suggests that the material soluble at 25°C is not removed from the crystalline regions, a view for which other evidence is available. It is noteworthy that polypropylene samples immersed in a density gradient column suffer from loss of soluble material, and this source of error should be allowed for when necessary.

(3) Soaking of polypropylene film in solvents at temperatures from 25° to 75°C involves dissolution of soluble material from the non-crystalline regions only, at least for a polymer density of 908 kg/m³. Up to 4 wt% of the samples is thought to be a mixture of atactic material and isotactic material, all excluded from crystallites. At temperatures from 75° to 100°C solvent soaking brings about considerable reorganization of the general morphology, previously non-crystalline chains or parts thereof being incorporated into new or existing crystallites. In the high temperature range of 100° to 110°C (just bordering on that

Figure 6 Sorption curves for polypropylene and liquid *p*-xylene at 25°C. Initial densities: □, 907.7; ○, 914.1; X, 917.9 kg/m³

required for total dissolution) the reorganization is overshadowed by the destruction and dissolution of the smaller crystallites. It appears that there are irreversible changes in the average lengths of the interlamellar ties.

(4) Sorption kinetics show that at 25°C liquid *p*-xylene swells polypropylene most rapidly at high sample density, and in addition more liquid is then imbibed per unit volume of non-crystalline material. This is explained in terms of morphology.

(5) The results of this paper form the foundation for the investigation of the conditions under which total, and not merely fractional, dissolution of polypropylene occurs. In particular the present results relate to the induction period preceding steady state dissolution.

Configurational and dynamic flexibility of polymer chains

M. G. Brereton and A. Rusli*

Department of Physics, University of Leeds, Leeds LS2 9JT, UK
(Received 27 October 1975; revised 22 January 1976)

The frequency of collisions between the end-groups of a polymer molecule is a useful measure of the dynamic flexibility of the molecule. An exact expression for this quantity is given in terms of the various distribution functions which characterize the polymer and the result compared with the experiments of Szwarc *et al.* on polymethylene chains in solution. The implication of some of the results for normal mode models of polymers is also discussed.

INTRODUCTION

There are two measures of molecular flexibility that are useful in the study of polymers. The first may be termed 'configurational flexibility' and arises from the multitude of conformations available to a polymer molecule. The second is 'dynamic flexibility' and comes about because, in thermal equilibrium in say a solvent, the molecule is not static but will be undergoing continual conformational changes. The rate at which these changes are occurring is clearly a reflection of the dynamic flexibility. As a measure of the configurational flexibility of a polymer we may take the probability of contact being made between the ends of the molecule (i.e. a ring closure). This, however, gives no indication of the rate at which end-to-end contacts are being made. We will use this latter quantity as a measure of the dynamic flexibility of the molecule.

In an attempt to quantify the concept of dynamic flexibility, Szwarc and Shimada^{1,2} have made a series of experiments designed to measure the frequency of collisions between the end groups of a polymethylene chain in solution. Furthermore, they were able to investigate the dependence of the collision frequency on the chain length, solvent viscosity and temperature. In this paper we will formulate the problem and give an exact expression for the frequency of the expected number of end-to-end collisions in terms of the various distribution functions which characterize the polymer molecule. The results of Szwarc and Shimada will then be discussed in the light of our results.

EXPECTED FREQUENCY OF END GROUP COLLISIONS

In Figure 1, the configuration of a polymer chain at some instant of time, t , is shown, together with a schematic sketch of the time dependence of the square of the end-to-end vector, $R(t)$. The forces governing the behaviour of $R(t)$ will be sufficiently complex to ensure that $R^2(t)$ may be regarded as a stochastic process. The problem of calculating the frequency of end-group collisions may then be formulated as finding the frequency of zeros in the stochastic process described by $R(t)$. In fact in the experiment of Szwarc *et al.* the collision of the end groups was detected using e.s.r. techniques by the transference of an electron between the end groups. In this experiment the end groups

needed only to be within a certain minimum distance, d , for the electron to be transferred. We are therefore interested in the frequency with which the stochastic process $R^2(t)$ crosses the level d^2 . This problem arises in many diverse fields of study, e.g. in electronics, fatigue studies, speech analysis etc. and is generally known as the level crossing problem. A solution was first given by Rice³, but the derivation we will use follows that given by Bendat⁴.

If we put $A(t) = R^2(t)$, then the expected number of level crossings of $A(t)$ through the interval $R^2, R^2 + dR^2$ for a given value of $dA/dt = \beta$ is:

$$\frac{f(R^2, \beta)dR^2d\beta}{|dt|} \quad (1)$$

where $f(R^2, \beta)dR^2d\beta$ is the probability that $R^2 < A(t) < R^2 + dR^2$ and $\beta < \dot{A} < \beta + d\beta$, and $|dt|$ is the time to cross dR^2 , i.e. $|\beta| = dR^2/|dt|$. The total number of crossings/unit time ν is then given by:

$$\nu = \int_{-\infty}^{\infty} |\beta| f(R^2, \beta)d\beta \quad (2)$$

Figure 1 Schematic sketch of the time dependence of the end-to-end vector $R(t)$

Figure 2 Log (electron transfer frequency, P) as a function of log (no. of monomers, n) for various temperatures: A, 40°C; B, 30°C; C, 15°C; D, 0°C; E, -15°C. Solvent HMPA

In thermal equilibrium $A(t) = R^2(t)$ constitutes a stationary process, i.e. the correlation $\langle A(t)A(t + \tau) \rangle$ is independent of the time t . Therefore:

$$\frac{d}{dt} \langle A(t)A(t + \tau) \rangle = \langle \dot{A}(t)A(t + \tau) \rangle + \langle A(t)\dot{A}(t + \tau) \rangle = 0 \quad (3)$$

in which case $A(t)$ and $\dot{A}(t)$ are uncorrelated and consequently $f(R^2, \beta)$ can be written as:

$$f(R^2, \beta) = g(R^2)h(\beta) \quad (4)$$

$g(R^2)$ is related to the usual probability density $p(R, L)$, that the end-to-end distance of a chain of length L is equal to R by:

$$g(R^2)dR^2 = p(R, L)4\pi R^2 dR$$

or

$$g(R^2) = 2\pi R p(R, L) \quad (5)$$

Using equations (4) and (5) we can write the frequency with which the stochastic process $R^2(t)$ crosses the level d^2 as:

$$\nu = 2\pi d p(d, L) \int_{-\infty}^{\infty} |\beta| h(\beta) d\beta \quad (6)$$

The integral in equation (6) is just by definition $\langle |\beta| \rangle$ and since:

$$\beta = |\dot{A}|_{R=d} = |2R\dot{R}|_{R=d} = 2d\dot{R} \quad (7)$$

we finally obtain that the number of end-to-end 'collisions' ($R < d$) is given by:

$$\nu = \frac{1}{2} 4\pi d^2 p(d, L) \langle |\dot{R}| \rangle \quad (8)$$

This is the main result of the paper; if ν is taken as a measure of dynamic flexibility and $p(d, L)$ as a measure of configurational flexibility, then equation (8) indicates that they are related primarily by the term $\langle |\dot{R}| \rangle$, i.e. the speed of the end-to-end separation.

In the next section we will discuss some aspects of the result and give a comparison with the experiment of Szwarc and Shimada.

COMPARISON WITH EXPERIMENT

In the experiment of Szwarc and Shimada they measured, using electron spin resonance techniques, the frequency P of intramolecular electron exchange in $N-(CH_2)_n-N^{\cdot-}$ in the solvent HMPA (hexamethylphosphoric triamide) where N denotes an α -naphthyl moiety. In this system, for $n \geq 5$ the frequency of electron transfer when the end groups are together, is much faster than the frequency ν with which the end groups actually come together. In other words there was a one-half probability that an electron on one end group before the encounter would be on the other end group after the encounter. Hence $P = \frac{1}{2}\nu$. The principal results of this experiment are shown in Figure 2 where $\log P$ is plotted as a function of $\log n$ for various temperatures.

In the previous section we showed (equation 8) that there are three factors which determine the collision frequency ν and hence P . They are: (a) an effective scattering cross-section $4\pi d^2$; (b) the probability $p(d, L)$ of an end-to-end separation d for a chain of length L ; and (c) the average speed $\langle |\dot{R}| \rangle$ of the end-to-end vector $\mathbf{R}(t)$. Of these factors, $p(d, L)$ is expected to depend most strongly on n . For a Gaussian chain of n links, each of length l we have that:

$$p(d, L) = \left(\frac{3}{2\pi n l^2} \right)^{3/2} \exp \left(-\frac{3d^2}{2nl^2} \right) \quad (9)$$

and the slope of $\ln(p)$ versus $\ln(n)$ is given by:

$$\frac{d \ln(p)}{d \ln(n)} = -\frac{3}{2} \left(1 - \frac{d^2}{nl^2} \right) \quad (10)$$

For large n we get a limiting slope of $-3/2$ characteristic of the Gaussian model. This is confirmed by Szwarc for the temperatures -15° , 0° and 15° C by plotting $\log(Pn^{3/2})$ versus $\log n$. The results are shown in Figure 3. For smaller values of n , equation (10) indicates that the slope should flatten and become zero when:

$$\langle R^2 \rangle = nl^2 = d^2 \quad (11)$$

i.e. when the root mean square, end-to-end distance is equal to the distance over which the electron can be transferred. Qualitatively the slope in Figure 2 does decrease as

Figure 3 $\text{Log}(Pn^{3/2})$ as a function of $\text{log } n$ for various temperatures; A, 45°C; B, 30°C; C, 15°C; D, 0°C; E, -15°C

n decreases and for $n \approx 10$ is approximately flat. In the experiment, d was estimated to be of the order of 7–9 Å, which gives using equation (11) for the link length l of the chain $l \sim 2.3\text{--}3$ Å. For polymethylene chain this estimate is about right. A much faster increase of P with n for $n < 5$ comes about because for these short chains the end-groups are always in the vicinity of each other for the electron to be transferred.

In general we might expect that $p(d, L)$ will be inversely proportional to the 'volume' $4\pi/3\langle R^2 \rangle^{3/2}$ of the polymer. The Gaussian result gives $\langle R^2 \rangle \sim n$, but if excluded volume effects are also included then for large n (strictly speaking $n \rightarrow \infty$) we have $\langle R^2 \rangle \sim n^{6/5}$. Therefore we would have that:

$$\nu \sim p(d, L) \sim n^{9/5} = n^{1.8}$$

In Figure 4 we have plotted $\text{log } Pn^{1.8}$ as a function of $\text{log } n$; however the experimental results do not appear to be sufficiently accurate to distinguish an exponent of 1.8 from 1.5.

Szwarc and Shimada also showed that the electron transfer frequency P and hence the end-group collision frequency ν was an activated process. For chains of more than five monomers the 'activation energy' was approximately 5 kcal/mol and independent of the length of the chain. This has important implications for the kind of theoretical model most appropriate for the description of the dynamic of the polymer molecules. The only factor in our expression (8) for ν likely to contain any strong temperature dependence is the term $\langle |\dot{R}| \rangle$, i.e. the average relative speed of the end-groups. However, any model of a polymer molecule which describes the motion in terms of normal modes will inevitably lead to a temperature dependence of $\langle |\dot{R}| \rangle$ of the form:

$$\langle |\dot{R}| \rangle \sim \left(\frac{kT}{m} \right)^{1/2} \quad (12)$$

where m is the mass of a segment. This result comes from the equipartition of energy, where for each normal mode

coordinate k_n , we have that:

$$\langle |\dot{k}|^2 \rangle \sim \frac{kT}{m} \quad (13)$$

The end-to-end vector can be obtained as a linear combination of normal modes and so we obtain equation (12). This result holds under considerably wide circumstances⁵ and in particular when chain stiffness and internal viscosity factors are included. Even though these factors may be regarded as activated processes, the use of normal modes is the overriding consideration and leads to the stated result for $\langle |\dot{R}| \rangle$. Thus Edwards and Goodyear⁶ considered a model where the motion of the polymer was dominated by potential barriers between conformations; however, as a result of reducing their model to a Rouse form their work contains the result (12). This indicates that for a discussion of the frequency of end-group collisions the dynamics of the polymer chain need to be treated in greater detail. This is being currently investigated and will be reported later.

CONCLUSION

A measure of the dynamic flexibility of a polymer chain is given by the collision frequency ν of the end-groups. In this paper we have shown that ν depends on three factors: (a) an effective cross-section $4\pi d^2$; (b) the probability of an end-to-end separation d ; and (c) the average speed of the end-to-end separation. In the experiments of Szwarc *et al.* the dependence of ν on the length of the chain is reasonably well accounted for by a Gaussian distribution function, although excluded volume effects could not entirely be ruled out. The most difficult factor to account for was the average speed $\langle |\dot{R}| \rangle$ of the end-to-end separation. A preliminary investigation based on the idea of normal modes

Figure 4 $\text{Log}(Pn^{1.8})$ as a function of $\text{log } n$ for various temperatures; A, 45°C; B, 30°C; C, 15°C; D, 0°C; E, -15°C

and the equipartition of energy indicates that the $\langle |\dot{R}| \rangle$ should depend on $(T)^{1/2}$. Experiments, however, show that the collision frequency is an activated process. Work is in progress to resolve this issue.

Molecular motion of poly(methyl methacrylate), polystyrene and poly(propylene oxide) in solution studied by ^{13}C n.m.r. spin-lattice relaxation measurements: effects due to distributions of correlation times

F. Heatley and Afrozi Begum

Chemistry Department, University of Manchester, Manchester M13 9PL, UK

(Received 11 November 1975)

The ^{13}C n.m.r. spin lattice relaxation times and Nuclear Overhauser Enhancements have been measured for solutions of poly(methyl methacrylate) (PMMA) in *o*-dichlorobenzene, polystyrene (PS) in pentachloroethane and poly(propylene oxide) (PPO) in CDCl_3 as a function of temperature. For PS and PMMA a T_1 minimum is observed close to ambient temperature. The single correlation time theory of relaxation is inadequate to explain the relaxation data, but within experimental error, the data can be interpreted in terms of either the Cole–Cole distribution of correlation times, the $\log -\chi^2$ distribution or a conformational jump model of chain dynamics.

INTRODUCTION

Several workers in recent years^{1–7} have used ^{13}C n.m.r. relaxation time measurements to study polymer motion in solution, and the topic has also been the subject of some theoretical investigation^{8–12}. In most work of this type, it has been assumed that the single correlation time model^{8,9} of segmental re-orientation is valid, but there is clear evidence^{10,11} that this is not necessarily so. Schaefer¹⁰ was obliged to use a distribution of correlation times to explain spin–lattice (T_1) and spin–spin (T_2) relaxation times and Nuclear Overhauser Enhancements (*NOE*) for both bulk and dissolved polymers. However, these results whilst of considerable importance, were limited to only a single temperature. This point was also noted by Hermann and Weill¹¹ who made an extensive series of ^1H , ^2H and ^{13}C relaxation measurements over a range of temperature for poly(ethylene oxide). Again the single correlation time theory was found inadequate but they chose to use a correlation function which was the sum of two exponentials, observing that a distribution of (single) correlation times is indistinguishable experimentally from a non-exponential correlation function. They assumed the anisotropic rotation model¹³ of relaxation but purely as a formal way of expressing a non-exponential correlation function. The results were satisfactorily interpreted by a self-consistent set of parameters, though each nucleus required a different set. This is surprising if the model is to be realistic, since the ^{13}C and ^2H relaxation times depend on exactly the same auto-correlation function viz that for the orientation of the C–H bond, and should therefore have the same set of parameters. The significance of this model is therefore doubtful.

At normal temperatures, poly(ethylene oxide) is a very flexible polymer, and it seemed likely that measurements on less flexible molecules could be more informative. We therefore have determined values of ^{13}C , T_1 and *NOE* for poly(methyl methacrylate) (PMMA) in *o*-dichlorobenzene (ODCB), polystyrene (PS) in pentachloroethane (PCE) and poly(propylene oxide) (PPO) in CDCl_3 over a wide temperature range. (These solvents were chosen for their large liquid range and lack of conflicting ^{13}C signals rather than

for thermodynamic reasons). These polymers provide a wide range of motional variety from the very flexible PPO ($T_g = 198\text{ K}$) to the stiff PMMA ($T_g = 298\text{ K}$), and contain side groups with varying amounts of freedom, from the mobile CH_3 groups in PPO to the highly restricted aromatic rings in PS. The observed relaxation data was interpreted in terms of three models: (I) the empirical Cole–Cole distribution^{14,15} used in analysis of dielectric relaxation^{16,17}; (II) the $\log -\chi^2$ distribution used by Schaefer¹⁰ referred to above; (III) the non-exponential correlation function deduced by Monnerie *et al.*¹² for a conformational jump model of polymer dynamics.

The necessary theoretical formulae are outlined in the Theory section, together with the results of trial calculations, and this is followed by a discussion of the experimental results.

EXPERIMENTAL

^{13}C relaxation times were measured on a Varian Associates XL-100 spectrometer at 25.14 MHz using the standard $\pi - \tau - \pi/2$ inversion recovery technique. The values of *NOE* were measured by comparing the integrals of spectra recorded first with complete proton noise decoupling and then with the decoupler offset 30 kHz in *cw* mode. This procedure eliminated sample temperature changes due to switching the decoupler on or off. Measurements were made for solutions of 100 and 400 mg polymer/ml solvent. The solutions were not degassed as the relaxation times of interest rarely exceed 500 msec. The theoretical maximum value of *NOE* was observed in a number of cases showing that the effect of paramagnetic impurities was indeed negligible.

The PMMA was a predominantly syndiotactic sample of $M_n = 90\,000$ supplied by the Rubber and Plastics Research Association, Shrewsbury, England. Two PS samples of $M_n = 10\,000$ and 110 000 with $M_w/M_n = 1.06$ were supplied by Pressure Chemical Co., Pittsburgh, Pa. Both samples were found to be atactic. The PPO was a sample of $M_n = 2020$ supplied by Waters Associates, Framingham, Mass.

THEORY

The ^{13}C spin-lattice relaxation time, T_1 , and Nuclear Overhauser Enhancement Factor, η , for a $^{13}\text{CH}_n$ group, are given in terms of spectral densities $J_n(\omega)$ by the formulae⁸ (in SI units)

$$\frac{1}{T_1} = \frac{\mu_0^2 \gamma_C^2 \gamma_H^2 h^2}{40\pi^2 r_{\text{CH}}^6} \{J_0(\omega_H - \omega_C) + 3J_1(\omega_C) + 6J_2(\omega_H + \omega_C)\} \quad (1)$$

$$\eta = 3.976 \left[\frac{6J_2(\omega_H + \omega_C) - J_0(\omega_H - \omega_C)}{J_0(\omega_H - \omega_C) + 3J_1(\omega_C) + 6J_2(\omega_H + \omega_C)} \right] \quad (2)$$

γ_H and γ_C are the magnetogyric ratios of ^1H and ^{13}C respectively, and r_{CH} is the C-H bond length. It is assumed that ^{13}C relaxation occurs solely by intramolecular dipole-dipole interaction with the attached protons, and this is undoubtedly true for motions of the time scale encountered in polymers. The spectral densities $J_n(\omega)$ are the Fourier transforms of the normalized autocorrelation functions of the second-order spherical harmonics of the C-H bond orientation angles:

$$J_n(\omega) = \int F_n^2(\tau) F_n^2(0) e^{i\omega\tau} d\tau \quad (3)$$

For an exponential autocorrelation function with a single correlation time τ_c (isotropic rotation), then:

$$J_n(\omega) = \frac{\tau_c}{1 + \omega^2 \tau_c^2} \quad (4)$$

For a distribution of correlation times, with distribution function $G(\tau_c)$ then equation (4) becomes:

$$J_n(\omega) = \int_0^\infty \frac{G(\tau_c) \tau_c}{1 + \omega^2 \tau_c^2} \cdot d\tau_c \quad (5)$$

Because n.m.r. correlation times may cover a very wide range, it is more convenient to use a logarithmic scale. Defining a new variable S by:

$$S = \ln(\tau_c/\tau_0)$$

the Cole-Cole distribution function of S , $L(S)$, is given by¹⁵:

$$L(S) dS = \frac{1}{2\pi} \cdot \frac{\sin \gamma \pi}{\cosh \gamma S + \cos \gamma \pi} \cdot dS \quad (6)$$

where the width parameter γ lies in the range 0 to 1. $\gamma = 1$ reduces to the single correlation time case. The expression for $J_n(\omega)$ is:

$$J_n(\omega) = \frac{1}{2\omega} \left[\frac{\cos(1 - \gamma)\pi/2}{\cosh(\gamma \ln \omega \tau_0) + \sin(1 - \gamma)\pi/2} \right] \quad (7)$$

In the log $-\chi^2$ distribution employed by Schaefer¹⁰, the logarithmic time scale (of adjustable base b) is defined by:

$$S = \log_b [1 + (b - 1)\tau_c/\tau_0]$$

and the distribution function $H(S)$ by:

$$H(S) dS = \frac{1}{\Gamma(p)} (pS)^{p-1} \exp(-pS) \quad (8)$$

where p is the width parameter. In addition to the time constant τ_0 , two parameters, p and b , are needed to specify this distribution. However, Schaefer has pointed out that it is really necessary to fix p and τ_0 , provided that b is sufficiently large. The larger p , the narrower the distribution; for $p \geq 100$, the distribution is so narrow as to be indistinguishable from the single correlation time case. The spectral density function is given by the integral:

$$J_n(\omega) = \int_0^\infty \frac{\tau_0 H(S) [\exp_b S - 1] dS}{(b - 1) \{1 + \omega^2 \tau_0^2 [(\exp_b S - 1)/(b - 1)]^2\}} \quad (9)$$

which was evaluated numerically.

In both distributions, τ_0 is the average correlation time but whereas the Cole-Cole distribution is symmetrical, the log $-\chi^2$ distribution is unsymmetrical with a tail towards longer correlation times. Other symmetrical distribution functions which have been briefly applied¹⁵ to n.m.r. relaxations include the Gaussian and Fuoss-Kirkwood distributions¹⁸, but these are very similar in effect to the Cole-Cole. The Davidson-Cole distribution^{15,19} is an unsymmetrical distribution which has been applied to dielectric relaxation. Here the tail is to shorter correlation times, but this does not seem physically reasonable for n.m.r. relaxation in polymers (see ref. 10 and the Discussion).

The third model employed is the non-exponential correlation function obtained by Monnerie *et al.*¹² for relaxation by conformation jumps of a polymer chain on a diamond lattice. This model is of course a highly simplified picture of the conformation freedom of a real polymer chain, which is generally considerably restricted by steric interactions. However, it is felt that it may be sufficiently realistic to be of some value in interpreting experimental observations. The same correlation function was obtained by Hunt and Powles²⁰ for a defect diffusion model of relaxation in supercooled liquids and glasses, but they found it necessary to include also an exponential term to take account of molecular rotation. The same approach was followed here, since polymer motion in solution is undoubtedly a combination of conformational jumps and overall molecular tumbling. The correlation function used is:

$$\overline{F_n^2(\tau) F_n^2(0)} = \exp\left(-\frac{\tau}{\tau_0}\right) \exp\left(-\frac{\tau}{\tau_D}\right) \left[1 - \operatorname{erf}\left(\frac{\tau}{\tau_D}\right)\right]^{1/2} \quad (10)$$

where τ_0 and τ_D are correlation times characterizing molecular tumbling and conformation transitions respectively. The spectral density function for this correlation function

Figure 1 Plots of (a) η and (b) T_1 vs. τ_0 for a CH group with a Cole-Cole distribution of correlation times, $r_{\text{CH}} = 1.1 \text{ \AA}$. Values of γ : A, A', 1.0; B, B', 0.8; C, C', 0.6

is given by¹²:

$$J_n(\omega) = \frac{\tau_0 \tau_D (\tau_0 - \tau_D)}{(\tau_0 - \tau_D)^2 + \omega^2 \tau_0^2 \tau_D^2} \left\{ \left(\frac{\tau_0}{2\tau_D} \right)^{1/2} \left[\frac{1 + \omega^2 \tau_0^2}{1 + \omega^2 \tau_D^2} \right]^{1/2} + \left(\frac{\tau_0}{2\tau_D} \right)^{1/2} \frac{\omega \tau_0 \tau_D}{(\tau_0 - \tau_D)} \left[\frac{(1 + \omega^2 \tau_0^2)^{1/2} - 1}{1 + \omega^2 \tau_0^2} \right]^{1/2} - 1 \right\} \quad (11)$$

By using equations (1), (2), (7), (9) and (11), the relaxation times and Overhauser enhancements are easily calculated as a function of correlation times and width parameters. Selected results are shown in Figures 1, 2 and 3. Such calculations of relaxation times have already been presented for the Cole-Cole distribution by Connor¹⁵, but these were given in reduced form and not specifically for ^{13}C relaxation. The effect of such a distribution on the Overhauser enhancement has not previously been studied. The results for the log $-\chi^2$ distribution have of course been published by the originator¹⁰, but are included here for convenient comparison with the others. The most prominent feature in Figures 1 and 2 is the raising and broadening of the T_1 minimum as the distribution increases in width. If the minimum can be observed, its value immediately determines the width parameter at that point. Furthermore, the sharp increase in η in the vicinity of the T_1 minimum is moderated. Equally notable is the decrease in effective activation energy for T_1 with increasing width of distribution. For the Cole-Cole distribution, Connor¹⁵ has shown that the effective activation energy for $T_1(E^*)$ is related to the true activation energy for $\tau_0(E)$ by:

$$E^* = \gamma E$$

For the conformation jump model (Figure 3) the crucial factor is the ratio τ_D/τ_0 . If $\tau_D/\tau_0 \geq 10$, the correlation decay is dominated by τ_0 , and the model reduces effectively to the single correlation time case. As τ_D becomes comparable to, or less than τ_0 , the T_1 minimum is raised and broadened, as in Figures 1 and 2, and also markedly shifted on the log τ_D scale.

Figure 2 Plots of (a) η and (b) T_1 vs. τ_0 for a CH group with a log $-\chi^2$ distribution of correlation times, $b = 1000$, $r_{\text{CH}} = 1.1 \text{ \AA}$. Values of p : A, A', 40; B, B', 20; C, C', 10

Figure 3 Plots of (a) η and (b) T_1 vs. τ_D for a CH group with a correlation function given by the conformational jump model (see text), $r_{\text{CH}} = 1.1 \text{ \AA}$. Values of τ_D/τ_0 : A, A', 0.01; B, B', 0.1; C, C', 1.0; D, D', 10.0

Figure 4 Plot of T_1 vs. τ_0 for a CH group undergoing simultaneous overall and internal rotation with a log $-\chi^2$ distribution of correlation times. (—), $\tau_g/\tau_c = 0.1$, τ_g same distribution as τ_c , $\rho = 40$; (---), $\tau_g/\tau_c = 0.1$, τ_g same distribution as τ_c , $\rho = 20$; (·····), $\tau_g/\tau_c = 1.0$, τ_g same distribution as τ_c , $\rho = 20$; (-·-·-), $\tau_g/\tau_c = 1.0$, τ_g independent of τ_c , $\rho = 20$

It would normally be expected that τ_0 and τ_D would vary with temperature according to the Arrhenius equation, and the calculated curves should therefore also correspond to $\log T_1$ vs. $1/T$ plots. However, it is quite likely that in the case of the distributions the width parameter varies with temperature, and in the case of the jump model τ_D and τ_0 have different activation energies so that the ratio varies with temperature. In practice therefore the temperature dependence of T_1 and η may be quite complicated.

For the $^{13}\text{CH}_3$ groups in PPO and PMMA, an additional relaxation process arises from internal rotation. Formula for the spectral densities for a nucleus undergoing simultaneous overall and internal rotation have been given by Woessner²¹. In the case of a three-fold potential well, the spectral density is:

$$J_H(\omega) = \frac{1}{4} \left[(1 - 3 \cos^2 \alpha)^2 \cdot \frac{\tau_c}{1 + \omega^2 \tau_c^2} + 3(\sin^2 2\alpha + \sin^4 \alpha) \times \frac{\tau'_c}{1 + \omega^2 \tau_c'^2} \right] \quad (12)$$

where:

$$\frac{1}{\tau'_c} = \frac{1}{\tau_c} + \frac{3}{2\tau_g}$$

τ_g is the lifetime of any of the three equivalent methyl positions and α is the angle between the CH bond and the rotation axis. For a polymer with a distribution of correlation times there are two extreme relationships between τ_g and τ_c . In the first case, exemplified by PPO⁶, τ_g is essentially independent of τ_c and is constant throughout the distribution. In the second case, exemplified by polyisobutylene⁶, τ_g is proportional to τ_c and therefore has the same distribution function. The appropriate versions of equations (1), (2), (5) and (12) can be used to calculate T_1 and η for each case and some results for the log $-\chi^2$ distribution are shown in Figure 4. Broadening the distribution raises and flattens

the T_1 minimum as for the backbone carbons, but its position on the τ_0 scale and its depth are much affected by the ratio τ_g/τ_0 . The relaxation times also depend a great deal on whether τ_g is independent of or proportional to τ_c , so it is important to choose the correct relationship for the particular polymer under investigation.

RESULTS AND DISCUSSION

The ^{13}C spectra of all polymers studied here have been presented elsewhere^{6,20}. For PMMA, the CH_2 and OCH_3 peaks lie close together and overlap strongly at the lower temperatures, limiting the accuracy of T_1 and particularly *NOE* measurements. Fine structure due to sequences of different tacticity is observed in the CH_2 region at the higher temperatures, but all peaks relaxed identically within experimental error. The $\alpha\text{-CH}_3$ region clearly showed three peaks due to syndiotactic, heterotactic and isotactic triads. The last one was very weak, but it proved possible to measure individual T_1 for the syndiotactic and heterotactic peaks, though not individual *NOE*. The results for two solutions of 100 and 400 mg/ml are shown in Figure 5. It is seen that in both cases a minimum in T_1 for the backbone $^{13}\text{CH}_2$ group is observed at about 30°C for the more dilute solution and 60°C for the more concentrated. The relaxation time at the minimum is in each case approximately twice as long as expected from the single correlation time theory, which is a clear imperative for the adoption of a more complicated relaxation theory. In addition, it is noteworthy that the activation energy for the CH_2 value of T_1 at the higher temperatures is apparently less for the 400 mg solution than for the 100 mg solution. This result is opposite to that expected intuitively, and points to the existence of a distribution of correlation times. The values of *NOE* for the CH_2 group increase as T_1 increases and are higher for the more dilute solution, as expected. The $\alpha\text{-CH}_3$ relaxation times are somewhat longer than the CH_2 values because of additional mobility conferred by internal rotation. It is noticeable that the T_1 of the heterotactic peak is greater than that of the syndiotac-

(b) X, backbone CH, 100 mg/ml solvent; O, backbone CH, 400 mg/ml solvent; Δ , aromatic $\text{C}_{2,3,5,6}$, 100 mg/ml solvent; \square , aromatic $\text{C}_{2,3,5,6}$, 400 mg/ml solvent

tic peak, suggesting faster internal rotation and a lower torsional barrier. This observation is in agreement with a neutron scattering measurement of barriers in PMMA²¹ which gave 34.3 kJ/mol for the syndiotactic $\alpha\text{-CH}_3$ barrier and 16.7 kJ/mol for the isotactic isomer.

The values of T_1 for the $-\text{OCH}_3$, backbone $-\text{C}-$ and $\text{C}=\text{O}$ carbons in PMMA are considerably longer than those of the CH_2 and $\alpha\text{-CH}_3$ peaks, in the first case because of high internal flexibility of the $-\text{COOCH}_3$ side group and in the last two cases because of the absence of directly bonded protons. These T_1 values were not measured, as the substantial additional experimental time was not supported by a confident interpretation of the values obtained.

For polystyrene, the backbone CH and CH_2 peaks lie very close together, the former being much sharper in atactic polystyrene²⁰. The *ortho* (C_2C_6) and *meta* (C_3C_5) aromatic carbons also overlap, but the *para* (C_4) carbon is fairly well resolved at all temperatures except the very lowest in the more concentrated solutions. The C_1 carbon is well separated from $\text{C}_2\text{-C}_6$ to low field but its T_1 value was not measured for the same reasons as the $-\text{C}-$ and $\text{C}=\text{O}$

carbons in PMMA. Also the CH_2 resonance is broadened so much by the effects of tacticity that its relaxation time is difficult to measure accurately. The results in Figures 6 and 7 therefore comprise relaxation times for the backbone CH, and aromatic C_2 , C_3 , C_5 and C_6 combined. The values of *NOE* reported are for backbone CH and CH_2 combined and for aromatic C_2 to C_6 combined. A clear minimum for T_1 for the backbone CH, at about 50°C is observed only for the 400 mg/ml solution, though it is obvious that the minimum for the 100 mg/ml solution is just beyond the lower limit of the temperature range covered here at about 15°C . As for PMMA, the T_1 at the minimum is roughly

twice the value expected for the single correlation time theory. The values of T_1 for the aromatic and backbone carbons lie on approximately parallel curves, with the aromatic carbons having slightly longer T_1 . The aromatic ring is therefore highly restricted compared to the $\alpha\text{-CH}_3$ group in PMMA, but still retains a small degree of oscillatory freedom. There is no variation of T_1 with molecular weight, in agreement with results reported some time ago by Allerhand and Hailstone¹.

In PPO, there is no difficulty in resolving the proton-decoupled CH, CH_2 and CH_3 signals, though in the uncoupled spectra, the CH doublet and CH_2 triplet overlap. Individual values of T_1 are therefore reported but only a combined CH + CH_2 value for *NOE* (Figure 8). PPO is a much more flexible polymer than PMMA or PS and only tentative indications of a minimum in T_1 were observed even at -60°C . The apparent activation energies increase with concentration, unlike PMMA, and since this is entirely reasonable, there is no obvious indication of a distribution of correlation times for this polymer. To elucidate such details, it is necessary to fit the observed values of T_1 and *NOE* to each model. However, before presenting the relaxation model parameters applicable to the experimental data discussed above, there are several points worth discussing concerning the accuracy with which such parameters can be obtained.

It is clearly necessary that both T_1 and the *NOE* be dependent of the model parameters. There are two regions where this is not so. The first is in the vicinity of the T_1 minimum, where T_1 is only slightly dependent on τ_0 (or τ_D). The minimum value of T_1 itself is quite strongly dependent on the parameters γ , p and τ_D/τ_0 , as Figures 1-3 show, but the usual uncertainty of at least 5% in T_1 does not permit an accuracy in τ_0 in this region of less than a factor of 2 or so (i.e. an error in $\log \tau_0$ of ± 0.3). It is true that the region of the T_1 minimum is where the *NOE* is most sensitive to τ_0 , but because the *NOE* is approximately propor-

Figure 7 ^{13}C T_1 and η for PS (MW 110000) in CDCl_3 . Legend as for Figure 6

tional to $\log \tau_0$, the experimental error of say ± 0.1 in the *NOE* leads to factor of 2 uncertainty in τ_0 .

The second region giving an imprecise interpretation of experimental data is to the high temperature (short correlation time) side of the T_1 minimum, where the *NOE* is approaching its limiting value. For the $\log -\chi^2$ distribution and the conformational jump model, the curves for all values of the parameters p and τ_D/τ_0 respectively approach the value 1.988 at varying rates, but below some critical correlation time the *NOE* becomes insensitive to the model parameters. T_1 here is strongly dependent on τ_0 , so if a value for p or τ_D/τ_0 is assumed, the corresponding value of τ_0 can be determined to the same accuracy. However, the

Figure 8 ^{13}C T_1 and η for PPO in CDCl_3 . (a) \circ , CH + CH_2 , 100 mg/ml solvent; \times , CH + CH_2 , 400 mg/ml solvent. (b) \circ , CH, 100 mg/ml solvent; \times , CH_3 , 100 mg/ml solvent; \square , CH, 400 mg/ml solvent; \diamond , CH_3 , 400 mg/ml solvent

NOE at that point cannot be used to distinguish between different values of p or τ_D/τ_0 (and hence different correlation times) except between wide limits. Figure 1 shows that this second structure does not apply to the Cole–Cole distribution where the limiting values of the *NOE* are strongly dependent on the width parameter γ . In practice, some limitation on the range of uncertainty may be placed by the need for physical coherence. For instance it may reasonably be expected that τ_0 will (at least approximately) follow the Arrhenius equation, and that γ and p will vary consistently with temperature.

With these restrictions in mind, the experimental data given above has been interpreted in terms of the parameters at the three models, and the results are presented in Tables 1 to 4. Values especially subject to the uncertainties described are placed in parentheses. It is estimated that the errors in the remaining parameters are approximately $\pm 20\%$.

There was little difficulty in fitting most of the data to any of the three models. Problems were encountered for the lowest temperatures of the more concentrated PS and PMMA solutions where the calculated values of *NOE* were consistently higher than the observed values of *NOE* for any reasonable model parameters, but no explanation has been found as yet. The discrepancy was common to all models, and there is little reason on the basis of these measurements to prefer one model over another. The experimental data certainly requires a distribution of correlation times, or its equivalent but the exact form is immaterial provided it has the flexibility to cover a wide range. The conformational jump model yields values for the ratio τ_D/τ_0 of less than unity, which is reasonable since it is expected that the correlation time for small-scale, limited local motions will be less than that for larger scale re-orientation. However, the conformity to reasonable physical behaviour may be no more than coincidence. It could well be that the non-exponential part of the jump model auto-correlation function, dominant since $\tau_D < \tau_0$, is simply a satisfactory representation of a certain distribution of correlation times of which τ_D is the average value. It is significant that for any system and temperature, the three models give values of τ_0 and τ_D which rarely differ by more than a factor of 2, and usually by much less. The temperature dependence of τ_D/τ_0 is erratic, in some cases increasing with temperature e.g. PMMA, and in others decreasing

Figure 9 $\hat{\eta}$ calculated according to equation (13) for $\log -\chi^2$ distribution. (—), $\rho = 40$; (---), $\rho = 20$; (- · - ·), $\rho = 10$. $b = 1000$ in all cases

e.g. PS. It is difficult to understand why PS and PMMA, two polymers of similar flexibility, should differ in this respect, and this anomaly does call the physical basis of the model into question.

The temperature dependence of the width parameters for the other two models is consistent for all systems, the distribution narrowing as the temperature increases; this is as expected. Greater thermal activity will lead to greater independence of successive units and less inequality between the time constants for different types of motion. The decrease in width is in most cases quite rapid at the lower temperatures, near the T_1 minimum, and there are indications that the distribution width tends to stabilize at the higher temperatures, though the evidence is not conclusive.

The distribution width appears to depend mainly on the chemical structure of the polymer and the temperature, but does not differ a great deal between the two concentrations. This is particularly true near the T_1 minimum where the appreciable decrease of T_1 with concentration arises from an increase in the correlation time. At higher temperatures, the variation of correlation time with concentration is less since the more concentrated solution has a higher activation energy. In some cases, notably PPO, the correlation times for the two solutions are very close and the observed decrease in T_1 with concentration arises from a small increase in the distribution width. The variation of molecular weight for PS has a greater effect on the width than on the correlation time, especially for the higher concentration. Experimentally the increase in width affects the *NOE* rather than the T_1 , the former decreasing with concentration to a greater extent than the latter.

The origin of the distribution of correlation times is difficult to decide. The evidence from the present data is that the distribution arises from intramolecular rather than intermolecular effects. Thus the fact that the distribution width is relatively independent of concentration, even though the bulk viscosity changes by an order of magnitude indicates an intramolecular origin. The environment

affects the correlation time and its activation energy but not the nature of the polymer motion. Further circumstantial evidence arises from calculations of the *NOE* by a different approach to equations (2) and (5). The distribution of correlation times may arise from a distribution of environments due to small-scale inhomogeneity of the polymer solution, or alternatively as an effective way of expressing a non-exponential correlation function. Substitution of equation (5) into (2) is correct in the latter case and also in the former case when the rate of environmental fluctuation is rapid compared to the average decay of the autocorrelation function. More probably, the fluctuation rate is slower than the autocorrelation function decay, in which case the expression for the *NOE* should be averaged, and averaged spectral densities should not be used.

The appropriate equation for the *NOE* is:

$$\hat{\eta} = \int_0^{\infty} G(\tau_c)\eta(\tau_c)d\tau_c \quad (13)$$

Since the expression for $1/T_1$ is linear in the spectral densities, there is no change in this expression. Figure 9 shows $\hat{\eta}$ calculated using equation (13) for the $\log -\chi^2$ distribution. Comparing with Figure 2, the *NOE* is much less sensitive to the distribution width, and in fact it proved impossible to fit the majority of experimental results to this model. It is probable therefore that the use of a distribution is necessary to represent a non-exponential correlation function arising from the character of polymer motion. The nature of this motion has been discussed by Schaefer¹⁰ and others¹¹ who conclude it is likely to consist of a rapid short range process leading to partial loss of correlation of the C-H vector followed by a slower, longer range process leading to complete loss of correlation. The less effective the initial process, or the greater the disparity in correlation times, the wider is the distribution. The rate of each process is strongly affected by the chemical structure of the chain, as is obvious from the fact that the correlation time appropriate to the T_1 minimum in the strongly hindered PS and PMMA molecules occurs at about 30°C, whereas that in PPO occurs at a much lower temperature, estimated at about -90°C. It is interesting however that the distribution width for PPO at the lower temperatures is comparable to the widths for PS and PMMA in the vicinity of the T_1 minima. It seems that the balance between short and long-range processes expressed by the width parameter correlates in roughly the same way for all polymers with the average correlation time. The correlation is not exact, as can be seen from the fact that the distribution width for PMMA is larger than for PS at the T_1 minima even though both polymers have similar flexibilities. There is however a major conformational difference between the two polymers which may explain this and indirectly support the above explanation of the distribution origin. PS possesses accessible conformations in which steric interactions are very small or non-existent whereas all conformations of PMMA contain some degree of irreducible steric conflict. The additional interactions in PMMA need not lead to higher barriers to rotation, as might be expected, provided the energies of both stable conformations and transition states between conformations are affected to the same extent. (This effect has been observed in dielectric relaxation of substituted polystyrenes¹⁶.) However the strong

interactions will lead to a greater degree of correlation between the motions of successive segments and hence a wider distribution of correlation times. It is interesting to compare distribution parameters obtained for PMMA from dielectric relaxation¹⁷. The Cole–Cole parameter for PMMA in dilute solution in CCl_4 at 25° to 50°C is approximately 0.75, rather higher than the values given here. However, the two values are not strictly analogous, since the present value applies to backbone motion only while the dielectric value must also incorporate a contribution from internal motions within the ester group in which the dipole moment resides. Such motions will tend to reduce the effective distribution width, though not eliminate it completely.

The $\alpha\text{-CH}_3$ relaxation times for the two PPO solutions and the less concentrated PMMA solution have been analysed using the extension of the relaxation theory outlined earlier for the $\log -\chi^2$ distribution. For PPO, it was assumed that τ_g is independent of τ_c , following previous work on this system⁶. For PMMA it was assumed that τ_g is proportional to τ_c because of the similarity in basic structure between PMMA and polyisobutylene for which this

has been found to be approximately true⁶. Knowing the correlation times and distribution widths for the backbone, it is straightforward to determine the value of τ_g reproducing the observed $^{13}\text{CH}_3$ value for T_1 . A graphical interpolation method was employed, giving the values in Table 5. For almost all cases, τ_g is less than τ_0 , though on average the ratio τ_g/τ_0 is comparable for the two polymers. The factors which determine the magnitude of τ_0 are also important in determining τ_g . It is interesting to note that the values of τ_g at the same temperature for the two PPO solutions are practically identical, though τ_0 differs considerably. This observation, surprisingly consistent in view of the propagation of experimental errors in the lengthy analysis, confirms a previous conclusion⁶ that the internal rotation of methyl groups in PPO is truly an internal process and is independent of the rate of molecular tumbling. PMMA on the other hand resembles polyisobutylene where the rate of methyl rotation correlates with the rate of molecular rotation. τ_g for the heterotactic $\alpha\text{-CH}_3$ group is shorter than τ_g for the syndiotactic group, indicating greater freedom of movement, though this is not revealed so clearly by the activation energies which are given in Table 6. The values of the $\alpha\text{-CH}_3$ barrier obtained here are similar to the value of 32.7 kJ/mol for syndiotactic PMMA reported by Higgins *et al.* from neutron scattering²³. In that work a value of 16.7 was given for isotactic PMMA, but unfortunately this isomer could not be obtained for the present work. The $\alpha\text{-CH}_3$ barrier in PPO is rather lower than the values of 11 kcal/mol from neutron scattering²³. It is significant that in PPO the $\alpha\text{-CH}_3$ barrier is appreciably less than the backbone activation energy, whereas in PMMA, the two quantities are comparable. This is further evidence that in PPO side group and chain motion are essentially independent while in PMMA the motions are linked. The backbone activation energy for PPO increases by a greater relative amount on increasing the concentration than the backbone activation energies for PS and PMMA. Presumably the viscoelastic properties of the polymer environment exert a greater influence on the backbone motion when the intramolecular barriers are small. The necessity of taking correlation time distributions into account is seen clearly by comparing the activation energies for the two solutions in Table 6 with the slopes of the T_1 plots in Figure 1. A cursory inspection of the T_1 data suggests that the activation energy decreases with concentration whereas the opposite is in fact true.

To progress further in studies of this kind, the first requirement is additional experimental relaxation data. The spin–spin relaxation time is measurable from the n.m.r. linewidth, if it is sufficiently short to dominate other line broadening processes, but unfortunately in the present polymers there is an unknown contribution to line broadening from chemical shift dispersion due to irregular tacticity. Further data could be obtained from measurements made at different resonance frequencies, and the possibilities in this direction are worth investigation.

ACKNOWLEDGEMENTS

New solid state polyamidation process

Emmanuel M. Kampouris

Faculty of Chemical Engineering, National Technical University of Athens, 42 Patission Street, Athens 147, Greece

(Received 15 October 1975)

Solid state polymerization reactions are of considerable scientific and industrial interest. In some cases nylon salts can be converted to polyamides through intermediates of lower melting point, involving a solid—melt—solid sequence which is incompatible with known solid state polyamidation processes. A new solid state polyamidation process is described for use with salts, prepolymers, or amino acids which provides good temperature control and the avoidance of agglomeration of particles. The process comprises: (a) suspension of the particles of raw material (salt, amino acid or prepolymer) in an inert solvent; (b) reaction at the boiling point of the solvent with continuous distillation and feeding of solvent; (c) reactions at higher temperatures by feeding with the correct solvent; (d) separation of the formed granules of polymer by centrifugation, and (e) washing and drying. This process was tested for the solid state polymerization of hexamethylenediammonium maleate, which polymerizes through intermediates of lower melting point, and the following factors were examined: (a) presence and amount of dispersing agents; (b) nature of inert solvent; (c) grain size of salt; (d) distillation rate; (e) the ratio of salt: inert solvent and (f) temperature and time.

INTRODUCTION

Polyamides can be prepared by a variety of methods. Of these only three have been found of importance for industrial application. These are melt reaction, ring-opening polymerization, and low temperature solution polymerization with acid chlorides.

The method of melt reaction is the one exclusively used in the case of polyamides prepared from diamines and diacids. The method is inapplicable in the case of diamines or diacids sensitive to the high temperatures of the melt reaction, and also when undesirable side reactions, such as cyclization, can proceed. Solid state reactions proceed generally at lower temperatures and can be topochemically controlled. Thus when the reaction is compatible with the geometry of arrangement of molecules in the solid state, the polymerization can be followed and cyclization excluded.

The proposed processes for solid state polyamidation generally include: (a) heating in an inert gas flow¹⁻³, and (b) heating in an inert solvent⁴. The first has been proposed for use in the case of further polymerization of given prepolymers, and the second for the polymerization of nylon salt.

In non-catalysed solid state polymerizations the reaction rate is strongly affected by the temperature and thus the reaction is generally studied in a narrow temperature range close to the melting point of the monomer⁵⁻⁷. In this case, the narrower the range the greater the need for satisfactory temperature control, in order to avoid the possibility of hot spots in which the melt phase forms and the particles tend to agglomerate. Experience in solid state polymerizations of a number of salts indicate that in some cases the conversion, from the solid salt to a polymer of higher melting point, passes through intermediates of lower melting points. In these cases and soon after the early stages of the reaction the solid particles become sticky and the reaction partly proceeds through a semi-solid or melt state. This state continues until formation of a product of higher melting point. After that the reaction occurs in the solid state. To avoid the semi-solid state, in the case of reactions close to the melting point, and to overcome the tendency

to agglomerate, in the case of lower melting point products formed during the course of the reaction, a suitable process is needed.

This paper presents a new solid state polymerization process designed for use with nylon salts, prepolymers and amino acids. It is also designed to secure the required temperature control and overcome tendency of semi-solid particles to agglomerate. The process is based on the principle of suspension polymerization and shows basic differences from that already proposed⁴. These include different methods of temperature control, ability to effect reaction at lower temperatures, ability to continue reaction for long times at a given temperature, and ability to overcome the tendency for agglomeration. The process comprises: (a) dispersion of the ground salt, prepolymer or amino acid, in an inert solvent with or without the presence of a suitable dispersion agent. The requirements for the inert solvent include non-solvent action for the raw materials, the intermediates and the polymer and a boiling point equal to the desired temperature of reaction; (b) reaction under continuous distillation and introduction of additional inert solvent, for the required time; (c) change of the reaction temperature by feeding with another suitable solvent; (d) separation of the product by filtration (centrifugation); (e) washing and drying.

In order to examine the various factors affecting the process, the polymerization of hexamethylenediammonium maleate was studied as an interesting example. The factors examined were: (a) the presence and amount of dispersion agents; (b) the nature of inert solvent; (c) the grain size of the salt; (d) the distillation rate; (e) the ratio of salt:inert solvent; (f) the temperature and time.

EXPERIMENTAL

Preparation of hexamethylenediammonium maleate

Hexamethylenediamine (250 g) was added in portions to a stirred solution of maleic acid (250 g) in water (300 ml), while cooling to maintain the temperature at ~40°C. Stirring was continued for 1 h, after the addition of all the

hexamethylenediamine, and the reaction mixture was cooled to assist deposition of the salt formed. The separated product was filtered off and dried, over CaCl₂, to give 410 g (76%) of hexamethylenediammonium maleate monohydrate. Recrystallization from water gave prisms, melting point 130°–131°C. (Found: H₂O, 7.7%; C₁₀H₂₀N₂O₄·H₂O requires H₂O, 7.2%.) Dilution of the mother liquors with an equal volume of methanol and cooling produced more product, to give a total yield of 95%. The anhydrous salt was obtained by drying the monohydrate over P₂O₅ *in vacuo* at room temperature. Recrystallization from ethanol gave the anhydrous form, melting point 150°–151°C. (Found: C, 51.4; H, 8.4; N, 12.3; and NH₂, 13.9%. C₁₀H₂₀N₂O₄ requires: C, 51.7; H, 8.6; N, 12.1; and NH₂, 13.8%.) The salt was soluble in water (pH of 1% solution, 7.8), slightly soluble in the lower alcohols, and insoluble in paraffinic, aromatic and chlorinated hydrocarbons.

Polymerization

50 g of screened anhydrous salt were suspended in 500 ml of the selected non-solvent, contained in a four-necked 1.5 l flask. The flask was equipped with side condenser, stirrer, inert gas inlet, and separating funnel, and was heated by an oil bath. The stirred mixture was de-aerated, blanketed with a weak flow of N₂ and the reaction was carried out at the boiling point of the inert solvent with a continuous feed of de-aerated solvent, to equalize the amount distilling. The water formed was continuously eliminated with the distilling solvent. At the end of the reaction, the mixture was cooled, and the product was separated, washed with hexane, and dried under vacuum. When dispersing agents were used, the calculated amount was dissolved in the inert solvent before the addition of the salt.

Characterization

The characterization of the products obtained was based on end-group analysis, melting point determination, and i.r. spectroscopy. End-group analysis was by NH₂ determination⁸ and parallel determinations for carboxyl groups indicated no considerable differences, indicating that only a little amine was eliminated during the process. I.r. spectra, obtained with KBr discs, showed a successive change from the salt to a polyamide structure⁹.

RESULTS AND DISCUSSION

Presence and amount of dispersion agents

The polymerization of hexamethylenediammonium maleate is one of the better examples of the process taking place through lower melting point intermediates. Even at 120°C, i.e. 30°C below the melting point of the salt, the particles soon become sticky and tend to agglomerate to a semi-solid mass. Suspension throughout the course of the reaction was assured by the use of a dispersing agent. The suitability of the following agents was examined: (a) montana wax (crude, decolourized, and bleached); (b) carnauba wax; (c) sodium stearate; (d) fatty acid poly(ethylene glycol) ester; (e) fatty alcohol poly(ethylene glycol) ether; and (f) alkyl phenol poly(ethylene glycol) ether.

The efficiency of the dispersion agents was tested at 125°C (n-octane) under the following conditions: (a) reaction time, 4 h; (b) salt to non-solvent ratio, 1:10 w/v; (c) salt grain size, 30 to 40 mesh (US Sieve Series); and (d) amount of dispersion agent, 0.1 to 5% w/v on the inert solvent.

As a measure of the efficiency of dispersion agents, the reaction product, was collected, on the 30 mesh sieve. The greater the efficiency of the dispersion agent, the lower the amount of product collected. The results obtained are given in Table 1 where 'good' signifies an amount on the sieve no greater than 10%, and 'poor' indicates greater percentages. As the data indicate montana wax (crude, decolourized, or bleached) can be satisfactorily used for concentrations of 0.8% and higher. Carnauba wax and sodium stearate were found good enough for concentrations greater than 1%. The other agents failed for all concentrations up to 5%. Accordingly decolourized montana wax was used, in 1% w/v concentration of the inert solvent.

Nature of the inert solvent

Paraffinic, aromatic, and chlorinated hydrocarbons were examined for use as inert solvents (non-solvents for the salt and the reaction products). Two pairs of solvents having similar boiling points were compared: (a) n-octane (125°C) and tetrachloroethylene (121°C) and (b) n-nonane (151°C) and cumene (152°C). The reaction was carried out for 4 h, in the presence of 1% montana wax (on non-solvent), for salt to non-solvent ratio 1:10 w/v, for salt grain size 30 to 40 mesh, and for a distillation rate of 400 ml/h. The results from Table 2 indicate no visible difference between a n-paraffin and a chlorinated hydrocarbon, also between a n-paraffin and an aromatic hydrocarbon, when the differences in boiling points are small. These results enable us to conclude that, at least between the experimental limits used, the nature of the non-solvent does not affect the polymerization process.

Table 3 Effect of the grain size of salt

Grain size (mesh)	NH ₂ content (%)
20-25	7.8
30-35	7.5
40-45	7.2
50-60	7.4

Table 4 Effect of the distillation rate

Distillation rate (ml/h)	NH ₂ content (%)
100	7.4
250	7.2
500	7.6
750	7.3
1000	7.3

Grain size of salt

The effect of the grain size of salt upon the polymerization rate was examined for grain sizes 20 to 25 mesh, 30 to 35 mesh, 40 to 45 mesh, and 50 to 60 mesh (US Sieve Series). The conditions of the reaction were: temperature 125°C (n-octane); duration, 4 h; distillation rate, 400 ml/h; ratio of salt to non-solvent, 1:10 w/v; and montana wax, 1% on non-solvent. The results obtained are given in Table 3. As the data indicate, the NH₂ content varies between 7.2 and 7.8%, thus there is no visible effect of the grain size upon the reaction rate. These results indicate that the reaction rate is not controlled by the diffusion process by which the water formed is eliminated from the grain. Similar results have been published for the solid state polymerization of nylon-6,6 prepolymers¹⁰.

Distillation rate

The effect of the distillation rate of non-solvent upon the polymerization process was examined for rates from 100 to 1000 ml/h. The conditions were; temperature, 125°C (n-octane); salt grain size, below 50 mesh; montana wax 1%; salt to non-solvent ratio, 1:10 w/v; and duration, 4 h. The results obtained are given in Table 4. As the data indicate there is no appreciable differences in NH₂ content, thus the distillation rate does not affect the reaction rate, at least not in the case studied.

Ratio salt: inert solvent

This effect was examined for n-octane (125°C) and cumene (152°C), and for the ratios 1/20; 1/15; 1/10 and 1/5 w/v. The two non-solvents were selected to have boiling points below and equal to the melting point of the salt. In all cases the concentration of montana wax was 1% of the non-solvent (w/v), the grain size of the salt 50 to 60 mesh, the distillation rate 400 ml/h, and the time 4 h. The results obtained are given in Table 5. As the data indicate the value of the ratio, at least between the limits used, does not affect the polymerization process or the effectiveness of the dispersing agent.

Temperature and time

The effect of temperature was examined in the range 125° to 180°C and that of time for 14 h. The non-solvents used were n-octane, cumene, mesitylene, and *o*-dichloro-

benzene. The grain size of the salt was below 50 mesh (US Sieve Series), the concentration of montana wax 1% w/v, the ratio salt to non-solvent 1/10 w/v, and the distillation rate 250 ml/h. In the case of reactions at 164°C (mesitylene) and 180°C (*o*-dichlorobenzene), the salt was first suspended in cumene and once the distillation started was continuously fed with the correct non-solvent. In these cases the ability of the method to proceed at various temperatures was tested, and the final temperatures were reached after about 3 h. The results obtained (Table 6) indicate in all cases that the polymerization proceeds through intermediates of melting points lower than that of salt. The case of n-octane represents a typical solid state reaction (the melting point of product being always higher than the boiling point of the non-solvent), while in the other cases the reaction starts in the melt and changes to a solid state polymerization (the melting point of product being at the early stages lower and then greater than the boiling point of the non-solvent).

All the products obtained, were in the form of small spheres, free flowing, and containing microscopic bubbles. The reaction rate and the conversion, as the examination of the amine group content indicates, were low at 125°C and increased both with temperature and time. The low molecular weight products of high NH₂ content, were soluble in water and 70% alcohol and highly hygroscopic. Solubility and hygroscopicity decreased with increase of molecular weight, and the high molecular weight products became non-hygroscopic and insoluble. Search for a satisfactory solvent, among the common polyamide solvents e.g. DMF, DMSO, trifluoroacetic acid etc. was unsuccessful and small amounts dissolved only in concentrated sulphuric acid. The melting point increases sharply from 145°–150°C to more than 300°C (discoloration beginning from about 250°C), but the products can be formed into sheets by pressing at 180°–200°C. The insolubility and infusibility, followed by formability under pressure, may be due to the polyamide structure rather than to possible reactions, such as crosslinking through the maleate double bonds. Analogous behaviour has been reported for the case of poly(hexamethylene fumaramide)¹¹ prepared by interfacial polycondensation from hexamethylenediamine and fumaroyl chloride. The consistency of the products of polymerization changed from brittle, in the case of low molecular weights, to stiff difficult to break, and hot-press formable, in the case of the high molecular ones.

The i.r. spectra, obtained with KBr discs, showed the characteristic polyamide bands at 1630 cm⁻¹ and 1540 cm⁻¹. The identification of the maleamide groups by i.r. analysis is quite difficult. In polyesters it is possible to distinguish between maleic acid and fumaric acid units, the

Sequence distribution of polyisoprenes

Yasuyuki Tanaka and Hisaya Sato

Department of Textiles and Polymer Science, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184, Japan

(Received 20 November 1975)

The ^{13}C n.m.r. spectra of hydrogenated polyisoprenes were investigated. Polyisoprenes were prepared with $n\text{-BuLi-Et}_2\text{O}$, $\text{Ti}(\text{OBu})_4\text{-AlEt}_3$, $\text{CoI}_2\text{-ROH-PhMgBr}$, Alfin, and radical catalysts. These polymer were hydrogenated with *p*-toluenesulphonylhydrazide. ^{13}C n.m.r. signals were assigned for triad sequences of

arising respectively from 1,4- and 3,4-units. Signals due to head-to-head and tail-to-tail linkages of 1,4- and 3,4-units were also assigned. It is disclosed that 1,4- and 3,4-units were randomly distributed in $n\text{-BuLi-Et}_2\text{O}$, $\text{CoI}_2\text{-ROH-PhMgBr}$, and radical catalysed polyisoprenes, rather alternating in $\text{Ti}(\text{OBu})_4\text{-AlEt}_3$ catalysed polyisoprene, and slightly in blocks in Alfin polyisoprene. It is also confirmed that Alfin, radical, and cobalt catalysed polyisoprenes contained significant amounts of head-to-head and tail-to-tail linkages of 1,4- and 3,4- units. Signals due to the tacticity of the polyads of 3,4-units were also discussed.

INTRODUCTION

Isoprene can be polymerized into four types of isomeric structures; *cis*-1,4, *trans*-1,4, 3,4, and 1,2, depending on catalysts and polymerization conditions. So far, the difference of mechanical and thermal properties among polyisoprenes has been discussed chiefly on the basis of amounts of these isomeric structures. However, it is quite reasonable to expect that the polymer properties are affected not only by the composition of isomeric structures but also by the distribution of isomeric structures, the arrangement of head and tail linkages, and the degree of branching. This idea was adopted by Hackathorn and Brock as an explanation of the poor crystallizability of lithium polyisoprene; i.e. head-to-head and/or tail-to-tail linkages of 1,4- and 3,4-units prevented the crystallization of the polymer¹.

Pyrolysis-gas chromatography has been applied to the investigation of the sequence distribution of 1,4- and 3,4-units in polyisoprenes^{2,3}. This method is based on the structural relationship between the isoprene dimers and the dyad sequences of 1,4- and 3,4-units. However, it is difficult to discuss the slight differences in the yield of each dimer because the absolute amount of the dimers is small (~30%) compared to the isoprene monomer (~65%). Ozonolysis has been used to measure the amount of head-to-head, head-to-tail, and tail-to-tail linkages of the 1,4-unit in polyisoprenes^{4,5}. This method, however, is limited to the detection of these linkages of 1,4-unit.

In a previous paper, we have investigated ^{13}C n.m.r. spectra of chicle and *cis-trans* isomerized polyisoprenes and determined the sequence distribution of *cis*-1,4- and

trans-1,4-units in these polymers⁶. We have also studied ^{13}C n.m.r. spectra of hydrogenated polyisoprenes prepared with $n\text{-BuLi-Et}_2\text{O}$ catalysts and found that 1,4- and 3,4-units were distributed randomly along the polymer chains regardless of the amounts of 3,4-unit⁷. In the present investigation we prepared various types of polyisoprenes and discussed the distribution of 1,4- and 3,4-units, arrangements of head and tail linkages, the branches of polymer chains, and the tacticity of polyads of 3,4-unit by the use of ^{13}C n.m.r. spectra of hydrogenated polyisoprenes.

EXPERIMENTAL

Materials

Polyisoprenes were prepared with $n\text{-BuLi-Et}_2\text{O}$, $\text{Ti}(\text{OBu})_4\text{-AlEt}_3$, Alfin, and $\text{CoI}_2\text{-MeOH-PhMgBr}$ catalysts, and a radical initiator (emulsion polymerization) in the conventional methods. Isomeric structures of the polymers were determined by ^1H n.m.r. and i.r. studies. Polymerization conditions and isomeric structures of the polymers are listed in Table 1. Isoprene-piperylene copolymer was prepared by adding isoprene dropwise into a pentane solution of piperylene after the addition of $n\text{-BuLi}$ as an initiator. Polyisoprenes and isoprene-piperylene copolymer were hydrogenated by the use of *p*-toluenesulphonylhydrazide in xylene according to the method of Sanui *et al.*⁸. Hydrogenation was carried out twice in order to reduce the residual unsaturation to less than 2%. The absence of cyclization of polymer chain during the hydrogenation was confirmed by the ^{13}C n.m.r. spectrum of

Table 1 Microstructure of polyisoprenes

Catalyst (mole ratio)	Solvent	Microstructure (%)		
		1,4-	3,4-	1,2-
(a) BuLi-Et ₂ O (1:24)	Pentane	51	48	1
(b) Ti(OBu) ₄ -AlEt ₃ (1:6)	Toluene	39	60	1
(c) Alfin	Hexane	72	23	5

(e) CoI ₂ -MeOH-PhMgBr (1:2:2.2)	Toluene	37	62	1

hydrogenated natural rubber. Poly(3-methylbutene-1) was prepared with TiCl₄-AlEt₃ catalyst according to the method of Natta *et al.*⁹. The crude polymer was washed with methanol and extracted with benzene in order to remove the amorphous fraction.

¹³C n.m.r. measurements

The ¹³C n.m.r. spectra were obtained at 25.1 MHz by using a JEOL JNM-PS 100 spectrometer equipped with a Fourier transfer accessory at room temperature or 60°C. About 25% w/v CDCl₃ solution was used for the hydrogenated polyisoprenes and the copolymer. In the case of poly(3-methylbutene-1), ¹³C n.m.r. measurement was carried out for a swollen polymer in CS₂ containing 5% of CDCl₃. Chemical shifts were referred to tetramethylsilane, added as an internal standard. All the spectra were proton noise decoupled and obtained with multiple scans at a pulse repetition time of 2.0 sec.

RESULTS AND DISCUSSION

Sequences of 1,4- and 3,4-units

Polyisoprenes containing *cis*-1,4-, *trans*-1,4-, and 3,4-units exhibit complicated ¹³C n.m.r. resonances resulting from various types of carbon atoms in different sequences. After hydrogenation *cis*-1,4- and *trans*-1,4-units are converted into the same structure (I), and 3,4-unit becomes the structure (II). Therefore, hydrogenated polyisoprenes containing only a slight amount of 1,2-unit can be regarded as copolymers consisting of structures (I) and (II).

The chemical shift of each carbon atom in the hydrogenated polymer can be predicted by using the empirical equations for branched and linear alkanes proposed by Paul and Grant¹⁰ or Lindeman and Adams¹¹.

Figure 1 shows ¹³C n.m.r. spectra of hydrogenated polyisoprenes prepared with n-BuLi-Et₂O and Ti(OBu)₄-AlEt₃ catalysts [polymers (a) and (b), respectively]. Both polymers exhibited sixteen main signals as indicated by symbols A to P in the spectra. These signals have been assigned to the carbon atoms in the central monomer unit of a triad sequence of the structures (I) and (II) as listed in Table 2⁷.

Signals due to head-to-head and tail-to-tail linkages

Figure 2 shows ¹³C n.m.r. spectra of hydrogenated polyisoprenes prepared with Alfin and radical catalysts [polymers (c) and (d), respectively]. In these spectra characteristic signals were observed at 34.41 (signal E') and 27.42 ppm (signal L'), which were scarcely observed in the polymers (a) and (b). These new signals are assigned to C₁ and C₄ carbon atoms of structure (I) in head-to-head (4,1-1,4) and tail-to-tail (1,4-4,1) linkages, respectively, from a comparison of the observed chemical shifts with the predicted values. It is also disclosed that C₂ carbon atom in head-to-head linkage resonated at 33.25 ppm, which is overlapped with the signal of C₂ carbon atom in structure (I) adjacent to structure (II) (Table 3).

An isoprene-piperylene (1,3-pentadiene) copolymer was prepared as a model polymer containing head-to-head (4,1-1,4) and tail-to-tail (1,4-4,1) linkages of polyisoprene. It was confirmed that the copolymer prepared with n-BuLi consisted of predominantly 1,4-addition for both monomers by ¹H n.m.r. and i.r. studies. Therefore, the hydrogenated copolymer corresponds to a hydrogenated polyisoprene containing significant amounts of head-to-head and tail-to-tail linkages as illustrated below.

Figure 1 ¹³C n.m.r. spectra of hydrogenated polyisoprenes prepared with (a) n-BuLi-Et₂O and (b) Ti(OBu)₄-AlEt₃ catalysts

^a The signal split into two peaks
Carbon atoms are denoted as follows:

The ^{13}C -n.m.r. spectrum of the hydrogenated copolymer displayed the signals at 34.41, 33.25, and 27.42 ppm corresponding to head-to-head and tail-to-tail linkages of 1,4-unit in hydrogenated polyisoprene. It has been reported that the central methylene carbon of squalene, which corresponds to tail-to-tail 1,4-linkage, resonated at 27.5 ppm characteristic of this linkage¹². These findings indicate the validity of the signal assignments described above.

In a previous paper the predominance of head-to-tail arrangement was confirmed for n-BuLi catalysed polyisoprenes regardless of the amounts of 3,4-unit⁷. Polymers having 4,1-3,4 (head-to-head) and 1,4-4,3 (tail-to-tail) linkages are expected to have characteristic signals around 38 and 25 ppm, respectively (Table 3). In the ^{13}C n.m.r. spectra of polymers (a), (c) and (d), a small signal was observed at 25.00 ppm (signal M'), which is assigned to the C₄ carbon atom of the structure (I) in 1,4-4,3 linkage. Polymer (d) exhibited also a small signal at 38.1 ppm (signal C'), which can be assigned to the C₁ carbon atom of the structure (I) in 4,1-3,4 linkage. In the case of polymers (a) and (d), however, no distinct signal corresponding to C' was observed.

Figure 3 shows ^{13}C n.m.r. spectrum of hydrogenated polyisoprene prepared with $\text{CoI}_2\text{-ROH-PhMgBr}$ catalyst. This polymer also exhibited signals E', L', and M', indicating that it contained head-to-head and tail-to-tail linkages of 1,4- and 3,4-units.

Distribution of isomeric structures

In a previous paper triad sequence distributions of 1,4- and 3,4-units in BuLi catalysed polyisoprenes were analysed using the signals F, G, and H, and also A, B, and C. In the case of polyisoprenes containing head-to-head and tail-to-tail linkages some of these signals were overlapped with the signals due to these linkages. In these cases distributions of 1,4- and 3,4-units, including head and tail arrangements, were determined as dyad sequences by using the signals M, L, E', L', M', and C', which arise from C₁ and C₄ carbons. On the basis of these assignments the fractions of dyad sequences were measured according to the following equations by using the relative intensities of signals:

$$\begin{array}{ll} 1,4-1,4 & \text{linkage} = M/\Sigma \quad (\text{head-to-tail}) \\ 4,1-1,4 & \text{linkage} = E'/2\Sigma \quad (\text{head-to-head}) \\ 1,4-4,1 & \text{linkage} = L'/2\Sigma \quad (\text{tail-to-tail}) \\ \left. \begin{array}{l} 1,4-3,4 \\ 3,4-1,4 \end{array} \right\} & \text{linkage} = L/\Sigma \quad (\text{head-to-tail}) \\ 1,4-4,3 & \text{linkage} = M'/\Sigma \quad (\text{tail-to-tail}) \\ 4,1-3,4 & \text{linkage} = C'/\Sigma \quad (\text{head-to-head}) \\ \left. \begin{array}{l} 3,4-3,4 \\ 4,3-3,4 \\ 3,4-4,3 \end{array} \right\} & \text{linkage} = [K - (L + M' + C')/2]/\Sigma \end{array}$$

where, $\Sigma = M + K + (L + E + L' + M + C')/2$

The results are listed in Table 4.

In the polyisoprene prepared with n-BuLi-Et₂O catalyst, a random distribution of 1,4- and 3,4-units with predominantly head-to-tail linkage is also demonstrated in this experiment. On the other hand, Hackathorn and Brock suggested that a 3,4-unit was incorporated into the polymer chain chiefly with 1,4-4,3 linkage, in the case of alkyl lithium catalysed polymerization, on the basis of crystal-

Figure 3 ^{13}C n.m.r. spectrum of hydrogenated polyisoprene prepared with (e) $\text{CoI}_2\text{-ROH-PhMgBr}$ catalyst

lization and ozonolysis studies¹. In our experiment, however, only a small signal due to 1,4-4,3 linkage was observed, while signals due to 1,4-3,4 and 3,4-1,4 linkages were clearly observed. Therefore, it may be necessary to take into account other factors to interpret the poor crystallizability of lithium polyisoprenes.

$\text{Ti}(\text{OBu})_4\text{-AlEt}_3$ system was reported to be a catalyst providing 3,4-polyisoprene from the i.r. spectrum of the polymer¹³. In our experiment the polyisoprene prepared with this catalyst contained only 60% of 3,4-unit. Furthermore, it is revealed that distribution of 1,4- and 3,4-units is rather alternating with exclusively head-to-tail linkage in this polymer.

It is ascertained that polyisoprenes prepared with Alfin and radical catalysts contained about 20% of head-to-head and tail-to-tail linkages of 1,4- and 3,4-units. It is also disclosed that 1,4- and 3,4-units were distributed slightly in blocks in Alfin polyisoprene and almost randomly in emulsion polyisoprene.

Table 4 Sequence distribution of polyisoprenes

Linkage ^a	Signal	BuLi-Et ₂ O	Ti(OBu) ₄ -AlEt ₃	Alfin	Emulsion	CoI ₂ -ROH-PhMgBr

Table 5 Signal assignments of poly(3-methylbutene-1) and structure (II)

Carbon ^a	Signal	Chemical shift (ppm)		Dyad tacticity
		Obs.	Calc.	
C ₃	C	38.13	39.52	
C ₄	I	31.96	33.60	meso
	J	30.58	33.60	racemic
C ₂	K	29.32	30.46	
C ₁ , C ₅	P	18.61	19.63	

^a Carbon atoms are denoted as follows:

CoI₂-ROH-PhMgBr system was reported as a catalyst providing equibinary polyisoprene composed of equal amounts of *cis*-1,4- and 3,4-units¹⁴. An alternating sequence of 1,4- and 3,4-units was expected by Teyssié *et al.* for this equibinary polyisoprene on the basis of polymerization mechanism. It is clearly demonstrated in Table 4 that the equibinary polyisoprene had a rather random distribution of 1,4- and 3,4-units along the chain with significant amounts of head-to-head and tail-to-tail linkages of these units. In Table 4 the discrepancy between the amounts of head-to-head and tail-to-tail linkages is probably owing to the fact that the amounts of 4,1-3,4 (head-to-head), 4,3-3,4 (head-to-head), and 3,4-4,3 (tail-to-tail) linkages were not separately determined in this measurement.

Configurational sequences of 3,4-polyads

The signals due to carbon atoms in the polyads of structure (II) are expected to display splitting because of the tacticity. In a previous paper signals I and J were assigned to the central methylene carbon (C₄) in the dyad of structure (II) on the basis of the finding that the intensity ratio of I and J signals did not vary with changing the ratio of structures (I) and (II) for *n*-BuLi-Et₂O catalysed polyisoprenes⁷. The detailed assignment of the signals I and J was carried out by using isotactic poly(3-methylbutene-1) prepared with TiCl₄-AlEt₃ catalyst as a model

compound of an isotactic sequence of structure (II). Four signals were observed by the measurement of a swollen polymer in carbon disulphide, though the spectrum was not well resolved owing to the poor solubility of the polymer¹⁵. These signals are assigned as shown in Table 5.

Signals I and J are assigned to methylene carbons in meso and racemic dyad of structure (II) from the comparison of the chemical shift of methylene carbon (C₄) in hydrogenated polyisoprene with that of poly(3-methylbutene-1). In the case of Ti(OBu)₄-AlEt₃ catalysed polyisoprene, the intensity ratio of the signals I and J was about 9 to 1, indicating the highly isotactic configuration of 3,4-unit in the polymer. The polyisoprenes prepared with *n*-BuLi-Et₂O, CoI₂-ROH-PhMgBr, and Alfin catalysts were less stereoregular.

Signals due to end groups

Low molecular weight polymers and highly branched polymers are expected to display signals due to carbon atoms in the end groups. It has been reported that almost all monomer units are incorporated into polymer chain by 4,1- or 4,3-addition in BuLi catalysed polymerization¹⁶. In such a case the terminal units become structure (III) after hydrogenation regardless of the isomeric structure of the end units:

The terminal methyl (C_{1'}) and methine (C_{2'}) carbon atoms are expected to resonate around 22 and 28 ppm, respectively.

Polymer (a) exhibited small signals at 22.30 and 27.64 ppm indicating that this polymer had measurable amount of the end groups. Furthermore, this polymer displayed a signal around 14 ppm attributed to the methyl carbon in n-butyl group derived from the initiator. The amounts of terminal group (III) and residual butyl group of the initiator were found to be 0.7 and 0.6 units, respectively, per hundred monomer units, demonstrating that this polymer had few branches. The absence of branches was also confirmed by the molecular weight measurement. The number of the end group obtained by vapour pressure osmometric measurement was found to be 1.1 units per hundred monomer units which is comparable to the values determined by ¹³C n.m.r.

Polymer (d) also showed a small signal at 22.3 ppm corresponding to the terminal methyl carbon. The degree of polymerization for this polymer was found to be about 300 by osmometric measurement, hence it is concluded that some part of this signal had arisen from end groups in branches. In the case of polymers (b), (c) and (e), no signal due to end groups was detected. This may be due to the fact that the molecular weight of these polymers was too high to detect end groups.

ACKNOWLEDGEMENT

The authors are very grateful to Dr Koei Komatsu of Japan

Synthetic Rubber Co. for preparing Alfin and emulsion polyisoprenes.

Laser flash photolysis investigations on primary processes of the sensitized polymerization of vinyl monomers:

1. Experiments with benzophenone

R. Kuhlmann and W. Schnabel

Hahn-Meitner-Institut für Kernforschung Berlin GmbH, Bereich Strahlenchemie,
1 Berlin 39, Germany

(Received 30 September 1975; revised 19 December 1975)

The laser flash photolysis technique was used in order to evaluate kinetic parameters concerning the efficiency of benzophenone (BP) as a photosensitizer for polymerizations. Rate constants (in $M^{-1} \text{sec}^{-1}$) of the reaction of triplet BP with monomers were measured (e.g. styrene, 3.3×10^9 ; methyl methacrylate, 6.9×10^7 ; acrylonitrile, 3.4×10^7 ; vinyl acetate, 5.4×10^6). The rate constant of the reaction of triplet BP with tetrahydrofuran is $3 \times 10^6 M^{-1} \text{sec}^{-1}$. From these results it can be derived, for example, that the BP photosensitized polymerization of styrene is not feasible. Ketyl radicals of BP were found to react relatively slowly with vinyl acetate ($5.5 \times 10^3 M^{-1} \text{sec}^{-1}$), acrylonitrile ($3.8 \times 10^3 M^{-1} \text{sec}^{-1}$) and methyl methacrylate ($9.0 \times 10^3 M^{-1} \text{sec}^{-1}$). Based on these data it was estimated that benzpinacol should not be formed as a major reaction product at relatively low incident light intensities and at monomer concentrations greater than 1 mol/l.

INTRODUCTION

During recent years the photosensitized polymerization of vinyl compounds has attracted attention for its applicability for technical processes¹. Besides other groups of compounds aromatic carbonyl compounds are used frequently as sensitizers. There are, however, limitations concerning the general usability of a certain compound as sensitizer. Benzophenone (BP) for example, was reported by Heine *et al.*² not to initiate the polymerization of styrene since it was assumed that styrene acts as a quencher for triplet excited benzophenone molecules ($^3\text{BP}^*$). Thus, the formation of polymerization-initiating radicals (by the reaction of $^3\text{BP}^*$ with hydrogen donor compounds present in the system) is inhibited. Slightly controversial to this are findings of Block *et al.*³ that BP and 3,3', 4,4'-tetramethoxycarbonyl benzophenone photosensitized the polymerization of styrene when the latter was irradiated in a 50% (v/v) solution in tetrahydrofuran.

Evidence of the triplet quenching ability of another vinyl monomer (methyl acrylate) was obtained recently⁴ from measurements of the quantum yield of the photoreduction of benzophenone by t-butanol and benzhydrol.

Questions concerning the influence of sensitizer triplet quenching by monomer molecules on the initiation of polymerization could in principle be readily answered if the respective kinetic parameters were available. It was the aim of our investigation to collect relevant information. In this paper we wish to report mainly on the reaction of several vinyl monomers with benzophenone triplets and ketyl radicals. We considered benzophenone as an appropriate substance to start our studies with, since its photochemistry has been investigated rather thoroughly before⁵⁻¹³. It appears to be useful to represent the elementary reactions this work is dealing with, in the following scheme:

EXPERIMENTAL

Materials

Benzene (Merck, 99.5%) was shaken several times with concentrated H_2SO_4 , washed with distilled water, dried over CaCl_2 and CaH_2 and distilled over a splitting tube column. Tetrahydrofuran (Merck, 99.5%) was treated with CaH_2 , distilled over a Vigreux column, dried over sodium wire and distilled again from KOH. The monomers contained stabilizers and were treated before use as follows: methyl methacrylate (MMA), acrylonitrile (AN), styrene (St) and α -methylstyrene (α -MSt) were washed with NaOH solution and water, dried over CaCl_2 and CaH_2 and distilled over a 1 m Vigreux column. Vinyl pyrrolidone (VP)

St, \blacksquare ; α -MSt, \circ ; VP, \square ; MMA, \blacktriangle ; AN, \triangle ; VAC, \bullet . [BP] = $7.4 \times 10^{-4} \text{ M}$. Absorbed dose per flash $7 \times 10^{-5} \text{ einstein/l}$. Solvent: benzene

Table 1 Quenching of benzophenone triplets by vinyl monomers

Monomer	$k_4 \text{ (M}^{-1} \text{ sec}^{-1}\text{)}$
Styrene	$(3.3 \pm 0.3) \times 10^9$
α -Methylstyrene	$(2.7 \pm 0.3) \times 10^9$
Vinyl pyrrolidone	$(3.6 \pm 0.4) \times 10^8$
Methyl methacrylate	$(6.9 \pm 0.7) \times 10^7$
Acrylonitrile	$(3.4 \pm 0.3) \times 10^7$
Vinyl acetate	$(5.4 \pm 0.5) \times 10^6$

was stabilized with 0.1% NaOH and therefore washed with aqueous H_2SO_4 , washed and dried over CaH_2 and subsequently distilled. Vinyl acetate (VAC) was treated as methyl methacrylate except that it underwent a 48 h treatment with NaHSO_3 immediately before distillation in a nitrogen atmosphere³. Benzophenone (Aldrich, 99%) was twice recrystallized from heptane (melting point 48.0°C).

Irradiation of samples

Solutions were de-aerated by bubbling with purified Ar. The oxygen content in the solutions was less than 3 ppm. Samples were irradiated in rectangular cells with 347.1 nm light flashes (25 nsec) of a frequency doubled ruby laser (Korad model K1QS2). Schott BG23 filters were used to reduce the incident intensity of light. A xenon lamp (Osram XBO450W) was used as light source for the analysing light. Further details have been given before¹⁴.

Actinometry

The dose absorbed per flash was measured with a potassium ferrioxalate actinometer¹⁵ ($\phi[\text{Fe}^{2+}] = 1.20$). Normal laser operation yielded $\sim 4 \times 10^{16}$ photons per flash. In calculating concentrations of triplets a quantum yield of 1.0, taken from the literature^{16,17} was used.

RESULTS AND DISCUSSION

Reaction of benzophenone triplets with vinyl monomers

With benzene solutions of BP ($7.4 \times 10^{-4} \text{ M}$), the well known^{9,12,13} T-T absorption spectrum of benzophenone was recorded by measuring the optical absorption of the

solution at the end of the laser flash. In the absence of added substances this spectrum decayed according to a first order law with life times between 3 and 12 μsec depending on the intensity of incident light. At a constant intensity corresponding to an absorbed dose per flash of $10^{-5} \text{ einstein/mol}$ ([BP] = $7.4 \times 10^{-4} \text{ M}$), the variation of first order life times with the concentration of added monomer was measured. Results are shown in Figure 1. Since the monomer concentration hardly changed during these experiments, the rate constant of the quenching reaction (4) could be evaluated by use of equation (10):

$$\frac{1}{\tau} = \Sigma k(1) + k_4[M] \quad (10)$$

where $\Sigma k(1)$ is the rate constant of decay of ${}^3\text{BP}^*$ in the absence of monomer. Values of k_4 are compiled in Table 1, which shows that the quenching effectiveness decreases in the sequence: styrene > α -methylstyrene > vinyl pyrrolidone > methyl methacrylate > acrylonitrile > vinyl acetate.

Reaction of ${}^3\text{BP}^*$ with tetrahydrofuran (THF)

The reaction of ${}^3\text{BP}^*$ with THF was studied by adding small amounts of THF to $7.4 \times 10^{-4} \text{ M}$ BP solutions in benzene. The decay of the T-T absorption of ${}^3\text{BP}^*$ at 532 nm was recorded as a function of time. Figure 2a shows a typical oscilloscope trace. The initial decay is due to benzophenone triplets which are converted to ketyl radicals by reaction (3). The absorption of the radicals is represented by the slowly decaying branch of the trace. Values of k_3 were obtained either from a plot of reciprocal life times of ${}^3\text{BP}^*$ versus [THF] as shown in Figure 2b by use of equation (11):

$$\frac{1}{\tau} = \Sigma k(1) + k_3[\text{THF}] \quad (11)$$

($\Sigma k(1)$ = rate constant of decay of ${}^3\text{BP}^*$ in the absence of THF) or from the optical density (OD) of $\text{K}\cdot$ at $t = 3 \mu\text{sec}$

Figure 2 (a) Oscilloscope trace demonstrating the variation of optical absorption at $\lambda = 532 \text{ nm}$ with time. (b) Reciprocal first order life times of the initial decay of the absorption at $\lambda = 532 \text{ nm}$ versus the concentration of tetrahydrofuran

Figure 3 Probability α_R for the formation of radicals capable of inducing polymerization versus the monomer concentration according to equation (13). VAC, ●; AN, △; MMA, ▲; VP, □; α -MSt, ○; St, ■. Competition of reactions (3) and (4) for the decay of ${}^3\text{BP}^*$ is assumed

after the flash recorded as a function of [THF] according to equation (12):

$$\frac{OD(S)}{OD} = 1 + \frac{\Sigma k(1)}{k_3[\text{THF}]} \quad (12)$$

$OD(S)$ denotes the saturation value of the optical density observed at high THF concentrations, i.e. when all triplets react according to reaction (3).

$k_3(\text{THF}) = (3 \pm 1) \times 10^6 \text{ M}^{-1} \text{ sec}^{-1}$ was obtained which is about as high as the rate constant for the reaction of ${}^3\text{BP}^*$ with isopropanol ($k_3(\text{isopropanol}) = 1.3 \times 10^6 \text{ M}^{-1} \text{ sec}^{-1}$) determined by Beckett and Porter⁵.

From a formal treatment, the probability α_R for the formation of radicals capable of initiating the polymerization of a monomer M dissolved in the solvent RH, may be derived. If a relatively simple case is considered where reactions (3) and (4) are the only competing reactions, equation (13) is obtained:

$$\alpha_R = \frac{k_3(\text{RH})[\text{RH}]}{k_3(\text{RH})[\text{RH}] + k_4[\text{M}]} \quad (13)$$

It is presumed here that all ${}^3\text{BP}^*$ particles are converted to pairs of ketyl and solvent radicals in the absence of monomer. If M is present in the solution a fraction of ${}^3\text{BP}^*$ is quenched by M according to reaction (4).

Figure 3 shows the probability α_R as a function of monomer concentration expected for THF solutions. α_R was calculated with the values of k_4 given in Table 1 and the value of $k_3(\text{THF})$ given above. It is hereby assumed that the rate constants determined in benzene are also valid for THF as the solvent. It results that for a typical

monomer concentration of 2 mol/l, radicals capable of initiating the polymerization of the monomer are hardly formed in styrene solutions whereas in the case of vinyl acetate polymerization appears to be feasible. With the other monomers intermediate situations are expected. Experimental results relevant to this subject were obtained by Block *et al.*^{3a}. They reported a sensitizing effect of BP in THF for St, AN and MMA. The rate of polymerization of VAC was retarded by BP in THF and accelerated of BP in toluene. The inability of BP to sensitize the polymerization of VAC in THF is according to these authors due to the fact that THF radicals are incapable of adding to VAC. A sensitizing effect of BP on the rate of polymerization of styrene is not expected according to the respective curve in Figure 3. It may be noted that the importance of the data by Block *et al.* is somewhat reduced by the fact that remarkable rates of polymerization were observed in certain cases already in the absence of sensitizer, a fact which pertains especially to the case of vinyl acetate.

Reaction of ketyl radicals with vinyl monomers

Since the reaction of ${}^3\text{BP}^*$ with the solvent yields solvent radicals as well as ketyl radicals the question arises as to whether or not ketyl radicals can initiate the polymerization of vinyl monomers via reaction (6). It is frequently assumed that ketyl radicals are deactivated essentially by reaction (7). However, it has been shown by Hutchinson *et al.*^{3b} that semi-pinacol radicals act as terminators during the free radical polymerization of MMA. The possibility that semi-pinacol radicals act as initiators of the polymerization of MMA has been pointed out by the same authors^{3b}. By monitoring the slow decay of the absorption at $\lambda = 532 \text{ nm}$ and plotting the respective values of the reciprocal optical density versus time we found by using $\epsilon_K(532 \text{ nm}) = 5.1 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$; $k'_7 = 6.4 \times 10^7 \text{ M}^{-1} \text{ sec}^{-1}$, which agrees fairly well with the value reported by Beckett and Porter ($2k_7 = 5.9 \times 10^7 \text{ M}^{-1} \text{ sec}^{-1}$)⁵. k'_7 may differ from $2k_7$ [rate constant of reaction (7), since reaction (9) may also be involved in the observed second order decay (compare equation (15))].

In order to determine k_6 experimental conditions were chosen such that the competing reactions (7) and (9) could be neglected. In this case the optical density due to ketyl radicals decayed according to pseudo first-order kinetics with a rate constant proportional to the monomer concentration:

$$k_{(\text{pseudo } 1)} = k_6[\text{M}] \quad (14)$$

This procedure of determination of k_6 could, however, only be applied for monomers with relatively low values of k_4 . Therefore, styrene ($k_4 = 3.3 \times 10^9 \text{ M}^{-1} \text{ sec}^{-1}$, α -methylstyrene ($k_4 = 2.7 \times 10^9 \text{ M}^{-1} \text{ sec}^{-1}$) and vinyl pyrrolidone ($k_4 = 3.6 \times 10^8 \text{ M}^{-1} \text{ sec}^{-1}$) were not included in this series of experiments, since in order to be allowed to neglect reactions (7) and (9) monomer concentrations must be kept relatively high. With styrene, α -methylstyrene and vinyl pyrrolidone thus, situations would be encountered where no ketyl radicals are formed owing to quenching of practically all triplets according to reaction (4).

Typical pseudo first-order plots are shown in Figure 4. Corresponding data are presented in Table 2 which shows that k_6 is relatively high in the case of vinyl acetate. The efficacy of ketyl radicals as polymerization-inducing agents in the presence of solvent radicals depends, of course, on

Figure 4 Semilogarithmic plot of the optical absorption at $\lambda = 532$ nm versus time for various monomers dissolved in THF: MMA, Δ ; VAC, \bullet ; AN, \triangle . Monomer concentrations are given in Table 2. [BP] = 7×10^{-4} M. The absorption was normalized relative to an absorbed dose per flash of 3.5×10^{-5} einstein/l

Table 2 Reaction of ketyl radicals with vinyl monomers for the determination of k_6 (see Figure 4)

Monomer	[M] (M)	$k_6 \times 10^{-3}$ ($M^{-1} \text{sec}^{-1}$)
Vinyl acetate	0.4	(5.5 \pm 1.5)
Acrylonitrile	0.4	(3.8 \pm 1.0)
Methyl methacrylate	0.4	(9.0 \pm 2.0)

Table 3 Numerical presentation for the estimate concerning the formation of benzpinacol, which is possible if $k_7' [\text{K}\cdot] \gg k_6 [\text{M}]$ (based on $k_6 = 3.8 \times 10^3 M^{-1} \text{sec}^{-1}$)

[M] mol/l	$[\text{K}\cdot]_{\text{St}^*}$ mol/l	$k_7' [\text{K}\cdot]$ (sec^{-1})	$k_6 [\text{M}] \times 10^{-3}$ (sec^{-1})
0.5	10^{-5}	6.4×10^2	1.9
	10^{-6}	6.4×10^1	1.9
	10^{-8}	6.4×10^{-1}	1.9
	10^{-10}	6.4×10^{-3}	1.9
2.0	10^{-5}	6.4×10^2	7.6
	10^{-6}	6.4×10^1	7.6
	10^{-8}	6.4×10^{-1}	7.6
	10^{-10}	6.4×10^{-3}	7.6

* Stationary concentration

the ratio $k_6 [\text{K}\cdot] / k_5 [\text{R}\cdot]$, which is equal to k_6 / k_5 since $[\text{K}\cdot] = [\text{R}\cdot]$. However, since k_5 is not known the fraction of polymer molecules generated by an initiation via reaction (6) cannot be predicted.

Knowing the values of k_6 and k_7 it can be estimated that at stationary concentrations of $[\text{K}\cdot] < 10^{-6}$ mol/l, the mutual deactivation of ketyl radicals must be negligible at sufficiently high monomer concentrations ($[\text{M}] > 0.5$ mol/l). This follows from equation (15) according to which the rate of decay of ketyl radicals is equal to the sum of the rates of reactions (6), (7) and (9):

$$-\frac{d[\text{K}\cdot]}{dt} = k_6 [\text{K}\cdot] [\text{M}] + 2k_7 [\text{K}\cdot]^2 + k_9 [\text{K}\cdot] [\text{R}\cdot] \quad (15)$$

$$= k_6 [\text{K}\cdot] [\text{M}] + (2k_7 + k_9) [\text{K}\cdot]^2$$

A predominant decay of $\text{K}\cdot$ according to reaction (6) is to be expected if $k_6 [\text{M}] \gg (2k_7 + k_9) [\text{K}\cdot] = k_7' [\text{K}\cdot]$. Some typical numerical data are given in Table 3. Under conditions frequently applied $[\text{K}\cdot]_{\text{stationary}}$ is certainly very small, which implies that benzpinacol should not be formed at monomer concentration of e.g., 2 mol/l.

Cobalticinium-bridged polybenzazoles: 1. Low temperature solution polymerization

Eberhard W. Neuse, Gernot Horlbeck, Heinz W. Siesler, and Kleantes Yannakou

Department of Chemistry, University of the Witwatersrand, Johannesburg, South Africa

(Received 10 November 1975)

The low temperature solution polymerization of 1,1'-bis(chlorocarbonyl)-cobalticinium hexafluorophosphate/chloride with 3,3'-diaminobenzidine in aprotic media furnishes linear, soluble polymeric intermediates, the recurring unit of which comprises the 1,1'-cobalticinium nucleus linked with the (diamino-substituted) biphenyl system by an amide bridge. The analogous interaction of the cobalticinium salt with 3,3'-dimercaptobenzidine produces corresponding polymers containing both amide and thioester links. Because of the heterogeneous nature of the reactions, the degrees of polymerization attained in both types of reaction are low ($\eta_{inh} = 10\text{--}20$ ml/g). A solid-state heat treatment at temperatures up to 300°C converts the pre-polymers to polyheterocyclics essentially composed of alternating cobalticinium-1,1'-diyl and 6,6'-bibenzazole-2,2'-diyl units, the heterocycle being, respectively, of the imidazole and thiazole type. Structural imperfections in the end products are indicated by their insolubility and by a t.g.a. performance (in both air and nitrogen) inferior to that of common phenylene-bridged bibenzimidazole polymers. Thermal instability of the PF_6^- counter ion at the conversion temperatures employed may be a factor contributing to the unsatisfactory t.g.a. performance observed.

INTRODUCTION

The excellent resistance of the cobalticinium ion to oxidative and thermal attack² prompted suggestions, many years ago³, that cobalticinium-based polymeric compounds should display outstanding performance in materials applications requiring high thermo-oxidative stability. Several reports of cobalticinium polymer preparations have since appeared in the literature. Thus, oligomethylene-bridged cobalticinium polymers were synthesized from α,ω -dicyclopentadienylalkanes (via their sodium salts) and hexamminecobalt (II) chloride⁴; several polyesters were prepared from diols and 1,1'-bis(chlorocarbonyl)- or 1,1'-bis(carboxy)cobalticinium salts^{5,6}, and a series of tin-, titanium-, and zirconium-containing polyesters were obtained by interfacial polymerization of cobalticinium dicarboxylate dianion with the appropriate reactants⁷⁻¹⁰. While most of the polymers described were of quite low molecular mass, one of the titanium-containing products⁹ exhibited a reduced viscosity value as high as 45 ml/g and showed excellent thermal stability in thermogravimetric analysis (t.g.a.) tests.

In an effort to obtain all-aromatic polymers devoid of functional groups in the bridging moieties between cobalticinium units, we have investigated synthetic routes leading to linear polymer structures in which cobalticinium-1,1'-diyl units alternate along the backbone with heterocyclic groupings of the bibenzimidazolyl and bibenzothiazolyl types. As part of this effort, the present communication is concerned with a polymerization study involving conditions of low temperature solution polycondensation.

EXPERIMENTAL

Melting points, uncorrected, were taken in sealed capillaries. Infra-red spectra, on KBr pellets, were recorded with a Perkin-Elmer, Model 521, spectrophotometer. Proton magnetic resonance spectra were obtained with a Var-

ian A-60 NMR Spectrometer at 60 MHz on CF_3COOH solutions (chemical shifts, δ , in ppm relative to internal TMS). Inherent viscosities were determined in Cannon-Fenske viscometers at 30°C (0.5% w/v in 98% formic acid); in order to minimize acidolysis, the period required for dissolution, filtration and thermal equilibration was restricted to 20-25 min. Microanalyses were performed by Robertson Laboratory, Florham Park, NJ, USA. Thermogravimetric analysis traces were obtained in the laboratories of the Polymers & Plastics Department, Westinghouse Electric Corporation, with a Du Pont Thermogravimetric Analyzer, Model 950, at a heating rate of 10°C/min and a gas (N_2 , air) flow rate of 0.2 l/min.

Materials

3,3'-Diaminobenzidine. The compound, prepared by the method of Vogel and Marvel¹⁶ and purified by sublimation¹⁷, melted at 178°-179°C; it was kept under N_2 in the dark until used.

3,3'-Dimercaptobenzidine. Preparation of the base in pure form presented appreciable experimental difficulties. Although synthesized by many workers^{12,17-23}, the oxidatively unstable base has preferably been used in the form of its dihydrochloride, for which analytical findings are available^{17,19}. The free compound, on the other hand, has never been unambiguously described in the literature. Dokoshi *et al.*²², while publishing the found (correct) elemental composition, listed a melting point of 287°C for the base. Rabilloud and coworkers²³ described the compound as infusible. Both groups of authors obviously had in their hands a polymeric disulphide of the base, which, according to Hergenrother²⁴, possesses about the same elemental composition and melts with decomposition at 273°C. In our work, preparation by the standard procedure¹⁸ failed to give a product pure enough for subsequent successful polymerization. Satisfactory purification was eventually

achieved by repetitive fractional precipitation of the compound from alkaline solution with acetic acid. To this end, the crude dipotassium salt, obtained as described¹⁸, was dissolved in water (150 ml/10 g of salt), and the free base was regenerated from the filtered solution by acidification with glacial acetic acid. The precipitated product was redissolved in 1 M aqueous potassium hydroxide (500 ml/10 g of base). Slow addition of acetic acid to the filtered, rapidly stirred solution produced a precipitate of yellow impurities (largely the polymeric disulphide²⁴) as the point of neutrality was approached. Following removal of the impurities by filtration, the addition of acid was continued to pH 5–6 whereupon the base separated as almost colourless and reasonably air-stable, fine crystals, m.p. 156°–160°C. Two more reprecipitations by the same procedure, followed by drying for 24 h at 50°C/0.1 mmHg, furnished a product with m.p. 158°–161°C* in an overall yield of 35–40%. No further narrowing of the melting range was observed upon additional reprecipitations. All operations described were performed under a blanket of nitrogen, and the solvents were meticulously degassed prior to use.

I.r. (KBr, prominent bands only): 3425, 3342 ($\nu_{\text{N-H}}$), 2544 ($\nu_{\text{S-H}}$), 1615 ($\delta_{\text{N-H}}$, $\nu_{\text{C-C}}$), 1480–1490 ($\delta_{\text{C-H}}$), 1272, 1280 ($\nu_{\text{C-N}}$), 875, 815 ($\delta_{\text{C-H}}$).

1,1'-Bis(chlorocarbonyl)cobalticinium hexafluorophosphate/chloride. 1,1'-Dimethylcobalticinium hexafluorophosphate, obtained from methylcyclopentadiene and anhydrous cobaltous bromide⁵ or, alternatively, from thallium (I) methylcyclopentadienide and cobaltous chloride hexahydrate²⁵, was oxidized as described previously^{5,11}. The crude oxidation products, precipitated as the hexafluorophosphate salts, were thoroughly extracted with hot acetone for removal of monocarboxy compound¹¹, leaving the dicarboxylic acid hexafluorophosphate as yellow, fluffy fine needles. The compound gave ¹H n.m.r. absorptions as reported previously¹¹, and no resonances due to monosubstituted or incompletely oxidized products were observed.

The dicarboxylic acid was chlorinated with freshly distilled thionyl chloride (10 ml/1 g of acid) for 24 h at the reflux temperature with moisture protection. (Heating periods of 6 h, corresponding to the literature value⁵, gave product contaminated with starting material or monochloride as indicated by i.r. absorption near 1725 cm⁻¹.) The dichloride, which crystallized from the cooled (0°C) solution, was separated by filtration, washed with dry benzene, and dried for 24 h at 60°C/0.1 mmHg. Yields in the chlorination step amounted to 80–87%. The compound gave the same i.r. bands as reported by the earlier authors⁵. Chlorine determinations on the hydrolysis products of samples from several runs indicated variable Cl⁻ contents generally 15–30% by wt in the anion moiety, (see, however, first footnote in results section); for stoichiometric calculations, throughout this work, the anion composition of the dichloride was taken to be 80% PF₆⁻, 20% Cl⁻. The extreme moisture sensitivity of the compound necessitated rigorous precautions, including the use of dry-box techniques, in handling and transfer manipulations.

* In a personal communication, for which we are most indebted, Mr P. M. Hergenrother, Whittaker Corporation, has recently brought to our attention some results of unpublished work in his laboratory on the synthesis of the free base, which was found to melt at about the same temperature as in our study.

Intermediate polymer I from 3,3'-diaminobenzidine and 1,1'-bis(chlorocarbonyl)cobalticinium salt

In this and all subsequent polymerization experiments, all glass ware was flamed and flushed with dry N₂. Solvent media were redistilled *in vacuo*, stored over Molecular Sieves, type 4A, and degassed prior to use. Transfer operations involving monomers were performed in the dry-box, and the poly-condensation reactions were conducted under an argon blanket with rigorous moisture protection.

In a 100 ml three-neck flask equipped with mechanical stirrer and fitted with gas in- and out-let tubes, 0.54 g (2.5 mmol) of pre-dried diaminobenzidine was briefly shaken under a rapid stream of dry argon and was dissolved in 15 ml of *N*-methylpyrrolidone. To the solution, cooled to -5°C, was added dropwise, with stirring, 1.09 g (2.5 mmol) of bis(chlorocarbonyl)cobalticinium salt, dissolved in 45 ml of acetonitrile. Throughout the addition period (45 min) and another 3 h thereafter, the temperature was maintained at -5 ± 3°C and was subsequently allowed to rise to 22 ± 3°C. Stirring was continued at that temperature for 15 h. The mixture remained heterogeneous throughout, as oligomeric condensation products began to precipitate shortly after the addition of the cobalticinium salt was started. Product precipitation was completed at the end of the reaction period by the addition of 300 ml of dry ether, and the separated dark reddish-brown polymer I was collected by filtration, briefly washed with methanol (low-molecular mass constituents partly extracted), and dried for 2 days over P₂O₅ at 60°C/0.1 mmHg; yield, 0.98 g (71.8%, based on A⁻ = 50% PF₆⁻, 50% Cl⁻, by wt). The polymer was soluble in water and formic acid, but insoluble in aprotic solvents. In acidic solutions, rapid chain degradation was indicated by viscosity reductions to nearly one-half the initial values upon standing for 40–60 min at ambient temperature.

For regeneration of the PF₆⁻ anion, a 0.20 g sample of the crude polymer was rapidly dissolved in 2 ml of 98% formic acid containing 0.1 g of NH₄PF₆. The filtered solution was stirred dropwise into 30 ml of diethyl ether/ethanol (1:1) saturated with NH₄PF₆, and the precipitated polymer I (A⁻ = PF₆⁻), after rapid separation by filtration, was washed successively with diethyl ether (50 ml), diethyl ether/ethanol (1:1) saturated with NH₄PF₆ (50 ml), and ethanol (200 ml). After drying for 50 h at 65°C/0.2 mmHg over P₂O₅, the reddish-black polymer weighed 0.11 g, corresponding to an overall yield of 39.5% (based on monomers). The product, while now insoluble in water, showed solubility in dimethylformamide and other aprotic solvents.

The reaction variables for the described polymerization run are summarized in Table 1 (experiment 1), which also lists analytical data for the crude and reprecipitated I.

Intermediate polymer III from 3,3'-dimercaptobenzidine and 1,1'-bis(chlorocarbonyl)cobalticinium salt

To the solution of 0.60 g (2.4 mmol) of the dimercaptobenzidine in 30 ml of hexamethylphosphoramide, rapidly stirred and precooled to -5°C, was added 1.05 g (2.4 mmol) of solid bis(chlorocarbonyl)cobalticinium salt. Following 1 h of stirring at -5 ± 3°C, the temperature was allowed to rise to 22 ± 3°C and was there maintained for another 48 h with continued stirring. Heterogeneity of the mixture obtained throughout the reaction period. The work up method as described in the preceding section gave 1.2 g (86.2%, based on A⁻ = 50% PF₆⁻, 50% Cl⁻, by wt) of crude, brownish-black polymer (III), which was partly soluble in

water and alkanols and completely soluble in formic acid, but essentially insoluble in aprotic solvents. Similar sensitivity to acidolytic chain scission was observed as with the polyamide I.

Regeneration of the PF_6^- anion was accomplished by rapid reprecipitation from formic acid solution in the presence of NH_4PF_6 as described for I. Polymer III ($A^- = PF_6^-$) so obtained in a yield corresponding to 43.6% (based on monomers) was insoluble in water, but moderately soluble in dimethylformamide.

The experimental variables and analytical results for both the crude and the reprecipitated polymer III are compiled in Table 1 (experiment 2).

A polymerization run conducted as above, except that the temperature was maintained for 4 h at $-5^\circ C$ followed by 96 h at $20^\circ C$, is summarized in Table 1 as experiment 3. A further run, employing the solvent system acetonitrile/pyridine (2:1 v/v), is tabulated as experiment 4; in this run, the dichloride was added as a 2.2% solution in acetonitrile. No reprecipitations were performed in the last-named two experiments, and the analytical data listed accordingly refer to the crude polymer products possessing mixed Cl^-/PF_6^- anions. Summarized results for additional polymerization experiments are found in footnotes j and k of the same Table.

Polyazoles, II and IV by thermal advancement of intermediate polymers I and III

Samples (0.05 g) of I and III, both crude ($A^- = PF_6^-/Cl^-$) and after reprecipitation from formic acid/ NH_4PF_6 ($A^- =$

PF_6^-), were placed in Schlenk tubes and were subjected to heating cycles as exemplified in Table 2. The samples were employed either in the solid, powdery state or else as films cast from aqueous solutions (crude I) or from dimethylformamide solutions (reprecipitated I and III). Because of the low degrees of polymerization attained, the films generally were quite brittle and tended to crumble on handling. Throughout the heating period, the pressure was reduced to 0.05 mmHg. Alternatively, in a few experiments, heating was conducted under a blanket of deoxygenated argon. The cooled tubes, on opening after completed heat treatment, were found to contain acidic (pH 3–4) vapours of pungent odour reminiscent of phosphorus fluorides. The brownish-black polyazoles obtained were insoluble in all common organic solvents and mineral acids. Analytical data on representative samples are collected in Table 2. Selected polymers, as marked in the Table, were used for the t.g.a. scans.

RESULTS AND DISCUSSION

Intermediary polyamides and polythioesters

The synthetic approach chosen for the preparation of polymers with bibenzimidazolyl backbone constituents comprised the low temperature solution condensation of 3,3'-diaminobenzidine and 1,1'-bis(chlorocarbonyl)cobalticinium hexafluorophosphate/chloride in *N*-methylpyrrolidone/acetonitrile. The analogous procedure selected for the synthesis of polymers with bibenzothiazolyl units in the backbone involved the low temperature solution con-

^k Sample employed in t.g.a. test

densation of 3,3'-dimercaptobenzidine with the same cobalticinium compound; the medium used was hexamethylphosphoramide, which in this case proved slightly superior to the methylpyrrolidone/acetonitrile mixture. Advancement to an acceptably high degree of polymerization called for utmost purity of the starting materials, a requirement presenting appreciable experimental difficulties with both the cobalticinium salt and the dimercapto compound (see experimental). The former compound was prepared as the mixed PF₆⁻/Cl⁻ salt⁵, a variable*, minor portion of the PF₆⁻ counter ion originally present in the dicarboxy-cobalticinium salt having undergone exchange with Cl⁻ anion in the course of chlorination in accord with earlier observations⁵. The two reactant pairs were allowed to undergo polycondensation at -5° to 25°C in the respective media (equations 1a and 2a).

Experimental conditions are summarized in Table 1 for two typical runs each employing equimolar reactant quantities (experiments 1 and 2). Insolubility in the aprotic solvents caused immediate partial precipitation of the product salts in both cases; for this reason, propagation largely proceeded in a heterogeneous system, and the degrees of polymerization attained were correspondingly low ($\eta_{inh} = 10\text{--}20\text{ ml/g}$). Product precipitation was completed at the end of the specified reaction periods by the addition of excess ether, use of this precipitant being dictated by the partial solubility of the products in water and, to a lesser extent, in lower alkanols. The separated polymeric intermediates gave C, H, N (S) microanalytical results (Table 1) in agreement with structures I and III respectively, having anion compositions of 40–50% PF₆⁻ and 60–50% Cl⁻.

* Although chlorine determinations indicate replacement of PF₆⁻ by Cl⁻ generally to be limited to 15–30%, halogen (F, Cl) and phosphorus analyses in the combination of elements present (notably Co) proved highly erratic and hence could not be used in our work for quantitative evaluation.

While a portion of this chloride anion percentage in both I and III is attributable to the cobalticenium salt reactant, the major part evidently resulted from anion exchange in the presence of the hydrogen chloride liberated in the propagation reaction. Such exchange was earlier observed by Pittman, Sheats, and collaborators⁵, but could not be verified quantitatively by a complete elemental analysis because of unreproducible results in the halogen determinations due to interference by the cobalt present†. We encountered the same analytical problems in our work, the experimentally found Cl and F contents generally adding up to 25–30% of the total (as against a maximum of 20.20%, calculated for $A^- = PF_6^-$ in I). Although, for this reason, we were unable to confirm the postulated anion compositions by halogen (and phosphorus) determinations, we found corroboration in the i.r. spectra. The spectrum of crude I, as isolated in these reactions, while showing in the expected intensities the common absorption patterns of the substituted biphenyl system and the 1,1'-disubstituted cobalticenium cation^{5,8} as well as the N–H and C–N stretching bands near 3350 and 1270 (sh) cm^{-1} associated with the primary amino groups and the amide I, II and III bands at about 1660, 1525, and 1305 cm^{-1} , displayed only weak absorption in the P–F stretching region of 830–840 cm^{-1} (partially merging with the benzene- and cobalticenium-aromatic C–H out-of-plane deformation bands at 810 and 860–870 cm^{-1}) and showed the typical 560 cm^{-1} peak of the PF_6^- complex‡ with appreciably lower intensity. The spectrum of crude III was characterized by a similarly attenuated P–F absorption in the two regions.

In order to regenerate the PF_6^- anion quantitatively, the crude polymers I and III were each reprecipitated from formic acid solution by ether/ethanol saturated with ammonium hexafluorophosphate. The polymers' extreme sensitivity to chain scission in contact with strong acids necessitated fast operation in this reprecipitation step. The C, H, N (S) contents of the polymers so treated conformed, respectively, to structures I and III with $A^- = PF_6^-$, and the i.r. spectra now featured the broad P–F stretching band system in the same dominating intensity as commonly observed with non-polymeric cobalticenium hexafluorophosphates and showed a strongly enhanced 560 cm^{-1} peak‡. Analytical data and inherent viscosities for the reprecipitated polymers are presented in Table 1.

Several polycondensations involving the reactant pair of equation (2a) were conducted over appreciably prolonged reaction periods under otherwise unchanged conditions in an attempt to raise both the conversion and the degree of polymerization in these largely heterogeneous reaction systems. Experiment 3 (Table 1), performed over a 96 h period, exemplifies this effort. In another experiment, the reaction temperature was gradually increased from -5° to $60^\circ C$. In still other polycondensation experiments, either the cobalticenium salt or the dimercapto compound was employed in a 5–10% molar excess over the respective reaction partner. In no case did an increase in conversion or polymer viscosity result from such modifications (footnotes j and k, Table 1). Changing to the solvent system acetonitrile/pyridine, at temperatures ultimately reaching $60^\circ C$ (experiment 4, Table 1), likewise proved of

no benefit in this respect. These findings rather conclusively point to the inhomogeneity of the reaction system as the principal hindrance to the attainment of high molecular masses and show the need for further scrutiny of the polymer solubility problem.

While the polyamide backbone structure of the intermediary polymer I can be regarded as established on the basis of the synthetic conditions, as well as the elemental analytical and i.r. spectroscopic findings discussed, the structural details of the analogous polymer III are by no means obvious. Hergenrother and Levine¹², discussing the two possible reaction paths originating from the condensation of isophthaloyl chloride with 3,3'-mercaptobenzidine, concluded from i.r. data that the principal reaction sequence leading to the intermediate polymer involved amide formation (path a), although preferred thioester formation (path b) was expected on the basis of relative nucleophilicity considerations. In the present case, i.r. evidence is inconclusive.

The spectra of polymers from different experiments invariably displayed the S–H stretching band near 2550 cm^{-1} (path a) in almost negligible intensities or failed to show it altogether, and the N–H stretching and bending vibrations of the primary amino group (path b) could not be detected in existing envelopes of other bands. While absorption was observed at the positions of the amide I, II and III bands, suggesting the existence of amide links, the amide I band appeared broadened, with a maximum emerging at 1670 cm^{-1} assignable to the thioester carbonyl stretching mode. We conclude that polyamide and polythioester structures both were formed under the conditions of our experiments, and the (idealized) representation polymer III takes account of these two isomeric types.

Polybenzazoles

The polymeric intermediates I and III, in both the crude ($A^- = PF_6^-/Cl^-$) and the reprecipitated ($A^- = PF_6^-$) forms, were subjected to thermal solid-state heat treatment under reduced pressure or under an argon blanket for cyclodehydration to the heterocyclic end-products, II and IV (equations 1b, 2b). Although preliminary checks by i.r. and elemental analyses had shown such cyclization to set in below $250^\circ C$, we employed temperatures in the vicinity of $300^\circ C$ to ensure optimal ring closure. (Higher temperatures still, up to $380^\circ C$, entailed no further changes in the spectral behaviour and elemental composition.) The heat treated, brownish-black polyheterocyclics were no longer soluble in organic solvents or mineral acids. Confirming substantially accomplished cyclodehydration, the i.r. spectrum of II featured the absorption characteristic of the aromatic benzimidazole system^{13–15} with maxima near 1625 (s), 1610 (m), 1505 (w), 1445–1470 (m–s, multiplet), 1280 (m–s), 1080–1130 (w–m, broad multiplet), 860 (m, partially merging with cobalticenium C–H deformation band), and 800 (s) cm^{-1} , as similarly shown by the benzene-aromatic polybenzimidazoles of Marvel's work¹⁶. The C–N stretching and amide I, II and III peaks, on the other hand, vanished in the envelopes of the adjacent benzimidazole absorptions. Analogously, the spectrum of IV was charac-

† Difficulties with P, F, Cl analyses have also been reported in studies involving other polymeric and non-polymeric cobalticenium hexachlorophosphates/chlorides^{9,11}.

‡ We found the band invariably at 550–570 cm^{-1} in the spectra of a large number of inorganic and organometallic hexafluorophosphates studied.

terized by absorption reasonably assignable to the benzothiazole unit at 1600–1590 (s), 1510 (s), 1445 (s), 1380 (m, shoulder on 1395 cm^{-1} cobalticinium band), 1270 (w–m), 865 (m, partly coalescing with cobalticinium band), and 815 (s) cm^{-1} , whereas the thioester and amide bands disappeared in the envelopes of these absorptions. The weak carboxyl end group absorption shown at 1720 cm^{-1} in the spectra of several samples also vanished upon the heat treatment, obviously as a result of thermal decarboxylation. 1,1'-Dicarboxycobalticinium hexafluorophosphate undergoes complete decarboxylation (concomitant with partial degradation of the PF_6^- counter ion) after 4 h at 250°C and 0.1 mmHg.

In further confirmation of substantially cyclized product structures, the C, H, N (S) microanalytical results (Table 2) obtained on polybenzazoles that were derived from the crude ($\text{A}^- = \text{PF}_6^-/\text{Cl}^-$) intermediary polymers agreed with structures II ($\text{A}^- = \text{PF}_6^-/\text{Cl}^-$) and IV ($\text{A}^- = \text{PF}_6^-/\text{Cl}^-$), respectively. Similarly, benzazole polymers obtained from the reprecipitated ($\text{A}^- = \text{PF}_6^-$) intermediates gave C, H, N (S) analytical data reasonably well in accord with product structures possessing $\text{A}^- = \text{PF}_6^-$, although the slightly higher C, H values found suggest a corresponding minor loss of fluorine and, perhaps, phosphorus contents. (For the reasons outlined further above, F and P could not be determined reproducibly and in any degree of reliability to verify such losses.) At the same time, the P–F stretching absorption in the i.r. spectra of the last named two polyazole types appeared in drastically reduced intensities relative to their precursor polymers with $\text{A}^- = \text{PF}_6^-$, clearly exposing the aforementioned C–H deformation bands of the cobalticinium and benzazole systems in this region. The weak evolution of acidic vapours observed during the heat treatment suggests rather limited thermal stability of the PF_6^- counterion in these polysalts, phosphorus fluorides being eliminated in the process. Conceivably, then, the cyclization steps in equation (1b) and (2b) were accompanied by a partial breakdown of PF_6^- into F^- and PF_5 , and the latter halide, being an aggressive fluorinating agent at these high temperatures, caused partial ring fluorination. Evidence for carbon-bonded fluorine in the products can indeed be found in the i.r. spectra, which invariably showed broad absorption at 1100–1150 cm^{-1} , whereas, not unexpectedly, this absorption was very weak or virtually absent in the spectra of polyazoles obtained from crude polymers I and III with grossly reduced PF_6^- contents. The PF_3 liberated in the fluorination step could partially escape and, to some extent, might also be re-incorporated into the polymers, e.g., through phosphorylation of amino groups. The various hexafluorophosphate degradation and ring fluorination reactions would account for both the considerably weakened 840 cm^{-1} i.r. absorption and the minor deviations of the C, H, N-contents from the calculated values in the hexafluorophosphate polysalts.

The loss of solubility accompanying the heat treatment of both I and III points to minor imperfections in the structural build-up of II and IV, including incomplete cyclization, branching, and crosslinking via functional groups escaping the ring-closing steps, and it remains to be studied to what extent these structural imperfections are caused and affected by the hexafluorophosphate counter ion and its inherent instability at the cyclization temperatures employed. As an immediate consequence of structural defects, the polyazoles, whether derived from precursors with $\text{A}^- = \text{PF}_6^-$ or from those with $\text{A}^- = \text{PF}_6^-/\text{Cl}^-$, showed a performance distinctly inferior to that of the

common all-aromatic polybenzimidazoles in thermogravimetric analysis. The thermograms of both II and IV recorded at a heating rate of 5°C/min, indicated weight loss to set in near 350°C in air and at 400–450°C in a nitrogen atmosphere. In the air runs, the relative weight loss at 500°, 650°, and 800°C was in the range of 45–55, 70–75, and 72–76%, respectively. In N_2 , the corresponding weight loss ranges were 10–15, 30–40, and 55–65%.

We are currently studying polymerizations in a more homogeneous phase as realized, for example, in polyphosphoric acid or ethylated polyphosphoric acid media. The consequences of replacing hexafluorophosphate by chloride and other anions in the intermediate polymers will also be examined.

ACKNOWLEDGEMENTS

This work was generously supported by the South African Atomic Energy Board with grants for both an assistantship and running expenses. The authors are also much indebted to Dr L. W. Frost and his staff, Westinghouse Electric Corporation, who kindly scanned the t.g.a. thermograms.

Syntheses and conformational studies of poly(γ -*N*-alkyl-L- α , γ -diaminobutyric acids) and their carbobenzoxy derivatives

Hiroyuki Yamamoto, Miho Miyazaki and Tadao Hayakawa

Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda 386, Japan

(Received 5 November 1975)

Three types of high molecular weight poly(γ -*N*-methyl, γ -*N*-carbobenzoxy-L- α , γ -diaminobutyric acid), poly(γ -*N*-ethyl, γ -*N*-carbobenzoxy-L- α , γ -diaminobutyric acid), and poly(γ -*N*-benzyl, γ -*N*-carbobenzoxy-L- α , γ -diaminobutyric acid) were synthesized by the *N*-carboxyanhydride method. The helix-coil transition of these poly(γ -*N*-alkyl, γ -*N*-carbobenzoxy-L- α , γ -diaminobutyric acids) in chloroform-dichloroacetic acid was followed by optical rotation measurements. The introduction of a methyl, an ethyl, or a benzyl group to the side chain of the carbobenzoxyated derivative of poly(L- α , γ -diaminobutyric acid) appeared to weaken the helical conformation at 25°C and altered the direction of the temperature induced helix-coil transition from a 'normal' to an 'inverse'. For water-soluble poly(γ -*N*-alkyl-L- α , γ -diaminobutyric acids), the coil-to-helix transition was little observed even when the polypeptides were uncharged at pH 12. At sufficiently high methanol concentration, however, the polypeptides underwent a complete transition from the random coil to the α -helical conformation even at pH 3.

INTRODUCTION

In aqueous solution at 25°C uncharged PLL* is known to exist in a helical form, uncharged PLO is only partly helical, and uncharged PLD is almost a random coil structure¹⁻⁴. The only difference among the three polypeptides is that PLD has one less methylene group in the side chain than PLO and two less than PLL. To study further the chain length effect of the non-polar alkyl group on the conformational stability, we have reported the syntheses and conformational studies of poly(ϵ -*N*-alkyl-L-lysine), poly(δ -*N*-alkyl-L-ornithine), and their carbobenzoxyated derivatives in previous papers⁵⁻⁸.

We now extend our investigations by introducing a methyl, an ethyl (aliphatic alkyl), or a benzyl (aromatic alkyl) group to the γ -amino group of the side chain, noting that γ -*N*-methyl-L- α , γ -diaminobutyric acid is an isomer of L-ornithine and γ -*N*-ethyl-L- α , γ -diaminobutyric acid is an isomer of L-lysine. In the present paper we report the

syntheses and conformational studies of PMLD, PELD, and PBLD and their carbobenzoxyated derivatives, PCMLD, PCELD, and PCBLD. The helix-coil transitions of the carbobenzoxyated polypeptides in mixed organic solvents of chloroform-DCA and the deprotected water-soluble polypeptides in aqueous solutions were followed by optical rotation and circular dichroism measurements.

EXPERIMENTAL

Polypeptides

PLD was prepared according to the method of Fasman *et al.*⁹. Three kinds of poly(γ -*N*-alkyl-L- α , γ -diaminobutyric acids) were synthesized according to the following scheme:

* Abbreviations used in this work: PLL, poly(L-lysine); PLO, poly(L-ornithine); PLD, poly(L- α , γ -diaminobutyric acid); PMLD, poly(γ -*N*-methyl-L- α , γ -diaminobutyric acid); PELD, poly(γ -*N*-ethyl-L- α , γ -diaminobutyric acid); PBLD, poly(γ -*N*-benzyl-L- α , γ -diaminobutyric acid); PCLL, poly(ϵ -*N*-carbobenzoxy-L-lysine); PCLO, poly(δ -*N*-carbobenzoxy-L-ornithine); PCLD, poly(γ -*N*-carbobenzoxy-L- α , γ -diaminobutyric acid); PCMLL, poly(ϵ -*N*-methyl, ϵ -*N*-carbobenzoxy-L-lysine); PCBLL, poly(ϵ -*N*-benzyl, ϵ -*N*-carbobenzoxy-L-lysine); PCMLO, poly(δ -*N*-methyl, δ -*N*-carbobenzoxy-L-ornithine); PCELO, poly(δ -*N*-ethyl, δ -*N*-carbobenzoxy-L-ornithine); PCBLO, poly(δ -*N*-benzyl, δ -*N*-carbobenzoxy-L-ornithine); PCMLD, poly(γ -*N*-methyl, γ -*N*-carbobenzoxy-L- α , γ -diaminobutyric acid); PCELD, poly(γ -*N*-ethyl, γ -*N*-carbobenzoxy-L- α , γ -diaminobutyric acid); PCBLD, poly(γ -*N*-benzyl, γ -*N*-carbobenzoxy-L- α , γ -diaminobutyric acid); DCA, dichloroacetic acid, o.r.d. optical rotatory dispersion; c.d., circular dichroism.

Tos = *p*-CH₃C₆H₄SO₂-; Bzo = C₆H₅CO-; Z = C₆H₅CH₂OCO-; TEA = triethylamine. In compounds II–III; R = CH₃- or C₂H₅-. In compounds VI–IX, R = CH₃-, C₂H₅-, or C₇H₇-.

γ -N-tosyl, α -N-benzoyl-L- α , γ -diaminobutyric acid

γ -N-tosyl-L- α , γ -diaminobutyric acid was prepared from L- α , γ -diaminobutyric acid monohydrochloride (I) and *p*-toluenesulphonyl chloride, as described in a previous paper⁶. The yield was 59%; melting point 209°–210°C; $[\alpha]_D^{25^\circ\text{C}} = 25.8$ ($c = 0.93\%$ in 6 N hydrochloric acid). Calculated for C₁₁H₁₆N₂O₄S: C = 48.52%; H = 5.92%; N = 10.29%; found: C = 48.43%; H = 6.01%; N = 10.10%. γ -N-tosyl, α -N-benzoyl-L- α , γ -diaminobutyric acid was prepared from γ -N-tosyl-L- α , γ -diaminobutyric acid and benzoyl chloride according to the Schotten–Baumann method⁶. This was recrystallized from ethanol and water; yield, 99%; melting point 141°–143°C; $[\alpha]_D^{25^\circ\text{C}} = -33.8$ ($c = 1.07\%$ in acetic acid). Calculated for C₁₈H₂₀N₂O₅S: C = 57.43%; H = 5.36%; N = 7.44%; found: C = 57.37%; H = 5.30%; N = 7.25%.

γ -N-tosyl, γ -N-methyl (or ethyl), α -N-benzoyl-L- α , γ -diaminobutyric acid (II)

To a solution of γ -N-tosyl, α -N-benzoyl-L- α , γ -diaminobutyric acid (32.7 g) in 32 ml of 33% sodium hydroxide, was added 12.4 ml of dimethyl sulphate. The mixture was stirred at room temperature for 3 h and at 50°C for 1 h. It was acidified to 'Congo' red with 3 N hydrochloric acid. An oily product separated which was extracted with ethyl acetate. The organic layer was washed with water and dried over anhydrous sodium sulphate, the solvent was removed under reduced pressure, and the residue was solidified as an amorphous foam from *n*-hexane; yield, 35.7 g (100% as mono-hydrate). The dicyclohexylamine salt, prepared from a 1.0 g sample in ethyl acetate, was recrystallized twice from ethyl acetate and *n*-hexane; yield, 1.24 g (86.4%); melting point 144°C; $[\alpha]_D^{25^\circ\text{C}} = 17.4$ ($c = 1.10\%$ in methanol). Calculated for C₃₁H₄₅N₃O₅S, H₂O: C = 63.13%; H = 8.03%; N = 7.12%; found: C = 62.87%; H = 7.85%; N = 7.05%.

The corresponding ethyl derivative was prepared as above from γ -N-tosyl, α -N-benzoyl-L- α , γ -diaminobutyric acid (31.4 g) and diethyl sulphate (16.3 ml); yield, 35.0 g (100% as mono-hydrate). A part of the amorphous foam was converted to the dicyclohexylamine salt; yield, 90.0%; melting point 78°–80°C; $[\alpha]_D^{25^\circ\text{C}} = 17.3$ ($c = 1.08\%$ in methanol). Calculated for C₃₂H₄₇N₃O₅S, H₂O: C = 63.63%; H = 8.18%; N = 6.96%; found: C = 63.86%; H = 7.91%; N = 7.12%.

γ -N-methyl (or ethyl)-L- α , γ -diaminobutyric acid hydrohalides (III)

A suspension of γ -N-methyl, γ -N-tosyl, α -N-benzoyl-L- α , γ -diaminobutyric acid (13.3 g) in 115 ml of 47% hydrobromic acid, was refluxed for 3 h at 150°C and cooled to 0°C. After filtration, the benzoic acid was removed by extraction with ether. The aqueous solution was then evaporated to dryness under reduced pressure. The oily residue was dissolved in ethanol and the solution neutralized to pH 6 with pyridine. The precipitate, γ -N-methyl-L- α , γ -diaminobutyric acid hydrobromide, was filtered and recrystallized from water and ethanol; yield, 4.0 g (62.6%); melting point 195°–196°C; $[\alpha]_D^{25^\circ\text{C}} = 19.8$ ($c = 1.04\%$ in 6 N hydrochloric acid). Calculated for C₅H₁₃N₂O₂Br: C =

28.18%; H = 6.15%; N = 13.15%; found: C = 27.95%; H = 6.02%; N = 12.99%.

γ -N-ethyl-L- α , γ -diaminobutyric acid hydrochloride was prepared from γ -N-ethyl, γ -N-tosyl, α -N-benzoyl-L- α , γ -diaminobutyric acid (30.5 g) and 180 ml of 12 N hydrochloric acid. The mixture was heated for 24 h at 100°C and treated in the same manner described above; yield, 4.2 g (30.5%); melting point 192°C; $[\alpha]_D^{25^\circ\text{C}} = 5.6$ ($c = 0.95\%$ in 6 N hydrochloric acid). Calculated for C₆H₁₅N₂O₂Cl, H₂O: C = 35.91%; H = 8.54%; N = 13.96%; found: C = 36.06%; H = 8.33%; N = 14.32%.

γ -N-benzylidene-L- α , γ -diaminobutyric acid (IV)

γ -N-benzylidene-L- α , γ -diaminobutyric acid was prepared from I (15 g) and benzaldehyde (10.3 ml) as described in a previous paper⁵; yield, 14.7 g (73.4%); melting point 173°C; $[\alpha]_D^{25^\circ\text{C}} = -4.0$ ($c = 0.50\%$ in 0.5 N sodium hydroxide). Calculated for C₁₁H₁₄N₂O₂: C = 64.06%; H = 6.84%; N = 13.58%; found: C = 63.88%; H = 6.65%; N = 13.23%.

γ -N-benzyl-L- α , γ -diaminobutyric acid (V)

γ -N-benzylidene-L- α , γ -diaminobutyric acid (14 g) in 68 ml of 1 N sodium hydroxide, was hydrogenated by sodium borohydride (3.9 g in 50 ml of water) as described in a previous paper⁵. The product was recrystallized from water (50 ml) and methanol (100 ml)—ethanol (10 ml); yield, 3.5 g (21.0%); melting point 200°C; $[\alpha]_D^{25^\circ\text{C}} = 8.7$ ($c = 0.58\%$ in 0.5 N sodium hydroxide). Calculated for C₁₁H₁₇N₂O₂Cl: C = 53.99%; H = 7.00%; N = 11.45%; found: C = 53.71%; H = 6.84%; N = 11.44%.

γ -N-alkyl, γ -N-carbobenzoxy-L- α , γ -diaminobutyric acids (VI)

γ -N-alkyl, γ -N-carbobenzoxy-L- α , γ -diaminobutyric acids were prepared by the usual procedure using carbobenzoxy chloride and cupric carbonate⁵ and recrystallized from 2 N hydrochloric acid and 2 N ammonium hydroxide (methyl and ethyl derivatives) or dilute acetic acid (benzyl derivative). γ -N-methyl, γ -N-carbobenzoxy-L- α , γ -diaminobutyric acid; yield, 82.1%; melting point 198°C; $[\alpha]_D^{25^\circ\text{C}} = -5.2$ ($c = 1.0\%$ in glacial acetic acid). Calculated for C₁₃H₁₈N₂O₄: C = 58.64%; H = 6.81%; N = 10.52%; found: C = 58.65%; H = 6.73%; N = 10.27%. γ -N-ethyl, γ -N-carbobenzoxy-L- α , γ -diaminobutyric acid; yield, 37.3%; melting point 200°C; $[\alpha]_D^{25^\circ\text{C}} = -2.3$ ($c = 1.0\%$ in glacial acetic acid). Calculated for C₁₄H₂₀N₂O₄: C = 59.99%; H = 7.19%; N = 9.99%; found: C = 59.65%; H = 6.94%; N = 10.17%. γ -N-benzyl, γ -N-carbobenzoxy-L- α , γ -diaminobutyric acid; yield, 51.1%; melting point 179°–180°C; $[\alpha]_D^{25^\circ\text{C}} = 2.1$ ($c = 1.17\%$ in glacial acetic acid). Calculated for C₁₉H₂₂N₂O₄: C = 66.65%; H = 6.48%; N = 8.18%; found: C = 66.69%; H = 6.60%; N = 7.90%.

γ -N-alkyl, γ -N-carbobenzoxy-L- α , γ -diaminobutyric acid N-carboxyanhydrides (NCA) (VII)

The NCAs were prepared by the usual procedure using phosgene for 1 h at 40°C in ten-fold dry dioxane. The crude NCAs were dissolved in dry acetone and then passed through a dry charcoal–silver oxide column to purify them. The acetone was evaporated to dryness under reduced pressure. γ -N-alkyl, γ -N-carbobenzoxy-L- α , γ -diaminobutyric acid NCAs were obtained as syrups and used for immediate polymerization. The three NCAs showed double absorp-

Table 1 Molecular weight of PCLD, PCMLD, PCELD, and PCBLD

Polypeptide	$[\eta]_{\text{DCA}}^{25^\circ}$	DP*	Molecular weight
PCLD	0.355	210	50 000
PCMLD	0.790	690	172 000

tion peaks at 1785–1788 and 1853–1855 cm^{-1} due to the cyclic anhydride.

Poly(γ -*N*-alkyl, γ -*N*-carboboxy-L- α , γ -diaminobutyric acids) (VIII)

High molecular weight polypeptides (VIII) were prepared by polymerizing the NCAs in ten-fold dioxane for a week at room temperature and for 2 h at 100°C using triethylamine as an initiator (A/I = 100). The polypeptides were precipitated with water and filtered. PCMLD: yield, 80.6% (from the methyl derivative of VI). Calculated for $(\text{C}_{13}\text{H}_{16}\text{N}_2\text{O}_3)_n$: C = 62.89%; H = 6.50%; N = 11.28%; found: C = 62.44%; H = 6.23%; N = 11.19%. PCELD: yield, 95.6% (from the ethyl derivative of VI). Calculated for $(\text{C}_{14}\text{H}_{18}\text{N}_2\text{O}_3)_n$: C = 64.11%; H = 6.92%; N = 10.68%; found: C = 64.49%; H = 6.64%; N = 10.63%. PCBLD: yield, 88.1% (from the benzyl derivative of VI). Calculated for $(\text{C}_{19}\text{H}_{20}\text{N}_2\text{O}_3)_n$: C = 70.35%; H = 6.21%; N = 8.63%; found: C = 70.49%; H = 6.17%; N = 8.59%.

Poly(γ -*N*-alkyl-L- α , γ -diaminobutyric acid) hydrobromides (IX)

The polypeptide hydrobromides were prepared from VIII by the usual procedure using hydrogen bromide in glacial acetic acid¹⁰. The polypeptides were re-precipitated from water (2 ml) and ethanol (20 ml)–ether (25 ml). PMDL, HBr: yield, 95.2%. Calculated for $(\text{C}_5\text{H}_{10}\text{N}_2\text{O}, \text{HBr})_n$: C = 30.79%; H = 5.69%; N = 14.36%; found: C = 30.97%; H = 5.51%; N = 14.37%. PELD, HBr: yield, 86.5%. Calculated for $(\text{C}_6\text{H}_{12}\text{N}_2\text{O}, \text{HBr}, \text{H}_2\text{O})_n$: C = 31.73%; H = 6.66%; N = 12.33%; found: C = 31.34%; H = 6.47%; N = 12.50%. PBLD, HBr: yield, 96.0%. Calculated for $(\text{C}_{11}\text{H}_{14}\text{N}_2\text{O}, \text{HBr})_n$: C = 48.72%; H = 5.58%; N = 10.33%; found: C = 48.94%; H = 5.33%; N = 9.94%.

Methods

O.r.d. and c.d. were measured with a Jasco ORD/UV-5 spectro-polarimeter under constant nitrogen flush. Constant temperature was maintained by circulating water or ethanol (cooled by dry ice) through the jacket of a specially designed cell holder from a Haake constant temperature bath. The temperature of the solution in the cell was measured on a Takara thermistor. The experimental data were expressed in terms of specific rotation $[\alpha]$ or reduced mean residue rotation $[m']$ (degree cm^2/dmol) for o.r.d. and mean residue ellipticity $[\theta]$ (degree cm^2/dmol) for c.d. The refractive indexes of the chloroform–DCA and water–methanol mixtures were assumed to be the average of solvent composition of that of each solvent.

The intrinsic viscosities were measured in DCA at 25°C using an Ubbelohde viscometer. The molecular weights were estimated from an empirical equation $\log DP = 1.47 \log [\eta] + 2.99$, in DCA at 25°C for ϵ -*N*-carboboxy-lyllysine⁴ and listed in Table 1.

RESULTS AND DISCUSSION

Poly(γ -*N*-alkyl, γ -*N*-carboboxy-L- α , γ -diaminobutyric acids)

Conformation. The o.r.d. above 340 nm for PCLD, PCMLD, PCELD, and PCBLD was fitted with the Moffitt–Yang equation¹¹. The b_0 values were large and negative in a helix-promoting solvent, e.g. dioxane or chloroform, and close to zero in a coil-promoting solvent, e.g. DCA (Table 2). The b_0 value –400 of PCLD in chloroform–DCA (95:5 v/v) at 25°C, was in good agreement with the reported value of Hatano⁴. In the ultra-violet region, the o.r.d. of the three γ -*N*-alkyl polypeptides showed a 233 nm trough in dioxane or chloroform and their helical contents based on the 233 nm trough coincided well with that based on the b_0 values. Therefore, PCMLD is mostly helical (right-handed) in dioxane or chloroform but PCELD and PCBLD are less helical (about 50%) in the same solvent. This difference of the helical contents might arise from the difference of the bulkiness in the side chain.

Solvent induced transition. Figure 1 shows the helix–coil transition of PCLD, PCMLD, PCELD, and PCBLD in chloroform–DCA mixed solvents at 25°C with midpoints at 40, 10, 10, and 4% (v/v) DCA, respectively. Thus, the introduction of an alkyl group to the γ -*N*-amino group in the side chain appears to weaken the helical conformation at 25°C. For comparison, the transition points for ω -*N*-carboboxylylated poly(basic L-amino acids) and their ω -*N*-alkylated polypeptides are listed in Table 3. Less DCA is required to destroy the helical conformation of PCMLD than its isomer PCLO and PCELD than PCLL.

Temperature induced transition. PCLO and PCLL are known to display an ‘inverse’ temperature induced transition in mixed solvents, i.e. high temperature favours the helical form and low temperature the coiled form^{12–15}. As contrasted with its higher homologues, only PCLD displays a ‘normal’ temperature induced transition. This fact suggests that the number of methylene groups in the side chain markedly influences the direction of the temperature induced transition. As listed in Table 3, in the previous papers^{6,8} we have shown that all the ϵ -*N*- and δ -*N*-alkylated polypeptides underwent an ‘inverse’ transition and the introduction of an alkyl group did not alter the direction of the transition.

Table 2 Values of $[m']_{233}$, a_0 , and b_0 for PCLD, PCMLD, PCELD, and PCBLD in various solvents at 25°C

Polymer	Solvent	$[m']_{233}$ (degree cm^2/dmol)	a_0 (degree cm^2/dmol)	b_0 (degree cm^2/dmol)
PCLD*	Chloroform– DCA(95:5 v/v)		50	–400
	DCA		–260	0
PCMLD	Dioxane	–12 800	30	–570
	Chloroform	–11 100	–30	–440
PCELD	DCA		–430	25
	Dioxane	–5700	20	–260
	Chloroform	–5500	0	–240
PCBLD	DCA		–240	15
	Dioxane	–6200	10	–250
	Chloroform	–6000	–10	–200
	DCA		–370	–10

* Insoluble in dioxane or chloroform

Figure 1 Helix-coil transition of PCLD (x); PCMLD (O); PCELD (●) and PCBLD (□) in chloroform-DCA mixtures at 25°C

One of the interests of the present study is whether a γ -*N*-alkyl group alters the direction or not. Figure 2 shows the temperature dependence of the rotation for PCMLD, PCELD, and PCBLD in the transition region (Figure 1) with 11, 11, and 5% DCA, respectively. At high temperature the three polypeptides decreased the negative rotation. Since $[\alpha]_{450}$ were smaller negative values (in magnitude) for the helical form than for the coiled form, PCMLD, PCELD, and PCBLD underwent an 'inverse' temperature induced transition. Thus, as contrasted with their ω -*N*-alkylated derivatives of PCLL and PCLO, the γ -*N*-alkylated derivatives of PCLD alter the direction of the transition from a 'normal' to an 'inverse'.

Poly(γ -*N*-alkyl-L- α , γ -diaminobutyric acids)

Conformation. PLD, PMLD, and PELD are soluble in water, 0.1 M sodium chloride solution, and up to 95:5 (v/v) methanol-water at all pH. PBLD hydrobromide is insoluble in water; below pH 7, however, it can be solubilized in 0.1 M sodium chloride solution by heating at 50°C (concentration less than 0.05%). Table 4 lists the $[m']_{233}$ values for the four polypeptides. The positions and the magnitudes of the trough suggested that the uncharged polypeptides (except PBLD) at pH 12 were within a few per cent of helix and the charged polypeptides at pH 3 were in a coiled conformation (see also Figure 5).

Charge induced transition. Figure 3 shows the changes in optical rotations at 233 nm with pH for the four polypeptides in 0.1 M sodium chloride solution at 25°C. PLD, PMLD, and PELD did not undergo a sharp charge induced coil-to-helix transition and judging from the magnitudes of $[m']_{233}$ the three polypeptides showed a very slight change from a random coil to within a few per cent of helix even at pH 12. At pH 12, unlike PLL (completely α -helical with $[m']_{233} = -12\,000$ to $\sim -14\,700^{1,16}$), its isomer PELD had a $[m']_{233} = -2050$ and, unlike PLO (25 to $\sim 35\%$ helical with $[m']_{233} = -5400$ to $\sim -6700^{1,3}$), its isomer PMLD a $[m']_{233} = -3400$. Thus, the conformation of PMLD or PELD differs completely from that of its isomer PLO or PLL. It is difficult to explain why PELD is less helical than PMLD, which has one less methylene group in the side chain than the former.

PBLD showed a marked tendency to increase its rotation but, because of its poor solubility, no data were obtained above pH 7.

Solvent induced transition. Figure 4 and Table 4 show the $[m']_{233}$ values for PLD, PMLD, PELD, and PBLD in mixed solvents of water and methanol at pH_{app} 3 and pH_{app} 12. At pH_{app} 3 the coil-to-helix transition of charged four polypeptides began sharply at ~ 70 to $\sim 75\%$ (v/v) methanol content. The four polypeptides became completely helical

Figure 2 Change in optical rotation with temperature for PCMLD (O); PCELD (●) and PCBLD (□) in the coil-to-helix transition region in chloroform-DCA mixtures. DCA concentration: 11% for PCMLD, 11% for PCELD and 5% for PCBLD

with $[m']_{233} = -11\,000$ to $\sim -12\,300$ in 90 to $\sim 95\%$ methanol at 25°C, showing no racemization during the syntheses. At $\text{pH}_{\text{app}} 12$ the partly ordered structure-to-helix transition of uncharged PLD, PMLD, and PELD began broadly at about 40% methanol. Since the three polypeptides are partially helical even in zero methanol content, the transition is not sharp. At above 80% methanol content, the polypeptides would have been in the helical conformation over the entire range of pH. Such was the case of PLL in 95% methanol or 76% 2-propanol^{17,18} and poly(δ -*N*-benzyl-L-ornithine) in 90% 1-propanol⁸.

Temperature induced transition. The $[\theta]$ in Figure 5 shows the temperature dependence of the ellipticity for PLD and PMLD. Lowering the temperature from 25°C to 4°C, enhanced the helicities of PLD and PMLD; PLD, $[\theta]_{220} = -2800$ (25°C) and $-10\,000$ (4°C), and PMLD, $[\theta]_{220} = -3100$ (25°C) and $-12\,300$ (4°C). In analogy to protein denaturation, both PLD and PMLD became helical at low

Figure 4 Effect of methanol content on $[m']_{233}$ of PLD (x); PMLD (O); PELD (●) and PBLD (□) at 25°C: (a) at pH 3 (b) at pH 12

Figure 5 C.d. spectra of (a), PLD and (b), PMLD in aqueous solution at indicated pH and temperature: random coil (---), at pH 3 and 25°C; partial helix (—), at pH 12 and 25°C; partial helix (- · - ·), at pH 12 and 4°C

temperature and disordered at high temperature. PLL and PLO showed also the same tendency¹.

To summarize, three kinds of new poly(γ -*N*-alkyl-L- α , γ -diaminobutyric acids) and their carbobenzoxyated derivatives were synthesized and the effect of the side chain was investigated. PCLD and PCMLD fold a complete helix in organic solvents, while PCELD and PCBLD, which have the bulkier alkyl groups, fold a partial helix. The three carbobenzoxyated γ -*N*-alkyl polypeptides alter the direction of the temperature induced transition from a 'normal' to an 'inverse'. The water-soluble polypeptides, PMLD and PELD, undergo a helix-coil transition slightly by increasing the pH of the solution. PMLD, an isomer of PLO, or PELD, that of PLL, behaves like PLD rather than PLO or PLL showing no increased alkyl effect. This suggests that the helical stability depends not only on the total number of methylene group in the side chain, but also on the steric arrangement of alkyl group around the ω -amino or imino group.

Response of macromolecular structure to shear gradients

B. Hlavacek and H. P. Schreiber

Department of Chemical Engineering, Ecole Polytechnique, Montreal, Canada
(Received 15 September 1975; revised 7 January 1976)

The response of macromolecular structure to increasing shear gradients is considered. It is suggested that the coiled configuration, characteristic of the macromolecule at zero shear gradient, persists far into the region of non-linear viscous response. The increase in recoverable shear, normal stress and related parameters of elastic response in this range of shear gradients is attributed to shifts in the orientation of the principal stress axis, the polymer coil remaining characterized by the gyration radius at zero shear. Uncoiling of the macromolecule is postulated only at shear gradients greater than that corresponding to the onset of flow instability, such as structural turbulence. Literature data for a variety of polymer solutions are used to confirm the postulates of the present model.

INTRODUCTION

This paper presents a simple model for the behaviour of macromolecular fluids (solutions and melts) at high gradients of shear. The problem treated here is of long standing concern. The interest stems from inter-relationships between molecular structure and the shear response of polymer molecules and equally from phenomena such as flow instability or melt fracture¹, which impose high shear limits on the commercial processing of polymer fluids. Ram² has summarized the current situation, noting that the commonest interpretations of non-Newtonian behaviour relate the reduction of viscosity to the gradual orientation and disentanglement of chain segments as the polymer chains deform and orient under the influence of a shear gradient. The concept of chain entanglement is a subtle one, however, experimental evidence indicating^{3,4} that viscous and elastic responses in polymers are probably due to short- and long-range associations owing to entanglement, respectively.

Existing theories for the behaviour of polymers in high shear fields generally do not differentiate between segmental and longer-range (domain) entanglements. Among the most familiar of these theories are the soft dumbbell approaches of Zimm⁵ and Bueche⁶, and non-linear viscoelastic flow models such as those of Meister and Biggs⁷ and Bird and Carreau⁸. These latter theories particularly, differ substantially in their handling of the variation of entanglement density with shear gradient, yet they tend to be non-discriminating in their goodness-of-fit to experimental data. Consequently it seems reasonable to avoid the complexity inherent in considerations of entanglements at the sub-chain (segment) level, and to attempt a rationalization of polymer fluid behaviour under high shear gradients via a simple method based on deformations at the supra-molecular level.

THEORETICAL CONSIDERATIONS

A convenient starting point for our argument is the assumed presence in polymers of supra-molecular structures of the type discussed by Busse⁹, or of 'viscoelastic drops', as introduced previously by Hlavacek *et al.*^{10,11}. In considering the response of these large structures to shear gra-

dients, we expect to gain information on the change with shear gradients of the number of interaction (entanglement) points at the domain level but, inherently, little detail can be expected about the situation at the sub-chain (segmental) level. Since interactions at the domain level relate more specifically to elastic than to purely viscous properties of polymer fluids^{3,4}, it is in the former area that relevant tests of the model must be sought.

We begin with two basic concepts:

(a) Following Bueche¹², at zero gradient the flexible macromolecule is subject to Brownian movement and is distributed uniformly about a centre of mass. In this state, assuming shear-thinning characteristics, its viscosity is at a maximum, η_{\max} , corresponding to the upper Newtonian limit, and a direct correlation can be expected between η_{\max} and the unperturbed gyration radius of the unit $(\bar{r}^2)_0$.

(b) At finite gradients in the range $0 < \dot{\gamma} < 1/\tau_{\max}$, where $\dot{\gamma}$ is the shear rate and τ_{\max} is the maximum relaxation time, the polymer structure should remain effectively unchanged. Consequently, the existence of relationships is called for between the principal stress and the quantities, $\eta_{\max} \dot{\gamma}$; $G'(\omega)$ and $G''(\omega)$, where the latter are the real and imaginary parts of dynamic moduli at rotational velocity ω . At gradients $\dot{\gamma} > 1/\tau_{\max}$, we should expect variations in these three parameters.

Introducing θ as the angle of orientation for the principal stress axis, and $\delta = 90 - \theta$, the following simple expression can be written:

$$(\eta_{\max} + \delta \eta_{\max}) \times \dot{\gamma} \cos \delta = [(P_{11} - P_{22})^2 + (2P_{12})^2]^{1/2} \quad (1)$$

where $P_{11} - P_{22}$ is the normal stress. Equation (1) is essentially a restatement of Philippoff's expression¹³ to which the dynamic component $\cos \delta$ in the response of the macromolecule to the shear gradient, has been added.

In the above equation, we note that:

$$\cos \delta = \frac{2P_{11}}{[(P_{11} - P_{22})^2 + (2P_{12})^2]^{1/2}}$$

It is surprising that for many polymer solutions at varying concentrations the relationship of equation (1) is well obeyed over 4–5 decades of shear^{10,11}.

In a majority of cases for which experimental results are available, simple relationships can be found between G' , G'' and $P_{11} - P_{12}$ ($\omega = \dot{\gamma}$) and P_{12} ($\omega = \dot{\gamma}$). Consequently, we can rewrite equation (1) in the form:

$$\frac{\eta_{\max} \times \dot{\gamma}}{F(\alpha)} \times \frac{\alpha G''}{[(\alpha^2 \times G')^2 + (\alpha G'')^2]^{1/2}} = [(2\alpha^2 G')^2 + (2\alpha G'')^2]^{1/2} \quad (2)$$

where $\alpha = \left(\frac{P_{11} - P_{22}}{2G'} \right)_{\omega = \dot{\gamma}}^{1/2}$

$$\simeq \frac{\eta(\dot{\gamma})}{\eta'(\omega = \dot{\gamma})} \quad (3)$$

Whilst $F(\alpha)$ is, in principle, a weak function of $\dot{\gamma}$, we find for many polymers^{10,11} that $F(\alpha) \simeq \alpha$, though for lower molecular weight systems such as polystyrene ($M \simeq 10^4$) and aluminium soap, $F(\alpha) = 1$, i.e. the macromolecular structure remains virtually undeformed over the entire shear gradient studied.

Further, in spite of the possible shear gradient dependence of the relationship:

$$\left(\frac{P_{11} - P_{22}}{2G'} \right)^{1/2} \simeq \frac{\eta(\dot{\gamma})}{\eta'(\omega = \dot{\gamma})}$$

equations (1)–(3) fit experimental data very well^{10,11} in the range $\dot{\gamma} > 1/\tau_{\max}$.

The emphasis in this paper is on the structural connotations of the above, particularly on the use of the expression:

$$\eta_{\max} + \Delta\eta_{\max} = \frac{\eta_{\max}}{F(\alpha)} \quad (4)$$

as a means for interpreting the shear response of viscoelastic drops or molecular domains. As noted already, η_{\max} reflects the number of entanglement points per unit structure and their distribution about a centre of mass. Further, according to the well-known Bueche theory¹², η_{\max} is proportional to the molecular weight of the polymer and to a friction coefficient, f_0 , per monomer unit. Any change in η_{\max} at gradients $\dot{\gamma} > 1/\tau_{\max}$ can therefore be construed as a change in the effective geometry of the structure, i.e. with some effective value of the gyration radius, such that: $(\bar{r}^2)_{\text{eff}} \neq (\bar{r}^2)_0$. Restating the point, only when changes in η_{\max} are observed following application of a shear gradient, can a corresponding change in the 'entanglement density', characteristic of the structure, be postulated. (We note that although our reference is the supra-molecular domain, an analogous set of statements can be made in terms of simple macromolecules and entanglements at the sub-chain level.) Experimental tests of these concepts are outlined in the following section.

EXPERIMENTAL TESTS AND DISCUSSION

Region of laminar flow

The experimental data of Carreau and coworkers¹⁴ and of others quoted by Carreau¹⁵, were used for the present

requirements. The former consider the behaviour, over a wide range of shear, of 7% aluminium laurate in decalin/*m*-cresol, (system I) and of a 2% solution of polyisobutylene in Primol 355 (system II) while the latter provides data for 4% polystyrene solutions in Aroclor 1248 (system III).

First, we consider the result of applying equation (1) to systems (I) and (III). The necessary parameters (η_{\max} , $P_{11} - P_{22}$, P_{12} , G' and G'') are given by the authors^{14,15}, making feasible a calculation of $F(\alpha)$ and hence of the sum ($\eta_{\max} + \Delta\eta_{\max}$). For convenience of presentation, we introduce the identity $\eta^+ \equiv (\eta_{\max} + \Delta\eta_{\max})$, and plot $\log \eta^+ / \eta_{\max}$ vs. $\log \dot{\gamma}$ in Figures 1 and 2. Since both systems (I) and (III) satisfy the demands of equation (3), it is reasonable to use data in our computation from both the linear and non-linear range of viscoelastic behaviour. Indeed over the 4 decades (approximately) of $\dot{\gamma}$ in which laminar flow persists, while the net solution viscosities vary by factors of about 10^3 , it is evident that the 'structural' viscosity, η_{\max} , varies by no more than a factor of 2–3. Thus, only minor changes can have occurred in the entanglement densities at the segmental level, and the large responses in the observed viscosity, a viscoelastic property, must be due to elastic effects at the domain or supra-molecular level.

We suggest that these elastic responses represent a shift from shear to normal stress effects as the principal stress axis of the flow units orients in the direction of flow. The situation can be inferred from a Mohr's circle argument¹⁶.

The instructive results of applying present concepts to system II, are shown as curves *A* and *A'* of Figure 3. Sec-

Figure 1 Dependence of 'structural' viscosity on shear rate, 7% Al soap solution. Data of Carreau et al.¹⁴

Figure 2 Dependence of 'structural' viscosity on shear rate, 4% polystyrene solution. Data of Carreau et al.¹⁴

Figure 3 Dependence of 'structural' viscosity on shear rate, 2% PIB solutions. Data of Carreau¹⁵. A, Calculations of structural viscosity using data from linear range and equation (2) (○); from non-linear range and equation (1) (■); B, calculation based on data from range of turbulent flow (▲)

tion A of the curve can be obtained by two alternative methods: the use of equation (2) and G' , G'' data from the linear range of behaviour, or by using equation (1) with $(P_{11} - P_{22})$ and P_{12} data calculated from the expression given by Bird and Carreau⁸. It is evident that in section A of Figure 3, the two approaches yield equivalent results. Application of the Bird and Carreau expression for calculations of $P_{11} - P_{22}$, P_{12} , etc. in the range $\dot{\gamma} > \dot{\gamma}_c$ yields section A' of Figure 3. This deviates sharply from curve B, denoting the fact that real and calculated normal stress data produce very different values of 'structural' viscosity in the range of unstable flow. The point is discussed further in the following section.

Thus, for diverse polymer solutions with highly non-Newtonian properties no major changes in the geometry of the macromolecule can be substantiated at shear gradients corresponding to laminar flow of the systems. For any individual macromolecule then, $(\bar{r}^2)_{\text{eff}} \approx (\bar{r}^2)_0$. Accepting the fundamental evidence for rotational motion of coiled macromolecules under shear gradients^{17,18}, we suggest that the frequency of changes in compressional and elongational force fields (proportional to $\dot{\gamma}$) is such as to require no significant change in the spacial arrangement of chain segments populating a given domain (viscoelastic drop). Therefore, in $0 < \dot{\gamma} < \dot{\gamma}_c$ (where $\dot{\gamma}_c$ is the shear rate for onset of elastic melt-fracture¹ or structural turbulence as defined by Ram²), we can find little reason for believing that individual polymer molecules uncoil, the principal mode of deformation residing instead at the interdomain level. Here, elastic energy is stored owing to the shift of the principal stress axis, as already noted above.

The slight deviations from η_{max} which can be seen in Figures 1–3, may in fact be due to changes in the density of segmental entanglements. Various causes may contribute to this relatively minor effect, including the gradual loss of solvent from the internal volume of the coiled macromolecule, as $\dot{\gamma}$ rises and the hydrodynamic volume of the coil tends to a minimum¹⁹.

Region of flow instabilities

The effects of structural turbulence² and elastic melt fracture, occurring deep in the non-linear flow regime of polymer solutions and melts, have been discussed frequently^{1,2,7,20}. Using a notation of recoverable shear strain

and working with polymer melts²⁰, Bagley noted a discontinuity in this parameter at the onset of flow turbulence and identified this flow defect as elastic in nature. A limiting value of recoverable shear (7–14 units), was found to depend essentially on the flexibility of the macromolecular chain. Philippoff²¹, working with polymer solutions, noted a similar discontinuity at the onset of turbulent flow in optical birefringence data and further noted a sharp increase in birefringence effects at very high shear strains. He attributed this feature to an uncoiling of the polymer chain.

Significantly the correlations arising from the use of our equations (1)–(3) break down for data collected in the shear gradient range $\dot{\gamma} > \dot{\gamma}_c$. As shown schematically in Figure 4, the parameters $P_{11} - P_{22}$ and P_{12} have distinct inflection points associated with this critical value of the shear gradient^{7,8,14,15}. Of the existing theories for flow behaviour at high shear gradients, only that of Meister and Biggs⁷ seems to have coped with this problem realistically. For $\dot{\gamma} < \dot{\gamma}_c$, these authors stipulate a rotational velocity $\omega = \dot{\gamma}/2$, a requirement which, they state, breaks down for $\dot{\gamma} > \dot{\gamma}_c$. A fundamental change in the rotational motion of the system's structural units apparently occurs. In the present context, the data for system (II) extend into the appropriate range of shear rate. The requirements of equation (3) are satisfied approximately, and equation (2) holds for $F(\alpha) \approx \alpha$. This time introducing real rather than calculated values of $(P_{11} - P_{22})$, P_{12} into equation (1), we now generate η^+ values which are shown in Figure 3 as curve B.

Evidently, for $\dot{\gamma} > \dot{\gamma}_c$, a major (nearly 10-fold) increase in the 'structural' viscosity η_{max} must be taken into account. From our previously introduced stipulates therefore, $(\bar{r}^2)_{\text{eff}} > (\bar{r}^2)_0$. Where primarily elastic effects associated with deformations at the level of domains were operative at $\dot{\gamma} < \dot{\gamma}_c$, it now appears that important deformations at the molecular level also occur, the individual macromolecules becoming more widely distributed about their centre of mass. We therefore suggest, in keeping with Philippoff's concept²¹, that only in the region of turbulent flow does the rotational motion of macromolecules result in significant changes of entanglement density at the level of individual chain segments.

CONCLUSIONS

(1) A simple supra-molecular domain, or viscoelastic drop model accounts for the behaviour of polymer fluids

Figure 4 Schematic view of shear rate dependence of $P_{11} - P_{22}$, (A) and P_{12} (B)

under shear gradients extending well into the region of non-linear viscoelasticity.

(2) The parameters η_{\max} , G' and G'' which characterize the systems in the region of linear viscoelastic behaviour, vary only slightly with $\dot{\gamma}$, following the correlations $2G' \rightarrow P_{11} - P_{22}$ and $G'' \rightarrow P_{12}$. Only in the area of structural turbulence (or elastic flow instability) does the η_{\max} value become a strong function of $\dot{\gamma}$ ($> \dot{\gamma}_c$). Uncoiling of the molecule, or similar deformations leading to a change in the density of segmental entanglements, is postulated for this region.

(3) In the region of steady, laminar shear flow, elastic deformations at the domain level of associations are postulated, the number of entanglement points on a molecular level being only weakly dependent, or independent of $\dot{\gamma}$.

ACKNOWLEDGEMENTS

We thank the National Research Council of Canada for financial support, and Dr P. J. Carreau for stimulating and helpful discussions.

Craze kinetics for PMMA in liquids

I. D. Graham*, J. G. Williamst and E. L. Zichy‡

(Received 9 May 1975; revised 12 January 1976)

Observations are reported on the growth of crazes in PMMA immersed in a range of alcohols, some less active crazing agents and some mixtures of methanol and inactive agents. When there is substantial plasticization of the craze, the growth is adequately described by the fluid flow model. Mixtures are also explicable in these terms since the active agent is preferentially absorbed. For lower degrees of plasticization, the craze growth is small and probably relaxation controlled.

INTRODUCTION

Several previous papers¹⁻⁴ have described a model for the growth of crazes in polymers in the presence of plasticizing environments. The criteria of craze initiation and growth rates were described in terms of stress intensity factors K involving both stress level σ and initial crack size a . The most recent work⁴ postulates that the governing factor in determining growth rate is the slower either of the relaxation processes of the polymer or the flow of the crazing fluid within the porous craze structure. The nature of the processes involved results in the initial behaviour being flow controlled while subsequent growth is relaxation controlled⁴.

For flow controlled growth the craze length x is given by:

$$x = \left(\frac{(1-m)P.C}{(1+m+n)6\mu\sigma_0 E_0} \right)^{1/2} \times K \times t^{1/2 + \frac{m+n}{2}} \quad (1)$$

where P = the pressure drop within the craze; usually atmospheric pressure 0.1 MN/m^2 ; μ = fluid viscosity. The yield stress and modulus are described as power laws of time in the form:

$$\sigma = \sigma_0 t^{-m} \text{ and } E = E_0 t^{-n} \quad (2)$$

where σ_0 and E_0 are unit time values.

The model proposes that the void area within the craze is determined by the deformation of the ligaments between void sites in the craze. If these sites have a spacing l_0 and the craze is strained to an extension ratio λ (deformed length/original length), then the void area is given by:

$$A = l_0^2 [\lambda - (\lambda)^{1/2}]$$

The void content of the craze is:

$$V = (1 - \lambda^{-1})$$

If the craze subsequently swells by a volume factor S then l_0 becomes $S^{1/3}l_0$ so that:

$$A = S^{2/3}l_0^2 [\lambda - (\lambda)^{1/2}]$$

while V remains unchanged.

λ may be estimated from the displacement applied at the craze tip:

$$u = K^2/\sigma E \quad (3)$$

and the original crack tip diameter d_0 so that:

$$\lambda = 1 + u/d_0$$

In the model described here, crazes are always formed in unplasticized (and unswollen) material so that λ is predetermined and so is V . It seems probable, therefore, that V will not change with S which will change with the fluid used, while A may well do so.

For small values of λ (i.e. < 2) we may write:

$$\begin{aligned} A &\approx S^{2/3}l_0^2 u/2d_0 \\ &= C \times u \end{aligned}$$

where

$$C = S^{2/3}l_0^2/2d_0 \quad (4)$$

Relaxation controlled growth has the form:

$$x = \frac{\pi}{8} \cdot \frac{K^2}{\sigma_0^2} (1-m)^2 \times t^{2m} \quad (5)$$

Since $m \approx n \approx 0.1$ for most polymers, we expect flow controlled growth with $x \propto t^{0.6}$ and relaxation control with $x \propto t^{0.2}$.

The craze is modelled as a line plastic zone so that the length implies an average craze stress for a given length given by:

$$\frac{a}{a+x} = \cos \left(\frac{\pi}{2} \times \frac{\sigma}{\sigma_c} \right) \quad (6)$$

so that σ_c may be determined for combinations of σ , a and x .

Previous work has used these models to describe the poly(methyl methacrylate) (PMMA)–methanol system, since it was convenient to use. In this work the ideas are explored for PMMA in various liquids; i.e. several alcohols, a set of relatively inactive liquids and then some mixtures of methanol and inert liquids.

Figure 1 Experimental arrangement

EXPERIMENTAL

The technique used has been described previously¹, and consisted of loading rectangular specimens $150 \times 50 \times 1.6$ mm thick in dead loading machines and measuring the craze growth from an initial flaw inserted in the side of the specimen. The environment was applied by means of small tanks made from microscope slides stuck onto the specimen using silicone grease and filled with a hypodermic syringe. The arrangement is shown in Figure 1. Craze growth was measured using a travelling microscope looking through the tank wall and all tests were performed at 20°C and 50% R.H.

The alcohol series methanol, ethanol, propanol and butanol, was first considered. Methanol was used originally because it gave a single craze with no evidence of surface crazing. As the series was used, the occurrence of surface crazing increased. In addition, bifurcations became more prevalent and of the form, 2 for ethanol, about 5 for propanol and 10 in butanol. It was observed that in both propanol and butanol there were coloured fringes clearly visible in the craze indicating very thin craze material.

All the crazes had a uniform silvery appearance and at low K levels growth at decreasing rates resulted in convex craze fronts as observed in methanol previously. At high K levels constant speeds could be induced with a concave craze front as described for methanol¹ and attributed to flow through the specimen sides. No description of constant speed growth will be given here other than to note its occurrence.

The relatively inert liquid series used was water, ethylene glycol, paraffin and white spirit. The last two are mixtures but of sufficient industrial interest as common crazing agents to be included. White spirit behaved as if it were just further up the alcohol scale than butanol giving 10 bifurcations and surface crazing. The other liquids all gave considerable bifurcation with many crazes formed but no evidence of surface crazing. No constant speed growth was observed and fringes were seen on all crazes.

Mixtures of 25, 50 and 75% methanol in both water and ethylene glycol were tested and there was a general trend towards the methanol behaviour as the methanol content increased. Constant speed behaviour was only found with the 25% water mixtures but with ethylene glycol, 50% mix-

tures gave some constant speed behaviour. A notable effect was that all the crazes grown in mixtures had very uneven craze fronts and a scaly appearance as opposed to the even silvery appearance in pure liquids.

VOID CONTENTS

The void content of dry crazes has been measured using changes of refractive index previously by Kambour⁵ but it was considered reasonable to observe any variation with crazing liquid. The void content may be deduced by assuming the Lorentz-Lorenz equation relating refractive index and density and if θ is the angle of total internal reflection then the void content V is given by:

$$V = \frac{\rho_0}{\rho_0 - \rho_1} \times \frac{3N}{N-1} \frac{1 - \sin^2\theta}{N \sin^2\theta + 2} \quad (7)$$

where ρ_0 = the density of the polymer; ρ_1 = the density of the liquid; N = the refractive index of the polymer. The experimental method for determining θ was a refinement of that used⁵ and consisted of a long thin tube, through which the craze was viewed, which was pivoted about an axis in the line of the craze. A protractor was also mounted on the axis and when the tube was rotated until the illuminated craze was observed to go dark, the angle of rotation could be measured. The test was performed by viewing the craze from both above and below and an average value of θ taken. Loaded crazes were used in all the liquids and at various loading levels and no appreciable variation was found with an average value of 50% as given by Kambour⁵. This indicates a similarity in craze structure independent of environment in accordance with the idea of a craze formed in unswollen material as mentioned previously.

MODELLING OF CRAZE KINETICS

In the liquids used there were clearly two types of behaviour. Water, ethylene glycol and paraffin produced very short crazes indicating high craze stresses and thus a low degree of plasticization. When craze growth was observed, the time power was generally in the region 0.2–0.3 with very rapid initial growth followed by the slow relaxation growth indicated by these powers. Careful observation was necessary to detect any flow controlled growth since the craze lengths were short ($\approx 20 \mu\text{m}$) and changing rapidly. By recording the growth on videotape it was possible to make some measurements and these gave approximately $t^{1/2}$ behaviour. The short time results, however, are not very accurate and should be treated with caution.

For the remaining liquids and mixtures the craze growths were much larger indicating considerable plasticization and in fact very good $t^{1/2}$ data was obtained indicating $m = n = 0$ followed by complete arrest of the craze. Figure 2 shows some typical data for ethanol. This is in line with Andrews' observation⁶ that the crazed polymer is swollen to a rubbery state with heavy plasticization so eliminating any viscoelastic behaviour. Figure 3 shows some data for craze arrest lengths plotted versus stress in accordance with equation (6) indicating good agreement with the line zone model. Table 1 lists the craze stress values for the liquids used and suggests that a decrease of σ_c from the air value of 100 MN/m^2 to around 33 MN/m^2 is sufficient to produce this effect.

Figure 2 Craze growth in ethanol

Table 1 also gives the slopes of the K versus $x(t)^{1/2}$ lines, the derived values of $C = S^{2/3}l_0^2/2d_0$, equation (4), and the initiation value K_m , of K . There is a clear correlation of K_m and σ_c and this is shown in Figure 4, which gives a value for the craze size at initiation from equation (6) of $11.5 \mu\text{m}$ for all fluids. This is the initial value, the condition for craze growth is that sufficient load must be applied to overload the softened craze for new craze material to form. The new craze material is then plasticized further; repetition of this sequence results in craze growth.

The newly formed voids appear in unplasticized material ahead of the softened craze and when C is calculated from equation (1), σ_0 and E_0 must refer to the unplasticized material. The data in Table 1 referring to methanol

Figure 3 Craze arrest lengths as a function of applied stress according to equation (6)

and its mixtures with water and ethylene glycol show that this concept is essentially valid assuming that in the mixtures methanol is the more active agent and controls S giving values of C between $2.41-3.15 \times 10^{-10} \text{ m}$. This indicates a practically constant material composition at the craze tip; by contrast the craze stress varies in tune with the proportion of the ingredients of the mixture.

Different C values are obtained for crazing agents other than methanol. As a first approximation one may expect a variation of C roughly parallel to the equilibrium swelling of PMMA in the crazing liquid as reflected in S . This view finds support in the observation that the ratio of C for the alcohols to C for water or hydrocarbon liquids given in Table 1 is about the same as the ratio of equilibrium swelling of PMMA in these liquids. However, this approach fails on closer examination because of its inherent oversimplification.

Table 1 Craze stress values for liquids used

Environment	σ_c (MN/m ²)	$K/x/(t)^{1/2} \times 10^3$ (MN sec ^{1/2} /m ^{5/2})	K_m (MN/m ^{3/2})	μ (cP)	$C(S^{2/3}l_0^2/2d_0)$ (Å)

Figure 4 Correlation of initiation K and craze stress

Polymers made up of ester groups along a hydrocarbon chain are essentially amphiphilic, they can react with liquids by hydrogen bonding at the ester–oxygen functions or by van der Waals forces along the hydrocarbon chain. PMMA is a good example of such behaviour as shown by the variety of liquids which can cause crazing and swelling. For example, H-bonding alcohols as well as hydrocarbons like paraffin and white spirit, which interact by van der Waals forces alone. The effect of the two interactions on the structure of the swollen polymer is not expected to be the same, because they affect different parts of the molecule. This differentiation should manifest itself especially clearly in the series of the lower alcohols, because of the gradual change of the balance between H-bonding and van der Waals interactions.

One sees accordingly considerable variations in C with the four lower alcohols. It is probably significant that the variations do not follow the sequence of the number of carbon atoms. Clearly we do not have a sufficiently detailed understanding of the polymer–liquid interactions taking place in these systems, nor of the influence on those of stress and strain. Without this knowledge any further discussion of the observed variations of C with the different

alcohols would be pointless. We have to limit ourselves to the first approximation, i.e. that C is broadly parallel to equilibrium swelling, if liquids are compared in which the equilibrium swelling of PMMA shows great differences.

The mechanical model used in fracture mechanics served us well in explaining craze propagation as long as one single crazing agent or a mixture of this agent with much less active liquids was used. The experiments reported here have shown that the material constant C is not a parameter characteristic of the polymer alone, but of the polymer liquid system. Fracture mechanics is not the framework in which the interaction of a polymer with different liquids can be discussed.

CONCLUSIONS

The use of liquids of various degrees of plasticization capacity has shown that provided there is a sufficient reduction in the craze stress (to about 1/3) then the fluid flow model is an adequate description of the behaviour. For mixtures of active and inactive liquids preferential absorption takes place of the active one. Thus there is good consistency for methanol and its mixtures. For other alcohols there is very similar behaviour but a difference in void spacing is apparent and this seems likely to be due to differences in swelling behaviour. The evidence of craze stresses and initiation behaviour is strong support for the concept that already formed crazes are softened by the liquids and that this leads to propagation.

For liquids which are less active in plasticizing the craze the experiments are difficult to perform because the crazes are very short. The growth curves are not, in general, $t^{1/2}$ and are probably relaxation controlled. The few values obtained for $t^{1/2}$ data indicate low values of void size consistent with low swelling as expected but the data are far from conclusive.

Melting of polymers in narrow annular shear devices

B. Yi and R. T. Fenner

Department of Mechanical Engineering, Imperial College of Science and Technology, London SW7 2BX, UK

(Received 24 July 1975; revised 31 December 1975)

The melting process of a compacted solid bed of polymer forced through a narrow annular shear cell has been investigated. This melting device is used in a continuous ram extruder¹, where melting rates are independent of throughput rates and are governed mainly by the tangential shear rates and heat conducted from surrounding walls. Theoretical results show that increasing shear rates promotes faster melting, but the rate at which melting accelerates slows down significantly at excessive shear rates. This is due to the reduction in polymer melt viscosity as shear rates and temperature increase in the melt film where most of the energy for melting is generated by viscous dissipation. A comparison with melting in a single screw extruder of similar size and capacity indicates that the present device may have superior performance.

INTRODUCTION

Polymers supplied to the processing industry are generally in the form of small particles. To manufacture the products, the polymer is first melted, then shaped and finally solidified. Screw extruders and screw plasticating units are the most commonly used devices for melting. The mechanism of melting in screw devices has been extensively studied² and under certain circumstances the process becomes unstable³. Screw extruders also act as melt conveyors. This pumping and the melting functions are interdependent to such an extent that often one of these functions is sacrificed for the other in commercial production.

A continuous ram extruder has been described by the authors¹ where a different method of melting and pumping polymers is employed in which these two functions can be made virtually independent of each other. The purpose of such a development was to provide a more flexible and versatile extruder, to overcome one of the major disadvantages of screw extruders. The technique relied on a positive ram conveying system for forcing material continuously through a narrow annular shear cell formed by an externally heated barrel with a concentric plasticating shaft rotating inside. The material was melted by the shear action of the shaft and heat supplied through the barrel. The plasticating action was controlled independently of the pumping system by adjusting the barrel wall temperature and the shaft speed.

A theoretical analysis of the melting process described above is developed here as a design tool with the aim of predicting the length of the shear cell necessary for melting completely the solid polymer pumped through. The theoretical model is also used for studying the effects of operating conditions on melting. It can be used for studying melting of polymers in any similar device using the same principle.

MELTING MECHANISM

Figure 1 shows a sectional view of the annular shear cell made up to the barrel with the rotating shaft inside forming a narrow annular channel. The solid polymer bed for-

med by compacted small particles is forced through the cell by an axial pressure gradient, and as it moves from left to right in the diagram, melt films are formed at the surfaces of contact with the barrel (which is heated) and the plasticating shaft. Melting is initiated by heat conducted through the barrel wall and heat generated by friction of solid polymer against the metal walls. Once the films have formed, their thicknesses increase as a result of further material melting off by heat conduction across and viscous dissipation in the melt, particularly in the film adjacent to the shaft. The molten polymer is conveyed downstream by the dragging action of the solid bed and also by pressure gradient in the polymer melts.

ASSUMPTIONS

To reduce the complexity of the problem, a rectangular coordinate system is used to describe the geometry rather

Figure 1 Annular shear cell

Figure 2 Rectangular geometry considered in theoretical model

than the more natural cylindrical coordinate system. The annulus is therefore regarded as a rectangular slit and the flow confined between two flat plates. This assumption is reasonable and errors are small provided the annulus is narrow, that is $h/D \ll 1$, where D is the internal barrel and h is the annular gap.

Figure 2 shows the geometry considered, in which the rotational speed of the shaft is replaced by an equivalent velocity V_x , in the x -direction (perpendicular to the plane of the diagram), for the lower plate.

In addition the following assumptions are made: (a) a steady state melting process prevails; (b) the polymer has a sharp melting point and linear relationships between enthalpy and temperature in the solid and the melt phases; (c) material properties other than viscosity are independent of temperatures and pressure; (d) the polymer melt is represented by a 'power-law' fluid constitutive equation with temperature dependent viscosity; (e) pressure varies in the downstream direction only and is therefore uniform across any downstream section; (f) the solid bed is assumed to be rigid enough to withstand shearing forces and moves as a plug in the downstream direction without rotating (it is, however, allowed to deform freely in the downstream direction). This assumption was later confirmed on the prototype continuous ram extruder to be valid⁴.

MATHEMATICAL MODEL

Considering a spatial element of infinitesimal length δz , conservation of mass in the film adjacent to the barrel requires that:

$$\frac{d\dot{m}_1}{dz} = \frac{C}{\Delta E_1} \left[k_m \left(\frac{\partial T_1}{\partial y_1} \right)_{y_1=0} - k_s \left(\frac{\partial T_s}{\partial y_s} \right)_{y_s=H_s} \right] \quad (1)$$

and for the film adjacent to the shaft:

$$\frac{d\dot{m}_2}{dz} = \frac{C}{\Delta E_2} \left[k_m \left(\frac{\partial T_2}{\partial y_2} \right)_{y_2=0} + k_s \left(\frac{\partial T_s}{\partial y_s} \right)_{y_s=0} \right] \quad (2)$$

where ΔE_1 and ΔE_2 are the changes in enthalpy given by:

$$\Delta E_1 = \lambda + c_s(T_m - \bar{T}_s) + c_m(\bar{T}_1 - T_m)$$

and

$$\Delta E_2 = \lambda + c_s(T_m - \bar{T}_s) + c_m(\bar{T}_2 - T_m)$$

Overall mass continuity requires that:

$$M - \dot{m}_1 - \dot{m}_2 - \dot{m}_s = 0 \quad (3)$$

The model is then completed by an equation expressing the equilibrium of forces acting in the z -direction on the solid bed:

$$\tau_1 + \tau_2 + \frac{dp}{dz} H_s = 0 \quad (4)$$

Equations (1) to (4) describe the melting process. An additional set of secondary equations must also be solved to provide values for the terms appearing in equations (1) to (4).

The temperature gradients are obtained from the temperature distribution in the material which for the melt films are given by (neglecting conduction in z -direction):

$$\rho_m c_m v_z \frac{\partial T}{\partial z} = k_m \frac{\partial^2 T}{\partial y^2} + \tau_{yz} \frac{dv_z}{dy} + \tau_{xy} \frac{dv_x}{dy} \quad (5)$$

The shear stresses and the velocity gradients in equation (5) are given by the equations of motion:

$$\begin{aligned} \frac{d}{dy} \left(\mu \frac{dv_x}{dy} \right) &= 0 \\ \frac{d}{dy} \left(\mu \frac{dv_z}{dy} \right) &= \frac{dp}{dz} = P_z \end{aligned} \quad (6)$$

where:

$$\begin{aligned} \mu &= \mu_0 \left[(dv_z/dy)^2 + (dv_x/dy)^2 \right]^{1/2} / \gamma_0 \eta^{n-1} \times \\ &\exp[-b(T - T_0)] \end{aligned}$$

Note that no subscript 1 or 2 has been used in equations (5) and (6) as they apply to both melt films. The initial and boundary conditions for these equations are (with the appropriate subscripts):

(a) for the film adjacent to the barrel:

$$T_1(y_1, 0) = T_1^*(y_1)$$

$$T_1(0, z) = T_m$$

$$T_1(H_1, z) = T_b(z)$$

$$v_{x_1}(y_1) = v_{z_1}(H_1) = 0$$

$$v_{z_1}(0) = V_{sz}$$

(b) for the film adjacent to the shaft:

$$T_2(y_2, 0) = T_2^*(y_2)$$

$$T_2(0, z) = T_m$$

$$\frac{\partial T_2(H_2, z)}{\partial y_2} = 0 \text{ (see footnote)}$$

$$v_{x_2}(0) = v_{z_2}(H_2) = 0$$

$$v_{x_2}(H) = V_x$$

$$v_{z_2}(0) = V_{sz}$$

The temperature distribution in the solid bed is given by:

$$\rho_s c_s V_{sz} \frac{\partial T_s}{\partial z} = k_s \frac{\partial^2 T_s}{\partial y_s^2} \quad (7)$$

with

$$T_s(y_s, 0) = T_s^*(y_s)$$

$$T_s(0, z) = T_s(H_s, z) = T_m$$

The solution of equations (5) to (7) provides the temperature and velocity profiles in the material. From the velocity profiles in the melt films, the flow rates are obtained as:

$$\dot{m}_i = \rho_m C \int_0^{H_i} v_{z_i} dy_i \quad (8)$$

and the shear stresses:

$$\tau_i = \mu_i \left(\frac{dv_{z_i}}{dy_i} \right)_{y_i=0} \quad (9)$$

Noting that v_{z_i} depends on V_{sz} , P_z and H_i , equations (8) and (9) may be expressed as:

$$\dot{m}_i = \dot{m}_i(V_{sz}, P_z, H_i) \quad (10)$$

and

$$\tau_i = \tau_i(V_{sz}, P_z, H_i) \quad (11)$$

In equations (8) to (11), $i = 1$ and 2 respectively for the melt film adjacent to the barrel and to the shaft.

METHOD OF SOLUTION

Using equations (10) and (11), equations (3) and (4) are expressed as:

$$f_1(V_{sz}, P_z, H_1, H_2) = 0 \quad (12)$$

The thermal boundary condition at $y_2 = H_2$ is difficult to establish without a complete analysis of the melt/metal heat transfer coupling effect. The condition used is:

$$\frac{\partial T_2(H_2, z)}{\partial y_2} = 0$$

which has been shown to be a valid assumption by Martin⁵ for Newtonian flows with the geometry and conditions considered in the present work.

and

$$f_2(V_{sz}, P_z, H_1, H_2) = 0 \quad (13)$$

If, in addition to \dot{M} , \dot{m}_1 and \dot{m}_2 are also known, then a set of values of the variables V_{sz} , P_z , H_1 and H_2 can be found to satisfy equations (12), (13) and:

$$\dot{m}_1 = \dot{m}_1(V_{sz}, P_z, H_1) \quad (14)$$

and

$$\dot{m}_2 = \dot{m}_2(V_{sz}, P_z, H_2) \quad (15)$$

which come from equation (10) with $i = 1$ and 2 .

An iterative procedure was used for calculating the values of V_{sz} , P_z , H_1 and H_2 . At the start of the solution, values for \dot{m}_1 and \dot{m}_2 were assumed. These were typically of the order of $\dot{m} \approx 0.001 \dot{M}$.

Having obtained the solution of equations (12) to (15) which also gives the solution of equations (6), the bulk mean temperatures in the expressions for ΔE are obtained as:

$$\bar{T} = \frac{\int_0^H v_z T dy}{\int_0^H v_z dy}$$

The temperature gradients are evaluated from the initially specified temperature profiles T^* and hence equations (1) and (2) integrated numerically to give a new set of values for \dot{m}_1 and \dot{m}_2 at a suitably small δ_z increment. The parabolic equations (5) and (7) are then solved using a finite-difference method and hence the temperature profiles at the same axial location are obtained. A new set of values of V_{sz} , P_z , H_1 and H_2 is calculated and the procedure is repeated until the material is completely molten when $H_s = 0$.

Starting conditions are somewhat difficult to define because at the initiation of melting, a different mechanism operates. The melt formed does not accumulate into a film until it has filled the gaps in the layers of the solid bed near the barrel and shaft. The values of $\dot{m} \approx 0.001 \dot{M}$ for starting were found to work well with the method of solution used. In fact, the general results are little affected by the initial values for \dot{m} provided these are kept relatively small, which they are in reality when the melting mechanism studied begins to function.

The initial temperature profiles assumed in the melt films were:

$$T^* = T_m + (T_r - T_m) \frac{y}{H} + \frac{\bar{\mu} V_r^2}{2k_m H} \left(1 - \frac{y}{H} \right)$$

where, for the film adjacent to the barrel:

$$T_r = T_b \text{ and } V_r^2 = V_{sz}^2$$

and for the film adjacent to the shaft:

$$T_r = \frac{\bar{\mu}_2 V_r^2}{2k_m} + T_m \text{ and } V_r^2 = V_{sz}^2 + V_x^2$$

Figure 3 Solid bed profile for $\dot{M} = 20$ kg/h, $T_b = 200^\circ\text{C}$ and $N = 120$ rev/min

T^* is the temperature profile in the drag flow of a Newtonian melt and is suitable for starting purposes.

The initial temperature profile in the solid bed T_s^* was assumed to be linear, varying from T_a at $y_s = H_s/2$ to T_m at the melting interfaces.

RESULTS

The annular shear cell size selected for performing the calculations was a 44.5 mm diameter barrel with a 3.18 mm annular gap. These are based on the prototype continuous ram extruder which has been operated successfully¹. The material properties supplied to the computer program were those for a grade of granulated low density polyethylene, and are given in Table 1. A typical throughput rate of 20 kg/h for this size of channel was assumed.

Figure 3 shows the predicted profile for the solid bed when the shaft is rotated at 120 rpm and the barrel temperature is uniform at 200°C. At this relatively high barrel temperature, the contribution of heat conduction from the barrel to melting is as significant as the heat generated by the rotating shaft. Figure 4 shows the variation of the ratio of shaft power to the total power input (shaft power + heat conducted from barrel) with operating conditions. The curves tend to flatten out with increasing shaft speed. This is due to the non-Newtonian nature and the temperature sensitivity of the polymer melt viscosity in that at higher shear rates and associated higher temperatures, the viscosity reduces and hence the amount of heat generated increases at a slower rate. Thus, for a given polymer/machine system, there is a shaft speed above which increased shear rates do not lead to corresponding increases in melting rates, and therefore resulting in little improvement to melting performance.

This aspect becomes more clear in Figure 5 where the length of channel required for the completion of melting is plotted against the shaft speed. It decreases rapidly as speed is increased from 60 rev/min, but above 240 rev/min, further increase in shaft speeds produces only a minor reduction in the melting length. Figure 6 shows that the melting length increases almost linearly with output rate.

An interesting exercise is to compare melting in the present situation with that occurring in a single screw plasticating extruder. Melting in the screw is inherently efficient in that the melt film across which most of the heat is generated and conducted for melting is kept thin by the continuous deformation of the solid bed of polymer. For this comparison, the melting model provided in ref 3 was used and the performance of a screw extruder of equivalent physical size was simulated. Details of this extruder are given in Table 2. Melting was assumed to start at the beginning of the transition zone and a barrel temperature of 200°C was assumed. To yield an output rate of 20 kg/h, a screw speed of 54 rev/min was selected to give a dimensionless flow rate of 0.5, which is a practical value found with many extruders. The dimensionless flow rate is defined as volumetric flow rate/(cross-sectional area of screw

Channel width	= 37.9 mm

channel in metering zone \times velocity component parallel to the screw flights of barrel relative to screw). The simulation has shown that the melting process in the screw is likely to become unstable at an axial location of 12 diameters where about 25% of the polymer remains unmelted. This instability is manifested in the breaking up of the solid bed producing surges in the output rate, and is detected in the simulation by a rapid acceleration of the solid bed.

Simulation of melting in the annular cell of the same material with $T_b = 200^\circ\text{C}$, $N = 54$ rev/min and $M = 20$ kg/h, shows that at an axial location of about 11 diameters from the beginning of melting, the polymer is completely molten and no significant acceleration of the solid bed occurs thus indicating that a stable melting process prevails. It should also be noted that in this case the output rate is independent of the shaft speed, whereas in the case of the screw extruder output rates are almost linearly proportional to the screw speed. The speed of 54 rev/min chosen for the shaft was to provide a shear rate of the same order of magnitude as that in the metering zone of the comparative screw extruder, and is completely independent of output rate.

CONCLUSIONS

In this work, the melting of a compacted bed of polymer particles moving through a narrow annulus subjected to tangential shear was studied. The mathematical model has been kept as simple as possible yet retaining the important features of the process. It can be applied as a powerful design tool, but solutions must be obtained numerically on a digital computer.

The melting mechanism described operates in a limited number of processing devices as yet. Basically the process is equally if not more efficient than melting in single screw extruders and should also be more stable. In addition, the independence of melting rates from throughput rates adds considerable flexibility to the process. As a consequence, it is envisaged that wider application of this method will be found in the processing industry.

D	diameter of barrel
f_1, f_2	functions in equations (12) and (13)
h	annular gap size
H	thickness of material
k_m, k_s	thermal conductivities of melt and solid
\dot{m}	mass flow rate
\dot{M}	overall throughput rate
n	power law index
N	shaft speed
p	pressure
P_z	pressure gradient
T	temperature in material
T_a	ambient temperature
T_m	melting point of polymer
T_0	reference temperature
T_r	temperature used in specifying T^*
T^*	initial temperature profile
\bar{T}	bulk mean temperature
v_x, v_z	velocities in x and z directions
V_{sz}	solid bed velocity
V_x	velocity of shaft
x, y, z	rectangular coordinates
γ_0	reference shear rate
ΔE	change in enthalpy
λ	latent heat of fusion
$\underline{\mu}$	viscosity
$\bar{\mu}$	mean viscosity
μ_0	effective viscosity at γ_0 and T_0
ρ_m, ρ_s	densities of melt and solid
τ	shear stress at melting interface
τ_{xy}, τ_{yz}	transverse and downstream shear stresses

Subscripts

1	variables related to melt film adjacent to barrel
2	variables related to melt film adjacent to shaft
s	variables related to the solid bed

ACKNOWLEDGEMENTS

The present work was carried out as part of a general project on new methods of processing polymers financially supported by the Science Research Council.

(Received 26 November 1975)

Nitroxide radicals were dispersed as paramagnetic probes in natural and acrylonitrile-butadiene rubbers, differing in the content of combined sulphur, and their molecular motions were investigated through the motion of the probe inspecting e.s.r. spectra. Broad e.s.r. spectra at low temperatures changed into sharp ones around or above T_g of the rubbers, showing the rapid narrowing of the extreme line separation of triplet spectra. From the activation energy of the rotational motion of the probe, calculated from the temperature dependence of the rotational correlation frequency, it was deduced that the self-diffusion of the probe through polymer matrices and polymer segments had occurred around or above T_g . The temperature narrowing of the line separation was correlated to the glass transition of the rubbers and a relation between the temperature narrowing, T_g and the molar volume ratio of the segment to the probe on the basis of the hole theory, was proposed. From this theory, the size of segments of the rubbers was estimated.

INTRODUCTION

The spin-probe method detects molecular motions of solid polymers through e.s.r. spectra of paramagnetic probes which are usually stable nitroxide radicals embedded in polymer matrices. Although this method is an indirect observation, it has been found by Strukov¹ that e.s.r. spectra enable us to study the molecular motions of host polymers since the motion of the probe is dominated by that of polymer matrices.

Further, Rabold² reported that this method was useful for characterizing polymers. Since then, studies have been made on the transition of rubbers³, blend polymers⁴, the crystallization of poly(ethylene terephthalate)⁵, styrene-butadiene block and random copolymers⁶, the distribution and motions of probes in polymer matrices⁷⁻⁹, latexes¹⁰, drawing^{11,12} and annealing¹³ effects on polyethylene and the surface problem of polyethylene single crystals¹⁴.

In this method, two kinds of parameters have been used to represent the motion of the probe. One of these, for instance, is the correlation frequency of tumbling motion of the probe, which can be estimated by use of the Kivelson theory¹⁵. However, the frequency range, for which this theory is valid is confined to a range of 10^9 – 10^{11} cycles/sec and the analysis of spectra often becomes difficult in practice. Another parameter is the extreme line separation of a triplet spectra of the nitroxide radical. This line separation varies with the motion of the probe owing to the averaging of the anisotropic hyperfine interaction and the anisotropy of the g -value. In almost all cases this narrowing of the line separation takes place rapidly, and the temperature at which the line separation crosses 50

gauss is defined as T_n which characterizes the polymer matrix².

Meanwhile, the motional mode of the probe in polymer matrices has not yet been clarified. In many cases the motion has been supposed to be isotropic, but in some cases it is anisotropic⁷. In a previous paper¹⁴, one of the authors has suggested that the probe possibly jumps from a hole to an adjacent one in the same manner as polymer segments do, and this jumping might be related to the narrowing of the extreme line separation mentioned above. In the present study, the motional mode of the probe was carefully taken into consideration and a theory was given on the relation between the temperature narrowing of line separation (T_n), glass transition temperature (T_g) of polymers and the volume ratio of the segment to the probe on the basis of the hole theory of the glass transition. Attempts were made to estimate the segmental size of the polymers.

EXPERIMENTAL

Materials

Natural (NR) and acrylonitrile-butadiene (NBR, nitrile content 35%, Nihon Synthetic Rubber Co.) rubbers were chosen as materials. The vulcanizing conditions are listed in Table 1. The samples contain 1 wt. % of 2-mercaptobenzothiazole and phenyl- β -naphthylamine as vulcanizing accelerator and antioxidant, respectively.

Introduction of paramagnetic probe

2,2,6,6-Tetramethyl-4-piperidinol-1-oxyl was employed as a paramagnetic probe. This was prepared as described in a previous paper¹⁴. The rubber specimens were soaked in 0.1 wt. % of xylene solution of the probe at 20°C for 10 h for specimens No. 1–4 and 24 h for No. 5–7, respectively. After soaking, the surface of specimens was lightly washed by methanol and then dried under reduced pressure for 2–3 weeks.
