A procedure similar to the above has been published by Weyland *et al.* which uses numerical increments for constitutional molecular groups to predict the glass transition temperature of polymers from the chemical structure¹⁴.

The scheme proposed in this paper is better suited for use with polyamides which Weyland *et al.* found did not conform to their general structural principles for other polymer types.

PART II: IMPACT STRENGTH, TENSILE STRENGTH AND FLEXURAL MODULUS

IMPACT STRENGTH

Two empirical relationships proposed in Part I relate (a) the asymmetry of the monomeric units to the physical nature (amorphous or crystalline) of the polyamide and (b) the chemical structure of the monomeric units to the Vicat softening point of the polyamide. The objective of the discussion below is to demonstrate that the impact strength (IS) of an amorphous polyamide is related, in a simple way, to the chemical structure, frequency of occurrence, and symmetry of the structural units in the polyamide chain. It is shown that the empirical relationships referred to above can be combined in a particular way which enables the impact strength of a polyamide to be computed with reasonable accuracy. The effect of molecular weight on impact strength has been ignored since the polyamides studied had a molecular weight level ($>20\,000$) above which their impact strength remained fairly constant.

Comparative effect of acids and diamines on impact strength

The examples of polyamides set out in Table 1 are arranged in pairs to illustrate the dependence of impact strength upon the nature of the acid(s) employed, when the diamine residues are fixed. The results of substituting one acid for another upon the impact strength is summarized in the final column of Table 1. Reference to this column will verify that the acids studied can be arranged in a particular order in which substitution increases impact strength: TPA $>$ IPA \approx AA $>$ DDA $>$ TMeSA.

The relationship between the diamine composition of the polyamide and its impact properties has been studied extensively, particularly in high impact resins containing iso- and/or tere-phthalic acids. The examples given in Table 2 are again set out in pairs, in which only the ratios of the diamines common to each pair have been varied.

An example of every possible substitution* of one diamine by another is given, and the data are arranged in five sections to show that impact strength is increased by diamine substitution in the order DMD $>$ HMD $>$ 5-MeNDA $>$ MPXD $>$ 2,2,4-TMeHMD $>$ IPD.

Monomer structure and impact strength

The significance of the comparative influence of the diacids and diamines upon the impact strength has been examined. In Part I monomers were divided into three

*Except the substitution of MPXD by DMD.

types: AM1, AM2 and AM3. It will now be convenient for the following discussion to classify all symmetric diacids or diamines studied, e.g. terephthalic acid, adipic acid, hexamethylenediamine etc., into a single group designated SM. In Part I, a symmetry index was defined by the relationship:

$$\text{Symmetry index} = 1 - \frac{\Sigma [\text{AM}]}{300} \quad (1)$$

where

$$\Sigma [\text{AM}] = [\text{AM1}] + 2[\text{AM2}] + 3[\text{AM3}] \quad (2)$$

[AM1], [AM2], [AM3] are the percentage molar concentrations of asymmetric monomers in the three groups.

The symmetry index (SI) is more conveniently calculated from the relationship:

$$SI = (3[\text{SM}] + 2[\text{AM1}] + [\text{AM2}])/300 \quad (3)$$

Each of the six diamines studied has been placed in Table 3 in the column corresponding to its symmetry group and in the row corresponding to its relative position in the order listed above (Vicat constants are quoted in parentheses). Reference to this Table indicates that impact strength is decreased by substituting a diamine with lower symmetry and/or higher Vicat constant.

The first observation was tested by plotting impact strength against the symmetry index for several series of polymers in which the composition of the acids were kept constant. Figure 1 shows linear plots of impact strength versus symmetry index, which are all statistically significant, for polydodecamides, polyadipamides, polyisophthalamides, polyterephthalamides and mixed polymers (IPA: TPA = 3:2). Furthermore, the slope of the line increases with the Vicat constant of the acid in the order TPA $>$ IPA $>$ AA $>$ DDA and confirms the conclusions drawn from Table 1.

The second observation was demonstrated by plotting the impact strength of polyterephthalamides against Vicat softening point. In spite of some variations in the symmetry index, of these polymers, (0.70–0.80) a significant relationship was obtained (Figure 2) which showed that

impact strength does increase with a decline in softening point (i.e. longer diamine chain length). The correlation between impact strength and Vicat softening point does not hold for the other series of polyamides based on other acids, the data for which covers a wider symmetry range.

The interaction between symmetry and softening point is better understood by referring to the schematic arrangement shown in Table 3. Impact strength can be decreased by substituting a diamine of higher Vicat constant from the same symmetry group or by substituting a diamine from a lower symmetry group. If the substitution is made from within the same symmetry group then a correlation

between impact strength and Vicat softening point can be expected. However, this correlation breaks down when the substitution is made from different symmetry groups. For example, the substitutions of 5-MeNDA by HMD or 2,2,4-TMeHMD by MPXD increase not only the symmetry and the impact strength but also the Vicat softening point. The effect of diacid structure on impact strength can also be appreciated better by a similar schematic arrangement (Table 4). The order in which the diacids were ranked, on the basis of the data given in Table 1 is broadly confirmed by the data plotted in Figure 1. The slope of the best straight line relating impact strength to symmetry index increases with the numerical value of the acid Vicat constant. The slope obtained in the series containing IPA is lower than would be expected, on the basis of Vicat constant only, and must be due to the asymmetry of this acid. This information is summarized qualitatively in Table 4.

The effect of amino-acids has not been studied in detail. Nevertheless, the data given in Table 5 clearly show that a reduction in impact strength occurs as the level of ϵ -caprolactam or 12-ADA in the polyamide is increased.

Prediction of impact strength

More information is needed about the interaction between monomer symmetry and Vicat constant before a quantita-

tive prediction of impact strength can be made using these parameters. Nevertheless, an empirical equation has been devised which has been applied to the experimental data with surprising accuracy. For polyamides containing symmetric acids only, equation (4) can be used.

$$\text{Impact strength} = \frac{150K}{V} [SI] V_A \quad (4)$$

where $[SI]$ is the symmetry index of the polyamide; V_A , the molar contribution of the acids to the Vicat softening point (in °C); V , the Vicat softening point (in °C) and K is a constant.

In Part I, it was shown that:

$$V = V_A + V_B = \sum m_a K_a + \sum m_b K_b \quad (5)$$

where m_a , m_b are mole fractions of diacids and diamines and K_a , K_b are contributions to v.s.p./mol of diacid or diamine.

Equation (4) is in accordance with the experimental observation discussed above.

In order to predict the impact strength of polyamides containing isophthalic acid, it has been necessary to introduce an additional assumption, viz. that impact strength depends on the sum of the products of symmetric monomer content and Vicat acid constant in the directions of the chain axis and two other planes mutually at right angles to each other and the chain axis. This equation takes the form:

$$\text{Impact strength (kJ/m}^2\text{)} = \frac{100K}{V} [\sum [SM]_x V_x + \sum [SM]_y V_y + \sum [SM]_z V_z] \quad (6)$$

where $[SM]$ is the mole fraction of symmetric monomer, and x , y , z denote each of the three non-coplanar directions. V_x , V_y , V_z are the Vicat contributions of diacids symmetrical in the planes x , y , z (°C).

Equation (6) simplifies to the form of equation (4) when only symmetric acids are employed. Both equations are applicable only if the Vicat constants are expressed in °C and are limited to those polyamides where $V_A > 0$. The direction of symmetry for each monomer was decided by its symmetry groups (SM, AMI etc.).

To avoid ambiguity, and to obtain the most accurate prediction asymmetric diacids and diamines in the same polymer were awarded the *least* number of possible coincident directions of symmetry.

The value of K in equations (4) and (5) was computed by inserting reproducibly established values of impact strength for two reference polymers (TPA/2,2,4-TeHMD = 68 kJ/m²; IPA/TPA/HMD/IPD = 46 kJ/m²) and found to approximate to unity. The equation was applied to polyamides containing amino-acids, by regarding these as completely asymmetric (Type AM3), (because they cause serious disruption to symmetry by reversing the order of amide groups along the polymer chain).

*Reference polymers

Figure 3 Relationship between the tensile strength and carbon chain length of the monomer unit in crystalline aliphatic polyamides. ○, Amino-acid homopolymers; ●, caprolactam/12-ADA copolymers; □, diamine/diacids homopolymers

The predictions made with equation (6) agree fairly well with the experimental values over a wide range of impact values. The predicted and average measured values of seventy five polyamides are compared in Table 6, for impact values ranging from 7 to 135 kJ/m². The agreement between these values was good, particularly in the range 20–80 kJ/m² but the equation tends to underestimate very high values by a substantial margin. Most of the high impact polyamides contain a substantial proportion of C₁₂-diamine, which appears to increase the impact strength rather more than it reduces softening point. The prediction of impact strength for polyamides containing amino-acids is also surprisingly good (see Table 5) and justifies the inclusion of these monomers in symmetry group AM3.

Worked examples of equation (6) are included in the Appendix. The reasonable agreement between equation (5) and experimental values indicates the impact strength of polyamides may be a constitutive property. Optimum impact strength depends on raising the symmetry of the polymer chain to the limit permitted without loss of amorphous nature, and by using a rigid acid structure alternating between flexible diamine links to absorb the shock of impact. Energy of impact is readily delocalized through the bonding in the carbonyl group, particularly when the carbonyl groups form part of a conjugated system with an aromatic ring, e.g. in terephthalamide units, and is dissipated through the long flexible diamine chains.

TENSILE STRENGTH AND FLEXURAL MODULUS

Crystalline polyamides

The tensile strength of linear crystalline polyamides is plotted as a function of the average number of carbon atoms in the monomeric unit, in Figure 3. The data were obtained from literature sources^{15–16} measured according to ASTM D238 and from measurements made in our laboratories.

A linear relationship was observed, the tensile strength decreased with increasing carbon number and was independent of whether the polyamide was derived from an amino-acid or from a diacid/diamine combination.

Amorphous polyamides

During the course of our research programme in amorphous polyamides, the tensile strength of a wide variety of formulations have been measured according to BS 2782, method 301C. The formulations which were most extensively studied contained one or more of the following monomers, each of which contained a linear backbone of six carbon atoms: adipic acid, hexamethylenediamine, a 1:1 isomeric mixture of 2,2,4- and 2,4,4-trimethylhexamethylenediamine, caprolactam. These monomers were copolymerized with at least one of the following cyclic monomers: isophthalic acid, terephthalic acid, a 7:3 mixture of *meta*- and *para*-xylylenediamines, isophorone diamine. The tensile strength of this type of formulation was found to be linearly dependent upon the molar concentration of the aliphatic monomers with a backbone of six carbon atoms, irrespective of the nature or combination of the linear monomers or of the cyclic monomers (see Figure 4). It was concluded that even substantial differences in the chemical structure of cyclic or linear monomers had relatively little effect on the tensile strength of amorphous polyamides. The tensile strength of a few amorphous polymers containing C₉- and C₁₂-monomers have been measured (see Tables 2–4, Part I). When those results are compared against those of polymers containing only C₆-aliphatic monomers it is evident that tensile strength does fall off with increasing chain length of monomer unit for amorphous polymers as well, as might be expected.

A linear relationship between tensile strength and flexural modulus (0.1% significant) was obtained by plotting values for polyamides containing terephthalic, isophthalic or adipic acids (see Figure 5). Results obtained for polyamides containing ϵ -caprolactam or 12-aminododecanoic acid did not fit this relationship.

CONCLUSIONS

The observations set out in Parts I and II demonstrate that a number of bulk physical properties of amorphous polyamides can be described by simple structural parameters which relate them to the chemical structure, symmetry and molecular concentration of the monomer units which build the polymer chain. Amorphous polyamides may therefore be regarded as an 'ideal class of polymers' because interactions between polymer chains have a negligible effect on the relationship between the chain structure and bulk properties.

Vicat softening point was shown to be a constitutive property which should be calculated from the contributions of individual constituent groups within the molecule. This treatment has been combined with a simple symmetry concept to predict impact strength in the amorphous state. It was shown that impact strength could be optimized by maintaining the highest level of structural symmetry compatible with an amorphous nature in a polymer chain composed of alternating rigid acid and flexible diamine structures. This type of structure facilitated the dissipation of shock energy along the chain, and was particularly effective when the carbonyl groups were incorporated into a delocalized π -bonding system by conjugation with an aromatic ring. It was demonstrated that on average only 20% of the monomer units need to be asymmetric for the polymer to

be amorphous, and a simple method was proposed for calculating the amorphous-crystalline transition point for structures containing monomer units with different degrees of symmetry.

The tensile strength of both amorphous and crystalline polyamides was found to depend on the average number of carbon atoms in the monomer units which comprised the polymer chain.

A statistically significant positive linear correlation was obtained between tensile strength and flexural modulus for polyamides not containing amino-acids.

By utilizing the relationships outlined in Part I and Part II of this paper, it is possible to predict the compositions of polyamides which will have an outstanding combination of physical properties.

ACKNOWLEDGEMENTS

The author gratefully acknowledges the help of Dr K. Lawrence who supervised the physical testing of polymer, and is indebted to Dr W. W. Kerr for his many useful suggestions and criticisms. Thanks are also due to Dr P. S. Thukral whose work provided much useful data on polyamides and to Dr R. C. Pitkethly who carefully checked the paper. Permission to publish this work has been given by the British Petroleum Company Limited.

$$V = V_0(1 - 0.8[\epsilon\text{-CAP}])$$

$$= 0.6 \times 245$$

$$= 147^\circ\text{C}$$

Symmetry

$$\Sigma(\text{SM})_x = (\text{SM})_{x1} + (\text{SM})_{x2} + (\text{SM})_{x3}$$

$$= 0 + 0.25 + 0$$

$$= 0.25$$

$$\Sigma(\text{SM})_x = \Sigma(\text{SM})_y = \Sigma(\text{SM})_z = 0.25$$

Vicat acid contribution

$$V_x = V_y = V_z = 0.25 \times 105 = 26.25$$

Impact strength (IS)

$$IS = \frac{100}{147} [3(26.25 \times 0.25)]$$

$$= 13.5 \text{ kJ/m}^2$$

Relative rate constants during the acidic hydrolysis of syndiotactic poly(methyl methacrylate)

V. Barth and E. Klesper

Institut für Makromolekulare Chemie, Universität Freiburg, D-78 Freiburg, W. Germany

(Received 29 April 1976)

The relative rates during acidic hydrolysis of triads of monomer units in syndiotactic methyl methacrylate/methacrylic acid copolymers in aqueous solution at different degrees of neutralization have been studied by proton n.m.r. Relative rate constants were determined by application of a graphical method to experimental and computer simulated relative rates of triads.

INTRODUCTION

When monoesters of dicarboxylic acids are hydrolysed in the acidic range, neighbouring group effects, i.e. anchimeric assistance by undissociated $-\text{COOH}$, has been found. This occurs, for instance, when an aryl group is directly bound to the carbonyl group of the ester moiety^{1,2}. While this general acid catalysis has also been found with the methyl monoester of a sterically hindered, aliphatic dicarboxylic acid, i.e. methyl hydrogen 2,3-di-(*t*-butyl)-succinate³, no such effect appears to be prominent with aliphatic monoesters of unhindered aliphatic dicarboxylic acids^{4,5}. However, it has been observed⁶ that an aryl ester with two neighbouring $-\text{COOH}$ groups shows a greatly enhanced rate of hydrolysis when partly neutralized to $-\text{COO}^-$, as compared to the fully unneutralized state. This points to a bifunctional, electrophilic-nucleophilic catalysis, which might also be operative for the acidic hydrolysis of the purely aliphatic acrylic acid/ethyl methacrylate copolymers⁷.

The apparent rate constants for the acid hydrolysis of tactic and atactic methyl methacrylate/methacrylic (MMA/MAA) copolymers have previously been studied by Smets^{8,9} by following the gross conversion with time at different degrees of neutralization. The rates were explained by simultaneous general acid and nucleophilic catalysis of $-\text{COOH}$ and $-\text{COO}^-$ respectively, the two catalysis mechanisms being largely independent. In the present communication we have investigated the relative rate constants of individual triads for the acidic hydrolysis of syndiotactic MMA/MAA copolymers of different degrees of neutralization by following gross conversion and change of triad probabilities by proton n.m.r.

EXPERIMENTAL

The kinetic runs were carried out as previously described¹⁰, except that with the syndiotactic, Bernoullian copolymer of $P(\text{A}) = 0.60$ for each 250 mg copolymer 1.5 mmol KOH were employed in the dissolution step and part of the KOH neutralized by titration with HCl before starting the hydrolysis, as indicated in *Figures 1* and *2*. Alternatively, runs with this copolymer were carried out in a mixture of 8 ml aqueous base and 4 ml dioxane instead of 12 ml

aqueous base for each 250 mg of starting copolymer*. The $P(\text{A})$ and $P(\text{XXX})$ were evaluated from the $\alpha\text{-CH}_3$ $^1\text{H-n.m.r.}$ resonance as before¹⁰.

For studying the reversibility of the acidic hydrolysis, 250 mg of syndiotactic poly(methacrylic acid) (PMAA) (2.91 mmol) was dissolved in 3 ml of 1 N KOH and 3 ml H_2O at 115°C . The syndiotactic PMAA was prepared by repeated hydrolysis of syndiotactic PMMA in concentrated H_2SO_4 ¹². After dissolution, 3 ml of 1 N HCl and 0.1 ml methanol (2.5 mmol) were added and the total volume brought up to 12 ml. After 144 h at 145°C a small degree of esterification of $P(\text{A}) \approx 0.01$ could be detected. The experiment was repeated adding only 1.5 ml of 1 N HCl because partly neutralized copolymer showed a greater rate of hydrolysis than unneutralized copolymer¹³. The degree of esterification was, however, not increased.

The homogeneity of the copolymers with respect to $P(\text{A})$ and $P(\text{XXX})$ was tested after acidic hydrolysis at 145°C . Starting with the Bernoullian copolymer of $P(\text{A}) = 0.83$ and 0.5 mmol KOH per 250 mg starting copolymer, the hydrolysis was stopped after 144 h at $P(\text{A}) = 0.40$. The resulting copolymer (500 mg) was fractionated from aqueous solution by incremental addition of HCl¹². Two fractions of approximately equal weight were obtained (fraction first precipitated 284 mg, final fraction 204 mg) which had the same $P(\text{A})$ and $P(\text{XXX})$. Therefore the measured data are representative of the individual chain. The fractionation was repeated starting with a copolymer of $P(\text{A}) = 0.60$ and 0.5 mmol KOH per 250 mg starting copolymer and hydrolysing for 72 h to $P(\text{A}) = 0.23$. Again, two fractions were obtained which had the same $P(\text{A})$ and $P(\text{XXX})$.

The accuracy of the determination of $P(\text{A})$ for a large number of copolymers was checked by total esterification with diazodiphenylmethane $[(\text{C}_6\text{H}_5)_2\text{CN}_2]$ ¹⁵. The copolymers were dissolved in dioxane and twice the stoichiometric amount of diazodiphenylmethane in dioxane added. After refluxing until the violet colour of the diazo compound had disappeared, the same amount of reagent was added and refluxing continued until the colour had turned again.

* In the latter case only the desired amount of KOH was used in the dissolution step, no backtitration being required before the run.

Figure 1 Dependence of triad probabilities, $P(AAA)$, $P(ABA)$, $P(AAB^+)$, $P(ABB^+)$ on conversion during the hydrolysis of a syndiotactic, Bernoullian copolymer of initially $P(A) = 0.60$. Data are from runs with different initial amounts of KOH for 250 mg copolymer in H_2O or H_2O /dioxane solution. \circ , 1.5 mmol KOH + 1.25 mmol HCl; \square , 1.5 mmol KOH + 1.00 mmol HCl; \triangle , 1.5 mmol KOH + 0.75 mmol HCl; ∇ , 1.5 mmol KOH + 0.50 mmol HCl; \bullet , 0.25 mmol KOH + 4 ml dioxane; \blacksquare , 0.50 mmol KOH + 4 ml dioxane; \star , 0.75 mmol KOH + 4 ml dioxane; \star , 1.00 mmol KOH + 4 ml dioxane. —, Calculated Bernoullian triad probabilities

After precipitation with methanol the fully esterified product was soluble in $CHCl_3$. The copolymer was reprecipitated from $CHCl_3$ solution with methanol and dried at $50^\circ C$ *in vacuo*. The 1H -n.m.r. spectra were recorded from $CHCl_3$ solution at $60^\circ C$ and $P(A)$ evaluated by:

$$P(A) = \frac{(5/3)I(-OCH_3)}{I(-CH_2-) + I(-CH_3)} \quad (1)$$

$$P(B) = 1 - P(A) = \frac{(5/11)I(-CH(C_6H_5)_2)}{I(-CH_2-) + I(-CH_3)} \quad (2)$$

where I are the relative areas of the resonances indicated in parentheses. The $P(A)$ values of equations (1) and (2) agree with each other and the $P(A)$ obtained directly from the precursor MMA/MAA copolymer to within ± 0.01 .

RESULTS AND DISCUSSION

In two previous communications^{10,11} the rates and rate constants as well as the relative rates and relative rate constants of triads have been studied for the hydrolysis of syndiotactic methyl methacrylate/methacrylic acid (MMA/MAA) copolymers of Bernoullian compositional statistics. The hydrolysis was carried out in aqueous solution, predominantly at $145^\circ C$, with more KOH than necessary to neutralize all carboxyl groups of the MAA-units, either present at start or formed during the hydrolysis. In the present study

Figure 2 Dependence of triad probabilities $P(BAB)$ and $P(BBB)$ on conversion starting with a copolymer of initially $P(A) = 0.60$. Data were obtained with different initial amounts of KOH in H_2O or H_2O /dioxane solution. Symbols as in Figure 1. Calculated Bernoullian triad probabilities shown for comparison (—)

Figure 3 Dependence of dyad probabilities, $P(AA)$, $P(AB^+)$ and $P(BB)$ on conversion. Data derived from curves of best fit in Figures 1 and 2. Calculated Bernoullian dyad probability $P(AA)$ shown for comparison and labelled $P(A)^2$. \circ , $P(AA)$; \square , $P(AB^+)$; \triangle , $P(BB)$

the amount of KOH was reduced to investigate the hydrolysis in the acidic range. Starting with a copolymer of $P(A) = 0.60$ ($A = \text{MMA}$, $P(A)$ is the probability of finding an A monomer unit) 1.06 mmol KOH is required for a 250 mg aliquot of copolymer in 12 ml H_2O to neutralize all the MAA-units at $t = 0$. Accordingly, runs were carried out with 1.0, 0.75, 0.50 and 0.25 mmol KOH at $t = 0$. All kinetic measurements were carried out in KOH, because the copolymer is insoluble in water. Because of slow dissolution, the copolymer was dissolved in excess KOH (1.5 mmol) and then titrated with HCl to the desired amount of KOH. Other kinetic runs were carried out by substituting one third of the volume of water by dioxane (4 ml), adding only the desired amount of KOH without titration with HCl. An additional reason for using dioxane is the possibility that the limited solubility of MMA/MAA copolymers in purely aqueous solution with small amounts of KOH may lead to the formation of aggregates, e.g. microgels, which in turn might influence the kinetics. It was found, however, that the kinetic results are almost the same with or without dioxane.

In Figures 1 and 2 the conversion dependent behaviour of the six possible triads is shown. The triad probabilities, $P(XXX)$, ($X = A, B$) and the conversion parameter, $P(A)$, have been determined by ^1H -n.m.r. at 220 MHz¹⁰. The points represent the experimental data, while the curves

of best fit have been drawn on the basis of generally valid statistical relations¹⁰. Barring the experimental scatter, all points trace out the same curve, regardless of the degree of neutralization or whether pure water or water/dioxane was the hydrolysis medium. Thus at a given $P(A)$

$$\left[\frac{dP(AA)}{dP(A)} \right]_{\alpha_1} = \left[\frac{dP(AA)}{dP(A)} \right]_{\alpha_2}$$

where α_1 and α_2 are any two degrees of neutralization, or in more general terms, states of ionization. From equation (15) of ref 10 this gives for a given $P(A)$:

$$\frac{-2k'(AAA)_{\alpha_1}P(AAA) - k'(AAB^+)_{\alpha_1}P(AAB^+)}{N_{\alpha_1}} = \frac{-2k'(AAA)_{\alpha_2}P(AAA) - k'(AAB^+)_{\alpha_2}P(AAB^+)}{N_{\alpha_2}} \quad (3)$$

the $k'(XAX)$ being relative rate constants and

$$N_{\alpha} = -k'(AAA)_{\alpha}P(AAA) - k'(AAB^+)_{\alpha}P(AAB^+) - k'(BAB)_{\alpha}P(BAB) \quad (4)$$

Because the $P(XAX)$ at a given $P(A)$ are shown to be the same at α_1 and α_2 , equation (3) leads to:

$$k'(XAX)_{\alpha_1} = k'(XAX)_{\alpha_2} = k'(XAX) \quad (5)$$

at a given $P(A)$. Thus the $k'(XAX)$ are invariant with α but may depend on $P(A)$.

Equation (15) of ref 10 is valid for irreversible, overall first order and overall second order reactions of triads. However, some other conceivable models for the polymer analogous reaction would also give equation (5) considering Figures 1 and 2.

Comparison of the data in Figures 1 and 2 with the calculated Bernoullian $P(XXX)$ indicates that the copolymers change from Bernoullian to block character during the course of hydrolysis. This finding is corroborated by the behaviour of dyads in Figure 3. The $P(XX)$ of Figure 3 (points) have been obtained from the broken curves of Figures 1 and 2, applying the principle of stationarity at intervals of $P(A) = 0.05$. The block character indicates that the carboxyl groups in different ionization states which are next neighbours to MMA units partake in the mechanism of the hydrolysis of these MMA-units. Figures 1 and 2 also show that the hydrolysis may be almost complete which would not be possible if the reaction was significantly reversible. The essential irreversibility of the reaction has also been shown using syndiotactic poly (methacrylic acid) with a corresponding amount of methanol (see experimental section). It has been demonstrated that the $P(XXX)$ measured by n.m.r. represent the probabilities for individual chains by fractionating the copolymers by a procedure which was previously shown¹² to fractionate according to $P(A)$.

In Figure 4 the graphically determined slopes $dP(XX)/dP(A)$, are shown for the $P(XX)$ versus $P(A)$ plot of Figure 3. A triple ordinate is employed as before¹⁰ for averaging the errors which originate by the deviations of the $P(XX)$ versus $P(A)$ curves from the principle of stationarity and/or by the graphical evaluation of slopes. As

Figure 4 Slopes $dP(XX)/dP(A)$ of $P(XX)$ versus $P(A)$ curves of Figure 3. Diagonal is $2P(A)$, valid for a hypothetical hydrolysis with $k'(AAA) = k'(AAB^+) = k'(BAB) = 0.33$. Shaded areas F_1 and F_2 as an additional test for correct slope measurement. Δ , $dP(BB+)/dP(A)$ vs. $P(A)$; \square , $dP(AB^+)/dP(A)$ vs. $P(A)$; \circ , $dP(AA)/dP(A)$ vs. $P(A)$

to be expected¹⁰, the ratio of areas $F_1/F_2 = 0.96$ is close to 1 in Figure 4.

Besides using a Bernoullian copolymer of $P(A) = 0.60$ (copolymer no. 9 of Table 4 in ref 10) with different initial α , a Bernoullian copolymer of $P(A) = 0.83$ was employed (copolymer no. 6 of Table 4 in ref 10) as a starting material. Using 0.5 mmol KOH initially, $\alpha = 1$ is reached almost immediately during the run. With 1.0 mmol KOH, however, the hydrolysis progresses first by attack of OH^- . At the point of consumption of OH^- ($\alpha = 1$), the hydrolysis continues by the acidic mechanism. Correspondingly, with 1.0 mmol KOH only the part of the data obtained by acidic hydrolysis is of relevance here. The $P(XAX)$ versus $P(A)$ data obtained with a starting copolymer of $P(A) = 0.83$ have already been discussed in connection with the change of mechanism from the basic to the acidic range¹⁰. The evaluation of $P(XX)$ and $dP(XX)/dP(A)$ was carried out analogously to that of the starting copolymer of $P(A) = 0.60$. No data are available with different α at the beginning of the acidic hydrolysis, contrary to the case of the starting copolymer of $P(A) = 0.60$. However, for the evaluation of the $k'(XAX)$ one may find for a given $P(A) - \alpha$ state during a run starting from $P(A) = 0.83$, the same state for the runs starting from $P(A) = 0.60$ if the first runs have reached $P(A) = 0.60$ or below and if the latter runs are considered to be invariant with α .

For the determination of the relative rate constants equation (20) of ref 10 was used. The intersections of the corresponding straight lines in the $k'(AAA)$ versus $k'(AAB^+)$ plot demonstrated that the values for $k'(AAA)$ are only small, while the $k'(AAB^+)$ are larger. Using all available $P(XAX)$ and $dP(AA)/dP(A)$ data, the data were replotted therefore in the equivalent $k'(AAB^+)$ versus $k'(BAB)$ diagram by means of equation (6).

$$k'(AAB^+) = C_1 + C_2 k'(BAB) \quad (6)$$

$$C_1 = - \frac{(S - 2)P(AAA)}{S[P(AAB^+) - P(AAA)] + 2P(AAA) - P(AAB^+)} \quad (7)$$

$$C_2 = \frac{(S - 2)P(AAA) - SP(BAB)}{S[P(AAB^+) - P(AAA)] + 2P(AAA) - P(AAB^+)} \quad (8)$$

where $S = dP(AA)/dP(A)$. In the corresponding plot of Figure 5 the first arabic numeral indicates the runs from which a given line originates, i.e. (1) initial $P(A) = 0.83$, with 0.5 mmol initial KOH; (2) $P(A) = 0.83$, with 1.0 mmol KOH, and (3) $P(A) = 0.60$, with 1.0, 0.75, 0.50 and 0.25 mmol KOH. The second numeral indicates the $P(A)$, e.g. 6 means $P(A) = 0.60$. Lines of the same run exhibit usually only small differences in slope, their intersects are therefore less reliable. However, lines belonging to different runs possess often less acute angles at their intersects. Nevertheless the latter intersects scatter also in a relatively large range of $k'(XAX)$ reflecting significant inaccuracy of the data. Taking the average of the intersects results in $k'(BAB) \approx 0.80$, $k'(AAB^+) \approx 0.15$ and $k'(AAA) = 1 - k'(AAB^+) - k'(BAB) \approx 0.05$. From these values it appears already that the acidic hydrolysis of A monomer units relies primarily on the attack of neighbouring B-units. This is in contrast to the hydrolysis with base where the attack of OH^- is retarded by neighbouring B due to electrostatic repulsion between OH^- and negatively charged B.

The ratio $k'(BAB)/k'(AAB)$ is much larger than two, which indicates that neither general acid catalysis by $-\text{COOH}$ nor nucleophilic catalysis by $-\text{COO}^-$ alone or simultaneously are primarily responsible for the hydrolysis. A concerted electrophilic-nucleophilic catalysis by $-\text{COOH}$ and $-\text{COO}^-$ seems to be operating. This conclusion is supported by the time dependent rates which exhibit a maximum between $\alpha = 0$ and $\alpha = 1$ ¹³.

In order to demonstrate that the similar slopes for a given run in Figure 5 are a property of the statistics of monomer units for the runs in question, several runs of 1000 monomer units each were simulated by computer as previously described¹⁴. The simulated runs started from the homo-

Figure 5 Relative rate constants $k'(AAB^+)$ versus $k'(BAB)$ according to equation (6). Lines identified by type of run (first digit) and $P(A)$ (second digit). Runs 1 and 2 start from $P(A) = 0.83$ with 0.5 and 1.0 mmol KOH in H_2O , respectively. Run 3 starts from $P(A) = 0.60$ with different amounts of KOH in H_2O or $\text{H}_2\text{O}/\text{dioxane}$

Figure 6 Relative rate constants $k'(AAB^+)$ versus $k'(BAB)$ according to equation (6) from the block-like part of computer runs of 1000 monomer units simulated with $k'(AAA) = 0.01$, $k'(AAB^+) = 0.10$, $k'(BAB) = 0.90$. Curves for values of $P(A)$ 0.25–0.65 are shown in the Figure

polymer with the Bernoullian set of relative rate constants $k'(AAA) = k'(AAB^+) = k'(BAB) = 0.33$ until $P(A) = 0.67$ was reached. The set of rate constants was changed at this point to $k'(AAA) = 0.01$, $k'(AAB^+) = 0.09$, $k'(BAB) = 0.90$ which is similar to the experimentally found set of rate constants. The resulting block part of the simulated curves of $P(XXX)$ was evaluated in analogy to the experimental curves yielding the $k'(AAB^+)$ versus $k'(BAB)$ plot of Figure 6. The random errors incurred with 1000 monomer units amount to $\Delta P(XXX) = \pm 0.01$ selecting individual runs at random at a given $P(A)$, and as compared to the average of a larger number of runs with 1000 monomer units each. This error, and the errors in drawing curves

through the selected points, as well as in measuring the slopes of the curves, suffice, in conjunction with the small slope differences of the straight lines in Figure 6, to distribute the intersects over a relatively large range. Thus a plot of the type of Figure 6 indicates the errors inherent in the evaluation of $k'(XAX)$, including the random errors in measuring the $P(XXX)$. Comparison with a plot of the type of Figure 5 indicates then the magnitude of the systematical errors in measuring $P(XXX)$ and/or the possible true variation of the $k'(XAX)$, provided the $k'(XAX)$ are the same or similar between the Figures.

Phosphonitrilic chloride : polymerization behaviour of some hexaalkoxycyclotriphosphazenes

M. Kajiwara, Y. Mori, and H. Saito

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

(Received 6 February 1976)

Electron conductivity of hexaalkoxycyclotriphosphazenes $N_3P_3(OR)_6$ is temperature dependent; the conductivity of the n-propoxy derivatives is dramatically raised at elevated temperature. $\tan \delta$ values of hexa-n-propoxy- and hexa-n-butoxy-cyclotriphosphazene increase appreciably at room temperature at high frequency. A chemical shift with ^{31}P -n.m.r. spectra of hexa-n-propoxycyclotriphosphazene appears at the lowest field compared with other hexaalkoxycyclotriphosphazenes. Dipropyl ether or dibutyl ether, respectively, were detected when hexa-n-propoxy- or hexa-n-butoxy-cyclotriphosphazene were heated. It is assumed that a polymerization rather than a rearrangement reaction occurs on heating with the elimination of ethers.

INTRODUCTION

The preparation of hexaalkoxycyclotriphosphazenes¹⁻³ and their pK'_a values have been reported^{4,5}. Shaw *et al.*⁶⁻⁸ observed that some hexaalkoxycyclotriphosphazenes are transformed to *N*-alkylcyclotriphosphazenes under certain conditions. Godfrey⁹ found that hexa-n-propoxycyclotriphosphazene is the best flameproofing agent of the series for rayon, and many patents¹⁰ describe its use for this purpose. In this paper some characteristic properties of several hexaalkoxycyclotriphosphazenes are presented.

EXPERIMENTAL

Materials

Hexachlorocyclotriphosphazene $(NPCl_2)_3$ was prepared by the modified method of Kajiwara¹². Pure trimer was obtained by repeated fractional crystallization from light petroleum.

Hexaalkoxycyclotriphosphazenes $N_3P_3(OR)_6$ (R = CH_3 , C_2H_5 , $n-C_3H_7$, $n-C_4H_9$) were prepared by the method of Shaw¹.

Methods

Ultra-violet spectra were measured with a Hitachi-124 type spectrometer in n-hexane, methanol and ethanol. ^{31}P -n.m.r. spectra were measured with a Nihon Denshi JNMC-60HL type spectrometer using dioxane as solvent and H_3PO_4 as standard. Electron conductivity measurements were carried out following the method of Kajiwara¹³ and dielectric constants were measured with a Shibayama Kagaku SS-802 type apparatus.

RESULTS AND DISCUSSION

The u.v. characteristics of hexaalkoxycyclotriphosphazenes are summarized in Table 1. The maximum absorption of hexaalkoxycyclotriphosphazenes appears at 215–217 nm in n-hexane. The maxima are not shifted with different

alkyl groups, but they change their position in methanol or ethanol. A slight blue shift is due to $n-n^*$ of nitrogen atoms rather than to $\pi-\pi^*$ transitions in the triphosphazene ring.

Dipole moments may indicate the planarity or non-planarity of a ring system. Results for some hexaalkoxycyclotriphosphazenes determined by dielectric constant measurements are given in Table 2.

High dipole moments suggest the presence of a relatively inflexible ring at 25°C whereas low dipole moments are consistent with a slightly planar ring at 95°C. Differences in dipole moments directly attributable to side groups have not been observed.

The $\tan \delta$ curves for some hexaalkoxycyclotriphosphazenes at room temperature are shown in Figure 1.

At lower frequencies a decrease in $\tan \delta$ results from dipole relaxation, deformation or electron polarization losses. At high frequencies an increase in $\tan \delta$ for hexa-n-

propoxy- or hexa-*n*-butoxy-cyclotriphosphazene is attributed to an ion split off from their R groups. However, this is not observed with hexamethoxy- or hexaethoxycyclotriphosphazene. The electron conductivity of some hexaalkoxytriphosphazene (Table 2) shows that the conductivity of hexa-*n*-propoxycyclotriphosphazene shows the largest increase with increasing temperature. Allcock and Best¹¹ found that above 200°C the conductivity of molten hexachlorocyclotriphosphazene increased dramatically with temperature, and ascribed this to dissociation of chloride ion from phosphorus, with concurrent polymerization of the trimer. Consequently, the highest conductivity of hexa-*n*-propoxycyclotriphosphazene obtained at 120°C is attributed to dissociation of an ion from R groups in hexa-*n*-propoxycyclotriphosphazene.

As shown in Table 3 ³¹P-n.m.r. spectra of some hexaalkoxycyclotriphosphazenes display a singlet peak, and the chemical shift of hexa-*n*-propoxycyclotriphosphazene appears at the lowest field. For this reason, it is believed that the electron density around phosphorus atoms is lowered by the deshielding effect, i.e. the electron may centre on nitrogen atoms.

A change in viscosity of some hexaalkoxycyclotriphosphazenes on heat treatment is shown in Figure 2.

It can be seen that the viscosity of hexa-*n*-propoxycyclo-

triphosphazene rapidly increases with temperature, and a crystalline product, *N*-ethylcyclotriphosphazene having a melting point of 61°C is obtained from hexaethoxycyclotriphosphazene.

The molecular weights of hexaalkoxycyclotriphosphazenes increases on heating as shown in Figure 3. The rapid change with hexa-*n*-propoxycyclotriphosphazene parallels the corresponding increase in viscosity.

The products formed from hexa-*n*-propoxycyclotriphosphazene on heating were collected in a glass tube cooled by dry ice, and were identified by gas chromatography or ¹H-n.m.r. spectra as propyl ether or butyl ether; other products were not observed.

From the analytical data it can therefore be estimated that polymerization rather than rearrangement becomes the predominant reaction on heating hexa-*n*-propoxycyclotriphosphazene or hexa-*n*-butoxycyclotriphosphazene.

Consequently, it can be presumed that the polymerization reaction proceeds as follows:

R = *n*-CH₂CH₂CH₃, *n*-CH₂CH₂CH₂CH₃

(Received 2 April 1976; revised 24 May 1976)

Isotactic polymers of optically active and racemic 4-methyl-1-hexene, obtained by polymerization with Ziegler–Natta catalysts, were studied by ^{13}C n.m.r. Polymer fractions with different stereoregularity and molecular weight, derived from the monomer with high optical purity, show in their ^{13}C n.m.r. spectra differences which are tentatively associated with possible conformation effects. Stereoselectivity is observed in polymers obtained from the racemic monomer.

INTRODUCTION

The investigation of the microstructure of vinyl polymers from chiral olefins led to a better knowledge of the nature and mechanism of steric control in stereospecific¹ and stereoselective^{2,3} polymerizations. Moreover information on the relation between microstructure and conformation in solution was obtained by studying chiroptical properties of the above polymers and by comparing experimental values of rotatory power with the calculated ones, according to Brewster's method⁴. For the detailed determination of the macromolecular conformation in the solid state, X-ray studies were essential. In the case of poly[(*S*)-3-methyl-1-pentene]⁵ and poly[(*S*)-5-methyl-1-heptene]⁶, the crystal structure shows the existence of macromolecules having helical conformation with the left screw sense only, while for poly[(*S*)-4-methyl-1-hexene] main chain helical conformation of both screw senses has been found in the stable form, a second metastable form existing with the left handed screw sense only⁷. Statistical models^{8–11} in addition allowed one to obtain indications of the most probable conformation in solution. All the authors agree on the general feature of the model which consists of a succession of main chain sections spiralled in both the possible screw senses with one screw sense largely prevailing. N.m.r. has proved to be a powerful tool for studying configuration and conformation of polymers in solution, and we have therefore examined 4-methyl-1-hexene polymers obtained with Ziegler–Natta catalysts by ^{13}C n.m.r. The results constitute the object of the present paper.

EXPERIMENTAL

Monomers

(*S*)-4-methyl-1-hexene, (*R*)-4-methyl-1-hexene with different optical purity and racemic 4-methyl-1-hexene were obtained as described previously^{12,13}.

Polymers

Polymerization experiments were carried out in the presence of TiCl_3 'ARA', or VCl_4 and $\text{Al}(\text{iso-C}_4\text{H}_9)_3$, and the polymers obtained were fractionated by extraction with different solvents as previously reported¹⁴. In Table 1 the characteristics of some typical analysed samples are collected.

Polymers were characterized by their optical rotation at 589 nm, viscosity-average molecular weight, and crystallinity by X-rays.

^{13}C n.m.r. spectra were run on 5% solutions in CDCl_3 at room temperature and at 70°C, on a Varian FTXL 100 and on a Bruker HF90, using TMS (tetramethylsilane) as an internal reference. The spectral conditions were as follows: spectral width, 5000 Hz; acquisition time, 0.4 sec; pulse width, 30 μsec ; sensitivity enhancement factor, 0.3 sec; K transients 10 to 50. The results obtained with the two spectrometers were absolutely reproducible.

RESULTS AND DISCUSSION

Assignment of the spectra

The ^{13}C n.m.r. spectrum of poly[(*S*)-4-methyl-1-hexene] (sample E_{1,2}, Table 1) is given in Figure 1. Apart from variation of the intensities, and the width of the lines of the two signals at 11.51 and 31.72 ppm, all polymers from monomers having high optical purity show identical spectra.

Let us consider the monomeric residue:

Table 1 Properties of the poly(4-methyl-1-hexene) samples obtained from optically active and racemic monomer analysed by ¹³C n.m.r.

Monomer absolute configuration	Polymeric sample	Catalyst	Fraction

Table 2 Assignment of ¹³C n.m.r. spectra of poly(4-methyl-1-hexene) obtained from high optical purity and racemic monomer

Assignment	Average δ-value (ppm) of the signals observed for polymer from:		
	Optically active monomer	Racemic monomer	Calculated δ-value (ppm)
C _a	11.51	11.41	10.87
C _b	31.13	*30.87†	29.60
C _c	31.74	*31.72†	32.52
C _d	19.52	19.59 20.35	19.63
C _e or C _g	42.77 broad	43.00	41.67
C _f	29.72	*30.00 broad high intensity	30.84
C _g or C _e	41.20 broad	41.70 intensity	39.98

*In the 30.00 ppm band of the polymer from racemic monomer, peaks due to C_b and C_c should overlap the C_f signal due to very strong intensity of this band; †with other signals at 30.00 ppm

The assignment of the peaks is made accordingly to the rules of Lindemann and Adams¹⁵, as well as on the basis of 'Off Resonance' experiments (Table 2).

The three signals at 29.70 ppm, 31.13 ppm and 31.70 ppm are due to the methine carbons C_f and C_c and to the

methylenic C_b respectively. The assignment of the peak at 31.13 ppm to C_b was obtained by an 'Off Resonance' experiment. The assignment of the peaks at 29.70 ppm and 31.70 ppm to methines C_f and C_c respectively is made on the basis of the application of Lindemann and Adams rules, and is supported by the observation that in polymers obtained from the racemic monomer, which show quite different spectra due to the broadening and overlapping of some resonances (Figure 2), the signal at 29.70 ppm does not change while the signal at 31.70 ppm is split; this splitting (present also in the signals due to C_d and C_b) can be related to the variation in the configuration of the asymmetric carbon atom C_c (see Table 2).

The peaks at 41.20 ppm and 42.70 ppm, due to methylenic carbon atoms C_e and C_g cannot be assigned unequivocally because of their broadness in all the samples examined*. Clearly optically active polymers obtained from the (R) monomer show spectra identical to those obtained from the (S) monomer¹⁶.

Conformational effects on poly[(S)-4-methyl-1-hexene]

In Figure 3 spectra of fractions of poly[(S)-4-methyl-1-hexene], extracted with diethyl ether and cyclohexane, run at room temperature and at 70°C are reported. The polymers, previously extracted with acetone and ethyl acetate, have a rather high isotactic content.

The spectra of different fractions, run at the same temperature, show some peculiar differences. The resonance line due to C_c, at 31.72 ppm and to a lesser extent that due to C_a at 11.41 ppm, show different line widths which seem to indicate a difference in the correlation times. If this difference in the spectra were due to differences of steric configuration about carbon C_f, one might expect that the signal due to this carbon atom would be split at least in the less stereoregular fraction. However it would seem that the more affected resonances are for C atoms (C_a and C_c) quite far away (6 and 4 bonds) from the hypothetical centre of irregularity C_f. Because of the high optical purity of the monomers used, and the very close values of the optical rotation of the two fractions, conformational effects on the side chain must be ruled out.

Consequently a possible explanation should be related to conformational effects on the side chain; different con-

* These assignments are confirmed recently by the elegant work of Neuenschwander in which the assignments of the methine carbons were obtained with ¹³C enriched (in position f) monomers. *Makromol. Chem.* 1976, 177, 1231
We thank Professor P. Pino and Dr P. Neuenschwander, for sending us the manuscript before publication.

Figure 2 ¹³C n.m.r. spectrum of poly[(*R*)(*S*)-4-methyl-1-hexene (sample E_{70,3}) at room temperature

formers for units of poly[(*S*)-3-methyl-1-pentene]⁵ and poly[(*S*)-4-methyl-1-hexene]⁷ have been observed in the solid state.

The similarity of the spectra at 70°C of sample E_{5,3} and of the spectra of sample E_{5,2} at room temperature strongly support this explanation.

Taking into account the slight stereoregularity difference between examined samples it might be possible that the extraction is controlled by molecular weight. So far it cannot be excluded that steric defects are present in similar amounts but have different distribution in the two fractions.

Configurational effects

Let us consider isotactic polymers obtained by polymerization of racemic 4-methyl-1-hexene with a Ziegler–Natta catalytic system or more generally isotactic polymers in which macromolecules consisting of both the monomer enantiomers may be present.

With respect to the side chain asymmetric C atom which can have *R* or *S* configuration, it is possible to have in terms of triads the following situation:

- | | |
|--------------|--------------|
| <i>R R S</i> | <i>R S S</i> |
| (1a) | (1b) |
| <i>S R R</i> | <i>S S R</i> |
| (2a) | (2b) |
| <i>S R S</i> | <i>R S R</i> |
| (3a) | (3b) |
| <i>R R R</i> | <i>S S S</i> |
| (4a) | (4b) |

The triads a and b are equivalent being in an enantiomeric relation.

The spectrum of the E_{70,3} sample (Figure 2) shows the splitting of the resonances due to the methyl C_d in three different peaks at 19.59 ppm, 19.94 ppm, 20.35 ppm. The analysis of these peaks in terms of triads is straightforward since the signal at 19.59 ppm is also observed in polymers obtained from the optically pure monomer. Hence the peak

Figure 3 ¹³C n.m.r. spectra of poly[(*S*)-4-methyl-1-hexene]: (a) ether soluble fraction (sample E_{5,2}) at room temperature; (b) ether soluble fraction (sample E_{5,2}) at 70°C; (c) cyclohexane soluble fraction (sample E_{5,3}) at room temperature; (d) cyclohexane soluble fraction (sample E_{5,3}) at 70°C

at 19.59 ppm has been assigned to the triads (4a) and (4b). Because of the inversion of configuration of both the side units it is reasonable to think that the shifts for the triads (3a) and (3b) differ to a larger extent from the shifts for the triads (4a) and (4b) than those for the triads (1a), (1b) and (2a), (2b). With this hypothesis it is possible to attribute the peak at 20.35 ppm to the triads (3a) and (3b).

This assignment is in agreement with the fact that in absence of structure of the type:

the intensity of signals due to triads (3) are lower than the intensity of the triads (1) and (2). The signals at 19.94 ppm can be then assigned to the triads (1) and (2). Quantitative analysis is unreliable since the signals are partly overlapped. However it seems that the process of polymerization is stereoselective³.

In fact, in a non-stereoselective polymerization, the probability (and as a consequence the intensity of the corresponding signals) of triad (4a) would be 1/8, and, due to the magnetic equivalence of the *SSS* and *RRR* triads, the probability of the peak at 19.59 ppm should be 1/4 of the total which does not correspond to the experimental results.

ACKNOWLEDGEMENTS

This work was supported by Consiglio Nazionale delle

Ricerche. We thank Dr F. Wehrli of Varian A. G. Zug who ran some of the spectra.

Melting in single screw extruders

J. Shapiro*, A. L. Halmos†, and J. R. A. Pearson

Department of Chemical Engineering and Chemical Technology, Imperial College, London SW7 2AZ, UK

(Received 10 March 1976)

A model for the melting of granules in a single screw extruder is presented in Part I. It is consistent with observations of earlier workers and retains some of the ideas introduced by Tadmor in his model; however, it assumes that the solid bed of granules cannot stand large differences of principal stresses and so account has to be taken explicitly of the downstream force balance on the solid bed and in the melt pool. Detailed quasi-analytic results are given for a Newtonian (constant viscosity) fluid in Part II. These illustrate the model for a particularly simple case and have relevance for some materials. A more elaborate numerical scheme is described in Part III for a non-Newtonian model and results are presented for comparison with the predictions of other theories and with experiments.

PART I: The Mathematical Model

INTRODUCTION

There is as yet no rational nor fully satisfactory mathematical model for the melting process in single screw extruders. Reliable predictive calculations that are based on fundamental physical principles cannot yet be carried out. However, experimental evidence obtained by several workers¹⁻⁵ on small to medium extruders had provided a fairly clear kinematic description of the process. Various physical and mathematical models have been described^{3,5-8} based on these observations, and comparisons have been made between calculations based on these models and experiment. In most cases the models are partly empirical, or fail to satisfy the full set of conservation laws that are generally accepted to govern mechanical phenomena, namely conservation of mass, momentum and energy⁹.

A new model attempting to satisfy all of these conservation laws was described at a meeting of an EFCE Working Party (1970) and was presented by Shapiro¹⁰. This model will be further developed here in relatively general form. It derives from the original observations of Maddock and Street and from the elementary model of Tadmor, the main difference from the last named being that the stress field is considered explicitly as part of the problem formulation. It is thus a full dynamical model and not merely a kinematical model.

The utility of the model must depend upon the approximations that can be shown to be relevant, because otherwise even numerical solution of the full governing equations is impracticable. Two particular approximation schemes are described and discussed in Parts II and III.

It is important to emphasize that a kinematical model for the process is needed and that it is not sufficient merely to write down the conservation equations for the whole system and to hope that the observed flow pattern will be predictable from first principles. A completely general approach would have to distinguish, for example, between a suspen-

sion of isolated granules in a molten matrix and the discrete solid bed observed in practice; it is not clear that the latter would be inevitably predicted.

THE 5-ZONE MODEL

Figure 1 provides in diagrammatic form the geometrical basis for the model we shall develop. The diagram relates to a cross-section of the screw channel taken perpendicular to the screw flights. The various geometrical approximations leading to this rectangular 'unrolled' form of the problem are now well known (see for example ref 11 pp.78-80, ref 12 and ref 13) and will not be discussed further. We choose a suitable Cartesian coordinate system with the x -axis parallel to the axis of the channel and the y -axis normal to the plane of the barrel (and to the floor of the screw

Figure 1 Geometry of the melting zone

* Present address: Canadian Industries Ltd, Quebec, Canada.

† Present address: Department of Chemical Engineering, Monash University, Clayton, Victoria 3168, Australia.

channel). The z -axis is thus normal to the screw flights. Curvature has been neglected.

The material flowing in the channel is divided into 5 zones, marked A to E . Zone A is formed of unmelted granular material, while zones B to E are regions of molten polymer. One essential feature of the model is that sharp interfaces exist between the solid and molten material, and that the cross-sectional shape of zone A is very nearly rectangular and fills most of the 'right-hand' side of the channel. The bulk of the mass flow in the downstream x direction takes place in the solid bed A and the melt pool B . Zones C , D and E are treated as relatively thin layers of molten polymer which 'lubricate' the surfaces of the solid bed, and across which heat to melt the solid bed can be conducted from the hot barrel and screw surfaces.

The cross-sectional shape shown in Figure 1 for a fixed value of x is assumed to vary slowly downstream, i.e. Z , the bed width, is a slowly varying (usually decreasing) function of x . Melting of the solid material at its interfaces with melt is a slow process. This means that no velocity gradient in the solid bed need be large. This is consistent with a second essential feature of the model, namely that the solid bed moves downstream with a velocity v_{Ax} that is independent of y and z and varies slowly with x . The y and z velocities in the bed are assumed very small everywhere.

It will be seen that the prime cause for any motion in the (y, z) -plane is provided by the crosschannel velocity v_{bz} of the barrel relative to the screw. This leads to a dragging of melt from zone C into zone B : put differently, the material that is melted at the AC interface is swept away by the barrel into the melt pool. Because of this, it may be anticipated that the thickness of the melt layer C will be small, and hence that both heat generation in and conduction across the layer C will be larger than similar effects in the other molten zones. Furthermore, the thickness will vary with z .

Zones D and E are treated as molten on the assumption that the screw temperature is higher than the melting point of the polymer. This need not necessarily be so: if the screw were kept cold enough, the bed of granules A would be in direct unlubricated contact with the metal screw, and frictional forces would replace the viscous ones that we shall be considering here. Because there is no significant motion of the bed A relative to the screw in the (y, z) -plane, the thicknesses of zones D and E will be treated as independent of y and z respectively at any station x , and the velocity in these zones as in the x direction only.

Because rheological forces are much larger than gravitational or inertial forces the momentum conservation equation degenerates to a stress equilibrium equation. A third essential feature of the model is that the rheological behaviour of the molten material is that of a temperature-dependent inelastic viscous liquid, while that of the solid bed is not specified in advance but is assumed to be consistent with the simple kinematics already presumed to apply in the solid bed. The stress equilibrium equation can therefore be satisfied locally everywhere in the molten material, i.e. in zones B – E , but only in an integrated form over the cross-section of the solid bed.

The consequences of these assumptions will become clear when we discuss the equations that are relevant in each zone treated separately, and when we then consider the overall relation that links the variables describing each zone. As with many such complex situations, it is difficult to decide which features of the model to treat as basic assumptions and which as consequences of the assump-

tions. What is important is to ensure that the model is self-consistent: this can only be done satisfactorily after numerical values have been calculated.

The relevant conservation laws and boundary conditions have been set out by Pearson¹¹. To these must be added those that apply at the solid bed–melt interfaces within the flow region. We shall require the velocity vector, the temperature and the stress tensor to be continuous. A discontinuity in the heat flux is permitted, which provides the heat necessary to melt the polymer at the interface.

Zone A: the solid bed

We have already stated that the solid bed's downstream velocity v_{Ax} and its width Z are to be treated as slowly varying functions of x only. To these variables we add the mass flowrate M_{Ax} and the melting rate R , also slowly varying functions of x . Formally

$$M_{Ax} = v_{Ax} \int_{-Z}^{-\delta_D} \left(\int_{\delta_E}^{H-\delta_C} \rho_A dy \right) dz \quad (1)$$

ρ_A can be regarded as temperature (T) and pressure (p) dependent and hence a function of y and z . However, since the pressure dependence is likely in practice to be more important than the temperature dependence, and our model treats (see below) the pressure as a function of x only, we can take ρ_A outside the integral. We note for later reference that if δ_C , δ_D and δ_E are taken to be $\ll H$, then

$$M_{Ax} \approx \rho_A v_{Ax} H Z \quad (1a)$$

where

$$\rho_A = \rho_A(p) \quad (2)$$

The mass melting rate, R , can again formally be written as

$$R = R_B + R_C + R_D + R_E \quad (3)$$

where the subscripts B – E refer to the melting taking place at the interfaces AB – AE . We shall take up the question of providing relations for each of these when we consider zones C – E .

The mass conservation equation for zone A then becomes, trivially,

$$\frac{dM_{Ax}}{dx} = -R \quad (4)$$

So far, there is no difference from all previous models.

We now consider the stress equilibrium equation for zone A . The kinematical model that we have chosen allows us to make use of the x component equation as a governing equation of the system; in particular, it effectively provides the extra equation needed to determine v_{Ax} in terms of the other variables that depend on x only. Formally we define the total shear stress/unit length in the x direction acting in the x direction over the interfaces AB – AE as S_{ABx} – S_{AEx} , so that the total shear force/unit length on the solid bed is given by

$$S_x = S_{ABx} + S_{ACx} + S_{ADx} + S_{AEx} \quad (5)$$

Note that this is the force caused by viscous shear stresses in the deforming molten material. Relations for S_{ABx} etc. will be derived in later subsections. This force will be balanced by the downstream variation in isotropic pressure p ($1/3$ the trace of the stress tensor) which is assumed to be a slowly varying function of x only, and to dominate all other 'normal' forces. We obtain

$$S_x = \frac{dp}{dx} \left[\int_{-Z}^{-\delta_D} \left(\int_{\delta_E}^{H-\delta_C} dy \right) dz \right] \quad (6)$$

or, using the same approximation as earlier,

$$S_x \approx \left(\frac{dp}{dx} \right) HZ \quad (6a)$$

The geometry is given in Figure 2.

The approximations inherent in equation (6) are completely equivalent to those usually made in dealing with the fully molten zone (metering or melt pumping section) and the dry granular zone (feed section), where an effective pressure p is used as the relevant dynamical variable at any station x . Gradients in p are balanced by viscous or frictional forces caused by local shear rates or slip velocities, the former being calculated in terms of a purely viscous fluid model and the latter using a coefficient of friction. Normal stress differences are neglected in the metering zone models, and in the simplest¹⁴ of the dry feed models, and are simply parametrized in the more complex feed zone models of Schneider¹⁵ and Lovegrove and Williams¹⁶.

We do not explicitly consider here the local stress equilibrium conditions within the slowly deforming solid bed A . Thus we do not need to specify its rheology. Because of the shear stresses imposed at the interfaces AB – AE , the implied stress state within the solid bed cannot be purely isotropic. However, if the absolute magnitude of p is large enough, we can assume that the stress tensor will be nearly isotropic. This is an assumption that we can check *a posteriori*. What we have assumed is that the almost isotropic stress state will be compatible with the small velocity gradients needed to cause the AB interface to move slowly towards the trailing flight $z = 0$ and the AC interface to remain sensibly fixed relative to the moving barrel, i.e. material is slowly squashed up towards the hot barrel surface. One rheological idealization that is compatible with this approach is that of an almost freely deforming hard granular bed, i.e. one with a low (and suitably variable!) angle of internal friction. However, it is not necessary for this to be the case: indeed, a relatively rigid viscoelastic local model may well be far more appropriate, provided that large (comparable with $|p|$) differences of normal stresses do not arise and so lead to significant modification of the overall balance relation equation (6).

The same arguments allow us to neglect detailed consideration of even the integrated y and z components of the stress equilibrium equation. Clearly there will be a z shear stress on the bed A , caused by the lubricated motion of the barrel sliding over the melting face AC . This must be balanced largely by variations of the normal stress (pressure) across the interfaces AB and AD , since we cannot expect comparable z shear stresses in zone E . Similar consideration of the balance of moments acting about a z -axis on the bed A lead to pressure differences between zones C

and E . What we are assuming is that these differences are small in absolute magnitude compared to the local pressure p and, as we shall see later, are therefore too small to provide significant pressure driven fluid motions in zones C , D , and E . All of these assumptions must be checked *a posteriori*.

Nothing has been said so far about the temperature field within the bed. This has been treated by previous authors^{3,6} in terms of a straightforward solution of the heat conduction equation. Shapiro¹⁰ and Pearson¹⁷ have made the coarse assumption that the solid bed remains at essentially the entry (feed pocket) temperature T_A everywhere and that solid granules are raised to the melting temperature in a thin layer near the melting interface. The relevant equations are derived later. Insofar as the layer may be relatively thick, then physical arguments show that the melting rate will be overestimated in the early stages of melting and underestimated in the later stages. The total amount of heat needed to melt the entire solid bed will however be correctly calculated.

Zone B: the melt pool

The flow in this region is very similar to the flow in relatively deep channels already analysed by Martin¹⁵. Two differences arise:

(1) The fixed trailing screw flight surface (at $z = 0$ in our notation here) is replaced by the interface AB (at $z = -\delta_D - Z$) moving downstream with velocity v_{Ax} .

(2) The outflow/unit length, m_{Fz} , over the leading flight edge (at $z = -W$) is no longer balanced by the inflow over the trailing flight edge (at $z = 0$); instead the mass inflow, m_{Cz} from zone C (at $z = -\delta_C - Z$) causes the downstream flow, M_{Bx} to increase according to

$$\frac{dM_{Bx}}{dx} + m_{Cz} - m_{Fz} = 0 \quad (7)$$

Note that m_{Cz} and m_{Fz} are both negative for the coordinate system chosen.

Figure 2 The force balance on the moving solid bed A ; the upper (barrel) and lower (screw) stresses S_{ACx} and S_{AEx} are both shown. The shear stress $\approx S_{ABx}$ is shown clearly inclined to the x -axis but the effect of the cosine of dZ/dx is assumed negligible. The equivalent $\sin(dZ/dx)$ term on the normal p forces is not negligible however. In practice, S_{ADx} and S_{AEx} will be negative

Figure 3 The flow region in zone C. The thickness of δ_F and δ_C is exaggerated. Typical velocity and temperature profiles are shown. Main development of depth δ_C is in z-direction

A full solution to the problem requires a local solution everywhere for the field variables $v(x, y, z)$, $p(x, y, z)$ and $T(x, y, z)$. Martin has already shown that at best one can hope to calculate fully developed solutions (independent of x , except that $\partial p/\partial x$ can be a non-zero constant) and that even so heavy numerical computation is in general required. The often relevant case of high cross-channel Graetz number¹¹ leads to simplifications that could allow in principle of developing solutions but the influx m_{Cz} and the consequential open streamlines would be difficult to cope with.

Hence we shall assume that the mechanics of flow in zone B leads to a single dynamical equation that we write here formally as

$$M_{Bx} = \hat{\rho}_B f \left(W - Z - \delta_D, v_{Ax}, \frac{dp}{dx}; H, v_{bx}, v_{bz} \right) \quad (8)$$

where f is also dependent on the material properties of the melt. Thus there is an implicit dependence in equation (8) on the viscous properties of the melt and hence on the temperature field. We defer any further consideration of the function f in equation (8) until we consider specific approximate models.

We note that our discussion of zone A left S_{ABx} and R_B unspecified; we should defer consideration of these also until a specific model for f is chosen, but it is convenient to assume here that they can be taken as negligible.

Zone C: the swept melting layer

Zone C is the most important region of all from the point of view of heat transfer and hence of melting. Except very near the beginning of the melting section, δ_C will be smaller than δ_E or δ_D unless the screw temperature is much closer to the melting temperature than the barrel temperature is. Certainly R_C will be the dominant component of R , and for a very good reason: if it were not so, then melting in an extruder would not be significantly more rapid than in a static reservoir with heated metal walls, which can easily be shown to be unacceptably slow.

We shall therefore analyse the flow and temperature distribution in zone C as precisely as possible. The problem is intrinsically more difficult than that in a fully-molten metering section, say, because of the more complex boundary conditions that apply at the melting interface. The matter has been discussed at some length by Shapiro¹⁰ and Pearson¹⁷ and so we try here to summarize the most important points of the arguments given there. The geometry is illustrated in Figure 3.

We first introduce the geometrical assumption, which will have to be verified later, that:

$$\frac{\partial \delta_C}{\partial z}, \frac{\partial \delta_C}{\partial x} \ll 1 \quad (9)$$

and hence that

$$v_{Cy} \ll v_{Cz}, \quad v_{Cx}(v_{bz}, v_{bx}) \quad (10)$$

(However we note that v_{Cy} cannot necessarily be neglected completely because its convective contribution to heat transfer must be important. What we shall seek to do here is to take account of its effect implicitly rather than explicitly, so as to retain as far as possible the advantages of a full lubrication approximation.) Thus we are led, using equations (9) and (10) to the stress equilibrium equations:

$$\frac{\partial p}{\partial x} = \frac{\partial}{\partial y} \left(\mu \frac{\partial v_{Cx}}{\partial y} \right) \quad (11)$$

$$\frac{\partial p}{\partial z} = \frac{\partial}{\partial y} \left(\mu \frac{\partial v_{Cz}}{\partial y} \right) \quad (12)$$

and may neglect $\partial p/\partial y$. We may note at once that the assumptions we made earlier, i.e. that the stress field in zone A is dominated by the isotropic component $p(x)$, requires us to make the equivalent assumption here that $\partial p/\partial z \approx 0$. This result can be reached in a quite different manner^{10,17} by considering flow in zone C alone, and using the further geometrical approximation that:

$$\delta_C \ll H \quad (13)$$

In simple terms, we showed that any significant departure from drag flow in zone C would lead to unacceptably large pressure variations [i.e. of the order of the mean pressure $p(x)$] around the surface of the solid bed. This result is consistent with the hypothesis of a freely but very slowly deforming solid bed in zone A if (see Figure 3)

$$\left. \begin{aligned} v_{Cx} &= v_{Ax} \\ v_{Cz} &= 0 \end{aligned} \right\} \quad (14)$$

at the interface AC, i.e. at $y = H - \delta_C$.

The other boundary conditions for equations (11) and (12) are provided by 'no slip' at the barrel,

$$v_{Cx}(H) = v_{bx}; \quad v_{Cz}(H) = v_{bz} \quad (15)$$

The viscosity μ in equations (11) and (12) must be specified by a constitutive relation. Following previous authors, we shall use

$$\mu = 2^{-2s} C_0 \exp[-b(T - T_0)] (I_2)^{-s} \quad (16)$$

where the second invariant I_2 of the deformation rate tensor is given by

$$I_2 = \frac{1}{4} \left[\left(\frac{\partial v_{Cx}}{\partial y} \right)^2 + \left(\frac{\partial v_{Cz}}{\partial y} \right)^2 \right] \quad (17)$$

$C_0(T_0)$, s and b are parameters for any particular molten polymer in a given range of temperature and shear rate.

The energy, or heat balance, equation can be written as

$$\rho_C C_C \left(v_{Cx} \frac{\partial T}{\partial x} + v_{Cz} \frac{\partial T}{\partial z} + v_{Cy} \frac{\partial T}{\partial y} \right) = k_C \frac{\partial^2 T}{\partial y^2} + 4\mu l_2 \quad (18)$$

where convection, conduction and generation are all accounted for, bearing in mind the obvious consequences of equation (9) on the conduction term. Two obvious boundary conditions to apply are

$$T(H) = T_b; T(H - \delta_C) = T_m \quad \text{all } z \quad (19)$$

We now have to account for the effect of melting at the interface AC . Formally, we obtain

$$\begin{aligned} \lambda \rho_A v_{Ay}(y = H - \delta_C) &\equiv \lambda \rho_C v_{Cy}(y = H - \delta_C) \\ &= k_C \left(\frac{\partial T}{\partial y} \right)_{y=H-\delta_C^+} - k_A \left(\frac{\partial T}{\partial y} \right)_{y=H-\delta_C^-} \end{aligned} \quad (20)$$

where we have assumed the position of the interface, i.e. δ_C , to be independent of time and of x . More precisely, it is the material derivative

$$\frac{d\delta_C}{dt} = \frac{\partial \delta_C}{\partial t} + v_{Ax} \frac{\partial \delta_C}{\partial x}$$

that is taken to be zero. λ is the latent heat of fusion of the polymer.

Earlier, we argued that

$$\left(\frac{\partial T}{\partial y} \right)_{y=H-\delta_C^+} \gg \frac{T_m - T_A}{H} \quad (21)$$

so that most of the solid bed would remain at the entry temperature T_A . This will be the case provided that

$$\rho_A C_A v_{Ay} \gg k_A/H \quad (22)$$

in which case

$$k_A \left(\frac{\partial T}{\partial y} \right)_{y=H-\delta_C^-} \simeq \rho_A C_A v_{Ay} (T_m - T_A) \quad (23)$$

We are thus able to represent the term describing heat transfer into zone A —in equation (2)—in a very elementary fashion, and it is convenient to write

$$\Lambda = \lambda + (T_m - T_A) C_A \quad (24)$$

to give

$$k_C \left(\frac{\partial T}{\partial y} \right)_{y=H-\delta_C} = \Lambda \rho_C v_{CyI}, \quad v_{CyI} = v_{Cy}(H - \delta_C) \quad (25)$$

as the relevant additional boundary condition for equation (18). Here Λ is an effective latent heat of fusion.

Equation (18) still contains v_{Cy} as an unknown field variable. Equations (11)–(13) need to be supplemented by the continuity equation

$$\frac{\partial v_{Cy}}{\partial y} + \frac{\partial v_{Cx}}{\partial x} + \frac{\partial v_{Cz}}{\partial z} = 0 \quad (26)$$

for the set of field equations to be determinate. The boundary conditions become complete if we include the obvious condition

$$v_{Cy}(H) = 0 \quad (27)$$

and a sufficient set of entry conditions on v_C and T along $z = 0$ and $x = 0$.

We could, with care and sufficient computing power, obtain numerical solutions to this governing set of equations. However, without further simplifications, the task would be more formidable than those we have already rejected as too expensive for other regions of the flow, e.g. the metering section, zone B or zone A . This is largely because δ_C is an initially unknown function of x and z .

The key to simplification is the convection term in the energy equation, i.e. the left-hand side of equation (18). We shall first suppose that

$$\frac{\partial \delta_C}{\partial x} \ll \frac{\partial \delta_C}{\partial z} \quad (28)$$

and that

$$\frac{\partial T}{\partial x} \ll \frac{\partial T}{\partial z} \quad (29)$$

For this to be a rational approximation, we need dv_{Ax}/dx to be sufficiently small, e.g.

$$\frac{dv_{Ax}}{dx} \ll \frac{v_{Ax}}{Z} \quad (30)$$

We note that the initial conditions at $z = 0$, which will be determined by the leakage flow over the flight, are likely to be very slowly varying functions of x . Thus the assumptions equations (28) and (29) are inherently plausible.

Physically this means that the material that is melted at the AC interface is effectively swept in the z -direction into the melt pool B : the v_{bz} sweeping velocity is more effective than the $(v_{bx} - v_{Ax})$ relative sweeping velocity because $dZ/dx \ll 1$. The full set of field equations for v and T in zone C are now functions of y and z only, with dp/dx and v_{Ax} as parameters. We are therefore looking for a local (i.e. fixed x) solution. Furthermore, v_{Cx} and hence v_{Ax} is only coupled to the equations for v_{Cy} , v_{Cz} and T very weakly through l_2 .

We have therefore effectively reached the starting point of Pearson¹⁷. There it was shown that a useful approximation to the solution of equations (12), (18) and (26) with $v_{Cx} \equiv 0$ can, in certain circumstances, be obtained by using

$$k_C \frac{\partial^2 T}{\partial y^2} + 4\mu l_2 = 0 \quad (18a)$$

instead of equation (18) to give T rather simply in terms of δ_C using boundary conditions equation (19). The relevant dimensionless group is

$$M = \Lambda / C_C (T_b - T_m) \quad (31)$$

If M^{-1} is sufficiently small, then equation (18a) can be used provided the local melting rate (given by v_{Cy} at the interface) is calculated from equation (25) using a modified value

Λ^* for Λ . Formally we can write

$$\Lambda^* = \Lambda + FC_C(\bar{T} - T_m) = \lambda + C_A(T_m - T_A) + FC_C(\bar{T} - T_m) \quad (32)$$

where F is a pure number and \bar{T} is some average value of the temperature in $H < y < H - \delta_C$. Shapiro¹⁰ took \bar{T} to be the mixing cup mean

$$\hat{T} = \frac{\int_{H-\delta_C}^H T v_{Cz} dy}{\int_{H-\delta_C}^H v_{Cz} dy} \quad (33)$$

and $F = 1$. Pearson¹⁷ showed that $F = 1/2$ would be a more obvious general choice, and also gave results for certain special cases.

When solving the simplified problem for zone C , we find that the relevant set of equations become equation (12) subject to equations (14) and (15), equation (18a) subject to boundary conditions equations (19) and (25) using Λ^* from equation (32) and the integrated mass conservation relation

$$v_{CyI} = \frac{\partial}{\partial z} \left(\int_{H-\delta_C}^H v_{Cz} dy \right) \quad (34)$$

which follows directly from equations (26) and (27). Equation (34) yields δ_C implicitly. The solution is dependent on v_{Ax} and on the initial condition

$$m_{Fz} = \rho_C \int_{H-\delta_C}^H v_{Cz}(z = -\delta_D) dy$$

Here we have assumed that all the molten material is flowing over the flight and no more enters zone C ; clearly $\delta_C(z = -\delta_D) \approx \delta_F$, the flight clearance. The solution is very weakly dependent on dp/dx through equation (11) and I_2 . The solution yields

$$m_{Cz} = \rho_C \int_{H-\delta_C}^H v_{Cz}(z = -Z - \delta_D) dy \quad (35)$$

which is required in equation (7) for zone B . We see at once that

$$R_C = m_{Fz} - m_{Cz} \quad (36)$$

which is required for estimating R in equation (4) using equation (3). Finally we note that

$$S_{ACx} = \int_{-Z-\delta_D}^{-\delta_D} \left(\mu \frac{\partial v_{Cx}}{\partial y} \right)_{y=H-\delta_C} dz \quad (37)$$

which is needed in equation (5).

Zones D and E : the lubricating layers

An analysis of flow in the lubricating layers D and E follows that of zone C in many respects. Equations (9) and (10) become

$$\frac{\partial \delta_D}{\partial x}, \frac{\partial \delta_E}{\partial x} \ll 1 \quad (38)$$

$$v_{Dz} \ll v_{Dx}, v_{Ey} \ll v_{Ex} \quad (39)$$

where v_{Dx} and v_{Ex} are of order v_{Ax} . Equation (13) is retained, i.e.

$$\delta_D, \delta_E \ll H \quad (40)$$

We shall see that a breakdown of equation (40) will prove to be the strongest constraint on our calculations for the melting process. Again, to be compatible with the assumptions made above, we treat p as a function of x only. Thus $\partial p / \partial y = 0$ in the analogue of equation (12) for v_{Dy} and for $\partial p / \partial z = 0$ in that for v_{Ez} . The zero boundary conditions

$$v_{Dy}(z = 0) = v_{Dy}(z = -\delta_D) = 0 \quad (41)$$

and

$$v_{Ez}(y = 0) = v_{Ez}(y = -\delta_E) = 0 \quad (42)$$

ensure that $v_{Dy} = v_{Ez} \equiv 0$. The flow pattern shown in Figure 4 for zone D is therefore the relevant 2-dimensional situation exactly equivalent to that considered by Pearson¹⁷. Thus

$$\frac{\partial}{\partial z} \left(\mu \frac{\partial v_{Dx}}{\partial z} \right) = \frac{\partial p}{\partial x} \quad (43)$$

with

$$v_{Dx}(0) = 0; v_{Dx}(-\delta_D) = v_{Ax} \quad (44)$$

μ still obeys equation (16) where now

$$I_2 = \frac{1}{4} \left(\frac{\partial v_{Dx}}{\partial z} \right)^2 \quad (45)$$

We obtain T from

$$k_D \frac{\partial^2 T}{\partial z^2} + 4\mu I_2 = 0 \quad (46)$$

with

$$T(0) = T_s; T(-\delta_D) = T_m \quad (47)$$

Figure 4 The flow region in zone D . A typical velocity profile is shown with development of depth δ_D in the x -direction

v_{Dz} is given by

$$k_D \left(\frac{\partial T}{\partial z} \right)_{z=-\delta_D} = \Lambda^* \rho_D v_{Dz} \quad (48)$$

where Λ^* is given by equation (32), \bar{T} being interpreted as the relevant average temperature in $-\delta_D < z < 0$.

The solution is obtained by 'marching' forward from some initial $\delta_{D0}(m_{Dx0})$ using

$$v_{Dz} = \frac{d}{dx} \left(\int_{-\delta_D}^0 v_{Dx} dz \right) \equiv \frac{d}{dx} (m_{Dx}/\rho_D) \quad (49)$$

Note that here, as elsewhere, variations in ρ across the layer have been neglected. The information needed for the overall calculation is provided by $\delta_D(x)$,

$$R_D = \frac{dm_{Dx}}{dx} [H - \delta_C(-\delta_D) - \delta_E] \quad (50)$$

and

$$S_{ADx} = \left(\mu \frac{\partial v_{Dx}}{\partial z} \right)_{z=-\delta_D} [H - \delta_C(-\delta_D) - \delta_E] \quad (51)$$

Similarly

$$R_E = \left(\frac{dm_{Ex}}{dx} \right) Z \quad (52)$$

and

$$S_{AEx} = \left(\mu \frac{\partial v_{Ex}}{\partial y} \right)_{y=\delta_E} Z \quad (53)$$

If $\delta_{D0} = \delta_{E0}$, then $\delta_D = \delta_E$ for all x and the solutions for v_{Dx} and v_{Ex} are essentially identical.

Summary of governing equations

The important quantities from an overall point of view are the major mass fluxes of solid and melt, namely M_{Ax} and M_{Bx} , the width and the downstream velocity of the solid bed, Z and v_{Ax} respectively and the downstream pressure gradient dp/dx . All of these are slowly varying functions of x . They are connected through the five approximated balance equations

$$M_{Ax} = \rho_A v_{Ax} H Z \quad (1a)$$

$$\frac{dM_{Ax}}{dx} = - (R_C + R_D + R_E) \quad (4a)$$

$$H Z \frac{dp}{dx} = S_{ACx} + S_{ADx} + S_{AEx} \quad (6b)$$

$$\frac{dM_{Bx}}{dx} = R_C \quad (7a)$$

$$M_{Bx} = \hat{\rho}_B f \left(Z, v_{Ax}, \frac{dp}{dx} \right) \quad (8a)$$

Clearly initial values M_{Ax0} , M_{Bx0} and p_0 and relations for R_K , S_{AKx} ($K = C, D, E$) and f in terms of Z , v_{Ax} and dp/dx are needed to make the problem determinate.

We have noted that R_K and S_{AKx} are only weakly dependent on dp/dx and involve the important ancillary variables δ_K ($K = C, D, E$). The basic equations needed to obtain these R_K and S_{AKx} functions are given above, and they are formally expressed as equations (35)–(37) and (49)–(53). The procedure for obtaining these functions is discussed at greater length by Shapiro¹⁰ and Pearson¹⁷. No detailed discussion of the functional form of f has yet been given, nor of means to calculate it numerically.

The complex non-linear nature of these equations implies step-by-step and iterative numerical procedures. Equations (4a) and (7a) carry forward information from one section x to the next section $x + \Delta x$, as do the subsidiary relations equations (50) and (52) for m_{Dx} and m_{Ex} . At any particular station x , the x -mass fluxes in each zone are treated as given, and equations (1a), (6b) and (8a) are solved iteratively for Z , v_{Ax} and dp/dx , using the ancillary relations relevant in zones C , D and E which yield the R_K and S_{AKx} implicitly in terms of Z and v_{Ax} .

Particular examples of solutions are given in Parts II and III of this paper.

DISCUSSION

A self-consistent 5-zone model has been described above which is based on a large number of interlocking assumptions. It might be possible to justify all of the approximations made by means of formal rational mechanical analysis. However, such severely analytical expansion methods usually appear to restrict the applicability of the formal theory to a far smaller range of situations than is ever met in practice. We argue here that the only sensible way to assess the model is to apply it in typical industrial or laboratory contexts. Once having obtained numerical solutions based on the model, it is a relatively simple matter to estimate the order of magnitude of the errors involved in the various approximations that have been made, and so to put limits on the applicability of the model. Such *a posteriori* estimates should also suggest modifications to the model to overcome its limitations far better than *a priori* argument.

We consider this first in Part II for the particularly simple case of a constant viscosity (Newtonian) fluid, choosing a viscosity which is representative, for the rates of shear encountered in the flow, of the apparent viscosity of commercial polymer melts. The adequacy of the various approximations made is examined, and within quite reasonable limits, they are found to be valid. The effect of using the approximations used for zone C on a representative non-Newtonian fluid are also examined and the basic contention of Pearson¹⁷, that a similarity solution is rapidly established, is found to be self-consistent. The advantage of using a Newtonian approximation for the full problem is that many of the relevant intermediate results, e.g. for δ_D , are analytic.

The full non-linear (non-Newtonian) problem is considered in Part III, where the elements of a numerical solution scheme and an associated computer program are described. Representative results are presented and discussed briefly, particularly a *post hoc* analysis of the initial assumptions.

INTRODUCTION

Part I of this paper has described a 5-zone mathematical model for the melting process in single screw extruders. It was based on a number of intuitive assumptions concerning the dominant geometrical and mechanical features of the flow. However, even with the simplifications imposed in Part I, a complex computational problem results. As a preliminary to providing computational results for a fully non-Newtonian (shear and temperature dependent) melt, a representative set of results will be given here for the much simpler case of a melt of constant viscosity. Various other approximations, not essential in the basic model, are also made here for convenience.

SIMPLIFIED SOLUTION SCHEME

The three equations (1a), (4a) and (6b) relating to zone A given in Part I are retained, with the added assumption that $\rho_A = \rho_S$ and H are constant. The two equations (7a) and (8a) relating to zone B are also retained, where now an exact solution can be given for f in the case where δ_F , δ_C , δ_D and δ_E are neglected in comparison with H and W . Thus, using Rowell and Finlayson¹⁹

$$f = v_{bx} \left(\frac{8(W-Z)^2}{\pi^3} \sum_{n=1}^{\infty} \frac{1}{n^3} \tanh \frac{n\pi H}{2(W-Z)} \right) + v_{Ax} \left(\frac{8H^2}{\pi^3} \sum_{n=1}^{\infty} \frac{1}{n^3} \tanh \frac{n\pi(W-Z)}{2H} \right) - \frac{1}{\mu} \frac{dp}{dx} \left(\frac{(W-Z)^3 H}{12} - \frac{16(W-Z)^4}{\pi^5} \sum_{n=1}^{\infty} \frac{1}{n^3} \times \tanh \frac{n\pi H}{2(W-Z)} \right) \quad (54)$$

We also assume that the density ρ_m , the specific heat C_m and thermal conductivity k_m of the melt are constant everywhere. All we need now are expressions for R_K and S_{AKx} ($K = C, D, E$). We note at once that equation (16) is replaced by $\mu = \text{constant}$.

Putting $\partial p / \partial z = 0$ in equation (12) gives

$$\frac{\partial^2 v_{Cz}}{\partial y^2} = 0 \quad (55)$$

with solution, using boundary conditions equations (14) and (15),

$$v_{Cz} = v_{bz} \frac{(y - H + \delta_C)}{\delta_C} \quad (56)$$

Similarly, neglecting dp/dx in equation (11)—the drag flow assumption—yields

$$v_{Cx} = v_{Ax} + (v_{bx} - v_{Ax})(y - H + \delta_C) / \delta_C \quad (57)$$

We now make the further assumption that the generation term in equation (18a) can be neglected. This is not, in any case, essential to this development but happens to be an approximation that is moderately well justified in the numerical case to be presented here. Thus

$$\frac{\partial^2 T}{\partial y^2} = 0; \quad T(H) = T_b; \quad T(H - \delta_C) = T_m \quad (58)$$

giving

$$T = T_m + (T_b - T_m)(y - H + \delta_C) / \delta_C \quad (59)$$

From equation (56)

$$v_{CyI} = \frac{k_m(T_b - T_m)}{\delta_C \rho_m \Lambda^*} \quad (60)$$

where, using equation (33) and putting $F = 1$

$$\Lambda^* = \lambda + (T_m - T_A)C_A + \frac{2}{3} C_m(T_b - T_m) \quad (61)$$

From equation (34) and equation (56) above we obtain directly

$$v_{CyI} = \frac{1}{2} v_{bz} \frac{\partial \delta_C}{\partial z} \quad (62)$$

whence

$$\delta_C = \left(\frac{4k_m(T_b - T_m)z}{\rho_m \Lambda^* v_{bz}} + \delta_F^2 \right)^{1/2} \quad (63)$$

where δ_D has been neglected in comparison with Z and $\delta_C(0)$ has been equated with δ_F . R_C is obtained immediately as

$$R_C = -\frac{1}{2} \rho_m v_{bz} \left\{ \left(\frac{-4k_m(T_b - T_m)Z}{\rho_m \Lambda^* v_{bz}} + \delta_F^2 \right)^{1/2} - \delta_F \right\} \quad (64)$$

and

$$S_{ACx} = -\frac{1}{2} \frac{\rho_m v_{bz} \Lambda^* \mu (v_{bx} - v_{Ax})}{k_m(T_b - T_m)} \times \left\{ \left(\frac{-4k_m(T_b - T_m)Z}{\rho_m \Lambda^* v_{bz}} + \delta_F^2 \right)^{1/2} - \delta_F \right\} \quad (65)$$

Similarly, for zones D and E we obtain

$$S_{ADx} = \mu v_{Ax} H / \delta_D \quad (66)$$

$$S_{AEz} = \mu v_{Ax} Z / \delta_E \quad (67)$$

Table 1

Geometry of the screw:	
Diameter, D_b	63 mm
Helix angle, β	0.31 rad
Screw channel depth (feed section)	9.4 mm
Screw channel width (normal to the flight)	54.15 mm
Screw flight clearance	76.3 μm
Physical properties of polymer (LDPE):	
Melting temperature	110°C
Viscosity	294.2 N sec/m ²
Thermal conductivity of melt	0.178 W/m°C
Thermal conductivity of pellets	0.178 W/m°C
Density of melt	760 kg/m ³
Bulk density of pellets	490 kg/m ³
Heat of fusion of the polymer	130 kJ/kg
Heat capacity of solid	2.76 kJ/kg°C
Heat capacity of melt	2.60 kJ/kg°C
Operating conditions:	
(standard conditions given first)	
Speed of rotation	2 π ; π , (4/3) π rad/sec
Temperature of barrel	230°C; 180°C, 280°C
Temperature of screw	130°C; 120°C, 140°C, 160°C
Temperature of feed	30°C; 20°C, 50°C, 80°C
Flowrate through the extruder	0.01; 0.015, 0.02, 0.03 kg/sec

where

$$\delta_E = \delta_D = \left(\delta_{D0}^2 + \int_0^x \frac{4k_m(T_s - T_m)}{\rho_m v_{Ax} \Lambda^{**}} dx \right)^{1/2} \quad (68)$$

and

$$\Lambda^{**} = \lambda + (T_m - T_A)C_A + \frac{2}{3} C_m(T_s - T_m) \quad (69)$$

No account is taken of R_D and R_E , since δ_D and δ_E are neglected in comparison with Z and H .

The five governing equations given in Part I, for zones A and B , can now be reduced at a given x to the three equations

$$\frac{dp}{dx} = - \frac{\mu}{HZ} \left\{ \frac{(v_{bx} - v_{Ax})v_{bz}\rho_m\Lambda^*}{2k_m(T_b - T_m)} \times \left[\left(- \frac{4k_m(T_b - T_m)Z}{\rho_m\Lambda^*v_{bz}} + \delta_F^2 \right)^{1/2} - \delta_F \right] - v_{Ax}(H + Z) \left(\delta_{D0}^2 + \int_0^x \frac{4k_m(T_s - T_m)}{\rho_m v_{Ax} \Lambda^{**}} dx \right)^{-1/2} \right\} \quad (70)$$

$$M_{Ax} = \rho_A v_{Ax} HZ \quad (71)$$

$$v_{Ax} = (M_T - \rho_m f) / \rho_A HZ \quad (72)$$

with f given by equation (54), and only 3 unknowns dp/dx , Z and v_{Ax} . Iterative numerical solution is necessary but not difficult. These equations give the solution for any given value of x , M_{Ax} being treated as known. The value of M_{Ax} at a new value of x is provided by

$$\frac{dM_{Ax}}{dx} = -R_C \quad (73)$$

where R_C is given by equation (64).

TYPICAL SOLUTIONS

Table 1 gives geometrical, physical and operating parameters for a 'typical' polymer and screw. The solution scheme given above requires additionally that δ_{D0} and δ_{E0} be specified. Shapiro¹⁰ showed that results obtained for $\delta_{D0} = 100, 200$ and $300 \mu\text{m}$ were virtually indistinguishable, and for convenience, he then took

$$\delta_{D0} = \delta_{E0} = \delta_F$$

Results are given in the Figures for separate variation about the 'standard' operating conditions of (a) barrel temperature, T_b ; (b) screw temperature, T_s ; (c) total flowrate, M_T ; (d) screw revolution rate, N ; (e) solid feed temperature, T_A ; (f) solid feed density, ρ_A .

A careful analysis of the dimensionless groups relevant in the very simplified circumstances considered here shows that only 3 of these need be varied to provide all possible dimensionless solutions. However, since more realistic cases introduce further dimensionless variables, the exercise of writing all the results in dimensionless form has not been undertaken here.

It is convenient to plot results as v_{Ax} , Z and dp/dx as functions of x for various values of the operating conditions. These are given as Figures 6–11. However, the performance of the melting section is more easily understood in terms of p and M_{Ax} which are also shown for the standard case and a few variations in Figure 5. Little need be said about the results obtained in that they contain no surprises, given the model used.

VERIFICATION OF ASSUMPTIONS

We now return to a consideration of the original assumptions, whose validity can now be assessed quantitatively in terms of our numerical solution.

δ_C values

The maximum value for δ_C using Table 1, i.e. with $Z = W$, and equation (63) is 0.44 mm. Hence $(\delta_C/H)_{\text{max}} = 0.047$. From equation (63) we have that:

$$\frac{\partial \delta_C}{\partial z} = \frac{2k_m(T_b - T_m)}{\rho_m \Lambda^* v_{bz}} \cdot \frac{1}{\delta_C} \quad (74)$$

which has a maximum value, when $\delta_C = \delta_F$, of 0.012. In our problem $\partial \delta_C / \partial x \equiv 0$. Thus δ_C is small as required.

δ_D, δ_E values

The maximum value for δ_D or δ_E using Table 1 and equation (68) with $x = 2$ m can be approximated by taking v_{Ax} as constant and equal to 0.06 m/sec. This yields $\delta_{E_{\text{max}}} = 1$ mm. Thus $\delta_E/H \sim 0.1$. The assumption that δ_E is negligible in going from equation (1) to equation (1a) or from equation (6) to equation (6a) clearly introduces a significant (10–15%) error which could have been eliminated; however, in simple geometrical terms, no major error is

Figure 5 (a) M_{Ax} vs. x ; (b) p vs. x . \circ , Standard operating conditions; \triangle , $T_b = 280^\circ$, $M_T = 0.02$ kg/sec, $N = \pi$ rad/sec

likely to have arisen. The consequences are likely to be much more important when investigating the assumption that $\partial p/\partial z$ and $\partial p/\partial y$ can be neglected. It can simply be verified that $\partial \delta_D/\partial x$ is quite negligible.

v_{Ax} , Z values

The lubrication approximation for zones C, D and E had assumed that

$$\frac{\delta_K}{v_{Ax}} \cdot \frac{\partial v_{Ax}}{\partial x} \ll 1 \tag{75}$$

Putting in the values used above, the ratio is readily seen to be $< 10^{-3}$. It is quite clear therefore that the lubrication approximation for zones C, D, and E is entirely justified and leads to insignificant error.

The stress balance equation (6a) has the largest length scale, namely W , and is based on the principle that v_{Ax} and Z are slowly varying functions of x . We can easily show that

$$\max \left(\frac{W}{v_{Ax}} \cdot \frac{dv_{Ax}}{dx}, \frac{W}{Z} \cdot \frac{dZ}{dx} \right) \approx 0.1 \tag{76}$$

A careful analysis of the equations shows that this is effectively very small and that v_{Ax} and Z (and likewise M_{Ax} and R) can indeed be regarded as very slowly varying.

R , S_x values

From equations (34) and (48) or equation (64) we can compare R_D or R_E with R_C . Using representative values for δ_C and δ_D we find that

$$\frac{R_D + R_E}{R_C} < 0.15 \tag{77}$$

and so neglect of R_D and R_E implied in equation (20) is

Figure 6 Effect of varying T_b . (a) Effect of T_b on Z . T_b values: \triangle , 280°C ; \circ , 230°C ; \square , 180°C . (b) Effect of T_b on v_{Ax} . Figure 7 Effect of varying T_s . (a) Effect of T_s on Z ; (b) effect of T_s on v_{Ax} ; (c) effect of T_s on dp/dx . T_s ($^{\circ}\text{C}$): \circ , 150° ; $+$, 140° ; \triangle , 130° ; \square , 120°

comparable with the errors made in neglecting δ_E and δ_D in equations (1a) and (6a). Indeed, to a large extent they are mutually compensating. R_B is readily seen to be completely negligible.

Similarly

$$\left| \frac{S_{AE_x} + S_{AD_x}}{S_{AC_x}} \right| < 0.25 \quad (78)$$

which shows that the dynamical effect of the layers E and D is not far from one of free lubrication. Small variations in δ_E and δ_D would not therefore alter the solution at all significantly. Clearly S_{AB_x} is negligible.

M, Λ^* values

By the definition given in equation (31)

$$M^{-1} \approx 2.4 \quad (79)$$

The discussion given by Pearson²⁰ was partly based on an expansion in powers of M^{-1} (see ref 20, Appendix). Relation (79) might be interpreted as suggesting that the simplification implied by equations (18a) and (32) was inapplicable in the case considered here as standard. However experience in cases where the full convective equation (18) is used (ref 11, p 81) suggests that M^{-1} (a Graetz number) has to be $O(10)$ rather than $O(1)$ before convective terms become comparable with conduction terms. To this extent, 2.4 may be sufficiently small for the approximation used to be a good one. What is wrong is the value chosen here for F , namely 1, which is probably a factor of 4 too

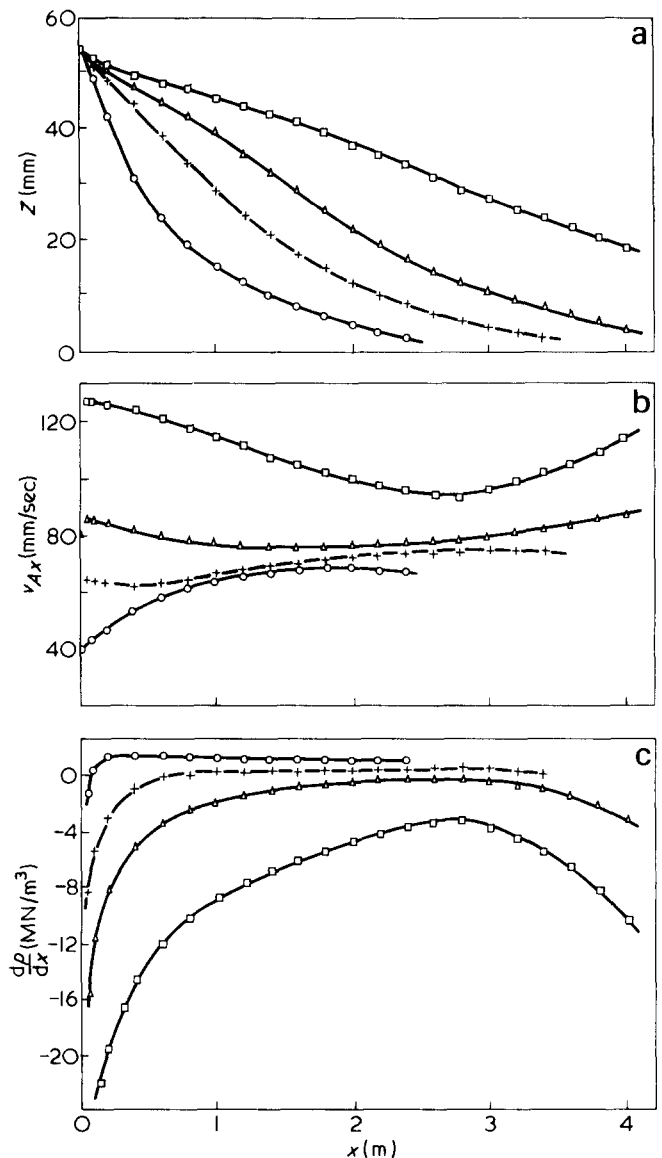

Figure 8 Effect of varying M_T . (a) Effect of M_T on Z ; (b) effect of M_T on v_{Ax} ; (c) effect of M_T on dp/dx . M_T (g/sec): \circ , 10; $+$, 15; \triangle , 20; \square , 30

large. Putting $F = 1/4$ would reduce Λ^* by a little over 15% and Λ^{**} by less than 10% and so significantly increase the rate of melting.

Generation

If generation is included, then its effect is simply to replace the coefficient of Z in equation (64) by

$$2[2k_m(T_b - T_m) + \mu\{v_{bz}^2 + (v_{bx} - v_{Ax})^2\}]/\rho_m\Lambda^*v_{bz}$$

This leads to an increase in melting rate of a further 8% in zone C. Combining this with the result from the previous section, we see that the largest error made is in underesti-

ating the melting rate by a factor of up to 25%. This however is not sufficient to invalidate any of our earlier arguments relating to the basic assumptions; for more accurate calculations, both $F = 0.25$ and generation could be included in either the Newtonian or the full 5-zone model, and so eliminate this numerically large error in the melting rate.

p and dp/dx values

Although absolute values of p have been shown in Figure 5, it is important to recognize that the melting section is preceded by a feed zone in which no melt pool arises, and for which dry friction may be relevant at all or some of the metal-polymer interfaces. A relatively large pressure may therefore be developed by the beginning of the melting zone ($x = 0$ in our coordinate system). In practice, for a given screw $p(x = 0)$ and M_T are not independently variable. It is therefore difficult to specify a representative value of p . We shall take 10 MN/m^2 as not unreasonable. We then see that

$$\frac{W}{p} \frac{dp}{dx} \approx \frac{1}{20} \quad (80)$$

which goes a long way to justifying the assertion made in Part I that differences in normal stress would be small compared with the isotropic pressure.

We now try to estimate the value of $\partial p/\partial z$ by considering the z balance of stress on zone A . We can obtain, analogously to equation (65) above,

$$S_{ACz} = -\frac{\rho_m v_{bz}^2 \Lambda^*}{2k_m(T_b - T_m)} \left[\left(-\frac{4k_m(T_b - T_m)Z}{\rho_m \Lambda^* v_{bz}} + \delta_F^2 \right)^{1/2} - \delta_F \right] \quad (81)$$

By equating this to $p(Z) - p(0)$ we get an estimate

$$\frac{\partial p}{\partial z} = \frac{S_{ACz}}{ZH} \quad (82)$$

which is, of course, of the same order of magnitude as dp/dx , namely 10 MN/m^3 . Hence the argument given after equation (80) still applies.

We now turn to the question of whether a drag flow approximation in zones C , D and E is justifiable. We use the result that a pressure gradient G in a channel of depth h yields a mass flowrate

$$m_p = \frac{\rho h^3 G}{12\mu} \quad (83)$$

This is to be compared with a drag flow

$$m_D = \frac{1}{2} \rho v h \quad (84)$$

The ratio is given by $Gh^2/6\mu v$. Putting $G = 10 \text{ MN/m}^3$, $h = 10^{-3} \text{ m}$, $v = 0.05 \text{ m/sec}$ and $\mu = 200 \text{ Nsec/m}^2$ gives

$$m_p/m_D \approx 0.1 \quad (85)$$

If we take $h = 0.4 \times 10^{-3} \text{ m}$, the ratio falls to less than 2%, and so the drag flow approximation was justified in our case.

The last question is whether the pressure difference acting between zones D and B could squeeze a significant amount of fluid from zones D and E into zone B and so cause the two-dimensional flow assumption in zones D and E to be inappropriate. The first thing we discover is that the pressure gradient would, if anything, cause flow towards zone D and so increase its thickness*. We have already decided that the mechanics are essentially those of a solid block unconstrained by the screw and so this would not lead to serious error. Simple calculations however, based on the constant values of δ_E and δ_D obtained above, and taking the z force balance above, predict the melt pool to form on the opposite side of the solid block to that which is observed. It is therefore clear that the actual pressure distribution in zones D and E is more complex. We have already argued that the x moment of forces on zone A must be zero. This may result in δ_E becoming very small near $z = -Z$ and so inhibit flow from zone E into zone B . Further progress in this matter can only be made when a full rheological analysis is made of zone A . This remains an outstanding problem.

The errors inherent in assuming that μ is constant are obviously large. We therefore consider a more realistic rheological model in Part III of this paper.

It should be pointed out that the results obtained here should not be interpreted as being always relevant. Assuming the polymer in question to be LDPE, the barrel temperatures chosen are on the high side, and so in practice generation would be more significant in zone C than here.

* Lindt²¹ has already shown that under certain circumstances, the melt pool model does not apply and that, instead, a rigid tongue of compacted granular solid advanced down the screw channel. He shows that this can be explained in terms of the z stress balance.

NOMENCLATURE

b	a material constant in a constitutive (temperature sensitivity of apparent viscosity),	S_x	total shear stress on solid bed in x direction,
$C_{A,C}$	specific heat of melt in zones A (solid bed) and C respectively,	s	material constant in the constitutive equation (power-law index),
C_m	specific heat of melt,	T	temperature,
C_0	material constant in the constitutive equation,	T_A	solid feed entry temperature,
F	constant introduced in equation (32)	T_b	barrel temperature,
f	a scalar function used in equation (8),	T_m	melting temperature of polymer,
G	pressure gradient,	T_0	base temperature for viscosity measurement,
H	depth of screw channel,	T_s	screw temperature,
I_2	second invariant of the rate-of-strain tensor,	t	time,
$k_{A,C,D}$	thermal conductivity of melt in zones A (solid bed), C and D respectively,	v	local velocity vector,
k_m	thermal conductivity of the melt,	$v_{Ax,Ay}$	velocity components of the solid bed (zone A)
M	ratio of apparent latent heat of fusion to change in heat content between barrel and melting temperatures,	$v_{bx,bz}$	velocity components of the barrel
M_{Ax}	mass flowrate in bed A in x direction,	$v_{Cx,Cy,Cz}$	velocity components in zone C ,
M_{Bx}	mass flowrate in melt pool B in x direction,	$v_{Dx,Dz}$	velocity components in zone D ,
$M_{Dx,Ex}$	mass flowrates in zones D and E in x direction respectively,	$v_{Ex,Ey}$	velocity components in zone E ,
$m_{Cz,Fz}$	mass outflow in z direction per unit length in x direction in zone C and under flight respectively,	$v_{CyI,DzI}$	velocities at AC and AD interface,
M_T	total mass flux in extruder,	W	width of screw channel,
N	rate of revolution of the screw,	x	Cartesian coordinate—downstream,
p	isotropic pressure,	y	Cartesian coordinate—radial,
R	total melting rate at the solid—melt interface per unit downchannel area,	Z	width of zone A ,
$R_{B,C,D,E}$	melting rates at the AB , AC , AD , and AE interfaces respectively,	z	Cartesian coordinate—cross-stream,
$S_{ABx,ACx,ADx,AEEx}$	forces due to x shear stress on the AB , AC , AD and AE interfaces per unit downchannel distance,	β	helix angle of the screw,
		δ_x	thickness of melt film in any of zones C , D , or E ,
		$\delta_{C,D,E}$	thickness of zones C , D and E ,
		$\delta_{D0,E0}$	initial thickness of zones D and E ,
		δ_F	screw flight clearance,
		$\Lambda, \Lambda^*, \Lambda^{**}$	'effective' latent heats of fusion,
		λ	latent heat of fusion,
		μ	viscosity function,
		ρ_A	density of solid bed (zone A),
		$\hat{\rho}_B$	mean density of melt in melt pool,
		$\rho_{C,D}$	density of melt in zones C and D ,
		ρ_m	density of the melt.

Osmotic pressures of moderately concentrated poly(γ -benzyl-L-glutamate) solutions in *N,N*-dimethylformamide

Kenji Kubo, Kenji Kubota, and Kazuyoshi Ogino

Department of Pure and Applied Sciences, University of Tokyo, Meguro-ku, Tokyo, Japan
(Received 5 April 1976; revised 13 May 1976)

INTRODUCTION

It is known that poly(γ -benzyl-L-glutamate) (PBLG) exists in a rod-like conformation in helicogenic solvents, such as *N,N*-dimethylformamide (DMF) and chloroform. Below some concentration (A-point) PBLG solutions are isotropic, while above another concentration (B-point) they are anisotropic (liquid crystalline). The coexistence of these isotropic and anisotropic phases is observed in an intermediate concentration range¹. Flory² proposed the theory of solutions of rod-like molecules based on a lattice treatment. The results predicted that rate of change in solvent activity for the anisotropic phase is much less than for the isotropic phase. Osmotic pressure measurements provide a means for determining the solvent activities in the moderately concentrated region, extending sufficiently over the two phases. Osmotic pressures for the PBLG-chloroform system have been determined in the concentration range up to $c = 0.19 \text{ g/cm}^3$ at 29°C ³. The difference between the solvent activities for the two phases was sufficiently small for a smoothed curve to be drawn for the range in contrast with the results predicted by Flory. Recently, the curve for the data on solvent activities has been found to correspond with that in the range above $c = 0.21 \text{ g/cm}^3$ at 30°C ⁴. The data in the concentration range below approximately $c = 0.5 \text{ g/cm}^3$ can be semi-quantitatively explained by the Wee-Miller theory, in which modification of Flory's lattice theory to allow for side chain flexibility has been made.

The present investigation was undertaken with the object of detecting the difference between the solvent activities for the two phases. The results of osmotic pressure for the PBLG-DMF system are reported in

the moderately concentrated region at 45°C . The results are compared with those predicted by the Wee-Miller theory.

EXPERIMENTAL

The PBLG used in the experiments was obtained by polymerizing γ -benzyl-L-glutamate-*N*-carboxy anhydride with triethylamine as an initiator and then refluxing with hot ethanol to remove low molecular weight impurities. The solvent, DMF was dried with MgSO_4 and then purified by vacuum-distillation before use. The semi-permeable membranes were prepared from regenerated cellulose membranes (Zartrius-Membranefilter Co., type Ultrafilter). Osmotic pressure was obtained in the concentration range up to $c = 0.23 \text{ g/cm}^3$ at 45°C . A high pressure osmometer described previously³ was used for solutions in the concentration range above $c = 0.05 \text{ g/cm}^3$. The solution charged in a solution cell was stirred as little as possible to avoid air-bubble formation in a solvent cell⁵. The rate of movement of solvent in a capillary was observed under a selected pressure. Osmotic pressure was determined by interpolating the relation between the pressure and the rate of meniscus movement to the null rate. The pressure was read using a mercury manometer. An equilibrium pressure was ordinarily attained within 6 h. The concentration was determined after the run, assuming no volume change on mixing. The specific volume of PBLG was taken to be $0.787 \text{ cm}^3/\text{g}$. After the osmotic pressures were determined for a few solutions of higher concentrations, solvent was removed from the solvent cell and tested for the presence of polymer; no polymer was detected. As the PBLG solution was gradually diluted with DMF, the following procedures were

necessary in order to maintain a high level of accuracy in the osmotic pressure measurements. (1) The solvent above the membrane was removed thoroughly with a blotter immediately before charging the solution. (2) In order to avoid dilution or concentration of the solution near the membrane due to the transport of the solvent through it, the external pressure was readjusted as frequently as possible until equilibrium pressure was attained. Osmotic pressure was determined in a low concentration range below $c = 0.02 \text{ g/cm}^3$ using a high-speed membrane osmometer (Hewlett-Packard Co., model 503). The molecular weight of the sample was 160 000.

For the determination of biphasic compositions at 45°C ten solutions of $c = 0.1$ to 0.25 g/cm^3 were prepared in glass tubes (i.d. 6 mm). The solutions were allowed to stand at 45°C for at least three weeks, and then observed over a wide temperature range using a polarizing microscope. The concentration at the A-point was found to be $c = 0.131 \text{ g/cm}^3$. Although it was difficult to determine accurately the point when no dark areas remained between crossed polars, we considered the concentration at the B-point to be $c = 0.17$ – 0.18 g/cm^3 .

RESULTS AND DISCUSSION

The dependence of osmotic pressure π on concentration c is shown in *Figure 1*. The biphasic compositions are satisfactorily within the range of the present osmotic pressure measurements. The osmotic pressure does not increase monotonously with increase in concentration within this range, unlike the ordinary curves of solutions of randomly-coiled polymers. It is evident from the form of the Figure that the osmotic pressure data show three regions of thermodynamic behaviour. It is reasonable to consider that the region below $\sim c = 0.13 \text{ g/cm}^3$ is the isotropic region, that the region above $\sim c = 0.17 \text{ g/cm}^3$ is the anisotropic region, and that the intermediate region is the coexistence region of the two phases. The change in thermodynamic

Figure 1 Osmotic pressure π versus concentration c (in g/cm^3) for PBLG solutions in DMF at 45°C . Curves were calculated from the Wee-Miller theory with $\chi = 0.462 + 0.213\nu_2$, $x = 376$, and $a = 1219$. Vertical broken line indicates position of A-point. B-point lies in vertical zone

Figure 2 Reduced osmotic pressure π/c versus concentration c (in g/cm^3) for PBLG solutions in DMF at 45°C . Curves were calculated from the Wee-Miller theory with $\chi = 0.462 + 0.213\nu_2$, $x = 376$, and $a = 1219$. Vertical broken line indicates position of A-point. B-point lies in vertical zone

behaviour between the regions is more clearly evident from the plot of π/c versus c , which is shown in *Figure 2*.

PBLG can be assumed to be a polymer composed of a rigid main chain and flexible side chains. Several studies have shown that the side chains of PBLG have some flexibility in the solid state⁶⁻⁸ and that they become

increasingly flexible as solvent is added⁹. Wee and Miller extended the Flory lattice theory for rigid rods by arranging rigid units and flexible ones on a lattice^{4,7}. Solvent activity a_1 for the isotropic phase is given:

$$\ln a_1 = \ln(1 - \nu_2) + [(x + a - 1)/(x + a)] \nu_2 + \chi \nu_2^2 \quad (1)$$

and that for the anisotropic phase by:

$$\ln a_1 = \ln(1 - \nu_2) + [(y + a - 1)/(x + a)] \nu_2 + 2/y + \chi \nu_2^2 \quad (2)$$

where ν_2 is the volume fraction of polymer, x the axial ratio of main chain, a the total number of side chain segments per main chain, y the disorientation index, and χ the parameter which is related to the interaction between the polymer and solvent. The value of y is given by:

$$\nu_2 = [(x + a)/(x - y)] \times [1 - \exp(-2/y)] \quad (3)$$

The parameter χ is assumed to be independent of whether the system is in the isotropic or anisotropic phase.

In order to allow these equations to be applicable to actual solutions, x and a are taken as adjustable parameters. Because $\ln a_1/\ln(1 - \nu_2)$ must approach the ratio of the molar volumes of solvent and polymer at infinite dilution, it is reasonable to take $x + a$ as the reciprocal of the ratio. The solvent activity is related to osmotic pressure by:

$$\ln a_1 = -\pi V_1/RT \quad (4)$$

where V_1 is the molar volume of solvent. The value of χ is estimated using equations (1) and (4). In *Figure 3* the χ values calculated using $x + a = 1595$ are plotted against the volume fraction of polymer. The χ value for the isotropic phase may be linearly related to the volume fraction regardless of whether the concentration is low or high. In *Figure 3* the straight line is drawn as $\chi = 0.462 + 0.213\nu_2$.

In view of the thermodynamic equilibrium between the isotropic and anisotropic phases, the biphasic compositions are calculated for given x and a from equations (1)–(3) together with equations⁴ for activity of polymer for the two phases. The concen-

Figure 3 Experimental values of χ plotted against volume fraction of polymer ν_2 for PBLG solutions in DMF at 45°C . Vertical broken line indicates position of A-point

tration at the A-point observed by the microscopic measurements can be fitted to the point calculated using $x = 376$, $a = 1219$, and $\chi = 0.462 + 0.213\nu_2$. The plots of π and π/c versus c calculated with these values are shown in *Figures 1* and *2*, respectively. The osmotic pressure data shown in *Figures 1* and *2* show that the rate of change in the solvent activity for the anisotropic phase is considerably less than that indicated by extrapolation of the curves for the isotropic phase. The horizontal line in *Figure 1* shows the region of the thermodynamic equilibrium between the two phases. However, the present data demonstrate that the solvent activity in the biphasic region is not constant, but increases with increase in concentration. The results may be due to the polydispersity of the polymer used. Above $c = 0.131 \text{ g}/\text{cm}^3$ the longer rods separated first of all from the isotropic phase. The shorter ones separated at higher concentrations. This polydispersity might, perhaps, exert some effect on the width of the biphasic region and the curve of solvent activity for the anisotropic phase. *Figures 1* and *2* indicate the discrepancies between the calculated values and experimental data for the width and the solvent activity. The discrepancies may be partly removed by applying the Wee-Miller theory to rods of different lengths, provided that a form on the dispersity of the polymer used is given. However, attempts to calculate this have not been considered meaningful, because the PBLG-DMF system is not perfectly within the limits of applicability of the lattice

model.

Equations (1)–(3) in the case of $\alpha = 0$ lead back to the original Flory equations². The Flory equations with the value of χ estimated here showed that the concentration at the A-point is small while the volume fraction at the B-point is near unity, so the present results cannot be accounted for by the Flory theory.

Study of polymer crosslinking by thermally stimulated current

P. K. C. Pillai, P. K. Nair and Rabinder Nath

Department of Physics, Indian Institute of Technology, New Delhi 110029, India
(Received 24 February; revised 11 May 1976)

Thermally stimulated current (TSC) has become a powerful tool in the investigations of dielectric relaxation in polymers. The relaxation time, activation energy and the distribution function of dipolar relaxation, attempt-to-escape frequency and capture cross-section have been successfully evaluated for many polymers^{1–4}.

In the present Note, the use of TSC for the study of crosslinking mechanism in polymers is illustrated with reference to poly(vinyl cinnamate) (PVCn). The crosslinking in PVCn, achieved by u.v. irradiation, is believed to cause photocyclodimerization of cinnamic groups with formation of cyclobutane bridges between polymer chains through the excited triplet state of the cinnamic groups and/or through the free radicals generated by the u.v. radiations⁵.

PVCn used in the present investigations was supplied by Polyscience Inc., USA. The benzene solution of PVCn, cast on plane glass sheets was allowed to solidify under saturated benzene atmosphere. The PVCn layer (6.25 cm² × 0.025 cm) was held between two Al electrodes forming a sandwich cell configuration. The crosslinked product was obtained by u.v. irradiation with 125 W, 220 V mercury discharge lamp for 3 h and the crosslinking was evidenced by the increased opacity of the film and its insolubility in benzene. Before the polarization and TSC measurements, the samples were preheated to 120°C (the maximum temperature used in TSC measurements) for 2 h. The satisfactory reproducibility of the a.c. capacitance measurements carried out during repeated heating and cool-

Study of polymer crosslinking by thermally stimulated current

P. K. C. Pillai, P. K. Nair and Rabinder Nath

Department of Physics, Indian Institute of Technology, New Delhi 110029, India
(Received 24 February; revised 11 May 1976)

Thermally stimulated current (TSC) has become a powerful tool in the investigations of dielectric relaxation in polymers. The relaxation time, activation energy and the distribution function of dipolar relaxation, attempt-to-escape frequency and capture cross-section have been successfully evaluated for many polymers^{1–4}.

In the present Note, the use of TSC for the study of crosslinking mechanism in polymers is illustrated with reference to poly(vinyl cinnamate) (PVCn). The crosslinking in PVCn, achieved by u.v. irradiation, is believed to cause photocyclodimerization of cinnamic groups with formation of cyclobutane bridges between polymer chains through the excited triplet state of the cinnamic groups and/or through the free radicals generated by the u.v. radiations⁵.

PVCn used in the present investigations was supplied by Polyscience Inc., USA. The benzene solution of PVCn, cast on plane glass sheets was allowed to solidify under saturated benzene atmosphere. The PVCn layer (6.25 cm² × 0.025 cm) was held between two Al electrodes forming a sandwich cell configuration. The crosslinked product was obtained by u.v. irradiation with 125 W, 220 V mercury discharge lamp for 3 h and the crosslinking was evidenced by the increased opacity of the film and its insolubility in benzene. Before the polarization and TSC measurements, the samples were preheated to 120°C (the maximum temperature used in TSC measurements) for 2 h. The satisfactory reproducibility of the a.c. capacitance measurements carried out during repeated heating and cool-

Figure 1 TSC of photocrosslinked PVCn for $V_b = 1.95$ kV and different polarization temperature T_b : A, 75°C; B, 90°C; C, 100°C; D, 110°C; E, 120°C. A', TSC of uncrosslinked sample for $V_b = 1.95$ kV and $T_b = 100^\circ\text{C}$. Inset: \bullet , T_m ; \circ , I_m

ing cycles (30°–110°C) of the same sample, suggests that the chemical degradation is not significant. A heating rate of 1.5°C/min was kept constant throughout the measurements.

The results of TSC on uncrosslinked and crosslinked products are shown in Figure 1. The crosslinking in polymers increases the glass transition temperature (until the gel-point is reached)⁶ and so the shift of the TSC peak towards the high temperature-side upon crosslinking of PVCn is understandable. As the heating rate is low, one also expects the TSC peak temperature T_m to correspond to the glass transition temperature. Since T_m is found to vary by about 16°C in the biasing temperature (T_b) range used (inset Figure 1), the glass transition in the photocrosslinked sample should be a slow transition. This can happen, because, the degree of crosslinking in the sample may not be uniform on a microscopic scale and the gelation on the surface may start before crosslinking has been initiated in the interior, particularly in the present study of solid state crosslinking where the movement of polymer chains is not possible. The width of the TSC peak and shift of T_m with T_b for the crosslinked samples are in marked contrast with PVCn which shows neither of these phenomena (Figure 1, curve A'). The activation energies for dipole relaxation calculated by the initial rise method⁷ for PVCn (2.48 eV) and the photocrosslinked product (1.43 eV) show a significant difference.

The evaluations of capture cross-section (σ_n) and attempt-to-escape frequency (ν) made from Grossweiner's formula⁸ are shown in Table 1

$$\sigma_n = \frac{\nu}{2.9 \times 10^{24} T_m} \text{ (m}^2\text{)}$$

$$\nu = \frac{3T' \exp(E/kT_m)}{2(T_m - T')T_m} \text{ (sec}^{-1}\text{)}$$

where β is the heating rate and T' is the half width temperature on the left of TSC peak.

It is seen that in the crosslinked product, the capture cross-section σ_n decreases with the increase of T_b (Table I). The dipolar relaxation times calculated using these values of activation energy are given in Figure 2, along with those obtained using the full curve method⁹. The agreement is good in the case of PVCn, but in the case of the crosslinked product the points are scattered towards the high

Optical observations of partly molten fibres of poly(ethylene terephthalate)

Enrico Pedemonte, Giovanni Carlo Alfonso and Giovanni Dondero
Istituto di Chimica Industriale dell'Università, via Pastore 3, 16132 Genova, Italy

and Girolamo Coppola and Piero Fabbri
Centro Sperimentale 'F. Marinotti' della Snia Viscosa, Cesano Maderno (Milano), Italy
(Received 20 April 1976; revised 10 June 1976)

The relevant interest for the fibrous state is well evidenced by the original investigations in fibre forming long chain polymers¹ and by the theoretical and experimental studies on the oriented crystallization, both from solution and from the melt²⁻⁸.

Some attempts have been made to classify the fibrous materials. Very recently Keller⁹ suggested a rather simple criterion which divides samples

into two classes 'according to the manner in which the fibrous nature was achieved even in the case of one and the same polymer', Class 1 comprises fibres formed from molecules pre-extended in an elongational flow field^{10,11}, i.e. for instance by particular stirring of solutions¹² or by very high speed melt spinning¹³. Class 2 includes the fibrous materials obtained by solid state deformation of preformed crystalline textures, i.e. for example by cold drawing⁶, where the original folded structure is disrupted and rebuilt in 'extended chain' crystals.

Optical observation of fibres is a well known and widely employed technique to obtain quickly fundamental information about their structure. Also according to Keller⁹ the shrinking test can be carried out on the hot stage of a polarizing microscope.

We have carried out some observations on fibres heated very close to the melting range; at these temperatures it can be seen that the filaments are only partly fused; individual birefringent fibrils are clearly visible inside the original fibre (*Figure 1*).

The polymer studied was a commercial poly(ethylene terephthalate), supplied by Snia Viscosa Co. under the trade name of Wistel.

Filaments were obtained by melt spinning followed by drawing at 107°C (stretching ratio: 1.70). The section of the single filament was triangular and the lateral size dimensions were ~20 μm. The density of the filaments was 1.3740 g/cm³, which corresponds to a crystallinity value of about 20%¹⁴; wide-angle X rays diffraction implies a good orientation of the crystalline phase.

The fibrils still present at high temperature (*Figure 1*) are very long and have a diameter of about 2 μm. They are oriented along the fibre axis and seem to be rather straight.

Scanning the specimen from 260° to 276°C at a heating rate of 1°C/min shows that the fibrils are stable well above the d.s.c. melting point of the sample ($T_m = 261^\circ\text{C}$). *Figure 2* shows that at 268°C the structure is very similar to that one observed at 260°C; only some connections between the fibrils seem to be disrupted. By increasing the temperature more and more polymer is melted; up to 276°C the birefringent filamentous entities are still visible in the inner core of the fibre, which is completely melted.

Incidentally it should be emphasized that the melting point of these fibrils is very close to the equilibrium melting temperature reported in literature by some authors^{15,16} but is higher than that quoted by Wunderlich (270°C)¹⁷.

Figure 1 PET fibre heated close to the melting range and rapidly quenched. Crossed polaroids (Heating rate, 3°C/min up to 260°C; storage time at 260°C, 10 min; quenching temperature, 214°C)

Figure 2 PET fibre scanned from 260.0° to 276.0°C. Heating rate: 1°C/min. (a) 260.0°C; (b) 268.0°C; (c) 272.0°C; (d) 274.0°C; (e) 276.0°C. Crossed polaroids

Keller¹⁸ has reported some similar data for polyethylene samples prepared from the melt by extrusion through, and crystallization in a capillary.

The thermal stability of the fibrils is in agreement with the expectations coming from the Peterlin model¹⁹. Actually Peterlin suggests that each fibril is made up of bundles of parallel microfibrils that differ slightly in the average draw ratio from the adjacent bundles; the packing of microfibrils within each fibril being more perfect than the lateral packing of fibrils¹⁹⁻²².

Nevertheless the fibrils observed in the present study are longer and have lateral size larger than those previously reported for linear polyethylene¹⁹. This result still fits with the Peterlin model if we take into account that the starting structure of the PET is certainly more complicated than that of polyethylene, i.e. the texture is approaching a defective crystal rather than a lamellar one. It would imply that the drawing would generate fibrils in which several tie molecules connect bundles of crystallites and therefore the boundaries of the microfibrils become partly lost.

Besides this, neither the fibres nor the fibrils shrink during the annealing in the hot stage of the polarizing microscope. According to Keller's criterion, our material should be assigned to Class 1; this is in disagreement with the preparative method of the specimens. As a matter of fact a contraction of about 10% can be mea-

sured by dipping the fibres in boiling water.

In order to justify the different behaviour of the two classes of materials we must take into account the morphology of the samples. We believe that in the Class 1 fibres many extended chain crystals are present; they are highly stable to temperature and consequently the whole structure is frozen in: the oriented non-crystalline sequences of the macromolecules having no possibility to relax. The specimen does not shrink. On the other hand, the structure of a Class 2 fibre is very different: the crystallites are defective and therefore the amorphous and oriented molecules can be easily pulled off from the paracrystallites by increasing the temperature. In this way a measurable shrinkage can occur. The shrinking test can never be fully satisfactory because the non-crystalline and oriented molecules of fibrous samples can crystallize very rapidly² and consequently the crystallization can take place before the relaxation occurs. The experimentally observed shrinkage is an undervaluation of the potential contraction or the molecules; if the relaxation time is very high in comparison with the crystallization time no shrinkage would occur².

Polymer chain cross-section and the Mooney–Rivlin constants

It is widely recognized that the stress–strain curves of real elastomers, even when tested under near equilibrium conditions, may depart to varying degrees from the theory of rubber elasticity¹. Instead, particularly under uniaxial tension at low extension ratios, they follow the Mooney–Rivlin equation^{2,3}

$$f = 2C_1(\lambda - \lambda^{-2}) + \frac{2C_2}{\lambda} (\lambda - \lambda^{-2}) \quad (1)$$

where f is the force of retraction at extension ratio $\lambda = l/l_0$ and C_1 and C_2 are the Mooney–Rivlin constants. Details of data treatment and numerical values of $2C_1$ and $2C_2$ for many elastomers have recently been summarized⁴.

An investigation of the variation of C_2/C_1 with chemical structure suggested an inverse correlation between cross-sectional area per polymer chain and C_2/C_1 ⁵. A more critical examination of the data has now been completed⁶.

Figure 1 shows a log–log plot of C_2/C_1 (at a fixed value of $2C_1 = 0.2 \text{ N/mm}^2$) against cross-sectional areas per chain in nm^2 . (Abbreviations used for polymer names and relevant data are given in Table 1.) The latter were calculated from lattice parameters of crystalline polymers⁷ on the assumption that they would not differ significantly for the amorphous elastomers. An averaging method was used for copolymers.

There is considerable controversy in the literature about the molecular significance of the Mooney–Rivlin constants⁴. This controversy will be discussed later⁶. Figure 1 seems to indicate an intermolecular rather than an intramolecular origin for $2C_2$.

Figure 1 predicts that an elastomer such as di(*n*-propyl siloxane) with a cross-sectional area of 90 nm^2 should have a substantially lower value of $2C_2$ and might indeed be indistinguishable from an ideal elastomer. However, from Vincent's⁸ correlation between strength and cross-sectional area, this same elastomer might have no practical utility.

Figure 1 Variation of C_2/C_1 at $2C_1 = 0.2 \text{ N/mm}^2$ as a function of cross-sectional area in nm^2 per polymer chain. The curve for $2C_2$ is parallel to the trend line

Table 1 Mooney–Rivlin constants and cross-sectional areas per chain

Polymer family	Area per chain (nm^2)	C_2/C_1 at $2C_1 = 0.2 \text{ N/mm}^2$
Polyethylene (PE)	0.183	4.3
Trans-polybutadiene (TPE)	0.181	2.75
Polybutadiene (<i>cis</i> and <i>cis-trans</i>) (PBD)	0.207	1.90
Ethylene–propylene rubber (E 60 wt%) random (E–P)	0.285	1.2
Styrene–butadiene rubber (25% S) (SBR)	0.32	1.3
Hevea rubber (NR)	0.280	1.15
Butyl	0.41	0.64
Poly(dimethyl siloxane) (PDMS)	0.436	0.33

We have found correlations of other physical parameters with cross-sectional area. Details of these correlations will be published in due course.

Properties of nylon-1 polymers and copolymers

Since Shashoua^{1,2} first showed that nylon-1 polymers of the type

could be prepared from alkyl or aryl isocyanates, several such polymers and copolymers have been prepared³⁻⁸ and their solution properties have been studied extensively⁹. In this way it has been shown that these polymers have an extended, nearly linear, chain in solution with a persistence length of 40–100 nm, and in this respect are more to be compared with the cellulose esters than with conventional vinyl polymers.

However, although the preparation of these polymers is well known there have been few, if any studies of their mechanical properties. This appeared to us to be unfortunate since considerable interest is attached to the question of the relation of chain configuration to physical and especially mechanical properties. For example, work on the yielding and post-yield deformation of polymers has postulated that these properties may be related to the number of deformable bonds in the

Figure 1 Stress-strain curves for butyl nylon-1 polymer and copolymer. (a) Homopolymer 30–40% crystalline, $[\eta] = 7.25$ dl/g, $M_v = 175,000$. A, -20°C ; B, 0°C ; C, 23°C . (b) Copolymer with $\sim 40\%$ molar ethyl isocyanate. Amorphous $[\eta] = 4.9$ dl/g (in benzene, 30°C). A', -20°C ; B', 0°C ; C', 23°C .

Figure 2 Photographs of poly(butyl isocyanate) test-piece showing uniform tensile deformation without necking. The sample on the left is the undeformed polymer

polymer chain^{10,11}. Thus polymers with straight chains would not be expected to undergo such large deformations as other polymers and orientation hardening (due to the exhaustion of deformable bonds) should set in at lower strains, thus counteracting the effect of strain softening. According to these theories therefore such polymers would show relatively uniform deformation in tension and 'necking' would be unlikely.

We have now made stress-strain measurements on cast films of poly(butyl isocyanate) (partly crystalline) and a butyl-ethyl isocyanate copolymer (amorphous). The polymers were cast from a 1:2 (v/v) mixture of toluene and chloroform. The curves obtained are shown in *Figures 1a* and *1b*. They clearly have a form similar to that reported for isotropic cellulose¹² and for cellulose ester films¹⁰. They also extend uniformly as shown in *Figure 2*.

Further studies at higher temperatures have shown that these polymers also differ from conventional vinyl polymers in other ways. Although, as shown in *Figure 3* they exhibit a damping peak at the temperature where the Young's modulus starts to fall, which may be regarded as a glass transition

Figure 4 Differential scanning calorimetric measurements with butyl nylon-1 polymer and copolymer compared with polystyrene. (A) Homopolymer (as for Figure 1a); (B) copolymer (as for Figure 1b); (C) polystyrene. Experiments carried out on Perkin-Elmer DSC-2 at 10°C/min and 5 m cal sensitivity

temperature (T_g) the fall in modulus with temperature is rather slow and the damping peak rather flat compared with more conventional polymers. This is accompanied by a very much reduced change in specific heat at ' T_g ' as shown by the d.s.c. curves in Figure 4, where the measurements recorded

for the two nylon-1 polymers are compared with those for polystyrene. It will be seen that on a scale in which ΔC_p (at T_g) is easily observed with polystyrene there is no significant effect with the nylon-1 polymers.

We hope to publish full details of this work at a later date.

COMPOSITES

the technology of composite materials

COMPOSITES is the only journal devoted to the science and technology of composite materials. All materials which can be classed as composites are included. The approach is therefore interdisciplinary, covering fields such as metallurgy and timber research, polymer chemistry and glass technology. Published quarterly, each issue of COMPOSITES contains a selection of news, conference reports and calendar, book reviews and abstracts of relevant articles and patents, in addition to papers on applications and current research and development work.

COMPOSITES subscription (4 issues)
£22 UK, £28 Overseas

Book Reviews

Emulsion Polymerization: Theory and Practice

D. C. Blackley

Applied Science, London, 1975, 566 pp. £16.00

It is 20 years since the only previous monograph in English on emulsion polymerization was published. Bovey, Kolthoff, Medalia, and Meehan summarized the work carried out under the Office of Rubber Reserve in the United States during the war on the development of synthetic rubber. Subsequently the emulsion polymerization of other monomers has become important: vinyl chloride, vinyl acetate for emulsion paints, butyl acrylate for leather finishes, vinylidene chloride, ethylene, and tetrafluoroethylene. These differ between themselves and from the much studied styrene model system. Although one or two reviews have appeared each year in the meantime, an up-to-date monograph was overdue. The field is thoroughly reviewed in this book although in a rather verbose style. A few previously unpublished results from the author's laboratory are included. Chapters explain the Smith-Ewart Theory and Gardon's revision of it in detail. The history of the topic, the effects of initiators, emulsifiers, modifiers, electrolyte additions, variation of aqueous phase composition, sequestering agents, and shortstoppers are all covered. There is a chapter on non-aqueous dispersion polymerization: the final chapter points out 'Some Unresolved Problems'. Continuous reactors for emulsion polymerization, emulsion copolymerization, and applications of polymer latices are excluded. Literature references are confined to those in English or available in English translation but these will cover 90% of the relevant material and readers may be encouraged to follow up references although most will find as much as they need to know in the book itself.

There are indications (mentioned in the last chapter) that the theory of emulsion polymerization is now due for a major revision. The importance of the micellization of emulsifiers and the solubilization of monomers in micelles has been exaggerated and the question of the stabilization of polymer latex particles has been neglected. So this account, written from the viewpoint of the classical theory of Smith and Ewart, may only just have appeared in time. Undoubtedly the Smith-Ewart theory accounts for most features of the emulsion polymerization of styrene and (when effects of transfer to monomer are taken into account) for those of the vinyl chloride and vinyl acetate too. But there has been a tendency for workers to force their results into the mould provided by the only available theory when an unbiased assessment would have shown that the results did not really fit the theoretical relations at all! It is greatly to be hoped that the advent of this admirable work may stimulate rather than delay the development of an alternative theory.

Deformation Kinetics

A. S. Krausz and H. Eyring

Wiley, New York, 1975, 398 pp. £13.50

The object of this book is to explain and describe plastic deformation and fracture processes in solids in terms of the kinetics of bond rupture. The point is made, cogently, that any deformations (other than purely elastic ones) in a condensed phase of matter involve the rupture and repair of inter-atomic bonds; to quote 'plastic deformation is a process *identical* to the isomerization of a giant molecule - the specimen'.

The philosophy having been established, the book launches into part I—The theory of deformation kinetics. The basic idea of thermally activated atomic processes is developed and applied briefly to viscoelasticity and, much more extensively, to dislocation mobility in crystals. This section contains a considerable amount of experimental data e.g. on dislocation velocities and the stress dependence of strain rate in creep. In all cases the experimental results can be described satisfactorily by rate-theory equations.

Turning from the microscopical to a continuum approach, the rate theory of thermally activated plastic flow is introduced, featuring as major parameters the apparent activation energy and the acti-

vation volume, both of which betray the underlying atomicity of the phenomena.

Part II, titled 'The analysis of deformation processes', introduces the familiar mechanical (spring and dashpot) models for inelastic processes. Having derived the relevant equations, the authors apply them to experimental phenomena such as yield (the Johnson-Gilman analysis), creep and recovery and stress relaxation. A refreshing feature of this section is the catholic treatment of materials, examples being taken from among metals, thermoplastics and thermosetting resins. Continuing the use of model analysis under 'special topics' the authors next consider mechanical hysteresis, vibration, and the effects of hydrostatic pressure on yield and flow.

A section on the interaction of deformation and chemical reactivity is mainly limited to effects on hair and natural fibres and an opportunity to include stress-corrosion processes seems to have been missed. The final section is devoted to the kinetic theory of fracture and includes reference to the direct observation of bond breakage in polymers by e.s.r. Appendices cover Boltzmann statistics, partition functions and the theory of absolute reaction rates for solids.

This is altogether a most useful, thorough and up-to-date book, eminently readable and thought-provoking on account of its synoptic approach to a wide range of physical phenomena. It is expensive at £13.50 but represents excellent value for money.

E. H. Andrews

Advances in Polymer Science

Volume 18: Macroconformation of Polymers

Springer-Verlag, Berlin, 1975, 149 pp. \$29.70

This volume comprises two authoritative highly specialized review articles which fall within the sub-title 'Macroconformation of Polymers'.

The first, on 'Long-Chain Branching in Polymers', by P. A. Small, runs to 64 pages with 208 references. It opens with a general introduction, followed by eight sections which deal with generalized aspects of the subject, viz. the general effects of long branches, the dimensions of branched molecules, the hydrodynamic properties of branched polymers, the melt viscosity of branched polymers, the thermodynamics of solutions of branched polymers, synthetically branched polymers as models and methods for the estimation of long branching. These are followed by three chapters in which long branching in specific polymers, viz. polyethylene, poly(vinyl acetate), polystyrene, poly(methyl methacrylate) and poly(vinyl chloride), is discussed. In a brief conclusion the author draws attention to the difficulties of applying theoretical treatments to branched polymers and discusses the origins of these difficulties.

The second article, by A. Teramoto and H. Fujita, deals with 'Conformation-Dependent Properties of Synthetic Polypeptides in the Helix-Coil Transition Region'; it occupies 83 pages and includes 137 references. Attention is drawn to the restrictions which the authors have imposed on themselves; they deal here only with non-electrolyte poly(amino-acids) and only in the helix-coil transition region, in which the conformation can be regarded as an 'interrupted helix'. The article opens with an outline of the statistical-mechanical formulation of polypeptides conformation in terms of the degree of polymerization, N , and the Zimm-Bragg-Nagai parameters s and σ . It then proceeds to discuss three properties of interrupted-helical poly(amino-acids), viz. molecular dimensions, intrinsic viscosity and translational friction coefficient, and mean-square dipole moment and mean rotational relaxation time derived from dielectric dispersion measurements. In all three cases, a theoretical treatment is followed by a discussion of experimental results. As the authors state, the article is to some extent a summary of the work of their own school, although it is by no means restricted to this.

A must for specialist polymer laboratories, the price of this volume will probably put it out of the reach of most individuals; it is not for the non-specialist reader.

H. N. Rydon

Professor Geoffrey Gee FRS—A Tribute

Geoffrey Gee's attachment to polymer science began soon after he had graduated with distinction at Manchester University in 1931. He had come under the ubiquitous wing of the Dye-stuffs Division of ICI and was promptly sent to work with Professor Eric Rideal in the Colloid Science Laboratory at Cambridge. This was probably the most exciting centre for physical chemistry in the country at the time because Rideal was adept at attracting a mixed bag of lively researchers from near and far, encouraged a catholicity of interests, and gave people their heads. In this nurturing environment, polymer synthesis and behaviour was becoming a main topic of interest, and Gee with a fellow ICI colleague swelled this stream by studying the kinetics of polymerizations relevant to the production of synthetic rubbers.

His career took a new turn in 1938. The British Rubber Producers' Research Association had just been founded to provide technical backing to the natural rubber industry in the shape of consumption research and development to complement the substantial agricultural effort that had been going on for some time. The first Director, Mr J. Wilson, was recruiting the start-up staff and, by a combination of luck and judgement, he assembled a small team that proved to be of more than ordinary ability. A star performer was Geoffrey Gee who, on Rideal's recommendation, had been invited to head and build up a physical chemistry cum physics group. Mr Wilson, happily still with us, was a decidedly unconventional character who, although coming from an entirely industrial background, had acquired as passionate a fervour for fundamental research as John Knox had for Calvinism. When, as years passed, remonstrances were sometimes voiced as to whether the emphasis on fundamental research was perhaps being overdone, his come-back was much in the colloquial vein of 'you've seen nothing yet'. But whatever the power and persuasion of this particular and, as it turned out, well justified spirit, somebody has to give it flesh and bones if it is to be credible and purposeful and this is where Gee's efforts in the early years of the BRPRA's existence have an enduring value. Amid the fog which shrouded rubber science at the time, and with any number of false trails to confuse and confound, he saw with acute perception where fundamental research on a modest scale could make worthwhile break-throughs. The outcome was that within a decade or two he and his colleagues had made major contributions to the remarkable advances in knowledge of this general field that occurred in the period and thereby set up the scaffolding on which developments of great commercial impact were later to be built.

To gauge the measure of this achievement one must recall the state of basic polymer science nearly forty years ago—though I doubt if anyone who was not around and involved at the time can quite visualize today how embryonic and murky it then was. Certainly Staudinger had revealed the general topography of the domain of high polymers and a few other pioneers such as K. H. Meyer and H. F. Mark had located important landmarks, but most explorers made little inroads and often managed to obscure rather than clarify the detailed features. This unsatisfactory state of affairs was thrown into greater relief by the striking developments coming forward on the technological and industrial fronts. PVC, Perspex, polyethylene, chloroprene and nylon were at different stages of large-scale commercialization and other synthetic rubbers were soon to be. These developments were broadly science based of course, but as regards polymer science *per se* the input was of 'inspired empiricism', to use W. J. S. Naunton's apt expression, rather than much by way of guiding principles. But the need for back-up basic knowledge was increasingly being felt and the flowering of polymer science and polymer scientists, notably in the USA, that soon followed in the wake of this stimulus is a matter of history.

For his own work Gee chose to tackle two truly basic problems in rubber science, namely to put the determination of molecular size on a sound basis and to rationalize the behaviour in solvents and swelling agents. Finding that the key to the latter lay in thermodynamics, he set himself to become thoroughly proficient in a subject of but limited familiarity to him hitherto. One recollection from those days is of him at his desk in the utilitarian laboratory he shared with other senior and junior staff working his way imperturbably through tomes and papers on thermodynamics, seemingly oblivious of the day-long comings and goings and the incessant clatter of vacuum pumps. By a combination of theory so absorbed and of elegantly simple experiments designed to dig out cleanly the data that mattered, the problems mentioned were clarified in out-

line within a handful of years and highways opened up for understanding vulcanizate behaviour and elasticity theory that are still being travelled today.

At the same time, Gee took any amount of trouble to help along the work of his colleagues—and did so to real effect. In particular, as no-one knows better than myself, he played a big part in resolving the mechanistic details of olefin and polyisoprenoid autoxidation—another piece of work which changed the face of knowledge and was to have important spill-offs later on.

In 1949 Gee succeeded to the Directorship of the Association and was confronted with problems of a different kind. More critical questioning of the 'dollars and cents' impact of the work was entering the scene and so, without fuss or upset and while ever concerned to sustain the scientific élan, he proceeded to put a more practical slant into the BRPRA's activities. Illustrative of this was his own analysis made in 1949, little known and barely remembered, of what the natural rubber industry needed to do by way of improved marketing and technical standardization of its product if this were to compete with synthetic rivals. His recommendations prompted action at the plantations and, while others in practising the art of the possible have since had to modify the approaches and emphases, the sequel to his early initiative is that something like a million tons of modern presentation natural rubber are currently being marketed annually—this representing one of the most dramatic technical achievements in up-dating a traditional agricultural, and high polymeric, product from developing countries.

Having put his distinctive imprint on the Association in ways such as this, Geoffrey Gee was obviously gratified to receive in 1953 an invitation to occupy the Chair of Physical Chemistry at his *alma mater*. He, and others, saw as an important objective in this appointment the bringing into being of a school of polymer chemical physics, and this was immediately turned to. But the going was not to be easy. In a year or so the Senior Professor moved to more cloistered pastures and Gee, a relatively raw recruit to the university scene, had perforce to assume the responsibility of managing a large department at a testing time of change. Expansion was then the thing; high student intakes had to be coped with, staff at all levels recruited when practically every university was doing likewise, and new buildings planned and organized—and all within the particular context of the massive redevelopment of the enlarged university site at Manchester. Becoming involved in these matters to a degree that both the pressures and his conscientiousness dictated he had to be, it is no wonder that the prosecution of his own research interests came under constraints. Nevertheless, work in his main speciality of seeking better descriptions of solution and kindred properties of polymers was soon put under way and a supporting team built up. From this has since come notable contributions to the deeper understanding now prevailing of the thermodynamics of polymer—solvent and polymer—polymer mixing, of intermolecular forces between polymers in solution, and of the structural and configurational features determining chain flexibility. With his collaborators and associates, the newer physical techniques of nuclear magnetic resonance and neutron scattering have been exploited with positive effect to supplement the traditional, though increasingly refined data obtained from older investigational methods such as calorimetry. Of special value in this general effort has been simply the existence of a strong group in the field, having close contacts with the polymer industry and critically familiar with work going on elsewhere, with whom Paul Flory has been happy to spend sabbatical leave, and which has served as a 'reference base' for polymer scientists in Europe with cognate interests.

Geoffrey Gee's original papers and review articles are in the literature to testify to his perceptive intellect and to his enviable clarity in analysis and exposition. But not on record are the finely sifting queries, the shrewdly pointed suggestions to measure this or work out that, and the rare skill to penetrate the perplexing that have placed so many who have worked alongside him so much in his debt. It is in the sum of his work and of his influence, so self-effacingly exerted, that the full worth of his conspicuous contribution to polymer science over four decades is to be found.

L. Bateman

Theory of glasses*

S. F. Edwardst

Science Research Council, State House, High Holborn, London WC1R 4TA, UK

(Received 19 May 1976)

It is argued that it is possible to define a 'perfect glass' which is both preparable experimentally and understandable theoretically. Some basic conditions and statistical thermodynamics are derived. Polymerized glasses are complex substances but it is argued that progress may be possible by considering them to have short range properties, and long range properties. Examples are given of models of glasses with such properties and their behaviour is shown to be amenable to theory.

INTRODUCTION

It is a pleasure to contribute a paper in honour of Professor Geoffrey Gee, for it was he who suggested to me that polymerized glasses present a great challenge to the theorist. The trouble with the study of such glasses lies not only in the irreducible difficulties which separate them from simpler systems, but also in their specification. From the point of view of a theorist, or indeed any investigator, one just does not know the nature of the substance under study. It is therefore worthwhile asking if there is possibly a 'perfect' glass, or perhaps a 'theorist's ideal glass' (*TIG*), where well founded calculations can be made of the thermodynamic properties. I believe this to be the case, and indeed some *TIG*'s already exist, and confirm strikingly the predictions of theory.

Polymerized glasses are bound to be more complex than these examples, but one must walk before one can run.

STATISTICAL MECHANICS OF A *TIG*

Suppose one could order the motions of a substance at a particular temperature and density, so that a label can be put on each of them, and any particular state built up from them. Suppose that at a certain temperature one or more of these motions are clearly slower than the rest. Suppose finally that it is possible to suddenly reduce the temperature or pressure of the system so that one maintains the population of the different modes of motion into the region where certain modes are very slow; so slow that they scarcely change over a period where all the other modes reach thermal equilibrium. Then one has a *TIG* in which some modes are characterized by the current temperature and density (or pressure), and others by previous conditions.

It is easy to find examples which can be made. For example if one has 1% of Cu dissolved in Au, and cools it from the melt, the rate at which it orders into crystallinity is much faster than the rate of migration of the Cu about in the Au lattice. So, although in the fullness of time atoms will migrate and either nucleate, or if they remain dissolved do so with the correlation functions of the CuCu CuAu etc. determined by the thermal equilibrium distribution, it is easy to obtain a specimen in which the Cu atoms are distributed with a distribution appropriate to a high

temperature (in fact virtually at random) whilst the specimen is at say 10K.

How can one describe such a system? Consider the problem, at constant volume for simplicity, with the glass formation due to temperature changes. Suppose the degrees of freedom of the system are arranged into the fast modes, called x_α and slow modes called X_α . The energy of the system is given by a Hamiltonian $H(X, x)$ and in thermal equilibrium the probability of finding... X_α ... x_α ... is:

$$P(\dots X_\alpha \dots; \dots x_\alpha \dots) = \exp[F - H(X, x)]/kT \quad (1)$$

where the normalization condition of the probability

$$\int P \Pi dX dx = 1 \quad (2)$$

gives the Helmholtz free energy F from

$$\exp -F(T)/kT = \int \exp[-H(X, x)/kT] \Pi dX dx \quad (3)$$

One may also introduce the probability of finding X with no restraint on x

$$P'(\dots X_\alpha \dots) = \int \exp\{[\hat{F}(X) - H(X, x)]/kT\} \Pi dx \quad (4)$$

where

$$\exp[-\hat{F}(X, T)/kT] = \int \exp[-H(X, x)/kT] \Pi dx \quad (5)$$

By putting equations (3) and (5) together, one has also:

$$\exp(-F/kT) = \int \exp(-\hat{F}(X)/kT) \Pi dx \quad (6)$$

Suppose the material is at T_0 , and is cooled to T_1 , in such a way that the distribution of the X is unchanged, and is therefore still

$$P'(X) = \int \exp\{[\hat{F}(X, T_0) - H(X, x)]/kT_0\} \Pi dx \quad (7)$$

The x variables thermalize at T_1 , whilst the X variables are no longer part of the dynamics of the system, being frozen at their T_0 values. It follows that the free energy of the glass is given, for a definite set of X 's by

* Presented at the Sixth Biennial Manchester Polymer Symposium, UMIST, Manchester, March 1976.

† Also at Cavendish Laboratory, Cambridge, UK.

$$\exp[-F_g(X, T_1)/kT_1] = \int \exp[-H(X, x)/kT_1] \Pi dx \quad (8)$$

i.e.

$$F_g(X, T_1) = -kT_1 \log \int \exp[-H(X, x)/kT_1] \Pi dx \quad (9)$$

But the X 's have the distribution (7), so the experimentally observed free energy will be

$$F_g(T_0, T_1) = -kT \int \{ \exp([\hat{F}(X, T_0) - H(X, y)]/kT_0) \Pi dy \times \log \int \exp[-H(X, x)/kT_1] \Pi dx \} \Pi dX \quad (10)$$

This is much more difficult to handle than the straightforward Gibbs formula, equations (1) and (2), but it must be emphasized that it is the *simplest* formula possible for a glass, and will be only applicable under *TIG* conditions.

The formula (10) already has applications in polymer science. The grand example is that of a rubber. In a rubber a set of crosslinks are established in the entangled polymer melt. Their positions are now fixed and their mobility essentially nil. The rubber is now sheared say, but the crosslinks are distributed in a way appropriate to the unsheared material, so a modulus of elasticity results. Notice that the Gibbs equations (1) and (2) cannot give a resistance to shear. It is surprising that text books do not generally discuss this point. When they study the transition from a liquid to a solid, the crystal axes of the solid are put in without comment. But the Gibbs formula, strictly interpreted, would integrate over these axes as well. In such a case $F = F(T, V, N)$ only, and cannot sustain shear.

The analogous formula to equation (10) has been given by the author (Edwards^{1,2}) and provides (at least to the author's mind!) a firm basis for calculations of higher detail of the elastic equation of state (see for example Deam and Edwards³).

Examples will now be given applying these ideas to models with short range order and long range order. The suggestion is that a polymerized glass will have both the properties of local difficulties in fitting together, and long range effects carried along the molecular chain by which atoms remote from each other can nevertheless interact. Such long range interaction is well known in polymer solution and gel studies, but harder to develop for glasses.

GLASSES WITH SHORT RANGE ORDER: THE SPIN GLASS

Suppose one dissolves a little Fe in Au. One can think of the Fe atom as a little magnet, but solid state physics shows that if the interaction energy is written as

$$\sum_{ij} J_{ij} s_i \cdot s_j$$

where the i th little magnet points in direction s_i , and the j th in direction s_j , then J_{ij} oscillates with the distance $R_i - R_j$ between the sites i and j . Roughly speaking this is why some materials like pure Fe are ferromagnets i.e.

the spacing between Fe neighbours hits an attractive value for J and all the little magnets line up parallel whilst other materials e.g. MnF_2 are antiferromagnets, where the lattice spacing hits a repulsive value for J and the Mn magnets line up alternately up and down. Such a material will not show external magnetism but will have anomalies in the specific heat showing the existence of a phase change when the random directions at high temperatures are replaced by the alternate up and down positions below the critical temperature.

In a spin glass, the magnetic atoms are placed at random, so any pair will interact with J positive or negative according to the distance. This is adequately described, since the distances between atoms is random being fixed by the high temperature from which the alloy was cooled, by taking J_{ij} to itself be a random distribution, albeit decreasing with distance. In other words one can model the problem by saying that:

$$H = \sum_{ij} J_{ij} s_i \cdot s_j \quad (11)$$

but J_{ij} have fixed values, by a probability distribution:

$$P(J_{ij}) = [\exp -(\frac{1}{2} J_{ij}^2 / J_0^2 \epsilon_{ij})] (J_0 \epsilon_{ij} \pi)^{-1/2} \quad (12)$$

where ϵ_{ij} is some monotonic decreasing function of distance. Thus equation (10) in this case is translated into a somewhat simpler form:

$$F_g = \int \Pi dJ_{ij} P(J_{ij}) kT \log \int \exp[(J_{ij} s_i - s_j)/kT] \Pi ds_i \quad (13)$$

This is equation (10) with the X being J_{ij} and with $T_0 = \infty$, P being given by equation (12).

Now one may ask what one would expect to happen. At a high temperature, the magnets will point at random i.e. paramagnetically. At a very low temperature there must be a position, or positions, of equilibrium and the magnets will settle into one of these. In one of these states they will still be pointing in different directions since their local fields will all be different, built out of the J 's of their neighbours. Thus one can expect a phase change from the paramagnetic state in which the direction of the little magnet varies over the whole 4π available to it, to a state in which the direction of each little magnet oscillates about some mean definite direction. The change will show up in a susceptibility anomaly and in a specific heat anomaly. These are found and a theory based on equation (13) has been given by Edwards and Anderson⁴. That this theory explains the particular experimental phenomena is of course to be confirmed by more detailed experimentation, but there seems no doubt that if solid is aptly described by equations (11) and (12) then it will show a phase change into a 'glassy' spin state.

The device which makes equation (13) a basis for calculation is the observation that

$$\log A = \text{coefficient of } n \text{ in } A^n \quad (14)$$

Hence if we think of n 'replicas' of our system, and evaluate

$$\mathcal{F}(n) = \int \prod J_{ij} P(J) \times \exp \left(\sum_{\alpha} \sum_{ij} J_{ij} s_i^{\alpha} \cdot s_j^{\alpha} / kT \right) \prod_{\alpha, i} ds_i^{\alpha} \quad (15)$$

then

$$\mathcal{F}(n) = \mathcal{F}(0) + nF_g \quad (16)$$

It turns out that with approximations it is possible to study equation (15) in n dimensions and evaluate equation (16). The mathematics is not far from the familiar mean field theory, but instead of a mean field, one makes the hypothesis that:

$$\langle s_i^{\alpha} \cdot s_i^{\beta} \rangle = 0 \quad T > T_c \quad (17)$$

$$= q(T) \quad T < T_c \quad (18)$$

$$\text{with } q(0) = 1 \quad (19)$$

There is some analogy with the fact that molecules in a polymer chain which is disordered will have an orientational interaction with their neighbours, although the analogy is by no means perfect. There is perhaps a stronger analogy with rod-like molecules, but these will normally have a potential energy which is doubly periodic whereas magnets are singly periodic.

LONG RANGE INTERACTIONS

At once one meets the difficulty that whereas the simplest theory of ferromagnetism produces an intuitive feeling for the spin glass, there is no simple theory of the simplest model of the long range effect, that of the liquid/solid transition; at least no simple theory which produces the crucial feature of a first order transition. It is argued for example in Landau and Lifschitz' text⁵ that the first order transition is a phenomenon requiring a transition between states of symmetry and no symmetry. I do not believe this is true, and will now develop an admittedly crude theory of the liquid/solid transition in which the crystal structure of the perfect solid is not introduced, and which does not indeed give a first order transition*.

The theory will follow many crude but successful theories of statistical mechanics in which the phase change is attributed to a phenomenon and the magnitude of the physical manifestation of the phenomenon, q say, is a parameter to be determined by the equilibrium condition:

$$\frac{\partial F}{\partial q} = 0 \quad (20)$$

Equation (20) represents a relation between T , N , V , q and the phase change comes when two roots of equation (20) cross over and the value of F which is the minimum corresponds to phase 1 for $T > T_c$ and phase 2 for $T < T_c$. The q of equation (17) is an example, but a much more familiar

one is the mean field of the Weiss theory of ferromagnetism. One assumes that such a field exists and calculates the value which makes F a minimum. For $T > T_c$ the mean field is zero, and the material paramagnetic. For $T < T_c$ the mean field is non-zero, and saturates as $T \rightarrow 0$ to the value obtained when every atom is aligned parallel.

The reference state will be taken to be the perfect solid, and the liquid state will be viewed as a solid which contains faults. It is well known that the simplest classification of faults in a solid is into dislocation and point defects. Point defects are fairly straightforward and local, whilst dislocations have long range effects and are difficult to create or destroy. The model will then assume that the solid state has no dislocations, whereas the liquid state does. Now a real solid does have dislocations of course, but these are the analogue of ferromagnetic fluctuations in a ferromagnet and can be ignored in the crude theory studied here. The idea of treating a liquid as a network of dislocations is not new, but the calculation to be reported on here will contain new features. The free energy of the perfect solid is taken to be known $F_0(V, T, N)$ and will be used as a given function. It will be taken to have the normal property appropriate to a solid under zero (or effectively zero) pressure i.e.

$$P_0(V) = - \frac{\partial F_0}{\partial V} = 0 \quad (21)$$

$$\frac{\partial P_0(V)}{\partial V} \quad (22)$$

At this point one may catalogue the changes expected when a dislocation density q appears.

An expansion

The dislocation will carry volume, say a^3 per unit length, total dislocation length being q . Then $F_0(V)$ becomes $F_0(V + qVa^3)$. Thus:

$$F_0(V + qVa^3) = F_0(V) + qa^3 \frac{\partial F_0}{\partial V} + q^2 \frac{a^6}{2} \frac{\partial^2 F_0}{\partial V^2} \quad (23)$$

to second order. Hence:

$$F_0(V + qVa^3) = F_0(V) + \frac{c}{2} \rho^2 \quad (24)$$

where $c = -\partial P_0 / \partial V$ and will be assumed approximately constant, i.e.

$$\Delta F_1 = \frac{c}{2} \rho^2 \quad (25)$$

Entropy

The dislocation edge will give rise to an entropy corresponding to the choices of direction open to it on formation. One immediately has the difficulty of the non-Markovian nature of the 'random walk' of the edge, and also by the fact that although energy effects are not strictly separable from the entropy, the effective step length of the system can involve local elastic energy and make sharp bends infrequent. Nevertheless the first approximation will be to associate an entropy per unit length of the dislocation, say

* Professor P. W. Anderson made substantial contributions to this work and Mr Mark Warner helped work out the details.

$$\Delta F_2 = -TS = -Tq\sigma \quad (26)$$

Elastic energy

The local elastic energy will simply be proportional to q , ϵq say. More tricky is the long range elastic field (of which ϵ is just the cut off term). A full calculation involves detailed elasticity theory as given by the books of Friedel⁶ or Nabarro⁷, but it will suffice here to consider an electro-magnetic analogy. Suppose one has a unit current j flowing along the dislocation line. The energy will be:

$$H = \mu \iint \frac{j(s_1) \cdot j(s_2)}{|r(s_1) - r(s_2)|} ds_1 ds_2 \quad (27)$$

where s is considered as the arc length of the locus of the line $r(s)$ and for unit current:

$$j = \frac{\partial r}{\partial s} \quad (28)$$

One must now evaluate $\exp(-H/kT)$ taken over a random distribution of dislocation lines being random walks of step length say l (of the order of a few lattice spacings). (The full elastic theory uses stress tensors but does not have an essentially different energy function.)

The calculation of $\int \exp(-H/kT)$ now can be performed after the Debye-Huckel theory of screened Coulomb interactions. It need not be reproduced here except in the final form that it gives rise to a free energy contribution:

$$\frac{\partial \Delta F_3}{\partial q} = \frac{2\pi^2 \mu b^2}{b + \left(\frac{q\mu}{kT}\right)^{1/2}} \quad (29)$$

where b is the point at which equation (2) is an inadequate description, so that as $q \rightarrow 0$ the contribution is:

$$\Delta F_3 \rightarrow 2\pi^2 \mu b^2 q$$

The term ϵq compensates for any errors in this expression due to short range detail.

$$F = F_0 + \Delta F_1 + \Delta F_2 + \Delta F_3$$

The condition of equilibrium is

$$\frac{\partial F}{\partial q} = 0$$

or

$$0 = cq - \sigma kT + \epsilon + \frac{\mu'}{b + \left(\frac{q\mu}{kT}\right)^{1/2}} \quad (30)$$

The perfect solid is $q = 0$ and q must always be ≥ 0 . A sketch of the right hand side $-P(q)$ of equation (30) shows three cases (Figure 1). Possible values of q are marked by crosses. In Figure 1a the perfect solid is the only solution and $q = 0$. Figure 1b is critical and $q_c \neq 0$. Finally in Figure 1c the right hand value gives the q for which F is a minimum.

Figure 1 Free energy curves

Thus a first-order transition has been obtained. The cases are in ascending temperature Figure 1a, 1b, 1c for constant volume.

GLASS WITH LONG RANGE ORDER

The work of the section above, crude as it is, will give a model of a glass. The view is that q represents a slow motion. When the glass is quenched from T_0 with q_0 , to T_1 , q remains the same. Clearly the identification of q with a dislocation density may be an oversimplification, but from a TIG point of view one now has a framework to employ (equation 10) and derive say the specific heat as a function not only of T_1 but T_0 . It will be seen that what in fact is derived is:

$$(C_v)_{\text{glass}} - (C_v)_{\text{perfect solid}}$$

since all the work is relative to the perfect glass free energy which is taken to be known.

It is possible to make sense of the various curves describing the behaviour of C_v through the glass transition by extending these ideas, and it is hoped to report fully on them (and some new experiments aimed to make the glass quickly rather than slowly) later.

I hope however to have shown that both local molecular orientation and long range effects may both be important contributors to glass behaviour, and doubtless polymerized glass contains elements of both of these phenomena.

Structure and properties of block polymers and multiphase polymer systems: an overview of present status and future potential*

S. L. Aggarwal

The General Tire & Rubber Company, Akron, Ohio 44329, USA

(Received 13 July 1976)

Work on the block polymers of styrene and butadiene indicates the potential of multiphase polymers of controlled solid state structure. The effect of chemical composition, molecular architecture (multichain 'star' shaped *versus* linear), block sequence length, processing conditions, and blending of homopolymer with the block polymers on their solid state morphology is discussed. Results on these block polymer systems indicate the future research directions in certain areas. Implications of these areas for polymers of controlled solid state structure to provide materials of desirable combination of properties are also considered.

INTRODUCTION

The scientific and technological advances resulting from the work on block polymers have constituted a major milestone in polymer science during the last decade. The exciting aspect of the block polymers and other multiphase polymers is that in a number of important cases, it has been found possible to control the morphology in the solid state and to be able to vary it over a broad spectrum through control of their molecular structure and composition. The scientific foundation for the advances in block and multiphase polymers goes back to early fundamental studies of Professor Geoffrey Gee, particularly the work in such areas as the preparation of polymers of controlled structure, thermodynamics of polymer solutions and phase separation, and the relation between chemical structure

and mechanical properties. Future advances in multiphase polymer materials, particularly in those polymers that are generally referred to as thermoplastic rubbers, are likely to depend on the scientific framework that the work of Professor Gee and his group provided in the area of network structure and rubber elasticity.

This paper is in two parts: Part I is an overview of the solid state morphology and combination of desirable properties that are attainable by the control of the chemical and molecular structure of block polymers. Part II is a brief discussion of a few of the recent research directions that appear particularly promising for multiphase materials of controlled structure with desirable combinations of properties.

PART I: STRUCTURE AND MORPHOLOGY OF MULTIPHASE POLYMERS — AN OVERVIEW

MORPHOLOGY OF STYRENE/BUTADIENE BLOCK POLYMERS

Preparation of styrene/butadiene/styrene triblock polymers by anionic polymerization

The system that has been studied in detail is that of block polymers of styrene and butadiene (or of isoprene in place of butadiene)¹⁻⁷. The polymerization chemistry that has made possible the preparation of block polymers of controlled structure is based on anionic catalysts such as butyllithium⁸⁻¹¹. The reactive species from such initiators, with suitable monomers, are long-lived carbanions^{11,12}. Thus, one may polymerize a monomer A (styrene) to completion, followed in sequence by polymerization of another monomer B (butadiene or isoprene) to obtain a diblock polymer. The triblock ABA block polymer may then be

prepared by adding monomer A to the diblock polymer with the active end, or the diblock polymer active species may be coupled by a chemical coupling agent^{10,13}. The scheme of preparing block polymers by sequential anionic polymerization is shown schematically in *Figure 1*. However, a number of kinetic and preparative details must be considered in the preparation of triblock polymers from styrene and butadiene, to eliminate the homopolymer and diblock impurities during polymerization and coupling reactions. These have recently been discussed by several authors¹⁴⁻¹⁶.

An especially convenient, and perhaps better controlled, method for the preparation of styrene/butadiene/styrene triblock polymers is by the use of difunctional catalysts such as 1,4 dilithio-1,1,4,4-tetraphenylbutane¹⁷⁻¹⁹.

* Presented at the Sixth Biennial Manchester Polymer Symposium, UMIST, Manchester, March 1976.

Figure 1 Scheme for preparing block polymers by anionic polymerization

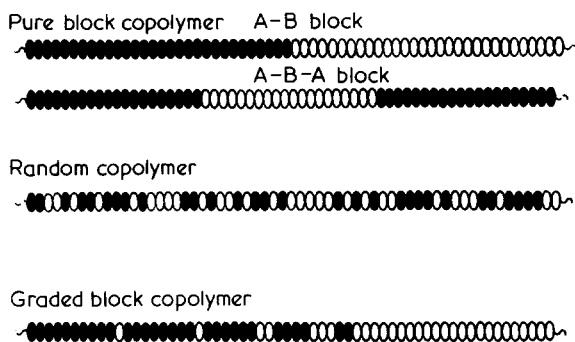

Figure 2 Schematic representation of copolymer structures

Butadiene is first polymerized at each terminal active end, followed by the polymerization of styrene to form the terminal blocks. This procedure was also used to prepare the triblock ABA polymers of α -methylstyrene (A) and isoprene (B)¹⁹.

Another aspect of anionic polymerization that makes it a very useful method for obtaining copolymers of controlled sequence length is the broad range of reactivity ratios that are possible in copolymerization of such monomers as styrene and the common dienes either in different solvents (e.g. benzene *versus* tetrahydrofuran) or in the presence of different concentrations of weakly basic ethers (e.g. diphenyl ether and anisole)²⁰⁻²⁵. Based on these features of anionic polymerization, using an organo-lithium compound as an initiator, a number of block polymers of styrene and the common dienes (butadiene and isoprene) have been prepared.

Styrene/butadiene/styrene thermoplastic rubbers

Figure 2 shows schematically the various block polymer structures that can be prepared. The graded block structures result when the comonomers are added together initially and the reactivity ratios are controlled by carrying out the polymerization in benzene containing a suitable concentration of a weakly basic ether such as diphenyl ether²⁴⁻²⁷. It results in long sequences of styrene at each end. The sequence length of the styrene units gradually decreases away from the terminal blocks, so that the central block may have only sequences of one or two styrene units, but it has long sequences of butadiene units.

The first block polymer that attracted wide interest was Kraton thermoplastic rubber by Shell^{2,3,28}. It consists of approximately 70% butadiene and 30% styrene by weight. The central block is of butadiene units, and the terminal blocks are of styrene units. At room temperature it is a strong rubber^{29,30}, can be processed as a thermoplastic at elevated temperatures and requires no crosslinking for

coverable large deformations characteristic of common vulcanized rubbers.

In Tables 1 and 2 are given the comparative strength and fatigue-to-failure properties of Kraton thermoplastic rubber and typical vulcanized rubbers at room temperature. At higher temperatures there is of course a large decrease in these properties for the thermoplastic rubber.

The model⁵ proposed to explain the above properties is shown schematically in Figure 3. It shows polystyrene domains segregating as glassy domains that act both as reinforcing filler and also provide physical crosslinks that are thermally labile. This model in its essential features, has been shown to be the correct one by the work of a number of workers³¹⁻⁴¹. The most direct evidence has been from the electron micrographs of such block polymers, stained by osmium tetroxide which stains the rubber phase, and thus appears dark in the electron micrographs. Figure 4 is one of the early electron micrographs from our laboratory

Table 1 Comparative strength values of typical vulcanized rubbers and Kraton 101 thermoplastic rubber

	Tensile strength (lb/in ²)	Elongation (%)
Triblock thermoplastic rubber (Kraton 101)	40 300	740
Natural rubber (carbon black reinforced and cured)	28 200	560
SBR synthetic rubber (carbon black reinforced and cured)	29 800	590

Figure 5 Electron micrograph showing short range order and morphology of styrene/butadiene/styrene (styrene/butadiene 25/75) block polymer

which shows the spherical polystyrene domains of approximately 100 Å dispersed in the polybutadiene matrix³⁵. Further studies revealed additional details in the electron micrograph that are important in understanding properties of such block polymers. Results of these studies may serve as a model for other block polymers that may not have as well defined structure as the block polymers from styrene and butadiene.

The electron micrograph, Figure 5, shows that between the polystyrene domains there are frequent interconnections, and there is an apparent short range order between the polystyrene domains. A consequence of such short range order, as shown in Figure 6, is that during the first stress-strain cycle, the material shows a high modulus typical of a plastic rather than that of a rubber (i.e. steep slope of the stress-strain plot), followed by a yield point and considerable cold-drawing^{25,35}. The short range order breaks down beyond the yield point during the first extension cycle. Consequently, during the second and subsequent cycles, the behaviour is that of a crosslinked rubber. Interestingly, the behaviour is completely reversible on annealing. The domains are thus shown to have appreciable elastic memory.

Another interesting aspect of the behaviour of polystyrene glassy domains in these polymers is shown in Figure 7. The polystyrene glassy domains in these block polymers are markedly ductile. The spherical domains present in the original sample are deformed to elliptical domains³⁵ at elongations above 300%. The high strength of styrene/butadiene/styrene triblock polymers mentioned above, may be attributed to the ductility of the glassy domains. On annealing a stretched sample, the elliptical domains revert to their original shape.

Phase separation in block polymers results in two distinct transition temperatures that correspond nearly to that of the two phases⁴²⁻⁴⁴. Figure 8 shows the transition behaviour of Kraton 101 triblock polymer from measurements of damping as a function of temperature^{25,35}. The transition peaks in the vicinity of -80°C and 100°C are close to the transition temperatures of polybutadiene and polystyrene respectively. How complete the phase separation is, depends also upon the nature of the solvent from which the film is deposited. Whenever there is appreciable mixing of phases, there is an intermediate transition peak, as is the case for the sample deposited from carbon tetrachloride. The completeness of phase separation, or the lack of it in films deposited from different solvents, has marked effect on their stress-strain behaviour^{25,35}.

Figure 7 Deformation of polystyrene domains in styrene/butadiene/styrene triblock polymers on stretching 300 %

Effect of composition and structure on the block polymers of styrene and butadiene

The range of solid state structure, i.e. the nature of morphology of the dispersed phase, and thus the useful combination of properties that can be realized in block polymer systems^{32,39,45}, is well illustrated by the examples discussed below for the block polymer of styrene and the common dienes.

In *Figure 9* are shown electron micrographs of those styrene/butadiene/styrene triblock polymers that contain increasing wt % styrene. In the block polymer that has butadiene as the major component, the dispersed phase is that of polystyrene spheres. As the amount of styrene increases, the morphology changes to short rods, lamellar structure of polybutadiene and polystyrene layers, and finally as styrene in the block polymer becomes the major component, the dispersed phase is that of polybutadiene in the matrix of polystyrene. The high styrene triblock polymers are glassy high impact materials, and are optically clear because of the submicroscopic size of the dispersed phase. The effect of composition on the morphology of block polymers is seen more clearly from the electron micrographs in *Figure 10* of styrene/isoprene/styrene block polymers from the work of Kawai and his associates^{39,46}. The block polymer that contains almost equal amounts of styrene and isoprene (*Figure 10c*) has a layered structure of polystyrene and polyisoprene domains. The composition

Figure 8 Transition behaviour of styrene/butadiene/styrene triblock polymers cast from different solvents: A, benzene/heptane; B, carbon tetrachloride; C, THF/MEK

of the triblock polymers is shown in *Figure 10* caption.

The morphology is also dependent upon the solvents in which the block polymer is prepared because of the effect of the solvent on the polymer morphology during work-up and isolation from solutions in different solvents. The two electron micrographs in *Figure 11* are for triblock polymers of the same composition (40% styrene and 60% butadiene), but one was prepared in toluene and the other was prepared in heptane. The difference in morphology results from toluene being a good solvent for the polystyrene terminal blocks, while heptane is a good solvent for the central block and a rather poor solvent for the terminal blocks.

Figure 12 shows the electron micrographs of styrene/isoprene/styrene triblock polymers of the same styrene/isoprene composition (75% styrene and 25% isoprene). The difference is that the pure block has terminal blocks of long styrene sequences, while in the graded block the styrene sequence length of the terminal blocks is smaller and the sequence length of the styrene blocks gradually decreases from each end toward the centre. The diffuse boundary of the dispersed phase for the graded block polymer results from the favourable conditions for phase mixing in block polymers of such structure.

Effect of processing on the morphology of block polymers

The morphology of the domains, for a particular composition and molecular structure of the block polymers, depends markedly on the flow conditions during processing and fabrication. *Figure 13a* is an electron micrograph of a thin section of a rod of Kraton 101 (styrene/butadiene/styrene block polymer containing 28% styrene terminal blocks marketed by Shell Chemical Company) extruded into the capillary of the Instron Rheometer, annealed in the capillary and then forced out. The electron micrograph shows long cylindrical polystyrene domains parallel to the direction of extrusion in contrast to the spherical or short cylindrical polystyrene domains present in samples of the polymer cast as films from solutions. When the sample is prepared by milling and then pressing the milled sheet under conditions of minimum flow, the morphology of polystyrene domains in the surface layers of the sheet is shown in *Figure 13b*. The domains in the surface layers are oriented parallel to the milling direction. The top and bottom layers thus may be regarded as 'macrodomains' of polystyrene with preferential orientation parallel to the milling direction. Optical birefringence measurement showed that as one goes away from the surface towards the mid-plane of the sheet, there is an increased tendency of the macrodomains to orient out of the plane of the sheet, and there is increasing disorder in the orientation of the principal direction of the macrodomains with respect to the mill-

ing direction. Because of preferential orientation of the polystyrene domains, these samples show highly anisotropic mechanical properties, and are discussed later. Orientation of lamellar domains is observed in triblock polymers which contain approximately equimolar amounts of styrene and butadiene. The electron micrograph in *Figure 13c* is that of a sample cast rotationally from a triblock polymer containing styrene and butadiene in the ratio of 60:40.

Keller and his collaborators in a series of papers^{47,48} have reported that it is possible to obtain an almost perfect hexagonal arrangement of polystyrene domains as con-

tinuous rods arranged parallel to the direction of extrusion, in a rod sample of Kraton, if extruded slowly as a plug and the plug allowed to cool slowly. *Figure 14* is an electron micrograph of an ultra-thin section cut parallel to the extruded and annealed plug. *Figure 15* is an electron micrograph of the cross-section of such an extruded rod, and shows the uniformity of the cross-section of these cylindrical domains and their regular hexagonal packing.

Effect of molecular architecture on the morphology of block polymers

The molecular architecture of the block polymers apparently has a marked effect on the regularity of the domain structure, and on the comparative ease with which such domain regularity develops. This is most dramatically demonstrated by the 'star' or 'radial' block copolymers prepared by Fetters and his associates⁴⁹⁻⁵¹. Schematically, the structure of such radial block polymers is shown at the bottom of *Figure 16*. Each arm of this poly-

Figure 16 Morphology of polystyrene domain in a film of 'radial' block polymer

having 15 number average arms with each arm having $M_n = 71\ 000$. The noteworthy point is the regularity of the domains and that this regularity is easily achieved in solvent-cast films. In Figure 17, morphology in cast films of linear triblock polymers is compared with that of multichain 'star' polymers of the same styrene/butadiene composition. These micrographs demonstrate the effect of the molecular architecture of the block polymers (linear triblock *versus* radial) on the morphology of the cast films.

BLOCK POLYMERS AS MICROCOMPOSITES

Similarity between multiphase structure of block polymers and of macrocomposites

The multiphase domain structure of block polymers, and the orientation of such domains under suitable processing conditions, results in materials that are analogous to macrocomposite materials fabricated by combining two types of materials. Some of the common examples of macrocomposites of technological importance because of the useful combination of properties, are the filled plastics and rubbers for high modulus and strength, glass fibre reinforced plastics, and laminated structure of fibre cord/rubber in pneumatic tires. Composite materials in general may be considered under three broad classes: (a) isotropic particulate composites (particles of one phase randomly dispersed in the matrix of another phase); (b) uniaxial oriented composites (fibres or similar shaped particles with uniaxial orientation in a matrix); and (c) laminated composites (layers of various

materials, or structures). In block polymer systems, some of which were referred to in the preceding discussion, similarities to each of these classes of composite materials are noted. In block polymer systems, the size of the phases may be of submicroscopic dimensions.

There has been considerable activity and significant progress in recent years in developing micromechanic theories of composite materials to calculate the various moduli of the composites, from the knowledge of the properties of the constituents and the geometry of the phases in the composite. Such theories have been successfully applied to block polymer systems. They serve as an important guide to understand and interpret the mechanical behaviour of block polymers, and to obtain a broad variation in composite properties by manipulating morphology and properties of phases. Following is a brief review of some of the theories of micromechanics of composite materials, and a discussion of their applicability to some of the block polymer systems.

Theories of micromechanics of composites

Particulate composites. Hashin, in a classical set of papers, made use of variational energy methods to establish the upper bound and lower bound for the moduli of composite systems of irregular phase geometry, for systems of randomly dispersed spheres and for systems containing uniaxially oriented fibres⁵²⁻⁵⁴. For a random assemblage of spheres, the system is isotropic and only two material parameters are needed to characterize the system completely. He found that the upper and lower

Figure 17 Comparison of morphology of polystyrene domains for the linear triblock *versus* multichain 'star' block polymers. 30/70 Styrene/butadiene block polymers: (a) linear triblock; (b) 'star' multichain, 40/60 styrene/butadiene block polymers; (c) linear triblock; (d) 'star' multichain

bounds for bulk and compression moduli were almost identical. For shear moduli, these bounds are close only when the moduli of matrix and particle are close. The lower bound for the shear modulus is:

$$\frac{G}{G_1} = 1 + \frac{15(1 - \nu_1) \left(\frac{G_2}{G_1} - 1 \right) \Phi_2}{7 - 5\nu_1 + (8 - 10\nu_1) \left[\frac{G_2}{G_1} - \left(\frac{G_2}{G_1} - 1 \right) \Phi_2 \right]} \quad (1)$$

where G is the shear modulus of composite, G_1 and G_2 are the shear moduli of the matrix and of the dispersed phase, and subscripts 1 and 2 refer to matrix and dispersed phase respectively. ν_1 is the Poisson ratio of the matrix, and Φ_2 is the volume fraction of the dispersed phase. This equation is equivalent to Kerner's equation derived by an entirely different method.

When the dispersed phase is much more rigid than the polymer matrix, equation (1) reduces to:

$$\frac{G}{G_1} = 1 + \frac{15(1 - \nu_1)\Phi_2}{8 - 10\nu_1\Phi_1} \quad (2)$$

We used this equation to calculate the shear modulus of Kraton 101 SBS triblock polymer films²⁵.

Halpin and Tsai have shown that Kerner's equation and other equations for moduli of composites, such as equation (1) above, can be put in a more general form for the particulate composites⁵⁶⁻⁵⁸. Nielsen⁵⁹, and then Lewis and Nielsen⁶⁰, further generalized the Halpin and Tsai equations to take account of the maximum packing fraction ϕ_m of the dispersed phase. For composites such as polystyrene domains in the matrix of polybutadiene, the shear modulus for the isotropic composite is given by the following modified Halpin-Tsai equations for the lower bound value of the modulus:

$$\frac{G}{G_1} = \frac{1 + AB\Phi_2}{1 - B\psi\Phi_2}$$

where

$$A = \frac{7 - 5\nu_1}{8 - 10\nu_1}$$

and

$$B = \frac{\frac{G_2}{G_1} - 1}{\frac{G_2}{G_1} + A} \quad (3)$$

A takes into account the morphology of the dispersed phase and the Poisson ratio of the matrix. For dispersed spheres in an elastomeric matrix, $A = 1.5$, for instance. ψ is a function of the maximum packing fraction, ϕ_m , of the dispersed phase:

$$\psi = 1 + \frac{1 - \phi_m}{\phi_m^2} \cdot \Phi_2 \quad (4)$$

Similar equations apply for those systems in which the dispersed phase is elastomeric in a rigid matrix, such as SBS block polymers containing a high amount of styrene, and give the upper bound value of the modulus. They are written in a form that takes into account that the continuous phase is more rigid than the dispersed phase. In systems where both phases may be continuous, such as in the case of SBS block polymers containing equal amounts of styrene and butadiene, the equations giving the upper and lower bounds have to be combined in some manner. Nielsen used a logarithmic rule of mixtures to combine the upper and lower bound values^{61,62}:

$$\log M = \phi_U \log M_U + \phi_L \log M_L \quad (5)$$

where M_U and M_L are the upper and lower bounds for the modulus respectively, at a given composition; ϕ_U is the fraction of the low modulus material that is in a continuous phase in the overlap region where both phases are almost continuous, and ϕ_L is the fraction of the rigid material in the overlap region.

Uniaxially oriented fibre composites and laminated composites. Uniaxially oriented fibre composite materials are transversely isotropic, i.e. properties perpendicular to the fibre axis are direction independent. The basic geometry of this system is shown in Figure 18. Five independent elastic constants are needed to characterize completely the elastic behaviour of such systems. There are two tensile moduli: E_{11} and E_{22} ; two shear moduli: G_{12} for shear parallel to the fibre direction, and G_{23} for shear normal to the fibre direction; bulk modulus, and two Poisson ratios. One Poisson ratio, ν_{12} , gives the transverse strain caused by the imposed strain in the longitudinal direction, and the second Poisson ratio, ν_{21} , gives the longitudinal strain caused by the strain in the transverse direction.

Material constants for the uniaxial composites are most conveniently calculated by Halpin and Tsai's equations⁵⁷ given below:

$$E_{11} = E_f V_f + E_m V_m \quad (6)$$

$$\nu_{12} = \nu_f V_f + \nu_m V_m \quad (7)$$

$$\frac{P}{P_m} = \frac{(P_f/P_m) + \mathcal{L} [1 + (P_f/P_m - 1)V_f]}{P_f/P_m - V_f(P_f/P_m - 1) + \mathcal{L}} \quad (8)$$

where E_f , E_m = Young's modulus of fibre and matrix, respectively; ν_f , ν_m = Poisson ratio of fibre and matrix, respectively; V_f , V_m = volume fraction of fibre and matrix; $P = E_{22}$, G_{12} or G_{23} for the composite; $P_m = E_m$, G_m or

Figure 18 Basic geometry of uniaxial composite and reference coordinate system (right) and corresponding elastic constants

ν_m for the matrix; $P_f = E_f, G_f$ or ν_f for the fibre, and $\mathcal{L} =$ a parameter which accounts for the geometry of the filler and the mode of deformation.

Equations (6) and (7) are the familiar 'Law of Mixtures' for principal Young's modulus and principal Poisson ratio, respectively. Equation (7) is a condensed formula for determining the elastic constants, E_{22} , G_{12} or G_{23} . Use of equations (6), (7) and (8) is not restricted to uniaxial continuous fibre composites. Halpin and Tsai⁵⁷ have shown that:

(a) Equation (8) can be applied to the calculation of the axial modulus of discontinuous composites by choosing an appropriate constant \mathcal{L} , which depends upon the particle shape and aspect ratio.

(b) The above equations can be extended to balanced ply laminates of discontinuous or continuous fibre composites, by application of laminated plate theory⁵⁹ and taking into account the angles between the ply orientation and the principal directions of the composite.

(c) These concepts can be extended to randomly oriented fibre composites which are treated as quasi-isotropic materials⁶⁴, that is, the material is treated as a many-ply laminated structure having equal probability of all orientations.

Experimental moduli and comparison with values calculated from theories of micromechanics of composites

The above equations and concepts for the composite materials moduli have been applied to a number of block polymers of definable morphology and geometry, considering them as composite materials.

Equation (1) was used to calculate the shear modulus of Kraton 101 SBS triblock polymer, considering it as a microcomposite with spherical polystyrene domains in a matrix of polybutadiene²⁵. The shear modulus of Kraton was assumed to be 1.13×10^{10} dyne/cm². Modulus of the rubber can be estimated on the basis that all rubbery chains are tied down at each end in the glassy domains of polystyrene. The modulus is then determined by the entanglement network, which for polybutadiene would give a value of about 1×10^7 dyne/cm². Using these values of moduli for polystyrene and polybutadiene in equation (1) gives a composite modulus for Kraton 101 equal to 1.85×10^7 dyne/cm². The experimental values are found to be much higher than this. For a film of Kraton 101 cast from benzene-heptane solution, a shear modulus of 10^8 dyne/cm² is obtained. This large discrepancy between the experimental and theoretical value can be ascribed to three possible factors: (a) the polystyrene domains are not strictly spherical and show some connectivity; (b) the effective size of the domains is larger than that observed in the electron micrograph because of the interfacial region; and (c) the modulus of the matrix is higher than the rubbery modulus value, which will of course be the case in the interfacial region near the domain boundaries. As referred to in the preceding discussion the studies on morphology and transition behaviour suggest that all the three factors are important considerations in the cast films of Kraton 101 block polymers.

The Young's moduli of block polymers of styrene and butadiene as a function of composition cover a range of almost four decades — from ~ 10 to 10^4 kg/cm². Nielsen has shown that, the moduli of such diverse polymers — from elastomers to rigid plastics, calculated from equations (3–5) fit the experimental values over a broad range of composi-

tions of the styrene/butadiene block polymers⁶¹. In block polymers of low styrene content (such as Kraton 101 discussed above), polystyrene domains appear to be either aggregates of six spheres or rods with an aspect ratio of 6 to 1. This corresponds fairly well with the morphology observed in samples of Kraton 101. The volume fraction of styrene, over which both polystyrene and polybutadiene

Figure 19 (a) Fibrous polystyrene domains of polystyrene in an extruded rod of Kraton 101; (b) oriented polystyrene domain in the outer layers of a milled sample of Kraton 101

phases in the block polymer are almost continuous, ranges from about 0.15 to 0.8. Outside this region, either spherical domains of polystyrene or polybutadiene are the dispersed phase⁶⁵.

As discussed above the polystyrene domains in a sample of Kraton 101 extruded into the capillary of a rheometer, and then annealed in the capillary have cylindrical polystyrene domains parallel to the extrusion direction. The morphology of a thin section cut parallel to the length of the rod is included in *Figure 13a*, and is shown in more detail in *Figure 19a*. Moduli of the extruded rod were measured in tension, bending and torsion. It was modelled as an uniaxial composite and the moduli were calculated from equations (6–8) for different geometries of the dispersed fibrous polystyrene domains. The experimental and calculated values for this sample are given in *Table 3*.

The ratio of tensile modulus to shear modulus is about 80 for this sample. The rod sample is therefore quite stiff under bending and tensile loading, but has comparatively very low torsion modulus typical of an elastomer. At loads of greater than 10.5 kg/cm², there appears to be a yield process which results in a five-fold decrease in tensile modulus. The torsion (shear) modulus shows a small but significant increase. On loading, there is some breaking up of the cylindrical domains which results in a decrease in tensile modulus and a slight increase in the torsion modulus. The calculated value of the tensile modulus for the composite of continuous polystyrene cylindrical domains is about twice that of the experimental value. The calculated shear modulus is appreciably lower than the experimental value. For a composite of discontinuous cylinders with $L/D = 750$, which appears reasonable from the electron micrograph, the calculated value of the tensile modulus is close to that obtained experimentally. The calculated shear modulus is still appreciably lower than the experimental value, but calculations show that only five percent of disorder in orientation of the fibres should account well for this discrepancy, without much effect on the calculated value of the tensile modulus.

In the sheet sample of Kraton 101 thermoplastic rubber prepared by pressing the milled sheet under conditions of minimum flow, the polystyrene domains in the outer layers are oriented parallel to the milling direction, as shown in *Figure 19b*. Optical birefringence measurements showed that in this sample, away from the surface layers, there is less preferred orientation of the cylindrical polystyrene domains. This sample may be modelled as a layered laminate composite of uniaxially oriented sheets with a core of quasi-isotropic material. Flexural, tensile, and torsional moduli of sheets cut both parallel and perpendicular to the direction of milling, measured according to the methods described in ref 25, are given in *Table 4*. The values of shear modulus are the same for the samples cut parallel and perpendicular to the milling direction. However, the flexural

Table 4 Experimental and calculated moduli of mill oriented Kraton 101 sheet

Modulus (and test method)	Experimental values (dyne/cm ²) × 10 ⁹		Calculated values laminated plate theory (dyne/cm ²) × 10 ⁹	
	MD	⊥ MD	MD	⊥ MD
Flexural modulus, E_B (vibrating beam)	1.655	0.331	1.72	0.103
Tensile modulus, E_T (longitudinal resonance)	0.538	0.331	0.504	0.076
Shear modulus (torsion pendulum)	0.241	0.241		
E_B/E_T	3.1	1.0		

modulus value parallel to the milling direction (*MD*) is about five times that perpendicular to the milling direction. Also, for the sample cut parallel to the milling direction, the bending and tensile moduli are in the ratio of 3:1. In the absence of longitudinal shear, the values would be the same for any homogeneous material. The observed difference, we attribute to the outer layers consisting of unidirectionally oriented high modulus material, while the centre is less well oriented and is of lower modulus. The outer layers from the neutral plane make a disproportionately large contribution to the flexural modulus, while they do not play as important a role in the tensile experiment.

The experimental values are compared with the calculated moduli based on the laminated plate theory. The agreement between the calculated and experimental values of the bending and tensile moduli for samples cut parallel to the milling direction is surprisingly good. However, in the transverse direction, the flexural and tensile moduli have about the same ratio as that predicted, but the experimental values of these moduli are much higher than predicted. This is to be expected because, in these modes of deformation, the moduli are very much dependent upon the transverse orientation of the cylindrical polystyrene domains. Considering the uncertainty in describing precisely the details of orientation of the polystyrene domains, especially away from the outer layers towards the centre, this discrepancy is not serious. Better agreement of values calculated from the laminated plate theory will be expected if the solid structure could be described more accurately.

In summary, the theories for composite materials can be useful in estimating the moduli of block polymer materials if information on morphology and orientation of domains is available. They can be useful in explaining the mechanical properties of block polymers. The noteworthy point is that, using theories developed for macroscopic composites, and using macroscopic bulk properties of the constituent

Table 3 Experimental and calculated moduli of extruded Kraton 101 rod

	Experimental (dyne/cm ²)		Composite theory calculations (dyne/cm ²)		
	Before loading	After loading 10.5 kg/cm ²	Orthotropic continuous rods	Orthotropic discontinuous rods, $L/D = 750$	Quasi-isotropic
Tensile modulus, E_{11}	4.28×10^9	0.93×10^9	7.55×10^9	5.0×10^9	$E = 1.5 \times 10^9$
Shear modulus, G_{12}	5.4×10^7	6.5×10^7	1.66×10^7	1.66×10^7	$G = 0.5 \times 10^9$

$$E_{11}/G_{12} = 79$$

materials, mechanical properties of block polymer samples in which the size of phases is of such submicroscopic dimensions, can be calculated with a fair degree of dependability.

BLENDS OF BLOCK POLYMERS AND HOMOPOLYMERS

Another class of composite materials based on block polymers, of both fundamental and technological interest, are the blends of block polymers with one or both of the corresponding homopolymers. Either the homopolymer may be solubilized in the corresponding domains of the block polymer, or the block polymer may act as a surface active material, in which case blocks of one particular type may be incorporated at the interfacial boundary between the homopolymer and the block polymer. In the latter case, blocks act as an 'alloying' agent by preventing the separation of

Figure 20 (a) Morphology of a polyblend of 60/40 styrene/butadiene triblock polymer (25 parts) and polystyrene (75 parts); (b) morphology of 60/40 styrene/butadiene triblock polymer

the incompatible homopolymers into macroscopic phases.

Kawai and his coworkers^{36,46,66,67}, in a series of studies with AB type block polymers of styrene and isoprene, showed that when the molecular weight of the added homopolymer is less than or comparable to that of the corresponding block of the copolymer, the solubilization of the homopolymer into domains of the corresponding block takes place. In such cases, the size of the domains increases in relation to the amount of the added homopolymers, and in some cases, morphology of the domains may also change. However, when the molecular weight of the added homopolymer is larger than that of the corresponding block poly-

mer, the block polymer behaves as if it were incompatible with the corresponding homopolymer. However, in such cases, the blocks in the interfacial region between the homopolymer and the block polymer are preferentially anchored in the homopolymer phase, and thus help to form a stable interface.

A technologically important application of the above concept is in the blends of a styrene/butadiene/styrene block polymer of overall 60/40 butadiene/styrene composition with homopolymer styrene^{68,69}. These blends have higher impact strength than the commercial high impact polystyrene, or rubber modified polystyrene materials. This is achieved without adversely affecting the flexural modulus, the softening temperature, and hardness. *Figure 20b* is an electron micrograph of the block polymer and shows the morphology and the domains of polystyrene. *Figure 20a*, an electron micrograph of the blend of polystyrene and the block copolymer, shows that the dispersed phase is that of the block polymer in a polystyrene matrix. *Figure 21* shows in more detail that the dispersed phase is itself a block polymer and has in it the two-phase structure of the block polymer. It has similarity with the electron micrograph of high impact polystyrene in which the dispersed phase is itself also a two-phase system of polystyrene and rubber (*Figure 22*), and it is dispersed in the polystyrene matrix. In the blend of the block polymer with polystyrene, the polystyrene domains in the dispersed block polymer

Table 5 Comparison of physical properties of polyblend containing block polymer to commercial high impact polystyrene and ABS materials

	Polyblend (85% total polystyrene)	High impact polystyrene (Styron 495)	ABS resin (Cycolac GSE 1000)
Unnotched Izod (ft lb/in)	22.0	14.0	25.0
Notched Izod (ft lb/in)	7.5	2.2	7.0
Flexural modulus \times 10^{-5} , (lb/in ²)	3.0	2.3	2.9
Deflection tempera- ture ($^{\circ}$ C) samples annealed at 73 $^{\circ}$ C. (60 mm deflection under 264 lb/in ²)	93.0	82.0	94.0

phase are of submicroscopic dimension, in contrast to that in the dispersed phase of high impact polystyrene. In *Table 5*, are given the comparative values of impact strength, flexural modulus, and heat distortion temperature of the polyblend of polystyrene and block polymer, a high impact polystyrene, and an ABS (acrylonitrile/butadiene/styrene) resin, showing that in the desirable combination of these properties, the polyblend properties are superior to those of high impact polystyrene, and approach those of ABS.

PART II: RECENT RESEARCH DIRECTIONS AND OUTLOOK ON THE FUTURE OF BLOCK POLYMERS AND MULTIPHASE POLYMER SYSTEMS

The discussion above is an overview of the recent work in block polymers and multiphase systems. Projection into the research areas in which future important advances of both scientific and technological interest in block polymers and multiphase polymer systems are likely to occur can only be subjective and to a large extent biased by personal experience and research interests. I have selected six research areas which I believe will play an important role in the development of advanced microcomposite materials and multiphase polymers of controlled solid state structure.

THERMODYNAMICS OF PHASE SEPARATION

Heading the list should be the basic understanding of the thermodynamics of phase separation in block polymers. Two dissimilar homopolymers are usually incompatible, because the heat of mixing is generally positive (endothermic process), while the only driving force towards compatibility is the entropy of mixing, which in polymers is generally very small. In block polymers, the blocks of A and of B units tend to separate because they are incompatible, but are prevented from doing so by the chemical bonds linking the blocks together. The important consequence of arranging the chains in this way is that the phases cannot grow indefinitely if the density of packing of the molecules in each of the phases is to remain uniform. The sizes of the domains in the block polymers is thus much smaller than aggregates found in a mixture of homopolymers

exhibiting phase separation. The restrictions arising from the small size of the domains and from the attachment of the blocks, cause a drastic reduction of the entropy of a polymer molecule in a phase separated system as compared to that of a free chain. The important entropy terms that need to be considered in calculating free energy differences between the completely mixed block polymer system and the system separating into domains of discrete size may be summarized with reference to the model shown in *Figure 23* for the case in which the domains are lamellar. In this model for an ABA triblock polymer, all

Figure 23 Model for phase separated domains in triblock polymers

Figure 24 Electron micrograph of sample from polymerization of a 10% solution of Kraton 1101 in styrene monomer. Dark lamellae are of polybutadiene phase. Magnification 30 000X

B chains start at the phase boundary, and terminate at either the same boundary, or the opposite boundary of the B domain. All A chains start at the boundary and end in the A domain. The principal entropy terms are the following: (a) the limit in entropy due to restricted volume of the domain; (b) the limit in entropy because the chain is constrained to start at the boundary; (c) the limit in entropy due to the placement of one block junction point in the vicinity of the interfacial boundary; (d) the limit in configuration entropy arising from the restriction of the second end of the B segment to lie at an interfacial boundary; (e) the entropy of mixing term, which is comparatively small and decreases with increasing molecular weight.

The entropy decrease due to the above factors is a serious restriction against phase separation of block polymers into discrete domains as compared to a completely mixed system. However, there is a large bonus in entropy over the increase in interfacial energy or heat of mixing if we relax the restriction of sharp interfacial boundary, and consider an interfacial region in which phase mixing is allowed. Thus, the interfacial boundary of mixed phases in which there is a gradient of composition seems to be necessary for a stable phase separated system as compared to completely mixed or completely incompatible systems. The size of this interfacial region, the composition gradient in this region, and how they are affected by the molecular weight and composition of the blocks, and presence of different solvents, and diluent molecules, controls many of the important properties of block polymers.

A number of workers, notably Meier, Krause, and Helfand, have developed thermodynamic analysis of block polymer systems to describe quantitatively the dependence of the size and shape of the domains on molecular weights and

composition of the blocks, and on the concentration gradient in and size of the interfacial regions⁷⁰⁻⁸³. Recently, Meier has extended his thermodynamic analysis to the consideration of factors that govern the solubilization of homopolymers in the domains of block polymers, and to the block polymers as surface active materials⁸⁴. Further advances in theory and detailed thermodynamic analysis of block polymer systems will guide the development of methods for the control of their solid state structure, and their applications.

Block polymer solutions which show liquid crystalline structure have many important implications. The thermodynamics of such solutions needs greater attention. Even more important are the solutions of block polymers in which the solvent is one of the monomers. In such solutions, block polymers form fairly organized micellar structure⁸⁵. After polymerization of such block polymer/monomer solution, the final solid has interesting morphology, particularly when the polymerization is carried out under controlled shear flow conditions. Figure 24 shows the lamellar regularity achieved when a 10% solution of styrene/butadiene/styrene block polymer (Kraton 101) in styrene monomer is polymerized under a small shear field. The regularity in thickness of the rubber domains is a consequence of the micellar structure of the block polymer in the styrene monomer solvent.

BLOCK POLYMERS OF CONTROLLED STRUCTURE

Control of block length and of the number of blocks is possible only in a limited number of systems: block polymers of styrene/butadiene (or isoprene), as discussed above being one of the notable examples. The glassy domains in styrene/butadiene block polymers lose their integrity at about 80°-90°C, and are susceptible to solvents. Block polymers in which the domains have higher glass transition temperature, and are less susceptible to solvents, will have a broader range of usefulness. Such block polymers offer an important area of future research.

Considerable effort in recent years has been directed to studies of block polymers in which the component blocks have either higher glass transition temperature, or better solvent resistance, or better thermal stability. Some of these materials have already achieved technological importance. Notable among them are the block polymers of poly(butylene terephthalate)/poly(tetramethylene ether terephthalate)^{86,87}, polysulphone/poly(dimethyl siloxane)^{88,89}, polycarbonate/polysiloxane⁹⁰, and polyethylene/polypropylene⁹¹. An important area for future research is the development of synthetic methods to obtain a similar type of control on the size and number of blocks as is now possible for styrene/butadiene block polymers. Block polymers of controlled structure in the following systems appear to be promising:

MULTILAYERED MACROCOMPOSITES

Alfrey and coworkers have shown that multilayer composites of high and low modulus materials exhibit mutual interlayer reinforcement^{92,93}. A multilayer composite film of polystyrene and polyethylene was shown to undergo 75% elongation without fracture, while the polystyrene by itself failed at 3.5% elongation. The high elongation layers act to prevent the propagation of transverse cracks across the brittle layers. Such multilayer composites consisting of as many as 300 alternate layers can be prepared through rotation of annular die boundaries during coextrusion of two polymers^{94,95}.

Recently, Shen and his coworkers have applied a similar concept to block polymer systems, and have obtained some very interesting results⁹⁶. They prepared, by spin casting, multilayer composites consisting of three to eleven alternate layers of a polymer blend of 60% polystyrene and 40% by weight of Kraton 1101 triblock SBS polymer, and polystyrene; and of polystyrene and Kraton 1101. The stress-strain behaviour of the 11-layer laminates is shown in Figure 25 from the results made available to the author by Professor Shen for this paper. The noteworthy feature is that these laminates can be stretched to 600% without fracture. This stress-strain behaviour is in contrast to fracture of polystyrene beyond 3% strain. Block polymers, which, as discussed above may be considered as microcomposites by themselves, may further be combined as multilayer macroscopic composites for useful applications. Considering that block polymers from a particular set of monomers or starting materials can be prepared over a broad range of modulus, they offer a promising area for advanced materials, when they are combined as multilayer composites. Multilayer composites may be prepared either by using non-diffusive multiple extrusion of two molten polymer streams, or by sequential spin casting of thin layers.

Another type of similar layered composites that appears interesting has been suggested by Shen and Beaver⁹⁷. A polymerizing monomer may be diffused into a sheet of block polymer. Concentration of the polymerizing monomer in the block polymer thus varies uniformly from the outer surface towards the centre. On later polymerization of such a sample, a multilayered structure having a gradient in composition and perhaps in morphology should result. Mechanical properties, particularly impact and fracture properties of such materials, offer interesting possibilities.

SEGMENTED POLYURETHANES

Segmented polyurethanes are a class by themselves of block and multiphase polymers. Because of the broad range of structural variations, both controlled and uncontrolled, that are possible in these systems, the spectrum of mechanical properties they show is surpassed by few classes of polymers. The molecular units and sequences in segmented poly-

urethanes are commonly divided into 'hard segments' and 'soft segments'. The hard segments consist of groups that are rigid and/or capable of strong intermolecular interaction, such as aromatic rings, urea and urethane groups. When hard segments crystallize, they do so generally by intermolecular aggregation, but systems containing long sequences of such segments may form crystalline lamellae by chain folding. The soft segments generally consist of long chain polyethers or polyesters, and are flexible. Figure 26 shows schematically a typical 'hard' and 'soft' segment in a segmented polyurethane. The soft segments in such a polymer are formed by the reaction of diphenylmethane-4,4'-di-isocyanate (MDI) with poly(propylene ether glycol) oligomer. When this reaction is carried out in the presence of excess di-isocyanate, a prepolymer with isocyanate terminal group is formed. This prepolymer is then extended with additional di-isocyanate and ethylene glycol (chain extender), resulting in the final segmented polyurethane with 'soft' and 'hard blocks'. Considerable literature has developed upon the structural variations and their effect on mechanical and performance properties by varying the structure of the oligomer, the di-isocyanate, and the chain extender used for the preparation of segmented polyurethanes⁹⁸⁻¹⁰¹.

Crystallization of soft segments can occur in certain cases, particularly when its molecular weight is large, and is enhanced by stretching¹⁰¹. However, it is the molecular aggregation and phase separation of the hard segments that has marked influence on the properties of the segmented polyurethanes. Phase separation of the hard segments in these systems comes about even when the sequence length of units in each hard segment is comparatively short. Strong intermolecular interaction and crystallizability of the units enhances phase separation^{78,82}. Such phase separation, often results in multiphase systems that exhibit multiple transition

Figure 25 Stress-strain plots of multilayered composites: L_1 : 11 layer laminate of blend of 40% SBS triblock polymer (Kraton 1101) and 60% polystyrene ($\bar{M}_n = 30\,000$), and SBS triblock polymer; L_{4A} and L_{4B} are 11 layer laminates of polystyrene ($\bar{M}_n = 30\,000$) and Kraton 1101 triblock polymer; L_{4A} and L_{4B} have innermost layer of polystyrene and triblock polymer respectively. A, L_{4A} ; B, L_{4B} ; C, L_1

Figure 26 (a) Hard and (b) soft segments in a typical segmented polyurethane

temperature. Transitions in these systems are traditionally labelled as α , β , and γ in order of decreasing temperature. Generally speaking, the γ -transition (or a lower transition) is attributed to a Schastzki type mechanism¹⁰², the β -transition is associated with the glass transition for the more flexible part of the chain, and the higher temperature α -transition, is associated with the hard segments. The α -transition temperature depends upon the concentration of the hard segments in the chain. As the hard segment concentration increases, this transition shifts to considerably higher temperature, and merges with the fusion temperature of the crystallinities of the hard segments. A number of studies have recently been reported on the transition behaviour of segmented polyurethanes and its relation with their molecular structure¹⁰³⁻¹⁰⁷

Figure 27 Schematic of spherulite structures in segmented polyurethanes: (a) hard segments crystallize radially, chain orientation is tangential; (b) hard segments crystallize tangentially, chain orientation is radial

The multiphase structure of segmented polyurethanes has been studied by a number of workers¹⁰⁸⁻¹²³. The general picture that emerges from studies of these polymers by differential scanning calorimetry, infra-red absorption, rheo-optical (low-angle light scattering), low-angle X-ray diffraction, and thermomechanical analysis, is that hard segments do not separate as discrete domains. Instead, the hard segments domains consist of two phases: crystallites or aggregates of hard segments in a matrix of soft segments. These domains are separated by elastomeric material richer in soft segments and which may also contain some uncrystallized hard segments. The domains of hard segments are likely to form spherulitic structure under suitable conditions. Figure 27 shows schematically the structure of spherulites proposed for the hard segment domains in segmented polyurethanes.

Direct observation by electron microscopy of the segmented polyurethanes appears possible by staining with a solution of phosphotungstic acid. This technique is similar to that used so successfully for studying the morphology of polyester-polyether block polymers^{124,125}. Figure 28 is an electron micrograph of a segmented polyurethane containing the oligomer, poly(propylene ether glycol) as the soft segment, and MDI and ethylene glycol as hard segments. The staining was done by immersing a microtomed section in a 10% aqueous solution of phosphotungstic acid. The elastomeric phase absorbs the stain, but not uniformly. The crystalline domains are visible as light fibrillar regions.

In spite of the extensive work in segmented polyurethanes, only a few studies have been made with controlled block length and number distribution of the blocks in the polymer chain^{118,126,127}. Our understanding of the structural factors that control the multiphase solid state structure in these

Figure 28 Electron micrograph of segmented polyurethane: poly(propylene ether glycol) (as soft segments); MDI and ethylene glycol as hard segments. Stained by 10% solution of phosphotungstic acid

Figure 29 Electron micrograph of an 80/20 PMMA/PU interstitial composite. Polyurethane phase from polybutadiene diol stained by OsO_4

systems, and how this relates to their performance is indeed embryonic. Studies on segmented polyurethanes in which the block lengths can be well controlled offer a promising research area. Use of moieties other than the commonly used low molecular weight diols and diamines, for use in hard segments, offers a number of promising approaches for materials with interesting properties. The moieties that are likely to enhance intermolecular hydrogen bonding and crystallization should be especially interesting. Only limited work has so far been done with soft segments that undergo strain-induced crystallization, and this should also be a fruitful research area. Thus, segmented polyurethanes offer a number of promising research directions for multiphase and microcomposite materials.

INTERSTITIAL POLYMERS

Another type of multiphase polymers based on polyurethanes, that seem to have intriguing possibilities, have been reported recently from the work in the laboratories of Professor Allen at the University of Manchester and in the Corporate Laboratory of Imperial Chemical Industries¹²⁸⁻¹³³. These polymers are prepared by the interstitial polymerization of vinyl monomers within polyurethane elastomer gels. The precursors for preparation of a polyurethane elastomer network (mixture of an oligomer diol and triol, and di-isocyanate), are mixed with a vinyl monomer (methyl methacrylate, acrylonitrile were most suitable). The crosslink points are introduced by the trifunctional polyol. Using dibutyltin dilaurate as the catalyst to promote polyurethane (PU) formation, a polyurethane network swollen in the vinyl monomer is formed. Subsequent polymerization of the vinyl monomer in the swollen polyurethane network results in a composite material: vinyl polymer and polyurethane being the two submicroscopic phases.

Figure 29 is an electron micrograph of an interstitial polymer composite from 80 parts of methyl methacrylate poly-

merized interstitially in a polyurethane network from polybutadiene diol. Osmium tetroxide stain was used to stain the polybutadiene elastomeric phase¹²⁹. The spherical domains of PMMA are clearly seen in the matrix of the elastomer. The size of the PMMA domains, for a given PMMA/PU composition is almost independent of factors connected with the vinyl polymerization, but is very sensitive to the physical condition and molecular details of the swollen PU network and on the state of gelation at the time of polymerization. Thus, it is quite sensitive to \bar{M}_c of the PU network. If the gel is 'loose', the domain size is larger than the domain size from a 'tight' network.

The systems amenable to interstitial polymerization must clearly have two important prerequisites: (1) the precursors for the PU network must be soluble in the vinyl monomer, and (2) there must be a mechanism for formation of an elastomer network prior to the polymerization of the vinyl monomer¹²⁸. Further, the solubility interaction parameter between the monomer and the gel should be such that the maximum swelling capacity of the gel is not exceeded, and that the density of crosslinks is high enough to prevent macroscopic phase separation during subsequent polymerization of the monomer.

A composite from interstitial polymerization containing 80:20 PMMA/PU was found to have notched impact strength and shear modulus of $12.5 \pm 1.0 \text{ kJ/m}^2$ and $0.65 \pm 0.05 \text{ GN/m}^2$ respectively, compared to $1.2 \pm 0.2 \text{ kJ/m}^2$ and $1.47 \pm 0.03 \text{ GN/m}^2$ in PMMA homopolymer¹²⁸. The impact strength is increased ten-fold with only a decrease in modulus to about one-half. The composites from interstitial polymerization of acrylonitrile in a polyurethane network were found to have the desirable combination of high notched impact strength and high modulus.

These interstitial polymer composites may also be treated as microcomposites. The equation for composite materials that is most suitable for calculating the moduli of these systems takes into account the interaction of the two phases in the interfacial layer. The experimental values of the shear modulus over a broad composition range of PMMA/PU interstitial composites was found to fit well the equation proposed by Davies^{132,134}.

The two-phase structure of the interstitial composites is also supported by their transition behaviour. Two transition temperatures associated with T_g of PMMA and PU are observed. The shift in the position of PU α process from that normally seen in the corresponding PU bulk polymer is in support of the phase mixing in the interfacial region between the vinyl polymer domains¹²⁹.

Interstitial polymer composites, similar to the systems that have been studied, are likely to play an important part in the future development of multiphase polymers and microcomposite materials.

IN SITU CRYSTALLIZATION

One of the intriguing ways of obtaining microcomposites is by crystallization of low molecular weight crystalline compounds or suitable crystalline polymers, in a polymer matrix, notably in the matrix of slightly crosslinked rubber. Only a few studies on *in situ* crystallization of one phase in the matrix of a rubber or plastic have been reported, but such investigations offer interesting possibilities for future research.

One of the early studies on the *in situ* crystallization of low molecular weight crystalline compounds in rubber^{135,136} showed that crystallization of only 5% phenyl- β -naphthyl-

Figure 30 Scanning electron micrograph of a cut section of a sample containing 30 vol % of acetanilide in butadiene-acrylonitrile rubber

Figure 31 Photomicrograph of polypropylene crystallizing in EPDM rubber

mine produced the same increase in modulus of rubber as 30–40% carbon black, commonly used for reinforcement and stiffening of gum rubber.

Kardos and his workers^{137,138} studied the *in situ* crystallization of acetanilide in a styrene/acrylonitrile copolymer (SAN) and in an acrylo rubber (butadiene/acrylonitrile copolymer). Figure 30 is a scanning electron micrograph of a cut surface of a sample containing 30 vol % of acetanilide (from ref 138). The needle-like crystals were shown to have excellent adhesion with the matrix. The arrow in Figure 30 points to the interlocking of two crystals, probably by twinning. There is a significant increase in the modulus of the composite relative to that of the matrix. Over a fairly broad filler loading range crystallized at 25°C, the modulus can be predicted by the Halpin-Tsai equation^{57,58}. At higher filler volume fraction (~0.3), because of the interlocking effect of the crystals, a Halpin-Tsai equation modified by Nielsen⁵⁹ is more appropriate since it takes into account the maximum packing fraction which the filler can achieve.

Figure 31 is a photomicrograph of a sample of EPDM rubber in which polypropylene was allowed to crystallize. It shows the fibrous structure of polypropylene crystallizing in a matrix of rubber.

The systems of the crystallizing filler and the matrix suitable for microcomposites of controlled solid state structure need to satisfy the criteria: (a) crystallizing polymer

should show solubility in the matrix at a temperature below the degradation temperature of each of the components; (b) broad range of temperature between the dissolution temperature of the crystallizing filler and the glass transition temperature of the matrix; (c) no chemical interaction of the crystallizing filler with the matrix, and low volatility at the fabrication and processing temperature^{137,138}. These are difficult requirements to satisfy, but a systematic application of these concepts appears promising. It offers the prospect for developing composite materials with good adhesion between the dispersed phase and the matrix, and for controlling the morphology of the dispersed phase, and thus the mechanical properties, by controlling the temperature at which the system is allowed to crystallize and by the volume fraction of the crystallizing filler.

CONCLUSION

In conclusion, the recent work on block and multiphase polymers has already resulted in a number of materials with unique combinations of properties. We have, however, barely scratched the surface in this area of polymer science. Further progress will depend upon systematic studies in the above areas. In addition, we need to develop a scientific base for the understanding of the strength properties of multiphase polymers, because the main interest in such materials is the promise they offer for strong and tough materials. To guide the development of such materials, we need also to develop our understanding of the yield and failure mechanism of multiphase materials of controlled structure and morphology, including the study of creep and crazes that relate to the toughening of multiphase materials.

ACKNOWLEDGMENTS

I wish to express my special appreciation to Professor Geoffrey Allen of Imperial College of Science and Technology, who made the facilities of his personal office available to me during my two weeks stay in the United Kingdom. The outline and major part of this manuscript was completed during this stay at Imperial College, London.

Molecular complexes in polymer synthesis – from Lewis acid adducts to exiplexes*

A. Ledwith

Department of Inorganic, Physical and Industrial Chemistry, University of Liverpool, Liverpool L69 3BX, UK

(Received 14 June 1976)

Specific intermolecular forces have been important to the development of many methods of polymer synthesis. This theme is developed so as to encompass major discoveries in ionic and complex organo-metallic polymerizations and the more recent utilization of Lewis acid adducts for control of copolymerization. In a final section, the rather weaker forces involved in charge transfer and exciplex binding are discussed in the light of existing and possible future mechanisms for polymer synthesis.

It is self evident that intermolecular forces and intermolecular complexes play an important role in a very wide range of chemical reactions, including synthesis of polymers. On the other hand, there are a number of rather specific molecular interaction phenomena of particular importance to the synthetic polymer chemist which provide the foundation for this survey. Many of these intermolecular complexes have been recognized and characterized during the time in which Geoffrey Gee has occupied the Sir Samuel Hall Chair of Physical Chemistry at the University of Manchester, and it is particularly appropriate to honour his retirement with a review of this nature as the first, and perhaps the simplest form of, molecular complex utilized in polymer synthesis was characterized in the same Department shortly before his arrival.

In the late 1940s the research group led by Polanyi showed conclusively that rigorously purified, dry, isobutylene failed to polymerize when in contact with dry BF_3 and/or TiCl_4 . Immediate polymerization ensued upon the introduction of traces of water¹. These observations established the requirement for a Lewis acid–cocatalyst complex as an initiating species for what is now termed a cationic polymerization, e.g.

Similar Lewis acid complexes are now widely employed for initiation of many types of cationic polymerizations and, whilst precise details of some reaction mechanisms remain to be elucidated, afford opportunities for synthe-

sis of new block and graft polymeric materials. Much of the recent development in this area is due to the work of Kennedy², following the commercial exploitation of butyl rubber (a random cationically prepared copolymer of isobutylene and isoprene) by the Standard Oil Development Co. (now Exxon Research and Engineering Co.). A particularly important development by the Kennedy group was the utilization of aluminium alkyls as Lewis acids in formation of catalytically active initiator complexes³. Whereas the more usual Lewis acid–cocatalyst complexes employed protic agents such as water or HCl as cocatalysts (and hence the ultimate source of initiating protons), it was demonstrated that carbocation precursors such as t-butyl chloride, allyl chloride, benzyl chloride etc. became extremely effective cocatalysts when complexed with trialkyl aluminiums and alkyl aluminium chlorides e.g.

It is well known that tertiary alkyl chloride units are present in commercially prepared samples of poly(vinyl chloride), as a result of side reactions during polymerization, and these abnormal structures may thus be used to co-initiate graft polymerization when activated by complex formation with Et_2AlCl_2 , e.g.

Similarly, chlorobutyl rubber (obtained commercially by partial chlorination of isobutylene–isoprene copolymers) possesses allylic chloride units in the main chain which are readily activated to graft copolymerization by complex formation with Et_2AlCl :

* Presented at the Sixth Biennial Manchester Polymer Symposium, UMIST, Manchester, March 1976.

We have already noted¹ that BF_3 was one of the first Lewis acids to be activated as an initiator for cationic polymerization by protic agents etc. and, until very recently, it was the only boron trihalide which appeared to function in the required manner even though BF_3 is formally the 'weakest' Lewis acid among BF_3 , BCl_3 , BBr_3 and BI_3 ⁴. Clarification of this apparent anomaly has become available again through the work of Kennedy and collaborators⁵. It is now known that the essential differences between cationic homopolymerization of isobutylene initiated by $\text{BF}_3/\text{H}_2\text{O}$ and $\text{BCl}_3/\text{H}_2\text{O}$ combinations respectively, arise because the former catalyst system gives rates of polymerization governed largely by rates of initiation, which decrease with decrease in temperature, whilst the $\text{BCl}_3/\text{H}_2\text{O}$ system gives rise to very rapid rates of initiation at all temperatures and rates of polymerization which increase with decrease in temperature as a result of much diminished termination rates. In contrast to the $\text{BF}_3/\text{H}_2\text{O}$ system where molecular weight is largely governed by chain transfer to monomer, polymerizations initiated by $\text{BCl}_3/\text{H}_2\text{O}$ exhibit spontaneous termination with transfer of chlorine from counterion to growing chain e.g.

In an elegant series of experiments, Kennedy and collaborators⁵ have established the termination mechanism indicated, and simultaneously generated a new technique for synthesis of block copolymers, by subsequent activation of the terminal tertiary alkyl chloride unit with diethyl aluminium chloride in the presence of styrene e.g.

Thus by suitable choice of catalyst or complexing cocatalyst homopolymer structures may be modified to provide a new range of graft and block polymers from readily available monomers.

As indicated in the foregoing paragraphs, molecular complexes between Lewis acids and a variety of cointiating species have dominated initiation processes in cationic polymerizations. However, there is a further complex equilibrium of equal importance to be considered, namely that of ion pair dissociation. Whatever the nature of Lewis acids and cointiators, an initiating complex, and the actual chain propagating cationic entity, will be subject to ion pair dissociation equilibria possibly involving covalently bound, ion paired, solvent separated, and freely dissociated ionic species, e.g.

Whether or not contact and/or solvent separated ion pairs are intermediates will depend on the particular system being considered but it is clear that full characterization of the effects of ion pair dissociation equilibria can only be successfully accomplished in the absence of cation forming equilibria such as those between typical Lewis acids and the usual cocatalysts.

In our own work⁶ we have sought to minimize complications due to cation forming equilibria by utilizing as initiators, thermally stable crystalline complexes of appropriate Lewis acids with comparatively stable carbocations such as triphenylmethyl (I) and tropylium (II). Hexachloroantimonate (SbCl_6^-) ion was the most convenient counterion.

Use of these types of stable salts offers many advantages not least of which is the convenience of measurement of ion pair dissociation equilibria⁷. Knowledge of the latter (e.g. for $\text{C}_7\text{H}_7^+\text{SbCl}_6^-$ in CH_2Cl_2 at 0°C , $K_d = 3 \times 10^{-5}$ M) is important in that it permits regulation of catalyst concentrations so as to ensure cationic propagation exclusively by free carbocations^{6,8,9}. Representative data for free carbocation propagation rate coefficients are given in Table 1. More recently we have used tropylium hexachloroantimonate in studies designed to evaluate the effects of chiral substituents on the stereochemistry of chain growth in propagation by free carbocations. This work is being pursued in collaboration with Chiellini and Solaro at the University of Pisa, in a group which owes its origins to Professor Pino who surveyed the effects of chiral substituents on the stereochemistry of polymerization at the Manchester symposium¹⁰.

Table 1 Propagation rate coefficients (k_p^+) for polymerization of $\text{RCH}=\text{CH}_2$ in CH_2Cl_2 at 0°C initiated by $\text{C}_7\text{H}_7^+\text{SbCl}_6^-$

R	$k_p^+ \times 10^{-3}$ ($\text{dm}^3/\text{mol sec}$)	E_a (kcal/mol)
$\text{CH}_3\text{O}-$	0.14	14
$\text{ClCH}_2\text{CH}_2\text{CHO}-$	0.2	7
$\text{CH}_3\text{CH}_2\text{O}-$	1.5	10
$(\text{CH}_3)_2\text{CHCH}_2\text{O}-$	4.1	6
Cyclohexyl-O-	3.3	9
$(\text{CH}_3)_3\text{CO}-$	3.5	<2
N-carbazyl-	340	6

In summary we find¹¹ that polymerization of (–)menthyl vinyl ether ($[\alpha]_D^{25} = -73.6$) (III) by $C_7H_7^+SbCl_6^-$ (10^{-5} M) in CH_2Cl_2 at $0^\circ C$ gives a product polymer ($M_n = 15\,000$) having highly enhanced optical activity ($[\alpha]_D^{25} = -206$). Highly isotactic poly[(–)menthyl vinyl ether] produced with more complex catalysts¹² has $[\alpha]_D^{25} = -198$. Polymerization initiated by $C_7H_7^+SbCl_6^-$ involves only freely dissociated ions, at the concentrations employed, and hence the high degree of stereoregulation observed must arise from steric, and chiral, effects between monomer and growing chains.

Very similar polymerizations of the less bulky monomer (*S*)-(1-methylpropyl)vinyl ether ($[\alpha]_D^{25} = +13$) (IV), yielded a polymer ($M_n = 6000$) having enhancement of optical activity ($[\alpha]_D^{25} = +142$) approximately 40% of that exhibited by the highly isotactic product ($[\alpha]_D^{25} = +312$) obtained at lower temperatures with more complex catalysts¹². Clearly the smaller alkyl substituent in IV (compared with III) leads to a lower degree of stereoregularity in the polymer. Nevertheless the fact that the freely growing carbocation can interact with monomer with significant stereoregulation requires modification of the usual mechanisms put forward to explain stereoregular polymerization of alkyl vinyl ethers by complex catalyst systems¹³.

The Lewis acid complexes used in initiation of cationic polymerization of olefins are, of course, special examples of the more usually encountered Friedel–Crafts complexes, important in many organic alkylation, acylation and sulphonation procedures. Whereas Friedel–Crafts reactions in organic synthesis normally employ large (i.e. equimolar) amounts of the Lewis acid component, the synthetic polymer chemist has been able to develop reaction conditions in which Friedel–Crafts complexes play a truly catalytic role. A good example is provided by the synthesis, developed by ICI, of various types of polyarylsulphones from cationic step growth polymerizations of arylsulphonyl chlorides, e.g.

Polyarylsulphones prepared in this way are now important commercial thermoplastic materials¹⁴.

Another important example of the use of Friedel–Crafts complexes to produce resins having good combinations of electrical properties, chemical resistance and good thermal stability, is provided by the recently commercialized Xylok resins, developed by Albright and Wilson¹⁵. In this case the Friedel–Crafts reaction is used to synthesise a range of prepolymers from phenol and α,α' -dimethoxy-*p*-xylene in the presence of $SnCl_4$. The prepolymer (soluble) materials are eventually converted into cross-linked resins by the conventional phenolic resin curing

agents such as epoxy compounds or, more particularly, hexamethylenetetramine, viz.:

Formation of Xylok resins is important in that it indicates how related cationic polymerizations of readily available monomeric units, which frequently give rise to products of low molecular weights may, in future developments, be readily converted to more useful products.

Ion-pair dissociation equilibria are perhaps the most common forms of intermolecular complex important in polymer synthesis and there can be little doubt that anionic polymerizations provide the best examples (both quantitative and qualitative) of specific ion–solvent interactions¹⁶. However these phenomena have been widely reviewed and will not be discussed further; a particularly lucid and revealing survey has been given by Szwarc¹⁷, who was the first to recognize these important effects. It is worth noting that the polymerization of olefin oxides, especially propylene oxide, to high molecular weight and sometimes stereoregular polymers might also be classified as anionic¹⁸ and involves molecular complexes of iron, zinc, and aluminium alkoxides. Indeed it is fitting to recall that the role of water as activating cocatalyst in several of these systems was first recognized by Gee and his colleagues¹⁹.

Similarly, the general area of Ziegler–Natta polymerization provides outstanding examples of molecular complex formation, notably between alkyl aluminium compounds and transition metal derivatives. Here again the subject matter has been extensively reviewed¹⁶ and will not be discussed further in so far as polymerization of olefin and diene monomers is concerned. Olefin metathesis however, is a development of studies in the general area of Ziegler–Natta polymerization and transition metal complex formation which is not only recent, but which could become increasingly important in polymer synthesis with the continuing improvement in types and yields of hydrocarbon structures from refining of petroleum.

OLEFIN METATHESIS

As developed initially by the Goodyear Co., olefin metathesis^{20,21} was a term used to describe a redistribution reaction in olefins e.g.

These truly remarkable transformations can be accom-

plished with a wide variety of catalysts but most readily by complexes derived from tungsten or molybdenum halides. A particularly good catalyst is formed from appropriate combination of tungsten hexachloride, ethylaluminum dichloride and ethanol. Many reaction mechanisms have been proposed to explain the course of olefin metathesis but there is now convincing evidence²² in favour of the metal-carbene complex chain reaction, originally proposed by Herrison and Chauvin²³ as illustrated schematically:

Applied to strained cyclic olefins such as cyclopentene, the reaction gives high molecular weight polypentenamer, a useful elastomer e.g.

Very recent work by Katz and collaborators²⁴ indicates how well known polymeric materials may be synthesised from new monomers. Application of the metal-carbene chain reaction to 1-methylcyclobutene yields a polymer having essentially the same structure as *cis*-1,4-polyisoprene. It is interesting that the most effective metathesis catalyst for this polymerization is a preformed tungsten-carbene complex $\text{Ph}_2\text{C} = \text{W}(\text{CO})_5$.

ALTERNATING COPOLYMERIZATION

Molecular complexes of the ubiquitous alkyl aluminium compounds are important in yet another area of polymer synthesis, in which completely new alternating copolymers are produced from the common polymerizable monomers.

It was first reported by Hirooka *et al.*²⁵ that free radical copolymerization of propylene and acrylonitrile in the presence of ethyl aluminium dichloride gave good yields of a 1:1 alternating copolymer:

Since the publication of Hirooka's observations, there have been a large number of similar reports for other monomer combinations and with other Lewis acid complexing agents. Typical examples include styrene/acrylonitrile/ ZnCl_2 ²⁶; vinyl chloride/acrylonitrile/ EtAlCl_2 ²⁷; butadiene and isoprene/acrylonitrile—with many Lewis acids²⁸. These types of copolymerization show the following general features:

(1) 1:1 alternating copolymer is formed over a wide range of monomer feed compositions, usually in complete contrast to the behaviour observed in the corresponding conventional free radical systems.

(2) The reactions are often spontaneous on addition of the donor monomer to a preformed Lewis acid-acceptor monomer complex, but may be promoted by conventional free radical initiation techniques to give copolymers of the same composition²⁹.

(3) Monomers which homopolymerize and copolymerize poorly by free radical techniques (e.g. propylene³⁰, allyl monomers)³¹ copolymerize readily in the presence of Lewis acids.

(4) The copolymerizations are usually affected by conventional free radical inhibitors (DPPH, hydroquinone)³² and are frequently complicated by competitive cationic homopolymerization of one of the monomers³³.

Thus, although these systems exhibit many of the characteristics of free radical copolymerizations, the nature of the end products shows the powerful directing effect of the complexing agent. Lewis acids most commonly used are ZnCl_2 , SnCl_4 , EtAlCl_2 and $\text{Et}_3\text{Al}_2\text{Cl}_3$. Acceptor monomers tend to be those with polar substituents (acrylonitrile, methacrylonitrile, MMA) and the donor monomers are generally neutral hydrocarbons such as styrene, propylene, butadiene and isoprene. Alternating copolymerization in the presence of Lewis acids is undoubtedly of practical importance and can be expected to feature prominently in the future design of copolymers. However, there is still considerable uncertainty as to the precise role of the Lewis acid component³⁴ and a full explanation must also account for the much earlier reports of the effects of metal salts on free radical homopolymerization of vinyl monomers, e.g. LiCl /acrylonitrile³⁵ and ZnCl_2 /methyl methacrylate³⁶.

Complexes of Lewis acids with monomers containing electron withdrawing groups such as acrylonitrile and methyl methacrylate, where the unshared electron pairs on oxygen or nitrogen supply Lewis base activity, are readily characterized by accompanying changes in the u.v. or i.r. absorption spectra of the olefinic compound. The complexes will certainly be more electrophilic, overall, than the uncomplexed olefin and would be expected to interact further with typical donor monomers, such as styrene, to promote alternating copolymerization. However, it is not at all clear whether the Lewis acid (which is usually present in large amounts) acts to complex a reacting monomer or a propagating radical. Both types of complex have been suggested³⁴. Bamford³⁷ has given an enlightened analysis of kinetic and mechanistic aspects with consideration of the complete range of monomer-Lewis acid phenomena and has suggested the more general description 'regulated copolymerization'. The latter implies copolymerization in which a change in monomer reactivity ratios is brought about by a Lewis acid, regardless of mechanistic implications.

Alternating copolymers were initially obtained from free radical polymerizations of mixtures of monomers having strong electron donor and acceptor character; important examples include styrene/maleic anhydride and alkyl vinyl ethers/maleic anhydride. In most of these cases there is evidence (usually spectroscopic) of ground state association between donor and acceptor monomer pairs, leading to the suggestion that alternating copolymers arise directly by free radical polymerization of monomer complexes. However, association constants for monomer complexes are frequently small and it is not yet clear how such weak forces of association could increase the polymerization reactivity of the complex (present in comparatively low concentration) relative to homopolymerization of the

monomers (where appropriate). A further difficulty with the concept of reactive monomer complexes arise because measurements of association constants indicate formation of molecular complexes for pairs of monomers which do not yield alternating copolymers. Proton magnetic resonance studies³⁸ of complexes between maleic anhydride and the monomers styrene, methyl acrylate, and methyl methacrylate give association constants 0.28 dm³/mol at 30°C, 0.32 dm³/mol at 60°C and 0.43 dm³/mol at 60°C respectively. Only the first monomer gives alternating polymers with maleic anhydride. Despite these anomalies there is a continuing interest in donor acceptor interactions in polymer chemistry especially those exhibiting charge transfer phenomena.

CHARGE TRANSFER COMPLEXES IN POLYMER SYNTHESIS

In principle, monomers exhibiting donor or acceptor function i.e. having low ionization potentials (I_D) and high electron affinities (E_A) respectively, should be polymerizable via charge transfer interactions with a suitable partner³⁴. There are comparatively few examples of homopolymerizable olefins having the required high electron affinity (vinylidene cyanide being a notable exception) but there are many examples of homopolymerizable electron donor monomers including *N*-vinylcarbazole, alkyl vinyl ethers vinyl derivatives of naphthalene and anthracene, and cyclic ethers such as tetrahydrofuran. Useful, natural, organic electron acceptors include tetracyanoethylene (TCNE), tetracyanoquinodimethane (TCNQ), chloranil, and maleic anhydride.

The simplified Mulliken scheme for charge transfer interaction i.e.

suggests the possibility of utilizing polymerizable olefins, as both donor and acceptor, in order to generate more than one type of polymerizing intermediate. Olefins having donor character polymerize best by cationic processes, and those having electron acceptor character by anionic or free radical processes. This distinction was first made use of by Gilbert *et al.*³⁹ who showed that mixtures of alkyl vinyl ethers (donors) and 1,1-dicyanoethylene (vinylidene cyanide) spontaneously polymerized to give products consisting mainly of poly(alkyl vinyl ethers) (known to form by cationic processes only) and poly(vinylidene cyanide) (known *not* to polymerize by cationic processes). A simple explanation for these observations although not generally known at the time, is that the reacting olefins undergo mutual oxidation and reduction with production of small amounts of initiating cations and anions respectively, e.g.

The early observations by Gilbert *et al.*³⁹ have been confirmed and substantially extended by Stille and colla-

borators⁴⁰ who have reported detailed studies of the mechanisms of interaction between a variety of unsaturated⁴¹ and saturated cyclic⁴² ethers with strong electron acceptors. Thus although in the presence of TCNE alkyl vinyl ethers form intermediate donor-acceptor complexes which ultimately collapse to 2 + 2 cycloadducts, the same monomers readily polymerize cationically in the presence of catalytic quantities of TCNQ and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ). Neither TCNQ nor DDQ can readily undergo facile 2 + 2 cycloaddition. E.s.r. experiments and quenching of reaction intermediates by methanol have established the following (typical) mechanism for initiation via a charge transfer complex:

The reactions of TCNE and vinylidene cyanide with dihydropyran are illustrative of the diversity of products which may be obtained in charge transfer initiated polymerizations; TCNE gives only the 2 + 2 cycloadduct while vinylidene cyanide gives the two homopolymers as well as the 2 + 2 cycloadduct:

Similar complications arise in the reactions of TCNE with *N*-vinylcarbazole⁴³ where the products include poly(*N*-vinylcarbazole) and 2 + 2 cycloadduct with the latter also being able to initiate polymerization in the presence of excess monomer.

Apart from the well documented studies by Stille and collaborators⁴⁰, there is considerable uncertainty as to the reaction mechanisms pertaining in many other charge transfer initiation processes. The topic has been fully surveyed by Hyde and Ledwith³⁴ and although it may be fairly said that charge transfer initiation of polymerization has not proved of any general value, despite considerable efforts, the closely related phenomenon of exciplex formation appears to hold promise for significant commercial exploitation.

EXCIPLEX INTERACTION IN PHOTOINITIATED POLYMERIZATION

Excited states of charge-transfer complexes have structures resulting from a considerable degree of electron transfer in comparison to their ground states, e.g.

Nevertheless, the excited states of a charge-transfer complex should not be equated with a thermally-equilibrated pair of ion radicals, a point which was first highlighted in the early, but stimulating, review by Kosower⁴⁴.

More recently, mainly as a result of the pioneering studies of Weller and his associates⁴⁵, it has become apparent that excited states, having structures equivalent to those of photoexcited charge-transfer complexes, may be formed by local excitation of one or the other component (i.e. D or A) in systems which do not give evidence of ground-state complex formation, e.g.

Here the excited state having the most electron-transfer character $(D^+, A^-)^*$ is termed an exciplex and its formation may be preceded by a variety of collisional complexes (encounter complexes) between an excited donor and ground-state acceptor or *vice versa*, e.g. (D^*, A) and (D, A^*) .

A simple molecular orbital treatment due to Weller⁴⁵ assumes that an electron is transferred from an excited state of one component to the ground state of another as illustrated below:

Molecular orbital treatment of exciplex formation (donor excited)

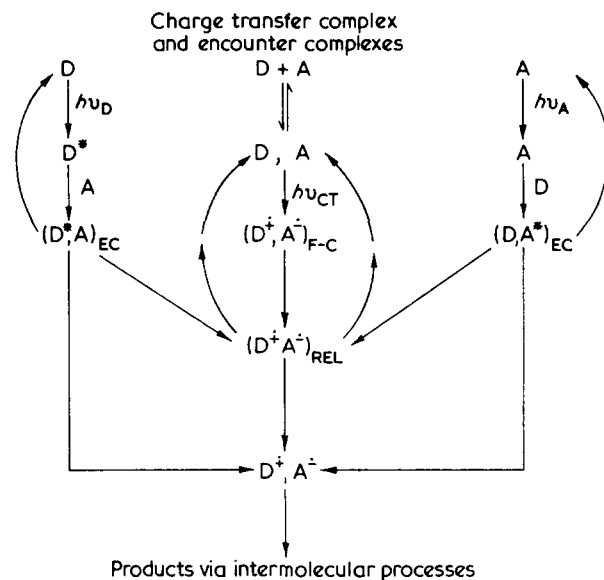

Molecular orbital treatment of exciplex formation (acceptor excited)

Since the ionization potential (I_D) and electron affinity (E_A) are measures of the energies of the highest bonding and lowest antibonding molecular orbitals respectively, ΔG , the energy of formation of the separated ions D^+ and A^- from D and A in their ground states is $I_D - E_A$. Since we actually start with an excited state (e.g. A^*), the energy of formation is diminished by the excitation energy of A^* . Bringing the separated ions D^+ and A^- to their equilibrium distance (r) in the exciplex reduces ΔG by an electrostatic term ($-e^2/r$). It follows therefore⁴⁶ that the free energy of exciplex formation is given by:

$$\Delta G = I_D - E_A - h\nu - \frac{e^2}{r}$$

where $h\nu$ is the excitation energy of A^* or D^* as appropriate. Because a molecule in its excited state is both a better electron donor and a better electron acceptor than in its ground state, exciplex formation should be a widespread phenomenon. The topic is the subject of a recent review monograph⁴⁷. A particular advantage of ion radical formation via exciplexes rather than ground state charge transfer complexes is that a much wider range of substrates may be employed, including many compounds which do not interfere with commercially important polymerization systems. However it must be stressed that molecules having ionization potentials or electron affinities typical of those observed in formation of ground state charge transfer complexes can equally well participate in exciplex formation with partners which do not give rise to ground state adducts. Likewise it is not necessarily the case that the photoexcited state of a ground state charge transfer adduct is the same as an exciplex formed by collisional interaction of an excited (uncomplexed) component⁴⁸. Interrelationships between charge transfer (CT) complexes and exciplexes are illustrated below:

Any distinction between collisional encounter complexes (denoted by EC) and exciplexes is indicated, in the diagram, by the potential interconversions of the two possible EC complexes to a pair of ion radicals $[(D^+, A^-)_{REL}]$ having a solvation shell considerably relaxed from the Franck-Condon state $[(D^+, A^-)_{F-C}]$ formed on direct excitation of a ground state CT complex between the same components. Either of the encounter complexes, or the solvent relaxed exciplex, could be responsible for formation of the solvent equilibrated pair of ion radicals leading to ultimate photochemistry in the system. Reversion back to the neutral starting components will be an important competing process at any stage of the equilibria indicated and, although the diagram uses a common donor D and acceptor A for both CT complexation and exciplex formation, there is no requirement for ground state association prior to EC or exciplex formation.

Exciplex formation between the excited states of most aromatic carbonyl compounds (acceptors) and a wide range of organic amines (donors) has been particularly useful as a

means of photoinitiating free radical polymerization^{48,49}.

Singlet and triplet states of aromatic ketones are efficiently quenched by a wide variety of amino compounds and a general correlation exists between quenching efficiency and ionization potential of the amine, for a particular class of amine^{50,51}. In many cases tertiary amines are more effective than the corresponding secondary and primary derivatives although specific solvation phenomena may change this order of reactivity. Products from these various photo-redox processes are related and, for the photo-oxidation of amines, may be generalized as follows:

Fluorenone is one of the most useful of aromatic ketones having lowest lying π , π^* triplet excited states and its photophysical characteristics have been extensively characterized⁴⁸.

Ionization potentials of amines are important in determining quenching ability towards both singlet and triplet excited fluorenone but it appears that *photoreduction* is consequent upon interaction of triplet excited fluorenone with amine donors⁵⁰, the main effect of singlet state quenching being to reduce triplet yields. Evidence for the existence of both ion-radical pairs and free radicals is available from detailed CIDNP studies of photoreduction of benzophenones by tertiary amines. Such combinations afford a useful initiation system for radical polymerization of methyl acrylate⁵³ and we have demonstrated^{49,54} that photoreduction of fluorenone by tertiary amines is also an effective free radical initiating system for polymerization of methyl methacrylate, styrene, and acrylonitrile.

Exciplexes produced on irradiation of naphthalene in the presence of acrylonitrile initiate polymerization of the latter⁵⁵, a reaction which helps to illustrate the wide range of organic structures which may be expected to participate in such processes. For initiation of radical polymerizations however, exciplexes of aryl ketones have been most widely employed and a particular interesting case arises from the use of Michlers' ketone (MK) (4,4'-dimethylaminobenzophenone) which possesses both carbonyl acceptor group and amine donor unit⁵⁶. It is also quite remarkable that Michlers' ketone enhances the light sensitivity of initiator systems derived from other ketones⁵⁷. There is experimental evidence⁵⁸ for the photoinduced self condensation of Michlers' ketone, presumably via an intermolecular exciplex, and similar exciplexes are probable intermediates in systems based on mixtures of Michlers ketone and other carbonyl compounds e.g.

During the past five years there has been an enormous upsurge in interest in photoinitiated polymerization for the hardening of decorative and protective surface coatings and soft mouldings as well as for the manufacture of printed circuits and relief printing plates^{59,60}. Exciplex interaction has provided the means of improving both light absorption and wavelength sensitivity of photoinitiator components and will continue to be important for the future, especially since a number of economic and environmental factors now demand the development of pigmented, photocurable, printing inks based on fully polymerizable components.

Molecular design of polymers*

Anthony H. Willbourn

Imperial Chemical Industries Ltd, Plastics Division, Welwyn Garden City, Hertfordshire, UK

(Received 14 May 1976)

This presentation is centred on what the chemist can achieve by control of molecular structure to achieve the 'simple properties' in linear, synthetic polymers which make them useful in a modern industrial environment. Transparency is a desirable property, readily accessible with amorphous polymers. Rather special structures are required to produce transparent crystalline polymers in the bulk state. The utility of many polymers is restricted by their susceptibility to chain scission, leading to a drop in molecular weight and hence loss of mechanical strength. A structural approach to defeating this effect is to make 'ladder' structures. An approach to the synthesis of novel ladder structures by bi-nuclear regulated copolymerization is suggested. Although copolymerization has been widely studied, little systematic work has been carried out on copolymer systems, which are more difficult to attain, to study the effect of copolymer composition on physical properties. The results are not always those expected, as illustrated by the acrylonitrile/styrene system. An example for further research of this type is proposed. The problems of correlating molecular structure with mechanical properties in any quantitative way are formidable, although much progress has been made on the phenomenological level in the understanding of the physical behaviour of polymers. Attention is drawn to a correlation which has been observed between modulus and certain structural parameters which may open the way to quantitative studies. Toughness is a more difficult property even to define, let alone correlate with structure. Nevertheless qualitative correlations may provide a useful starting point for future research.

INTRODUCTION

Design is for a purpose. Design comes after the recognition of the need for what is to be achieved, and after a satisfactory answer to the question: why do it? It leads on to the question: how is it to be done?

It is only in a mature field of science that these questions can be posed and answered at all, because they presuppose a wealth of knowledge about what it is possible to achieve and the ability either to do so, or to discover means of so doing by pursuing lines of research of known promise. Hence the fact that it is possible to talk on 'molecular design of polymers' is itself a tribute to the many able scientists who have, over the past 50 years or so, provided this wealth of background knowledge and who have discovered many remarkable ways of making polymers of all sorts of shapes and sizes. These different shapes and sizes result in an equal diversity of properties, and it is particularly in striving for understanding of some of these properties that Professor Geoffrey Gee has contributed so significantly.

This discussion will be restricted to a consideration of the relationship between the molecular design of synthetic linear polymers and some of those simple properties which are relevant to their usefulness to man. This will be the unifying theme, which may not be scientifically very defensible but in practice it is among the most powerful motivators of scientific research.

The 'simple properties' that are useful are not always simple in scientific terms and the future direction of much polymer research will be governed by efforts the better to

understand these properties and to improve on them. In reviewing what has been done, and what might be done in the future, emphasis will be placed on what can be achieved by the *chemist* by the control of the molecular architecture of polymers. There are other ways of changing properties, e.g. by adding plasticizers, stabilizers, 'reinforcing' agents, etc., which are often the only practicable means of producing polymeric compositions (plastics) with the processing characteristics and final properties to suit particular needs. However, on this occasion attention will be focused on what the chemist can do.

MOLECULAR ENGINEERING

Transparency

Water-white transparency is on the face of it a very simple property. All that is required is that the material should neither absorb nor scatter radiation of wavelengths between 4000 and 7000 Å. In principle the former should be no great problem with polymers based on carbon chemistry, since the electronic states of the ordinary simple carbon bonds in synthetic polymer do not give rise to significant absorption of this radiation. In practice however there are two major problem areas.

The first problem is that most polymers when first made turn out to be coloured – usually dark brown, or at best yellow – and even if they start colourless they discolour on heating or on exposure to light. The pure scientist may dismiss this unfortunate result as due to an aberration – the use of impure reagents, the formation of ionic complex chromophores from metallic contamination, thermal or photochemical degradation of the polymer to form conjugated

diene sequences in the chain, and so on. He will be right, but nevertheless a vast amount of both industrial and academic research has been, and will be, aimed at eliminating colour in polymers, and in devising stabilizers to prevent the formation of chromophores (or to eliminate them by reacting with them). The problem arises not only from thermal decomposition during synthesis and processing, but from photochemical and thermal reactions during service. There is however one very helpful empirical rule to comfort the industrial chemist: the yellowness of a moulded thermoplastic polymer decreases with each increase in the scale and volume of commercial production and tends asymptotically to zero.

This comes about for many reasons, the main one being that much effort is devoted to achieving it. Qualitatively the evidence for this 'law' may be seen in the history of PVC, polystyrene and polycarbonate among other commercial plastics.

The second problem area is more fundamental and arises because, in general, those polymers having geometrically regular repeat units will crystallize to form crystalline domains larger than the wavelength of visible light.

In polymer samples prepared by melting and forming (as most of them are), the individual lamellae are small, typically 100-300 Å in thickness with lateral dimensions that can be up to several thousand Å. But the lamellae aggregate in twisted ribbons to form spherulitic structures of sizes from about a micron up to units easily visible in the microscope. Therefore crystalline polymers are opaque, or at best translucent, in the bulk state. In forming these polymers into films they can be made more transparent which is fortunate considering how important these materials are in such uses as photography. The rapid quenching which a thin film is subjected to produces some improvement in transparency since rapid quenching from the melt reduces the degree of crystallinity and retards aggregation into spherulites. More drastic modification is achieved by orientation which not only results in the absence of spherulites but can produce lamellar structures in which the orientation is correlated over distances large in relation to the wavelength of light, resulting in a marked decrease in intensity of scattered light¹. For example when

polypropylene film is biaxially oriented, the spherulitic structure is completely disrupted and the final film has no visible structure and is highly transparent. However there are crystalline polymers which are transparent in the bulk state because of their molecular architecture, which is something that the chemist can control.

An unusual method of achieving transparency is exemplified by poly(4-methylpentene-1). It is taken for granted that a polymer crystal has a greater density than the amorphous phase, a larger refractive index and is optically anisotropic. These things are not true for poly(4-methylpentene-1)². For instance the polymer chain in the crystalline unit cell forms a fairly open helix (less tightly coiled than the polypropylene helix, see Figure 1), and the packing of the large isobutyl side groups is such that the total assembly of bonds is vectorially quite well randomized. The result is that individual crystallites have low anisotropy and polymer spherulites exhibit unusually low birefringence compared, for instance, with polypropylene or polyethylene (Table 1). A second crucial and unusual factor is the fact that the specific volumes of the crystalline and amorphous regions are very close to each other; in fact at room temperature the specific volume of the crystalline phase is greater (1.208 cm³/g) than that of the amorphous polymer (1.193 cm³/g). But the system is more complicated, otherwise the polymer would not crystallize at all. The amorphous polymer has a larger coefficient of thermal expansion than the crystalline phase, and has a greater specific volume above 60°C (Figure 2). The difference is large at around 200°C which is the temperature region at which the polymer crystallizes on cooling slowly from the melt (m.p. = 245°C). Under these conditions large spherulites are formed, and in forming they produce voids and the optical transmission drops to about 20%. If however the samples are quenched, such crystallization as occurs is at a lower temperature; voiding is reduced, and transparency is good (~80% transmission). In practice quenching produces other problems and is not always practicable, and in fact the need to quench can be eliminated by some delicate molecular engineering. Copolymerization with a minor amount (~2%) of a linear 1-olefin helps, probably by lowering the temperature at which crystallization sets in. If in addition a very small amount (<1%) of a high melting polyolefin is incorporated as a fine dispersion, to provide nuclei which persist in the molten polymer, then moulded parts can be made in which the average spherulite size is less than 5 μm, with optical transmissions around 97% (Table 2).

There is another industrially important way chemically to affect the transparency of crystalline polymers if they can be made with ionizable groups. Examples are polyethylenes and polyoxymethylenes containing small molar percentages of carboxylic acid groups which, when neutral-

ized with metallic cations, exhibit markedly increased transparency⁴. These 'ionomers' (as they are known) are complex structures with many unusual features which can be illustrated by the Surlyn* range of plastics: these are ionomers based on ethylene copolymerized with methacrylic acid and (partly) neutralized with Na^+ or Zn^{++} ions. The acid copolymers themselves with up to about 4 mol% of acid are structurally not very different from the parent low density polyethylenes, being translucent with typical spherulitic crystallinity (Figure 3). The introduction of cations however destroys the spherulitic structure (Figure 4), and the process is reversible. The 'ionomerized' structure is still crystalline (as shown by X-ray diffraction) and

the ions form clusters a few tens of Angstroms in diameter. Other properties change also: ionomers are generally more transparent than the parent acid copolymers, depending on the type and concentration of the cation; they have greatly increased water absorption (which can be up to 25% by weight), the water presumably solvating the ionic clusters; ionomers are tougher than polyethylene, and are resistant to stress-cracking agents but they start to soften at quite low temperatures. In fact ionomers show some of the properties of crosslinked structures, but the 'crosslinks' are labile because ionomers are melt processable although they have much higher viscosities than the parent copoly-

mers. Studies of other properties: dielectric relaxations, mechanical relaxations, thermal behaviour, X-ray diffraction etc. display a complex dependence of properties on composition and no very convincing correlation with molecular structure. There seems to be plenty of scope for further research to understand these effects and to seek novel combinations of properties in such systems.

Seemingly simple uses often demand unusual property combinations. Consider the laminated windscreen as used in motor cars. All that is apparently required to make such a windscreen is a transparent, colourless tough plastic foil, which can be sandwiched between two sheets of (curved) glass. Further study shows that the optical quality of the interlayer foil must be of a very high order so that a glass laminate made with it has a minimum light transmission of 70%, negligible haze (i.e. wide-angle scattered light) and low optical distortion. The foil must also be tough over a wide temperature range so that laminates are highly resis-

Figure 5 Variation of dynamic shear modulus G' with temperature. Method: torsion pendulum 0.3–3 cycles/sec. — — —, LDPE; ·····, ionomer B; —, Terpolymer X; — · — ·, plasticized poly(vinyl butyral)

tant to penetration over the temperature range -20° to $+40^{\circ}\text{C}$, but at the same time the laminate must yield on impact to give controlled deceleration below the threshold value causing brain damage. On top of all that, when the windscreen is broken, the glass fragments should still adhere to the foil. To achieve these effects, the adhesion between foil and glass must be closely controlled, not too great, and not too small. There is only one foil material which has been found satisfactory on a commercial scale for this use. It is poly(vinyl butyral) (PVB), an amorphous polymer, compounded with a specific plasticizer, which was introduced some 30 years ago and which has of course been gradually improved over this period. A crucial requirement of PVB foil for this use is that its water content shall be carefully controlled at near 0.4%, because this governs not only the adhesion behaviour of laminates, but also the ability to make laminates and their integrity in service. PVB when saturated takes up 3 to 5% of water.

Various commercial ethylene copolymers and ionomers, which are partly crystalline, have some of the right sorts of properties for the windscreen application but none have the right balance. For example, ethylene/vinyl acetate copolymers may have the desired stiffness and toughness but have poor adhesion to glass and inadequate optical properties. Ionomers tend to be fairly transparent and give better adhesion to glass but are likely to be too stiff and to show too high a sensitivity to ambient relative humidity (r.h.). A much more suitable foil can be made by specific design of an ethylene/methacrylic acid terpolymer system. The level of acid copolymerized sets adhesion characteristics, while optical and mechanical characteristics can be optimized by controlling the content of a third monomer which can for instance be methyl methacrylate⁵. It turns out that a system with 4 mol% of each comonomer (Terpolymer X) possesses the right balance of properties: comparison of these materials is shown in Figure 5 and Table 3. An additional advantage of this terpolymer is that, unlike PVB, it has low water absorption and hence low sensitivity to ambient r.h. (Figure 6). One final thing is needed to achieve the highest transparency and minimum haze: the terpolymer foil should be cooled rapidly from the molten state during the process of making the windscreen. This quenching process renders the foil practically amorphous. Figure 7 shows what happened when a car fitted with a windscreen* made using Terpolymer X was involved in an (accidental) head-on collision, and illustrates the advantage of laminated screens. The driver's head impacted onto the

screen, but he emerged without a scratch on his face (although he did break his arm!).

Glass transition temperatures of crystalline polymers

No discussion of the temperature dependence of physical properties can be coherent without agreement about the nature of the glass transition temperature, T_g , and its relationship to features of molecular structure. This has been a fruitful field for research, and there is no need to emphasize its continuing importance. There is however one recent development worth drawing attention to because of its wider implications. For the simplest of polymers, viz. polyethylene, there is still controversy about its glass transition temperature: values of T_g are variously quoted as either around -120°C , or around -30°C ⁶. This disagreement leads to great confusion in the abundant literature on the properties of polyethylene and of related polymers (including the ionomers). Part of the problem undoubtedly arises because the 'glass transition temperature' can be defined in different ways which lead to different criteria for recognition and measurement of T_g . A definition favoured by the author (although it is admittedly incomplete) is 'that temperature at which the main polymer chain acquires large-scale mobility'. Following this definition there is a simple criterion for T_g for those crystalline polymers that can be quenched from the melt into the fully amorphous glassy state: T_g is that temperature at which crystallization occurs⁷. Crystallization must involve fairly large scale chain movement, translational as well as rotational, especially as we now know that lamellae of folded chains are formed in the process.

This criterion was of no value in the case of polyethylene because amorphous linear polyethylene had never been produced despite many efforts to do so. Quite recently however Hendra has succeeded in quenching a linear high density polyethylene to the fully amorphous state in which it is stable at -150°C . He has followed the onset of crystallization by observing infra-red spectra, Raman spectra and X-ray diffraction and has concluded that crystallization sets in at around -100°C which sets an upper limit for T_g , using this criterion^{8,9}. This work opens up a new

and fruitful field of research on the properties in their amorphous states of normally crystalline polymers, since this quenching technique can no doubt be applied to other crystalline polymers such as the aliphatic nylons, polyacetal and perhaps to polytetrafluoroethylene, polymers which have never been reported in the amorphous glassy state.

Ladder polymers

Permanence in physical behaviour is very desirable but most polymers are restricted in their utility by degradation, by light or by heat or by oxidation or by a combination of these. Typically such degradative reactions cause random chain scission, which results in a rapid drop in average molecular weight and this in turn results in a rapid fall in those properties dependent on average MW : impact strength, tensile strength and elongation at break. However there has been little work published on the quantitative aspects of this very important phenomenon. Adams has published data on MW changes of (unstabilized) polypropylene caused by thermal oxidation, photo-oxidation and by melt processing, and noted that samples were quite brittle by the time their MW were halved¹⁰. The effect is quite dramatic: polypropylene of $M_n = 84\,000$ becomes brittle after 2 h exposure at 138°C if it is not stabilized. Similar data have been presented by Birley and Brackman on the photo-degradation of low density polyethylene¹¹.

Most commercially available thermoplastics are produced with molecular weights as low as is safe and reasonable to confer the required mechanical properties, in order to make fabrication by moulding, extrusion, etc. as easy as possible by keeping the melt viscosity low. With this in mind, and taking account of the published data, it seems that when degradation has proceeded to the extent of about one bond broken per molecule present (thus halving M_n) the mechanical strength of the polymer has been effectively destroyed.

A means of defeating this effect by redesign of molecular structure is to form ladder polymers in which two parallel chains are connected together at regular intervals. An individual chain in a ladder polymer can undergo cleavage of any single bond without any effect on MW . If cleavage is a random process, then only after extensive degradation will two bonds in the same section of the ladder be cleaved

Figure 7 Car fitted with Terpolymer X windscreen after head-on collision

Figure 8 A ladder structure can withstand many bond cleavages without reduction in overall length

Figure 9 Diels-Alder condensation and polymerization of 2-vinylbutadiene and benzoquinone

and the chain itself be broken, with consequent drop in MW and in related physical properties (Figure 8). The first deliberate synthesis of a ladder polymer was by Bailey and Economy in 1954^{12,13} of the polymer from 2-vinylbutadiene and benzoquinone by Diels-Alder condensation (Figure 9). A proportion of the product was of fairly high MW , softening at over 340°C and soluble only in powerful solvents such as hexafluoroisopropanol. Many such ladder polymers have since been made, often containing condensed heterocyclic rings and giving intractable infusible solids¹⁴. However some polyester types with a significant aliphatic content have been synthesised, and degradation studies on these and other systems have demonstrated that these ladder structures are more resistant to degradation than the analogous single-strand polymers^{15,16}.

This is a tantalizing field because there are polymers it would be interesting to examine but synthetic methods to make them have yet to be devised. One such is a polyethylene-type ladder polymer with the 'rungs' irregularly spaced at intervals with an average of around 4 per 100 chain atoms, i.e. at about the same frequency at the short branches in low density polyethylene (Figure 10). It is interesting to speculate what its properties would be. It is likely to be not very crystalline, the rungs not being regularly spaced, and also it is difficult to see such a ladder structure being incorporated in a chain-folded lamellar structure. A small amount of copolymerization with an α -olefin (say propylene or butene-1) to introduce some random short branches (R in Figure 10) might be expected to produce a completely amorphous polymer. Its thermal stability (and light stability) should be good, and although its melt viscosity would presumably be high for a given 'ladder length', it should be processable at high temperatures without significant degradation. What its mechanical properties would be depends on one's view of the T_g of polyethylene (hence the comments above on this matter).

Taking the view that the T_g is below -100°C , then this amorphous branched polyethylene-type ladder polymer will have an effective T_g around -70°C and (if lightly cross-linked) will be elastomeric over a wide temperature range, say from -60°C up to its limit of stability which could be well over 100°C depending on the conditions, the life required and the effectiveness of stabilizing systems.

Clearly some very advanced molecular engineering will be needed to synthesise a polyethylene ladder polymer. The obvious elegant way is to persuade, say 1,7-octadiene to copolymerize regularly, and coincidentally, between the same two growing polyethylene chains. Whilst this looks to be impossible to achieve in the way set out in Figure 11, published work on transition metal compounds which are catalysts for olefin polymerization¹⁷ perhaps provides the basis of a possible synthesis. These catalysts function by 'growing' the polymer chain from the metal atom, the monomer being first coordinated to the metal and then being inserted into the polymer chain. Thus zirconium tetrabenzyl is such a catalyst, and it retains its activity when bonded to a silica surface as a siloxy-tribenzyl zirconium. Under the right conditions structures of this

Figure 10 A polyethylene-type ladder structure

Figure 11 Growth of polyethylene-type ladder structure by bi-copolymerization with 1,7-octadiene (schematic)

Figure 12

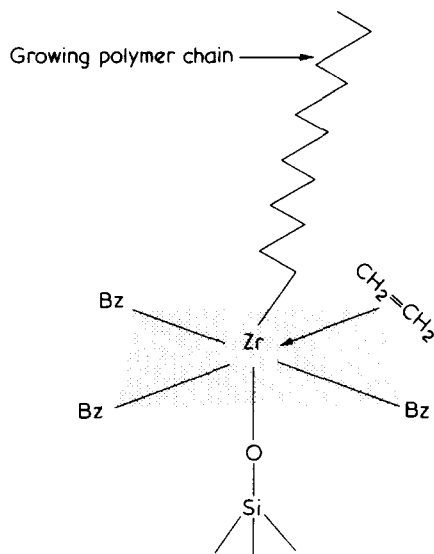

Figure 13

type can indeed be formed (Figure 12).

In this state the bonds are tetrahedrally disposed, but it is probable that during polymerization the zirconium is 6 coordinated with an octagonal structure (Figure 13).

Now the procedure would be to synthesise a binuclear catalyst, joining two Zr (Bz)₃ moieties with a *para*-xylyl ligand to form (Bz)₃Zr.CH₂.C₆H₄.CH₂.Zr(Bz)₃. This binuclear complex is then reacted onto a silica surface previously heated to about 400°C so as to leave the surface only sparsely covered with OH groups (so that paired structures like those in Figure 12 are formed). When ethylene is presented to the system, polyethylene chains will grow from each of the paired Zr nuclei, and the problem is: how to join these two growing chains together? In principle this might be done by copolymerizing with 1,4-diallylbenzene if the two allyl groups could be placed simultaneously next to the two neighbouring Zr nuclei. To achieve this some 'template' mechanism must be provided to attract 1,4-diallylbenzene molecules onto the surface in between the paired Zr nuclei, so that their relative concentration is much greater there than at any other surface site. Such a mechanism could be the formation of a weak complex between diallylbenzene and the *para*-xylyl ligand by appropriate substitution of the respective aromatic nuclei by attracting groups X and Y. The complete system is shown in Figure 14. It would clearly be a formidable task to realize this system, but one might suggest an approach using X = F and Y = NR₂ (R = alkyl), or *vice versa*. The effect of the substituent X on the stability of the xylyl ligand and on the polymerizing activity of the Zr nuclei may well be an important factor.

Novel copolymer systems

Copolymerization is one of the most direct and widely used techniques of molecular engineering and the kinetics of copolymerization have rightly been the subject of extensive academic study. The principles of the free-radical copolymerization of vinyl monomers are to be found in standard texts, with tables of reactivity ratios, and *Q* - *e* diagrams. From these data it is apparent that there are many copolymers which are difficult to make. It is somewhat surprising that more of these systems have not been taken as projects in, say, chemical engineering, the objective being to make significant quantities of truly random, thermally stable copolymers using the special monomer composition control and feeding techniques now practicable with the advent of on-line process instrumentation and real-time computer control. It should be possible to make enough of these copolymers in laboratory scale apparatus to study their properties as a function of composition¹⁸. These properties sometimes turn out to be quite different from what was expected.

Examples of 'difficult' copolymers which have become industrially important are the truly random copolymers of styrene and acrylonitrile (AN) containing 75 and higher mol% AN. This is a system in which¹⁹:

$$\text{AN is monomer 1, } r_1 = 0.04$$

$$\text{Styrene is monomer 2, } r_2 = 0.4$$

The copolymer composition plot is skew sigmoidal, as shown in Figure 15. This reflects the fact that over much of the range of monomer compositions the copolymer (instantaneously) formed has a very different composition from the monomer mixture. Inevitably therefore if such a monomer mixture is fully polymerized, the copolymer formed will be structurally heterogeneous. This is illustrated in Figure 16 for a 25:75 molar mixture of styrene and AN. The properties of these heterogeneous copolymers are dreadful: thermal stability is poor and they are so brittle that the properties can hardly be measured. If however the monomer composition is controlled during reaction to produce a truly

Figure 14 System for polyethylene-type ladder polymer synthesis

Figure 15 The relationship between monomer mixture composition and copolymer composition for acrylonitrile and styrene

Figure 16 The composition of the product resulting from the batch copolymerization of acrylonitrile (75 mol %) and styrene (25 mol %). [Reproduced from HENDY, B. N. 'Copolymers, Polyblends and Composites', Advances in Chemistry Series, No. 142, Am. Chem. Soc., Washington D.C., 1975, pp. 115-128 by permission of The American Chemical Society, Washington D.C. ©]

random copolymer having even as much as 80 mol% AN, then a strong, clear and thermally stable copolymer can be made¹⁸. The contrast in properties is indicated in Table 4.

These particular copolymers, with high AN contents, are important because of their very low permeability to permanent gases and in particular to CO₂ and oxygen (Table 5). Such copolymers are classed industrially as 'barrier resins',

and are used in the manufacture of bottles for carbonated beverages.

Permeability is an important property which governs the use of many polymers in film form to protect foodstuffs, chemicals, and agricultural products. In its simplest terms, permeability is a function of both the solubility (*S*) of a gas in the polymer and of its rate of diffusion (*D*). Both *S* and *D* are dependent on polymer structure in ways that are qualitatively understood, but there is certainly scope for better understanding and there are structural effects which are still mysterious. One of these is the relatively low permeability of vinylidene polymers, shown by for instance polyisobutene compared with natural rubber and poly(vinylidene chloride) compared with poly(vinyl chloride) (Table 5). An interesting research project would be to synthesise a range of vinylidene chloride¹/isobutene² copolymers, truly random composition. This is likely to be difficult since one can guess that for this system $r_1 \sim 3$, $r_2 \sim 0$.

The structures, and hence the properties, of these copolymers might well show some interesting and unusual features. The methyl group, although slightly larger than the Cl atom and not spherically symmetrical, is not very different in size from the Cl atom. The available evidence suggests that the chain configurations of the two polymers in their individual unit cells are somewhat similar. Polyisobutene (PIB) only crystallizes on stretching; however in the unit cell the conformation of the molecule is a 8₃ distorted helix with a repeat distance of 2.32 Å per monomer unit²⁰; the corres-

Figure 17 Vinylidene chloride/isobutene copolymers: dependence (hypothetical) of melting point (T_m) and of glass transition temperature (T_g) on composition. A, T_m ; B, T_g

ponding conformation for poly(vinylidene chloride) (PVdC) is a 2_1 helix with a repeat distance of 2.34 Å per monomer unit²¹. Both molecules are very overcrowded in any configuration, so much so that the main chain bond angles at the CH_2 groups are opened up from the tetrahedral 109.5° to 128° for PIB and 123° for PVdC; the difference in bond angle at the CX_2 group is rather greater, the angle being 110° for PIB and 120° for PVdC. These molecules are therefore rather similar in size and in preferred conformation, and in random copolymers of low isobutene content the comonomer units might be expected to cocrystallize.

Some estimates can be made of the properties of such a cocrystallizing system. Although PIB does not crystallize unless stretched, from observations of the melting point of PIB at different elongations it appears that its notional melting point is around 0°C ; the T_g of PIB is -70°C . For poly(vinylidene chloride) $T_m \sim 210^\circ\text{C}$ and $T_g \sim -20^\circ\text{C}$. Hence one would expect a random, cocrystallizing, copolymer of 80:20 VdC/IB composition to have (Figure 17): $T_m \sim 175^\circ\text{C}$; and $T_g \sim -30^\circ\text{C}$.

Quite apart from this being an interesting academic research project, these random copolymers should have technologically useful properties, especially if their lower melting points could be combined with thermal stability adequate to permit fabrication by melt processing. They should have good mechanical properties and be tough and extensible (the amorphous phase having such a low T_g), and might be expected to retain low permeability to CO_2 and oxygen.

MECHANICAL PROPERTIES

Problem of structure correlation

It is evident that, however desirable may be properties such as transparency, resistance to degradation, low dielectric loss, low flammability and low permeability, these are of little practical value unless they can be combined with 'good mechanical properties' in a polymer which can be readily processed into desired shapes — mouldings, extrusions, sheet and film. It is impossible really to define 'good mechanical properties' because what is acceptable in practice is the result of a compromise between properties which

are essential for a particular application, adequate performance in other respects, and the overall cost involved. However, prescinding from specific properties and applications, it is reasonable to generalize to the extent of stating that for structural uses one is seeking for high strength, rigidity, toughness and a wide usable temperature range.

Although the dependence of mechanical behaviour on a variety of parameters (time, stress, geometry, environment, temperature), has been the subject of detailed investigation and some progress has been made in an understanding in phenomenological terms, understanding at the level of molecular design is still qualitative, fragmentary and imperfect, and compares unfavourably with the state of knowledge about low molecular weight compounds, metals and even of elastomers.

This point has recently been emphasized by Flory²². He points the way to a rigorous mathematical approach to the calculation of physical properties using such basic data as energy barriers to bond rotation, intermolecular forces, the dimensions of chain links and of sub-units, the distribution of chain lengths, and the conformations of the long chain molecules. While in principle possible, this is a daunting task for the ordinary polymer scientist, if only because of the large amount of quantitative information needed for each polymer before a start can be made with the calculations, and also the difficulty of formulating the mathematical functions and programming the computations.

A complementary approach is to consider the total system and to concentrate on those essential molecular features which determine a few basic properties. If one can establish some real correlations then these will point the way to profitable lines for future research, both practical and theoretical. Two examples of such correlations are proposed for consideration.

Toughness and structure

A tough material fails in ductile fashion, at large strains. Why is it that some glassy, amorphous (linear) polymers exhibit ductile failure, while others are brittle? Of course distinctions are not all clear cut, and are dependent on temperature, strain rate, etc. but the reality is quite recognizable in contrasting polystyrene with polycarbonate. There is no real correlation with modulus, glass transition temperature or secondary mechanical transitions. One clue is perhaps to be found in the shape of the molecule.

In the 1930s and the 1940s when free-radical polymerization of vinyl compounds was the only readily available synthetic route to high molecular weight polymers, and most of these were amorphous being of the types $-(\text{CH}_2-\text{CHX})-$ or $-(\text{CH}_2-\text{CXY})-$, much effort was put into seeking useful polymers with softening points above 110°C which was the top limit of T_g values for the polymers then in general use [polystyrene, poly(vinyl chloride), poly(methyl methacrylate)]. A favoured approach was to incorporate large side groups (X) in the vinyl $(-\text{CH}_2-\text{CHX}-)_n$ chain units, but the effect of this was invariably to make brittle materials. Perhaps the ultimate example was polyvinylcarbazole, which has been used commercially because of its excellent dielectric properties and high softening point:

Table 6 Effect of structure on impact behaviour of aromatic sulphone polymers

Structure	Impact behaviour
	Tough
	Brittle
	Tough
	Brittle
	Tough
	Brittle
	Brittle

In more recent years conditions for carrying out a variety of coupling and condensation reactions have been devised (and intermediates of the requisite purity have been synthesised) to produce a wide range of macromolecular structures. These routes have been exploited to make high softening amorphous polymers by synthesising more rigid chain structures in which large aromatic groups are incorporated in the main chain itself. If one compares these with polymers having bulky pendant groups, the striking difference is that the ring-in-the-chain polymers combine higher softening points (T_g) with increased toughness over vinyl polymers. They fail in ductile fashion, even at temperatures well below T_g , and therefore are able to absorb and dissipate mechanical energy: they are tough.

It is in this context that the simple concept of *shape* becomes significant. Put in its crudest terms large pendant groups interlock. This inhibits relative movement of neighbouring chain segments and the dissipation of elastically stored energy and the redistribution of stresses over the system thereby, thus leading to sequential failure at local high stress concentrations and to brittle failure of the total system. This mechanism is widely accepted as relevant on the macroscopic scale.

The ring-in-the-chain amorphous polymers which are tough have chain structures without protuberances. It is interesting to note that if large side groups are introduced

into these structures, then they become brittle also as was exemplified by Rose²³ for a series of aromatic sulphone polymers (Table 6). He also found that with the poly-(phenylene ethersulphone) series of polymers the all *para*-linked polymer was tough but the *ortho*-*para* and the *meta*-*para* structures resulted in polymers which were brittle (Table 6). This is not inconsistent with the reasoning suggested, in that the *ortho* and *meta* linkages result in abrupt 'kinks' in the chains which could be envisaged as causing neighbouring chains to interlock.

This approach to the understanding of 'toughness' is clearly much over-simplified but it does suggest that a systematic study of the failure behaviour of glassy amorphous polymers of widely different structures could be rewarding.

Modulus and structure

There is no satisfactory quantitative correlation between parameters dependent on molecular structure and elastic modulus, although in qualitative terms it is clear that modulus must be dependent on the energy of interaction between molecules and hence on parameters such as internal energy and coefficient of thermal expansion. Recognition of this has prompted a number of basic simple approaches to the problem.

Combining a standard thermodynamic approach to the derivation of an equation of state of a simple molecular crystal with the Lennard-Jones model for the dependence of the energy of interaction between molecules on their distance of separation, gives for the bulk modulus (B) of a face-centred cubic lattice at 0K²⁴:

$$B^0 = 8.04 \left(\frac{E_{\text{vap}}^0}{V^0} \right) \text{ dyne/cm}^2 \quad (1)$$

where E_{vap}^0 is the molar energy of vaporization at 0K (erg/mol) and V^0 is the molar volume (cm^3/mol).

This equation holds well for neon, argon and nitrogen at cryogenic temperatures.

Tobolsky²⁴ suggested that equation (1) would be a fair approximation at higher temperatures, and might even be relevant to amorphous polymers in the glassy state. The term (E_{vap}/V) is the cohesive energy density (CED), and this is 83 cal/ cm^3 at 25°C for polystyrene. With CED expressed in cal/ cm^3 equation (1) becomes:

$$B = 3.37 (CED) \times 10^8 \text{ dyne/cm}^2 \quad (2)$$

which gives a modulus value for polystyrene of 2.8×10^{10} dyne/ cm^2 . The experimental value is 3.5×10^{10} dyne/ cm^2 , and at first sight this seems to be a very promising measure of agreement.

A test of the general applicability (and utility) of equation (1) is to plot modulus vs. CED for a number of polymers. Nielsen²⁵ collected such data but noted that there was no correlation. His data are plotted in Figure 18.

Lack of interest in this approach is therefore understandable. However a broader consideration of the structural parameters which will determine modulus, combined with a similar approach to the glass transition temperature, enables one to demonstrate by an empirical procedure that there does indeed seem to be a relationship between modulus and cohesive energy density.

Consider the simplest case of a linear, amorphous polymer of very high molecular weight (so that chain ends can be ignored) in the glassy state at temperature $T < T_g$. The indi-

Figure 18 Cryogenic Young's modulus and cohesive energy density for various polymers. \circ , Amorphous polymers; \bullet , crystalline polymers. —, $E = 3.37 (CED) \times 10^8$

vidual macromolecules will take up completely random configurations, such as they assume in infinitely dilute solution²². The force per unit area needed to produce uniaxial deformation at vanishingly small strain (i.e. the Young's modulus, E at zero strain) will in the ultimate be determined by three parameters:

- (1) A molecular flexibility parameter, $F(T, t)$, which is a function of temperature, T , and of the time scale of the experiment, t ;
- (2) a parameter which is a measure of interchain forces, assumed to be of the form of equation (2);
- (3) a parameter which is a measure of bond angle distortion, assumed to be negligible at temperatures significantly $>0K$.

The glass transition temperature is clearly determined by two of the same parameters, namely molecular flexibility and interchain forces. At the glass transition temperature the Young's modulus of amorphous plastics drops from $>1.0 \text{ GN/m}^2$ to $\sim 0.01 \text{ GN/m}^2$, the lower limit being set by the value for an ideal rubber—

$$E \sim 3\rho RT/M_c \quad (3)$$

which typically will be around 0.001 GN/m^2 . So for amorphous linear polymers at their glass transition temperatures $E \sim 0.01 \text{ GN/m}^2$.

What this means is that, in a sense, T_g is a 'normalized' temperature and it suggests an approach to identifying the individual parameters which determine the modulus. Assume as an approximation that at temperatures just below T_g the parameter F (molecular flexibility) has the same dependence on temperature for all polymers, and hence that in this temperature region differences in modulus are determined by interchain forces (the contribution from the flexibility parameter F being constant). Pursuing this hypothesis, Figure 19 shows a plot of E'_{50} versus δ_{50}^2 from data currently available on amorphous polymers, where: E'_{50} is the dynamic modulus in GN/m^2 at $\sim 300 \text{ Hz}$ measured at the temperature T_{50} ; T_{50} is the temperature 50°C below the T_g ; δ_{50}^2 is the cohesive energy density at T_{50} .

The key to the data plotted is:

- PAN polyacrylonitrile,
PEX polyethylene (amorphous, crosslinked, see ref 7),

- NR natural rubber,
PVAc poly(vinyl acetate),
PET poly(ethylene terephthalate) (amorphous),
PVC poly(vinyl chloride),
PC polycarbonate (of Bisphenol A),
PS polystyrene,
PMMA poly(methyl methacrylate),
PES poly(phenylene ethersulphone),
PSA polysulphone (of Bisphenol A),
PPO poly(dimethylphenylene oxide).

The E'_{50} values were taken from dynamic mechanical data measured in these laboratories between the years 1955 and 1965 except for the value for polysulphone (from Bisphenol A) which is a static modulus value and may therefore be slightly low relative to the other data. CED values were derived from solubility parameter values at 25°C calculated by the additive scheme proposed by Small²⁶ and collated by van Krevelen and Hoftyzer²⁷ who also give the specific heat data needed to make the derivations²⁸, except for values for the two aromatic sulphone polymers which were estimated by Small²⁹. T_g values were taken as generally quoted in the literature, except that T_g for (amorphous) polyethylene was taken as -120°C .

The line of slope 0.034 drawn in Figure 19 is simply the theoretical proportionality coefficient in equation (2), corrected for a change in units ($1 \text{ GN/m}^2 = 10^{10} \text{ dyne/cm}^2$) and assuming that the bulk modulus is (approximately) equal to the Young's modulus:

$$E \approx 0.034 (CED) \text{ GN/m}^2 \quad (4)$$

In contrast to Figure 18, it is apparent that the data plotted in Figure 19 do indicate a significant correlation between

Figure 19 Relation between dynamic Young's modulus (E') and cohesive energy density (CED) for some amorphous polymers at $(T_g - 50)^\circ\text{C}$. $E'/CED = 0.034$

E'_{50} and CE_D which is not very different from equation (4). It is interesting to note that the T_{50} values range from -170° to $+175^\circ\text{C}$.

While some relationship between the relaxed Young's modulus and short-range intermolecular forces (of which CE_D is a measure) is to be expected, the excellence of the particular correlation observed is surprising and is further discussed elsewhere³⁰. In the meantime it is clear that further work to explore the scope of these observations is called for, and it would be particularly interesting to obtain modulus data for the amorphous states of those polymers which are normally crystalline.

ACKNOWLEDGEMENTS

The author is indebted to his colleagues in the Research Department of the Plastics Division of ICI for helpful discussions and assistance in preparing this paper, and in particular to Mr I. T. Barrie, Dr D. J. Blundell, Dr J. D. Burnett, Dr A. D. Caunt, Mr P. R. Hendy, Mr A. Pajaczkowski, Dr J. E. Priddle, Dr J. B. Rose, Dr F. M. Willmouth and Dr D. G. M. Wood. The author would also like to thank Dr R. Longworth for permission to reproduce Figures from ref 4.

Some aspects of stereoregulation in the stereospecific polymerization of vinyl monomers*

Piero Pino and Ulrich W. Suter

Swiss Federal Institute of Technology, Department of Industrial and Engineering Chemistry, 8092 Zurich, Switzerland

(Received 19 July 1976)

Stereoregularity in vinyl polymers, although theoretically foreseen since 1929, became one of the main topics in polymer research after the discovery of the stereospecific polymerization of α -olefins in 1954. The theoretical and practical significance of a thorough knowledge of stereoregulation became immediately evident; however, in spite of extensive efforts made by different industrial and academic research groups, the mechanism of stereoregulation is far from being understood and the control of stereoregulation, particularly in Ziegler–Natta polymerization, is still carried out on a purely empirical basis. In this review, after a short survey of the methods used to determine polymer stereoregularity and a discussion of the information which can be obtained from examination of the microtacticity of the polymer chains, some of the factors which can influence the stereoregulation in radical, ionic and Ziegler–Natta polymerization will be considered. For the last type of polymerization, in which the nature of the catalyst seems to have an overwhelming importance, some analogies with the transition metal catalysed asymmetric reactions will be discussed. Finally, an attempt will be made to identify the main difficulties in further improving our knowledge of the control of stereoregulation.

INTRODUCTION

In 1929 Staudinger *et al.*¹ pointed out that in vinyl polymers, even in those of completely regular chemical structure of the macromolecular main chain, steric irregularities should be expected, since the tertiary carbon atoms were indeed asymmetric and could assume both possible absolute configurations.

Unfortunately, no methods were available at that time to control the configuration of the newly formed asymmetric carbon atoms during polymerization. The first attempts in this direction were made by Marvel *et al.*², who used optically active initiators in radical polymerization; the resulting polymers, however, were not optically active and were found to have similar properties to polymers prepared with the usual initiators. A paper by Huggins³, in which he attributed the different solution properties of polystyrenes produced at different temperatures to a different stereoregularity, did not induce polymer chemists to investigate possible stereospecific polymerization processes. Schildknecht and collaborators⁴, investigating the cationic polymerization of vinyl ethers with boron trifluoride in different solvents, found two different types of polymers, one of which showed some crystallinity. Unfortunately, the crystallinity was low and the authors apparently assumed that all polymer chains in the sample had a similar steric structure. Therefore, they did not look for a suitable method of separation of polymers in a crystalline and in an amorphous fraction. Since the crystallinity of the polymers was too small to establish the actual type of stereo-

regularity, and since the properties of the crystalline samples were not excitingly different from those of amorphous polymers, this research did not persuade polymer chemists to look for polymerization processes having a high degree of stereospecificity. Furthermore, the possibility that the properties of stereoregular polymers could be entirely different from those of the amorphous materials known at the time was not seriously considered.

A few years later, styrene was polymerized using 'Alfin' catalysts⁵. Although the 'Alfin' systems were shown to be highly stereospecific in the butadiene polymerization, yielding almost exclusively 1,4-*trans* polymers, the polystyrenes were not investigated in detail. It was only after the synthesis of isotactic polystyrene with Ziegler–Natta catalysts⁶, that the above polymers were again considered and it was shown that they were isotactic⁷.

The concept that a catalyst could produce both stereoregular and non-stereoregular chains was so far from the mind of polymer scientists that some α -olefin polymers obtained with heterogeneous catalysts containing chromium⁸ or cobalt⁹ in the early fifties, which showed a slight crystallinity, were treated as if each macromolecule contained some stereoregular sections able to crystallize and some stereoirregular non-crystallizable sections. Therefore, no systematic attempt was made to separate crystalline and amorphous components.

Only when Natta and his group⁶ obtained a partly crystalline polypropylene, using catalytic systems similar to that proposed by Ziegler for ethylene polymerization, the way of looking at partly crystalline vinyl polymers changed. In this case the first polymer obtained was clearly non-homogeneous, and a successful attempt was made to separate

* Presented at the Sixth Biennial Manchester Polymer Symposium, UMIST, Manchester, March 1976.

crystalline and amorphous polymers. In this way highly stereoregular polymers of propylene and other α -olefins were obtained⁶ which had completely different properties than both the non-fractionated and the amorphous material.

These results opened a broad field of research, including the synthesis and the properties of stereoregular vinyl polymers. The investigation of the crystalline structure and of the properties of these macromolecular materials have proceeded rapidly. The research on the origin of the stereospecificity in polymerization processes and on the stereoregulating factors, however, is proceeding much more slowly and still has a largely empirical character.

In our opinion there are two reasons that are mainly responsible for the persistent ignorance about stereoregulating factors in vinyl polymerization. First, the tools available for the separation of the raw materials in fractions having different stereoregularity and for the quantitative determination of the stereostructure of the fractions thus obtained are limited. For the separation, no large progress has been made since 1954⁶, when the boiling solvents extraction technique was first used for this purpose. This is still the most widely used method, even if many evident disadvantages and failures have been pointed out⁷⁵. For the determination of the stereostructure, proton and ¹³C n.m.r. have replaced some relative methods such as determination of the crystallinity by X-ray diffraction or intensity measurement of i.r. bands connected with crystallinity or stereoregularity¹⁰. Very interesting results have been obtained with high resolution proton n.m.r., but ¹³C n.m.r. promises to become even more useful, although there are at present still some disadvantages connected with the difficulty in relating signal intensity to concentration. In any case, experimental uncertainties do not allow in general the detection of less than ~2% steric irregularities in a polymer chain¹¹. Furthermore, the amount of information obtained is restricted by the limited length of the observable sequences, usually 2 or 3, exceptionally 4 or 5 monomeric units. The second reason for our lack of knowledge on the stereoregulating factors in vinyl polymerization lies in the nature of the process leading to highly stereoregular polymers. Most of these processes are in fact heterogeneous, and the most important ones in practice involve heterogeneous catalysts containing a very small number of catalytic centres, the nature of which cannot be suitably investigated by direct methods. Under these conditions the work carried out in most industrial laboratories has an empirical character and, even though it has been very successful in identifying catalytic systems with very high stereospecificity and, recently, exceptionally high reactivity, has not contributed remarkably to the basic knowledge on stereoregulation. In an academic environment, on the other hand, this type of research is not carried out easily, since it requires a rather advanced knowledge of polymer chemistry, n.m.r. spectroscopy and catalysis; a combination of specialties not readily achievable by graduate students during the relatively short period assigned for the preparation of a thesis.

In the following, we will try to summarize briefly the state of our knowledge on the stereoregulating factors in vinyl polymerization and to identify the main directions for future development for the research in this field. However, it must be emphasized that no attempt has been made to prepare a complete survey of the literature, which is very extensive indeed and even very important contributions may have been overlooked.

THERMODYNAMIC AND KINETIC ASPECTS OF STEREOREGULATION

The relative thermodynamic stability of isotactic and syndiotactic sequences in vinyl polymers has never been experimentally investigated. Some data have been obtained for 'oligomers'¹²⁻¹⁸ and are shown in *Table 1*. Racemic dyads (i.e. couples of monomeric units arranged in a syndiotactic way), denoted by (r), are thermodynamically slightly favoured over meso dyads, denoted by (m), in all cases investigated. The free energy differences involved are apparently so small, however, that under equilibrium conditions highly stereoregular polymers would never be formed. The formation of stereoregular chains must therefore be kinetically controlled and the stereoregularity is controlled by the difference in activation energy for the insertion of a monomeric unit in the growing chain yielding an isotactic or a syndiotactic dyad. In radical polymerization, for instance, the situation can be schematized as in *Figure 1*, if none of the preceding units in the chain has an effect on the reactivity of the chain end (i.e. in the case of a Bernoullian propagation process). The degree of stereoregularity of the polymer formed depends on the difference in the free energies of activation for the two processes leading to isotactic (II) or syndiotactic (III) diads, $\Delta\Delta G^\ddagger$ ($\Delta G_i^\ddagger - \Delta G_s^\ddagger$) (see *Figure 2*). Thus, to obtain a polymer at room temperature that contains more than 97% syndiotactic (or isotactic) dyads, i.e. whose stereoregular sequences have an average length of at least 33, $\Delta\Delta G^\ddagger$ must be larger than 2 kcal/mol.

This description of a single step in vinyl polymerization is analogous to that of a diastereoselective synthesis. Of course, for most polymerization reactions, e.g. ionic and especially Ziegler-Natta polymerization, the reaction path will be much more complicated than the one shown in *Figure 1*. However, the stereoregulation will always be connected with the difference in free energy of activation between the two non-reversible steps of the growth reaction leading to the isotactic or syndiotactic dyads. This step can, but does not need to be the rate determining step of the growth reaction.

Unfortunately, conventional kinetic measurements yield only the sum of the rates of formation of isotactic and syndiotactic dyads, and ΔG_i^\ddagger and ΔG_s^\ddagger cannot be determined separately. This situation is analogous to the one existing for instance in catalytic asymmetric synthesis. The information obtained there from the enantiomeric purity of the products is extracted, in the case of vinyl polymerization, from the microtacticity of the synthesized polymer chains. In fact, in the most simple case (e.g. radical polymerization) the ratio between the relative amounts of isotactic and syndiotactic dyads, (m)/(r), corresponds to the ratio between the rate constants of the reaction steps leading to the respective sequences, k_i/k_s . Then, the ratio (m)/(r) gives the difference in free energy of activation, $\Delta\Delta G^\ddagger$, as noted above, and the difference between the enthalpies of activation ($\Delta\Delta H^\ddagger = \Delta H_i^\ddagger - \Delta H_s^\ddagger$) and the difference between the entropies of activation ($\Delta\Delta S^\ddagger = \Delta S_i^\ddagger - \Delta S_s^\ddagger$) can be determined by plotting $\ln(k_i/k_s)$ measured at different temperatures versus $1/T$ ^{10,20}. As expected, in free radical polymerization, a linear relationship between $\Delta\Delta G^\ddagger$ and T has often been observed²¹.

STERIC ASPECTS OF STEREOREGULATION

Besides yielding information on the difference in activation

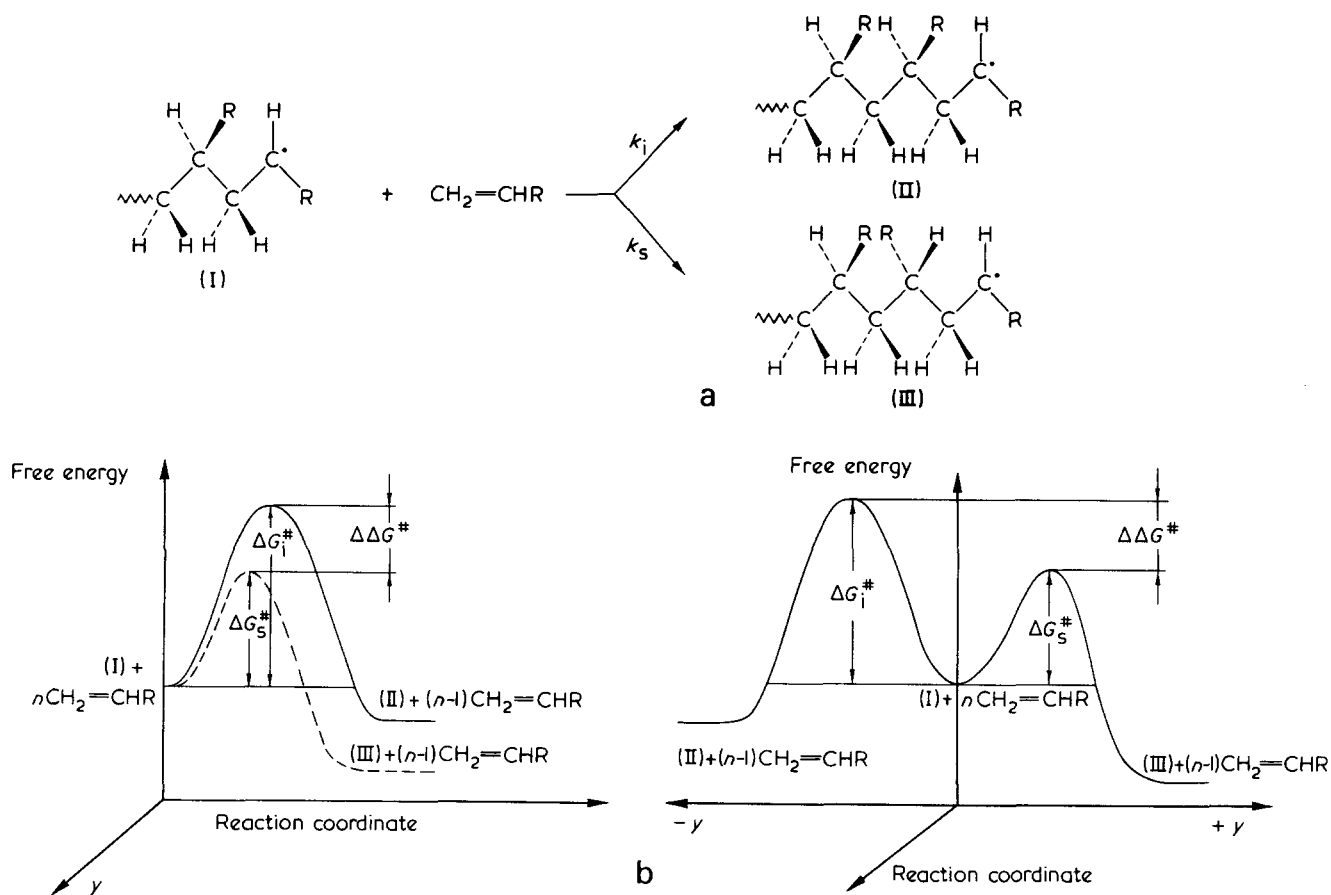

Figure 1 Possible reaction paths for the addition of a vinyl monomer unit to a growing chain by a radical mechanism

Figure 2 Difference in the free energies of activation (at 25°C) for the formation of isotactic and syndiotactic dyads in a Bernoullian propagation process, required to obtain a given degree of stereoregularity

parameters for the formation of isotactic dyads, n.m.r. experiments can also give interesting insight into the steric course of the growth reaction. Depending on the polymerization mechanism, the growth of, for instance, an isotactic chain in vinyl polymerization can occur according to the two paths depicted in scheme (1). In the first case (1a),

which has been verified in the Ziegler–Natta polymerization to isotactic chains, the configuration of the asymmetric carbon atom of the new monomeric unit that forms in each polymerization step is decided at the very moment of the addition. Therefore, it is possible to speculate about steric interactions between the R group of the entering monomer and the growing chain. Nothing can be said on this basis about the type of opening (*cis* or *trans*) of the monomeric double bond or about the side of the growing chain, approached by the entering monomer the growing chain terminal group being a CH₂ group.

In the second case (1b), which occurs for instance in radical polymerization, the configuration of the asymmetric carbon atom of the ultimate monomeric unit of the chain is defined when the new monomer joins the growing chain. In this case, information on the side of the ultimate carbon atom (assumed as planar) of the growing chain which is attacked by the newly arriving monomer can be obtained, but nothing can be said about which prochiral face of the monomer is attacked or about the type of the double bond opening.

More information can be obtained if deuterated monomers with known stereochemistry are used. In scheme (2)

formation of a diisotactic dyad is shown. In both cases of addition, labelled (a) and (b) in analogy to scheme (1) steric information concerning both the side of the growing chain which is approached by the monomer and the prochiral face of the monomer preferentially attacked can be obtained from a knowledge of the microtacticity of the polymer. Furthermore, the type of double bond opening can be established if the growth reaction occurs simultaneously at the two unsaturated carbon atoms of the entering monomer. Unfortunately, most of the research up to now has involved non-deuterated vinyl monomers, but some cases of radical, cationic, anionic and Ziegler–Natta polymerization using deuterated monomers have been described and have yielded very important indications on stereoregulation^{22–33}.

STEREOREGULATION IN FREE RADICAL POLYMERIZATION

Free radical polymerization occurs substantially as shown in equation (1b). We can think of the terminal group with the unpaired electron as being substantially planar or a rapidly inverting trigonal pyramid. Then the stereoregulating effect is connected with the prochiral side of the terminal trisubstituted carbon atom to which the new monomer is joined. The stereoregulating effect must originate from the steric interaction of the entering monomer with the R group of the penultimate unit of the chain. Interaction of the CHR group of the entering monomer with the growing chain apparently does not contribute to the stereoregulating effects, since experiments with monomers having a CHD

group show, that no preference for one of the prochiral faces of the entering monomer exists³⁴.

The stereoregulating effect of the CHR group of the penultimate unit (or CRR' in 1,1-disubstituted ethylenes) could be due to a conformational effect along the growing chain, causing a preferential orientation of the terminal CHR (or CRR') group with respect to the chain already formed, and hence to a preferential orientation of the CH₂ group of the newly incoming monomer toward one or the other side of the terminal CHR (or CRR') group (compare Figure 1a).

The extent of this type of regulation is very small, as expected. Experimental data, some of which are collected in Tables 2 and 3, show that a slight prevalence of syndiotactic dyads exists in most cases, especially in polymers of 1,1-disubstituted ethylenes. The polymers obtained from monosubstituted ethylenes can be divided roughly into two groups: those with aromatic substituents (phenyl or pyridyl groups) that are quite syndiotactic, (m) = 0.2 to 0.3, and all other ones, which are very nearly atactic. Poly(iso-propyl acrylate) seems to be an exception to this rule. No similar simple rule is obvious for the polymers from 1,1-disubstituted ethylenes.

In most cases where the content of dyads and triads could be determined experimentally, the polymerization

appears to follow Bernoullian statistics. This is a confirmation of the statement that the type of dyads already existing in the growing chain does not influence the stereochemistry of the addition of the new monomer unit, but that only the configuration of the ultimate tertiary (or quaternary) carbon atom in the chain has an influence. The only polymers that according to the value of the ratio $4(mm)(rr)/(mr)^2$ are non-Bernoullian¹⁰ have extremely large side groups, i.e. the polymers from diphenylmethyl methacrylate and triphenylmethyl methacrylate⁵⁶, and perhaps (2,4,6-triphenylbenzyl) methacrylate⁵⁷ in Table 3. Poly(triphenylmethyl methacrylate) is also the only one that is distinctly isotactic.

The quantity $4(mm)(rr)/(mr)^2$ is a test for Bernoullian statistics with triad data only¹⁰. It is listed in Tables 2 and 3 whenever triad data were available. As Bovey has pointed out⁶³, this criterion is extremely sensitive and can deviate substantially from the Bernoullian value of 1, if the triad data used are not very accurate. In general, a value of $4(mm)(rr)/(mr)^2$ between ~2 and ~½ seems not to contradict the assumption of Bernoullian statistics.

Attempts to improve stereoregulation by polymerization in different solvents were made, but very poor results were obtained. In the polymerization of methyl methacrylate in bulk and 13 different solvents at 70°C, for instance, the

*Exact conditions are not known. †AIBN, azobisisobutyronitrile; BPO, benzoylperoxide. ‡Thermally initiated. Values in parentheses are calculated from triad data

meso dyad content (m) varied between 0.257 and 0.319⁶⁴. Having in mind the mechanism outlined above, it is clear that strong changes can only be expected between solvents that include drastically different chain (or chain end) conformations.

A decrease in temperature generally increases the relative number of syndiotactic dyads. The case of methyl methacrylate, where (r) increases from 0.64 at 250°C to 0.87 at -78°C, has been particularly well investigated^{54,65,66}. Similar observations have been made for many other monosubstituted and 1,1-disubstituted ethylene compounds. Accurate analysis of the experimental data still leaves questions open¹⁰. However, in general a small difference in activation entropy seems to favour syndiotactic placements. The difference in activation enthalpy also seems to work in favour of the syndiotactic dyads, in many cases of monosubstituted ethylenes, however, this factor seems to be very small^{10,67}.

The stereoregulating factors in free radical polymerization are thus relatively well known. The possibility of good stereocontrol seems at the present time to be really scarce, considering the points mentioned above. The only real success has been obtained on a different route, by ordering the monomer molecules prior to the polymerization using inclusion complexes^{19,68} and then initiating the polymerization by X-rays; however, this method has not found practical application up to now. Template polymerization of the type found in methyl methacrylate⁶⁹, does not seem to be very promising at the present time, although it offers very interesting possibilities, in principle.

STEREOREGULATION IN IONIC POLYMERIZATION

Polymers with marked stereoregularity have been produced both with cationic and anionic initiators from monosubstituted and 1,1-disubstituted ethylenes. Although this stereoregulation was often achieved under homogeneous conditions, the best results were obtained where either the catalyst or the polymer or both were insoluble in the reac-

tion medium. From literature data, however, it is not always clear if the system under consideration is homogeneous or heterogeneous, and we will list the data in common Tables regardless of the physical state of the components in the reaction mixture, although the existence of only one or two phases can be significant for stereoregulation. Results on polymers obtained from the most investigated monomers are listed in Tables 4 to 10. Tables 4 to 7 concern monosubstituted ethylenes, the others show results for 1,1-disubstituted ethylenes.

Table 4 summarizes some results on styrene. Here, in the non-stereoregular polymers, investigation of the microtacticity is hindered by the high band width of the n.m.r. peaks¹⁰. Only in very recent publications it was claimed that a detailed analysis of the microtacticity was performed, using ¹³C n.m.r.^{35,36}. Cationic systems in toluene seem to yield polymers with low crystallinity and meso dyad contents similar to the value measured in free radical polymers^{23,36}. On the other hand it appears that with anionic initiators isotactic polymers can be produced under homogeneous conditions in apolar solvents, such as toluene^{70,71}. Even better results are obtained with heterogeneous systems containing anylsodium or Alfin catalysts^{7,71-73}. In polar solvents, such as ethers, however, no highly stereoregular materials were formed^{23,36,70}.

Vinyl ketones (Table 5) polymerize with anionic initiators in hydrocarbon solvents to isotactic macromolecules^{45,74}, some fractions having very high stereoregularities, (m) >0.95⁴⁵. Often, the highly isotactic fractions amount to more than 80% of the total material. While lithium aluminum hydride gives an inherently heterogeneous system, the polymerization with dialkyl zinc start homogeneously but a part of the polymer begins to precipitate already at low conversions⁴⁵.

Cationic polymerization of vinyl ethers is illustrated by the data shown in Table 6. In homogeneous systems, polymerization in hydrocarbon solvents yields predominantly isotactic chains, whereas almost atactic polymers are obtained in polar solvents such as methylene chloride⁷⁷⁻⁷⁹.

* Fraction of dyads that are meso and have the deuterium on the methylene group in *threo* position

Temperature does not seem to change these results drastically. In both cases mentioned, it would not seem unreasonable to assume Bernoullian statistics⁷⁷.

Isotactic polymers can be obtained with heterogeneous systems, e.g. with boron trifluoride etherate in toluene/saturated hydrocarbon mixtures^{4,78} or with a catalyst obtained from aluminium oxide and sulphuric acid using aluminium alkyls as activators^{80,81,102}. The latter system, in addition to being stereospecific, is also stereoselective⁸⁰ and stereoelective⁸¹.

A few results for polyacrylates are also listed in Table 6. These monomers polymerize anionically to isotactic chains in pure hydrocarbon solvents^{29,30,34}. In oxygenated solvents, predominantly syndiotactic chains are obtained²⁹. Table 7 shows the results of a particularly detailed study of the stereochemistry of anionic acrylate polymerization with (*Z*)- α,β -*d*₂-iso-propyl acrylate. It shows that the portion of meso dyads decreases somewhat with added ether, but that the stereochemistry of the methylene group is much more sensitive to this factor. With a Grignard initiator in virtually ether-free hydrocarbon solvent the *erythro* configuration is preferred at CHD in meso dyads, and this preference changes to the one for the *threo* placement as ether is added. With aryl lithium as initiator and otherwise unchanged conditions the preferential stereochemistry at the methylene group (in meso dyads) is reversed.

For the 1,1-disubstituted ethylenes we begin the tabulation of selected experimental values (Table 8) with poly(α -methylstyrene) and some polymers obtained from *para*-substituted α -methylstyrenes. Polymers obtained with cationic initiators in polar or aromatic media, such as methylene chloride or toluene, are strongly syndiotactic^{22,82,85}. In saturated hydrocarbons, syndiotactic chains of somewhat lower stereoregularity are obtained^{62,84}. The presence of a substituent in the *para* position and, in polar solvents, the type of initiator, have only little influence on the stereoregularity. Anionic initiators also lead to syndiotactic chains, but less so in polar solvents than in hydrocarbons^{22,83}.

Also reported in Table 8 are some values for α -chloroacrylates. The usual anionic initiators, e.g. alkyl lithium or Grignard reagents, yield nearly atactic polymers^{72,86}.

Breslow and Kutner⁸⁷ found in 1971 that the solid product of the 1,4-addition of a Grignard reagent to an α,β -unsaturated ketone such as benzalacetophenone converts methyl methacrylate and methyl- α -chloroacrylate quantitatively to higher isotactic polymers. Application to several α -chloroacrylates show an equal stereospecificity^{62,86}.

The most intensely investigated monomer in ionic polymerization is methyl methacrylate. Table 9 shows a selection of published data. With Grignard reagents in hydrocarbons highly isotactic chains are obtained. Addition of ethers lowers the isotacticity²⁹. With small amounts of ether, stereoblock structures are formed²⁹. Under most conditions, chains with different types of steric structure are formed, and the polymers must be fractionated before investigation⁸⁸. As in the case of α -chloroacrylates, the addition products of Grignard reagents to conjugated ketones give highly isotactic polymers in quantitative yield⁸⁷. With alkyl or aryl lithium as initiator, isotactic polymers are obtained in hydrocarbon solvents. Solvents with higher ability to solvate the lithium cation give polymers with lower isotacticity. In the presence of amines substantially syndiotactic chains have been obtained^{29,89-91}.

Triad data in Table 9 indicate clearly non-Bernoullian statistics in toluene [where $4(\text{mm})(\text{rr})/(\text{mr})^2 \approx 8$] and increasingly more Bernoullian behaviour as the solvation power increases [the quantity $4(\text{mm})(\text{rr})/(\text{mr})^2$ is 0.9 for ethylamine and 1.4 for ammonia as solvents]. Counterion size plays a clear role. In hydrocarbon solvents stereoregulation decreases with increasing size of the counterion ($\text{Li} < \text{Na} < \text{K}$), the decrease is smaller in pyridine and practically absent in amines^{89,91}. Finally, with lithium aluminium hydride as initiator, highly isotactic polymers are obtained in ethyl ether and toluene, while in tetrahydrofuran predominantly syndiotactic chains are produced⁵⁷.

With (*E*)- α -ethyl- β -*d*₁-methyl acrylate, Fowells, Schuerch, Bonvy, and Hood obtained information on the stereochemistry of the methylene group (Table 10)²⁹. They polymerized this monomer in the presence of various amounts of tetrahydrofuran in toluene, using alkyl or aryl lithium as initiator. In the absence of tetrahydrofuran the process was highly stereospecific, both for the quaternary chain carbon atoms and for the CHD groups, yielding *threo*-diisotactic chains. Addition of ~2 molecules of tetrahydrofuran per lithium atom resulted in virtually no change. By further addition of THF, stereoblock polymers are obtained at first (at least at the low temperature listed in Table 10) and finally, predominantly syndiotactic structures with random configuration of the methylene group are formed. With Grignard initiator systems one obtains a reversed stereochemistry, since *erythro*-meso placements predominate at low ether concentrations and *threo*-meso structures in the presence of larger ether concentration.

Finally, recent work on anionically polymerized methyl- α -ethyl acrylate shows an unusually strong dependence of stereoregularity on temperature for the butyllithium/toluene system⁹². In contrast to observations on methacrylates, here (m) changed from 0.51 at -78°C to 0.99 at 0°C . The authors suggested that the low temperature material is actually a mixture of isotactic and syndiotactic chains. Similar to alkyl methacrylates, syndiotactic polymers form in tetrahydrofuran and isotactic ones in ethyl ether.

The data of Tables 4 to 10 suggest some general lines that seem to be valid for stereoregulation in both, anionic and cationic polymerization. The ionic species can occur in several different forms in equilibrium with each other⁷⁶,

and each form has an individual behaviour for polymerization and stereoregulation⁹³⁻⁹⁵. Most polar solvents exhibit a specific solvent effect by solvating the cation or the ion pair, e.g. pyridine, ethers or amines; in this case either free ions or solvated ion pairs are formed. On the other hand, in apolar solvents, for instance in hydrocarbons, contact ion pairs occur predominantly. Additionally, different ion pairs might aggregate here to form unreactive species⁹⁶. Depending on the type of charged chain end (carbonium ion or carbanion) and on the state of solvation of the ions or ion pair, a different behaviour might be anticipated.

Under homogeneous conditions, in solvents with high 'solvating power' where solvent separated ion pairs or even solvated free ions exist^{93,97}, the polymers formed contain atactic or prevalingly syndiotactic structures, similar to those found in free radical polymerized chains. In the case of free ions we expect principally the same stereoregulating factors to exist as in the case of free radicals, except for differences in solvation of the chain ends. In the case of solvent separated ion pairs, which occur in the media of lower 'solvating power' and seem to predominate under usual polymerization conditions in polar solvents, a very small influence of the counterion seems to exist. If 2- d_1 -monosubstituted ethylenes are used, we expect the configuration of the CHD groups to be random, as was observed in the case of free radical polymers³⁴. Indeed, in the case of (Z)- α -ethyl- β - d_1 -methacrylate, polymerized with aryllithium in tetrahydrofuran, such a random stereostructure has been observed (see Table 10)²⁹.

In solvents having little 'solvating power', the polymers formed are in general isotactic. Here, the charged chain ends are involved predominantly in contact with ion pairs. These seem to be somewhat less reactive than the more separated species encountered above^{94,95}, but a stereoregulating influence of the counterion seems to exist during the polymerization process. Different models have been proposed to explain the occurrence of isotactic structures, and several factors are probably important. Many authors have made the assumption of a cyclic and/or chelated chain end. Many authors believe that poly(vinyl ethers), for instance, have a ring structure as suggested in Figure 3 the oxygenated chain acting as a specific solvating agent itself⁹⁹. For the anionic polymerization of methacrylic esters a propagating chain end structure like the one in Figure 4 was proposed^{29,98}; other authors however, regard such structures as unreactive^{100,101}. Also, for anionic metha-

Figure 3 Cyclic transition state proposed for the polymerization of vinyl ethers to isotactic polymers in solvents having little 'solvating power'

Figure 4 Cyclic transition state proposed for the polymerization of methyl methacrylate to isotactic polymers in solvents having little 'solvating power'

crylate polymerization a specific interaction between entering monomer and counterion has been postulated⁸⁹. None of these models seems to suit the case of styrene, however, with which one can still obtain isotactic structures under apparently homogeneous conditions (see Table 4).

Under the same conditions, for instance in the system styrene/perchloric acid in methylene chloride at room temperature and below, it seems that at least part of the growing chain end contains a covalent bond between 'chain end' and 'counterion'^{95,103-105}. This structure and the free ion model are the extrema in the concept of the growing species of ionic polymerization. They form the bridges to free radical polymerization and coordinative polymerization respectively.

If small amounts of good solvent are added to systems with low 'solvating power', stereoblock structures can appear, that are characterized by relatively high (mm) and

Table 11 Stereoregulating factors in ionic polymerization

(rr) triad contents as compared with (mr). Table 10 shows an example²⁹, with aryllithium/tetrahydrofuran (1:7.5) in toluene as initiator for (*Z*)- α -ethyl- β -*d*₁-methacrylate. There, (mm), (rr) > (mr) and 4(mm)(rr)/(mr)² is larger than 18. These facts have been explained by assuming two different, simultaneously active propagating species in equilibrium with each other, solvent separated ion pairs and 'peripherally solvated' contact ion pairs²⁹. The former are thought to propagate yielding predominantly syndiotactic chains, the latter generated isotactic structures. Here, as well as in all other cases where different propagating species are thought to compete, a strong temperature effect is observed, and assumed to originate in the changing equilibria between the ionic species. The above mentioned case of methyl- α -ethyl acrylate⁹² is a drastic example. In contrast to this, temperature effects are relatively small whenever one single species is responsible for polymer formation.

The experiments with acrylates and methacrylates, stereospecifically monodeuterated at the methylene carbon, show that the stereochemistry of propagation in solvents where contact ion pairs predominate, i.e. where isotactic structures are formed, is not the same for all systems. While the case of alkyl lithium or aryl lithium in toluene is relatively well understood²⁹, the mechanistic speculations are less well founded for Grignard reagents^{29,30,106} or lithium aluminum hydride^{34,107} as initiators.

The fact that the polymerization of vinyl ethers under certain (heterogeneous) conditions is stereoselective⁸⁰ seems to indicate that chiral catalytic centres, possibly formed by interaction of a chiral monomer with a counterion, can play an important role in stereoregulation in ionic polymerization. Since the stereoselectivity persists even in chains with relatively large numbers of steric irregularities (5–10%), a chiral counterion seems very probable. The fact that these initiators are also stereoselective⁸¹ suggests, that this chiral counterion contains one or more monomeric units.

From the large amount of the experimental data the picture schematized in Table 11 seems to emerge for the stereoregulating factors in ionic polymerization of mono- and disubstituted ethylenes. The interaction between solvated growing chain and monomer gives in general polymers having a low to medium stereoregularity degree of syndiotactic type. Stronger interactions between non-

solvated chain ends and monomers seem to lead to a prevalence of isotactic structure. However, a really large stereoregulating capacity seems to be connected with interactions between ionic couples and monomers and lead to prevalently isotactic structures. As a special case the stereoregulating capacity of ionic couples must be considered in which an asymmetric counterion exists which might be responsible of the stereoselectivity and stereoselectivity phenomena observed for instance in the racemic vinyl ethers cationic polymerization.

STEREOREGULATION IN TRANSITION METAL CATALYSED POLYMERIZATION

Catalytic systems or initiators containing transition metal compounds are known to polymerize olefins and other unsaturated monomers. These polymerizations are believed (and to a large extent proved) to occur through a monomer insertion on a metal-carbon bond. We shall not consider the polymerization of monomers containing polar groups carried out in the presence of the above catalysts or initiators as polar groups react very easily with organometallic catalysts. For this reason the nature of the catalytic species is in general not well understood and the existence and role of the metal to carbon bonds in the polymerization can be questioned.

The first indications concerning the possibility of polymerizing ethylene and α -olefins in the presence of transition metal catalysts appear in some patent applications between 1952 and 1954 in which these monomers are claimed to polymerize in the presence of chromium oxides supported on SiO₂/Al₂O₃ or nickel and cobalt supported on molybdenum oxides^{8,9,108}. Although the formation of solid polymers was reported in some cases, the structure of the polymers was not well understood and only some years later the possibility of obtaining stereoregular polymers with particular catalytic systems of this type was shown¹¹⁸. The real breakthrough in the field of α -olefins stereospecific polymerization came in 1954 when Natta and his group discovered the high stereoregulating capacity of some Ziegler catalysts obtained by reacting transition metal halides with an organometallic component⁶, the best organometallic com-

ponents being the ones (e.g. BeR₂, AlR₃, LiR) which polymerize ethylene also in the absence of transition metal components.

In the following years it was confirmed that supported and non-supported organometallic complexes of transition metals can act as active polymerization catalysts also in the absence of non-transition metal organometallic components. Today we can distinguish for the polymerization of olefins three classes of catalysts having a certain degree of stereoregulating capacity in the α -olefins polymerization: the first class consists of soluble catalysts which in general have a relatively low stereoregulating capacity and in the case of propylene can yield both isotactic and syndiotactic polymers. The second class consists of the typical Ziegler-Natta catalysts which are insoluble in the reaction medium and in which the catalytic centres are supported on the transition metal compounds used to prepare the catalyst or on other products arising from these compounds in general by alkylation and reduction. The third class consists of transition metal compounds supported on non-transition metal compounds such as SiO₂, Al₂O₃ or MgCl₂. In Table 12 some examples of catalysts active in propylene polymerization are given with the type and the maximum degree of stereoregulation which have been achieved in the most stereoregular fractions.

Most of the investigations on stereoregulation in α -olefins polymerization have been carried out on Ziegler-Natta catalytic systems and the knowledge thus arising has been very often unduly extended to other catalytic systems which do not appear to be deeply investigated up to now; this is particularly true for the supported catalysts. Therefore we shall limit our remarks to the Ziegler-Natta catalytic systems and after a brief survey of some facts concerning the polymerization mechanism we shall discuss separately the isotactic and the syndiotactic type of stereoregulation.

Nature of the growth reaction

The nature of terminal groups in ethylene polymerization demonstrates beyond any doubt that Ziegler-Natta polymerization occurs through an insertion of the monomer in a metal to carbon bond (scheme 3) similarly to the insertion of ethylene in a Li-C, Al-C or Be-C bond (growth reaction)¹¹⁹⁻¹²¹.

When propylene is used two possibilities exist for the insertion of a new monomer molecule into a Me-C bond (scheme 4):

As shown by the existence of crystallinity as well as by i.r. and n.m.r. spectra, stereoregular polymers of propylene possess a very high chemical regularity corresponding to a head-to-tail enchainment. This chemical structure is in principle possible with insertion of both types (schemes 4a and 4b), the important factor in obtaining the chemical regularity being only that the type of insertion remains constant during the formation of each chain.

In 1956 it was proved by i.r. investigation of the terminal groups that in the case of the most used Ziegler-Natta catalysts (TiCl₄-AlR₃ or TiCl₃-AlR₃) the fractions having the highest stereoregularity are formed according to an insertion of type (4a)¹²². This regioselectivity was shown to be smaller, but still very large, in the formation of the non-stereoregular polymers¹²².

These results have been unduly generalized and for about a decade the general belief has been that the insertion in transition metal catalysed polymerization always occurs according to scheme (4a). However, dimerization of propylene with Ziegler type catalysts prepared from nickel^{123,124} or palladium¹²⁵ compounds and aluminium dichloro monoalkyls has shown that both types of insertion are possible¹²³⁻¹²⁵, that catalytic systems exist where regioselectivity is very poor¹²⁴ and that regioselectivity can be regulated using appropriate ligands^{123,125}.

Furthermore, it has been shown that, using a VCl₄/Al(C₂H₅)₂Cl/Anisol catalytic system which yields syndiotactic polypropylene having a relatively high stereoregularity, insertion of α -olefins according to scheme (4a) or (4b) might be possible^{126,127}, although no proof has been given that a macromolecular chain can grow after an insertion of type (2b). Some n.m.r.^{129,130} and i.r.¹²⁸ evidence shows, however, that in the case of syndiotactic propylene polymerization a chain growth according to scheme (4b) is not unlikely.

No evidence has been provided up to now concerning

the possibility of obtaining isotactic poly(α-olefins) according to scheme (4b). On the other hand, catalytic systems are known which produce polypropylene chains with long individual sections of isotactic and syndiotactic structure^{114,131,132,162}. In conclusion the present state of our knowledge seems to indicate that, in the case of propylene, isotactic polymers are formed only according to scheme (4a), while syndiotactic polymers are formed both according to scheme (4a) and (4b). The type of insertion has been very little investigated with other α-olefins and even in the case of styrene the type of insertion in the formation of isotactic polymers with Ziegler–Natta catalysts is still open to discussion.

Stereochemistry of the growth reaction

Polymerizing (Z)- or (E)-1-deutero-propylene with Ziegler–Natta catalysts to isotactic polymers *erythro*- or *threo*-diisotactic polymers¹³³, respectively has been performed (see Table 13). If the reaction at the two carbon atoms of the olefinic double bond is simultaneous this fact proves that the type of addition during the insertion reaction is *cis*. If, however, the above reaction does not occur simultaneously, an attack to one olefinic carbon atom, being followed by a rotation around the remaining single bond of the former olefinic group and finally by a *trans* addition

to the second carbon atom of the olefinic group would yield the same result as simultaneous *cis* addition.

As the isotactic type stereoregularity requires a constant type of addition which might be difficult to achieve admitting the occurrence of rotations between the attack to the first and to the second olefinic carbon atom, and in view of the fact that *cis* addition is a rather common feature in the reactions between organometallic compounds and double bonds, it seems likely today that insertion in Ziegler–Natta polymerization to isotactic polymers occurs with a *cis* stereochemistry. Some evidence mainly based on n.m.r. data has been published indicating that also propylene polymerization to syndiotactic polymers occurs according to a *cis* mechanism³².

Mechanism of the insertion reaction

There is no direct experimental evidence concerning the mechanism of the insertion reaction. A one step reaction occurring through a four centre intermediate or transition state (scheme 5) has not found experimental support. On the other hand, addition of propylene to *sec*-butyllithium¹⁴² which is believed to occur through a four centre intermediate or transition state¹³⁹, although a highly regioselective process, shows a poor stereospecificity (scheme 6). Therefore the hypothesis of a four centre intermediate or transition state is not attractive, from a stereochemical point of view, to explain the formation of isotactic chains.

For these reasons, and in view of similarities with other transition metal catalysed reactions such as hydrogenation or hydroformylation, a two step mechanism involving formation of a π-olefin complex followed by the insertion of the complexed olefin into a metal–carbon bond is preferred at present, although the experimental evidence for the first step is still very scarce^{140,141}.

Taking into account that in the typical Ziegler–Natta catalysts both a transition metal [Me_T] and a non-transition metal [Me_N] are present, the mechanism can be formulated as in scheme (7).

The mechanism (7a + 7b) is often described as a bimetallic mechanism¹³⁸ while the mechanism (7a + 7c) involving two transition metal atoms Me_T and Me_T' , which is also possible and for which some evidence exists^{135,136}, is mostly ignored. The mechanism (7d + 7e) is described in general¹³⁸ as a monometallic mechanism but (7d + 7f) is equally possible. A molecular orbital description of centres (equation 2) and of reaction (7e) has been published¹³⁷ but all attempts to polymerize olefins with complexes containing only one metal atom as for instance $TiCl_3CH_3$ ¹³⁶ or $Cp_2Ti(C_6H_5)_2$ ¹³⁵ failed. $Ti(CH_2-C_6H_5)_4$ or $Zr(CH_2-C_6H_5)_4$ show a very poor activity in the propylene polymerization¹¹⁰ and only very few of the metal atoms present are catalytically active as shown from the average molecular weight of the polymers obtained. On the other hand as mixtures of $TiCl_3CH_3$ and $TiCl_3$ ¹³⁶ and of $Cp_2Ti(C_6H_5)_2$ and $TiCl_4$ ¹³⁴ give moderately active catalysts, it is possible that also in the case of $Ti(CH_2-C_6H_5)_4$ the catalytically active complexes contain more than one metal atom.

For the above reasons bimetallic centres involved in mechanism [(7a + 7b) or (7a + 7c)] seem more probable than monometallic centres involved in the other mechanisms, (7d + 7e) or (7d + 7f); it must be emphasized that mechanism (7a + 7c) in which only transition metal atoms are involved is certainly possible as shown since 1957¹³⁵ but does not exclude mechanism (7a + 7b).

Stereoregulation in Ziegler-Natta polymerization of α -olefins to isotactic polymers

As previously discussed the formation of an isotactic polymer seems to involve a *cis* addition always to the same prochiral face of the α -olefin; therefore the catalyst-growing chain complex must be able to distinguish between the two prochiral faces of the α -olefin, the difference in the activation energy for the insertion reaction being more than 2 kcal/mol when an highly isotactic polymer is formed (see Figures 1 and 2). This type of stereospecific polymerization can be considered an asymmetric reaction as either one or the other prochiral face of the α -olefin must be preferred by the couple growing chain-catalyst. The pair must therefore be chiral. Considering the growing chain-catalyst pair the chirality of the centre can be connected only with the presence of asymmetric carbon atoms in the last unit or units of the growing chain, or with the presence of a chiral catalyst or with both factors (scheme 8).

The following facts indicate that the presence of chiral catalytic centres play the principal role in stereoregulation:

(a) The polymerization of racemic α -olefins in the presence of heterogeneous catalysts to highly isotactic polymers is stereoselective, when the asymmetric carbon atom is in α or β position with respect to the double bond (scheme 9).

Frequent inversion of configuration in the main chain does not cancel or appreciably alter stereoselectivity^{143,146} and starting of the chains with alkyl groups of the type

of a single chirality type does not induce preferential (stereoselective) polymerization of one antipode of the monomer¹⁴⁴. The polymerization of the same racemic olefins with soluble catalysts is not stereoselective¹⁴⁵. These facts show that the chirality of the asymmetric carbon atoms in the main chain is not an important factor in determining stereoselectivity. Therefore, the ability to distinguish between two antipodes must be connected with the chiral character of the heterogeneous catalyst.

(b) Copolymerization of racemic olefins with ethylene is stereoselective^{147,148} (scheme 10) confirming that the chiral character of the tertiary carbon atoms of the main chain is not decisively important for the distinction between the two antipodes implicit in stereoselective polymerization.

(c) The copolymerization of a large excess of propylene with $^{13}C_3H_6$ in the presence of catalyst $TiCl_3/AlR_2Cl$ yields copolymers with only two bands in the ^{13}C n.m.r. spectrum attributable to isolated $-CH_2-CH_2-$ (scheme 11)¹⁴⁹. In the same experiment carried out with non-stereospecific catalyst $[VCl_4-Al(C_2H_5)_3]$, five of the expected six peaks have been detected¹⁵⁰.

If the catalyst is chiral and accepting the previously dis-

cussed two-step mechanism for the polymerization of propylene (scheme 7), the stereoregulation might occur in the first step (formation of the π -complex) or in the second step (insertion reaction) or in both steps. Up to now no sufficient experimental evidence exists to decide between the three hypotheses. Based on the fact that stereospecific complexation to transition metals (e.g. platinum) is known¹⁵¹, it can be assumed as a working hypothesis that the two π -complexes arising from the attack of the catalyst to one or the other face of the α -olefin are in equilibrium. They may have a sufficient difference in free energy of formation ($\Delta\Delta G^0$) to justify the synthesis of highly isotactic poly(α -olefins), even if the free energy of activation for the insertion reaction yielding isotactic or syndiotactic diads are not very different (see Figure 4 in ref 143). Work is in progress to find experimental support in favour of this hypothesis.

The known dependence of the degree of stereoregularity on the structure of the alkyl group in the α -olefin [using typical Ziegler–Natta catalyst ($\text{TiCl}_4/\text{AlR}_3$), *t*-butylethylene does not polymerize; 3-methylbutene gives only isotactic polymers; propylene gives a mixture of isotactic, partly isotactic and atactic polymers¹⁴⁰] is well explained by the above hypothesis as the structure of the alkyl group of the olefinic ligand has been shown to influence remarkably the complexation equilibrium in *cis* (dichloro)(amino)(olefin) Pt^{II} complexes¹⁵².

An independent control of the hypothesis that the chirality of the catalyst is the main stereoregulating factor can be obtained from the investigation of the few steric irregularities in the isotactic polypropylene fractions. In fact if the main stereoregulating factor is the chiral catalytic centre, the insertion of a monomer molecule with an opposite stereochemistry with respect to the preceding one would remain isolated (Figure 5a). On the contrary, if the main stereoregulating factor is the growing chain, the growth would continue maintaining the configuration of the unit causing the first steric irregularity until another irregularity occurs in the insertion (Figure 5b).

In the first case couples of syndiotactic dyads would occur while in the second case isolated syndiotactic dyads should exist. Unfortunately, many possible mechanisms exist by which a change in the stereochemistry of an isotactic chain can occur. While all the authors agree that both types of irregularities can be observed with n.m.r. techniques, discrepancies exist concerning the prevalence of (rr)

or isolated (r) dyads. In a recent paper in which the different pentads of polypropylene have been investigated¹⁵³ a larger amount of pairs of syndiotactic dyads than of isolated ones has been found in a number of highly isotactic polymers prepared with different catalysts, confirming that the chirality of the catalyst is the main stereoregulating factor. Similar investigation on other poly(α -olefins) has not appeared in the literature up to now and even the simple quantitative determination of the degree of stereoregularity is in many cases difficult because of the very small chemical shift difference between the methylene signals of the isotactic and syndiotactic diads.

Research is in progress on poly(4-methyl-1-pentene) using specifically deuterated monomers and high resolution n.m.r. techniques.

Control of stereoregulation in the Ziegler–Natta polymerization of α -olefins to isotactic polymers

Although the factors determining the formation of the isotactic polypropylene are reasonably well known, very little is known about the structure of the chiral catalytic centres. The n.m.r. investigation of the polypropylenes produced with $\text{TiCl}_4/\text{AlR}_3$ catalysts shows that the degrees of isotactic stereoregularity in different fractions continuously change from more than 98% to about 50% of isotactic dyads showing that centres having a different stereoregulating capacity exist. However, the detailed planning of a modification of the structure of the centres leading to a predetermined change of stereoregularity is still not possible and changes in stereoregulating capacity of the catalysts can be obtained only empirically.

Back in 1955 Natta and his group thoroughly investigated the factors causing a change in the ratio between highly stereospecific and non-stereospecific centres. Among these factors the nature of the transition metal compound used for the preparation of the catalyst seems to be overwhelmingly important. However, other factors such as the nature of the non-transition metal component¹⁵⁴ and the addition of Lewis bases to the catalyst¹⁵⁵ seem also to be effective. The last factor brings dramatic changes in the stereospecificity of titanium catalysts supported on magnesium chloride¹⁵⁶ as shown in Table 14.

The effect of the Lewis base is still not well understood; in fact, it has been supposed¹³⁸ that the Lewis base, which in general causes a decrease of the activity of the catalysts, simply inactivates the non-stereospecific centres thus causing an increase in the ratio between stereospecific and non-stereospecific catalytic centres and hence an increase of the highly isotactic polymer fraction. However, on the basis of the experimental results it is not possible to exclude that the stereospecific catalytic centres have a complicated structure in which the Lewis base plays an important role influencing the complexation equilibrium of the

Figure 5 Principal possibilities for defects in highly isotactic polymers. (a) Isolated error, leading to a pair of racemic dyads. (b) The defect leads to a further polymerization with reversed stereochemistry, yielding an isolated racemic dyad

Table 14 Influence of Lewis bases on stereoregulation in propylene polymerization with supported $\text{MgCl}_2/\text{TiCl}_4/\text{AlR}_3$ catalytic system

Catalytic system	Boiling heptane insoluble polymer (%)	Reference
$\text{TiCl}_4/\text{MgCl}_2/\text{Al}(\text{iso-C}_4\text{H}_9)_3$	21	156
$\text{TiCl}_4[(\text{CH}_3)_2\text{N-CH}_2]_2/\text{MgCl}_2/\text{Al}(\text{C}_2\text{H}_5)_3(\text{C}_6\text{H}_5)$	93.5	117

Figure 6 Content of meso and racemic dyads in 'atactic' (ether soluble) polypropylene as a function of polymerization temperature. Catalyst: $\text{TiCl}_3/\text{Al}(\text{iso-C}_4\text{H}_9)_3$ (1:4). Polymerization in decalin at 6 atm. ●, % i-dyad placements; ○, % s-dyad placements. $\Delta H^\ddagger_M - \Delta H^\ddagger_R = 2.2$ kcal/mol; $\Delta S^\ddagger_M - \Delta S^\ddagger_R = 5.0$ cal/mol K

monomer with the catalyst. Similar hypotheses are at the present formulated to explain the enantioselectivity of nickel catalysts on which chiral compounds are adsorbed¹⁵⁷.

By increasing the temperature of polymerization of propylene both a decrease of the highly isotactic polymer¹⁵⁸ and an increase in the percentage of isotactic dyads in the polymers having a lower isotacticity have been noticed (Figure 6)¹⁵⁹. The result might be taken as an indication of a decrease, with increasing temperature, of the number of highly stereospecific catalytic centres and of a larger free energy of activation for the isotactic insertion than for syndiotactic insertion at the non-stereospecific catalytic centres. However, by increasing the polymerization temperature the average molecular weight decreases and the solvent fractionation does not yield a sharp separation according to stereoregularity. Therefore, the increase in content of isotactic dyads in the diethyl ether soluble fraction might be due to the formation (at high temperature) of highly isotactic but low molecular weight polypropylene. In any case, the propylene polymerization at high temperature has shown that some catalytic centres have a remarkable stability at temperatures up to 180°C, since, even at that temperature, they yield a highly isotactic polymer. The large decrease of the heptane insoluble polymers with temperature (even considering, that part of the highly isotactic polymer has such a low molecular weight that it becomes soluble in boiling heptane or ether) seems to indicate that the stereospecificity of some centres, that is, according to the previously formulated hypothesis, the capacity to discriminate between the two prochiral faces of the olefins, decreases with temperature as in other asymmetric catalysts. Polymerization temperature remains therefore the parameter which can be best used for fundamental investigation of the stereoregulating capacity of the catalytic centres.

STEREOREGULATION IN POLYMERIZATION OF PROPYLENE WITH ZIEGLER-NATTA CATALYSTS TO SYNDIOTACTIC POLYMERS

The polymerization of α -olefins to syndiotactic polymers, because of its limited scope, as only propylene and butadiene have been shown to yield polymers with a high syn-

diotacticity, has been much less investigated. The polymerization was first believed to occur with a regioselectivity similar to that demonstrated for the isotactic polymerization¹¹² and with a *cis* type of addition¹⁶⁰. Then some chemical^{126,127}, n.m.r.^{129,130} and i.r.¹²⁸ indications have been obtained showing that with vanadium catalysts the regioselectivity could be opposite in syndiotactic and isotactic type of propylene polymerization respectively (see above). However, no investigation has been carried out on regioselectivity in the synthesis of syndiotactic polymers obtained with typical isospecific catalysts $[\text{TiCl}_3/\text{Al}(\text{C}_2\text{H}_5)_2\text{F}]$ ¹⁶² or catalysts obtained from TiCl_4 and sodium-alkyls¹¹⁴. The problem of regioselectivity being not yet completely settled, and the maximum degree of syndiotactic stereoregularity achievable being not systematically investigated, only speculations are possible concerning stereoregulating factors in propylene polymerization yielding highly syndiotactic polymers. As a possible working hypothesis, the following can be suggested for the syndiotactic polymerization at low temperature with soluble catalysts, which is at least in part in agreement with the recent literature and is not in contrast with n.m.r. data on ethylene-propylene copolymers (scheme 11). Propylene would still insert into a metal to carbon bond but with a regioselectivity opposite to that proved for the isotactic polymerization; the stereoregulation is not connected with the chirality of the catalyst but with the chirality of the last monomeric unit, the asymmetric carbon atom of which is bound to the metal atom of the catalyst and does not racemize during the insertion reactions*.

Two limiting cases are possible (scheme 12): (a) an equilibrium between π -complexes exists, regulated by the asymmetric carbon atom of the growing chain bound to the metal, the position of the equilibrium being sufficiently displaced toward one of the complexes to justify the maximum degree of stereoregularity observed (90–95% of (r) dyads); or (b) the free energy of formation of I and

* Insertions of carbon monoxide into a bond between an asymmetric carbon atom and a metal atom without racemization are known¹⁶¹.

II is the same but the activation energy for the insertion of the olefin bound to the metal with one or with the other prochiral face is sufficiently different to justify the stereoregularity achieved. The diastereomeric composition obtained in the insertion of propylene in a Li to *sec*-butyl bond (46% of *erythro* and 54% of *threo*) which can be taken as a proper model for syndiotactic polymerization, seems to indicate that the first hypothesis is at the present more acceptable. The above totally speculative scheme for the steric control in syndiotactic polymerization of propylene at low temperature has the merit of explaining why the steric factors, which do not hinder inversion of configuration during the polymerization to atactic polymers with typical Ziegler–Natta catalysts of α -olefins with alkyl groups other than methyl group (1–2 type of insertion), can hinder completely the low temperature syndiotactic polymerization (2–1 type of insertion) of the same monomers.

PERSPECTIVES OF STEREOREGULATION IN VINYL POLYMERS

As it results from the topics discussed in the present review the problem of the control of stereoregularity in vinyl polymers is far from being solved.

The perspectives for stereocontrol in free radical polymerization are not very promising and research in this field should mainly be directed to polymers in which large attractive interactions exist between the last monomeric unit containing the unpaired electron and the preceding units of the growing chain. A further direction for research would be the radical polymerization of monomers regularly adsorbed on a surface¹⁶³ simulating the polymerization of monomers included in solid matrixes which seem to be today the only way to obtain highly stereoregular polymers with radical polymerization.

The stereoregulating factors in ionic polymerization are fairly well understood and by varying the polymerization conditions, and particularly the type of solvent and temperature, the degree of stereoregulation can be fairly well controlled. Further progress will lead to improvement of the degree of stereoregularity, and is bound to give a more detailed knowledge of the type of coordination around the counterions and of the structure of the growing chain ends. This type of knowledge requires both a clever choice of the system to be studied and improvements in the methods for the investigation of structures of complex ions in solution.

More complicated is the situation in the case of transition metal catalysed polymerization. Here much basic knowledge of the chemical aspects of the growing reaction and on the nature of the catalytic centres is still lacking. Therefore, a thorough discussion of the stereoregulating factors is not possible and we are still in the stage in which we try to improve our knowledge of the polymerization processes by investigating the stereoregularity of the polymers obtained. In this field the success of the industrial production of isotactic polypropylene shows how enormous progress can be made on a purely empirical basis. Progress in the basic knowledge of transition metal catalysed polymerization and on the stereoregulating forces will probably be very slow in the future because of the complexity of the problems. A purely empirical approach will probably yield more results of practical interest in a relatively short time.

Possible lines of development of the basic research in

the field of transition metal catalysed polymerization are further studied on model systems to obtain a better understanding of the role of the different components of the catalysts as well as attempts to synthesize catalytically active chiral transition metal complexes. Attention should be given also to a thorough investigation of the kinetics of the polymerization in homogeneous systems. One of the most fascinating and important fields is the investigation of the stereoregulating effects of bases in the Ziegler–Natta catalysts supported on $MgCl_2$. However, here, despite extensive progress in the techniques of investigating heterogeneous catalysts, a final proof of the structure of the stereospecific catalytic centres is not likely to come very soon.

Mechanical motions in amorphous and semi-crystalline polymers*

Raymond F. Boyer

Midland Macromolecular Institute, 1910 West St. Andrews Drive, Midland, Michigan 48640, USA

(Received 14 May 1976)

Ten areas of the field, all with some special interest to the author, were selected for predictions about the near future. In order to gain perspective, a brief review is presented of some key developments which occurred after the publication of the book 'Anelastic, and Dielectric Effects in Polymeric Solids' by McCrum, Read and Williams in 1967. The following predictive areas are then discussed in varying degrees of detail. (1) Apparatus: current status and the need for automation and more sophistication. (2) Extending the temperature range above T_g or T_M and the molecular weight range down to the oligomers. (3) Study of rarefied polymers (higher than normal free volume). (4) Nature of the in-chain β relaxation ($T < T_g$) in addition polymers. (5) Use of nitroxide probes as an auxiliary tool to study amorphous phase relaxations in highly crystalline polymers. (6) Computer simulation of molecular motion at sub-group relaxations. (7) Nature of the amorphous state and its possible effect on mechanical relaxations other than through free volume. (8) Correlation between mechanical strength of glassy polymers and secondary, glassy state relaxations. (9) The need to prepare highly crystalline polymers in the completely amorphous state. (10) The impact of new polymer types. It is concluded that mechanical spectroscopy is still a quite viable field with exciting potentialities. A synergism between automation of apparatus, new materials, new techniques (not necessarily in the field of mechanical spectroscopy) and theory is anticipated.

INTRODUCTION

Historical perspective

Any considerations about the future prospects for the mechanical spectroscopy of polymers should start properly with recognition of the land-mark book by McCrum, Read and Williams¹ followed by a precis of key events between the 1967 publication of this book and the current time. This book presented six elements of the subject: historical perspective; definitions of terms; theory; experimental techniques; numerous relaxation spectra on all major polymers; relaxation maps, where data warranted, showing plots of log frequency $-1/T$ for two or more of the major loss peaks in a given polymer. Granting authors the privilege of knowing and citing their own most recent work, including papers in press, one must conclude from the bibliography section that literature references terminated sometime prior to 1965, when this subject was accelerating in interest and number of publications.

Today, there are three commonly used dynamic mechanical loss instruments: torsional pendulum in several variants; the Rheovibron (dynamic tensiometer); and to a much more limited extent, the torsional braid apparatus (t.b.a.) which is a form of torsion pendulum using an impregnated glass braid rather than a strip of polymer. In the book by McCrum *et al.*¹, the torsion pendulum was treated in detail, the then new Rheovibron method was mentioned in one sentence; and the t.b.a. not at all. Some Rheovibron data were included. We have summarized elsewhere the salient features of these three methods². Since that time Sternstein³ has modified the torsion pendulum technique by applying a

tensile force along the length of the specimen which is then under both shear and tensile deformation. Gillham⁴ has presented a comprehensive review on t.b.a., including his current completely automated instrument. Tabor *et al.* have miniaturized a torsion pendulum and placed it inside a hydrostatic pressure vessel to measure the effect of pressure on mechanical relaxations^{5,6}.

It is not possible within the scope or space limitations of this article to summarize all of the key developments in mechanical spectroscopy between 1965 and the present. Some of them will emerge in subsequent discussion. The following selections are in some measure subjective, having in mind topics to be covered later.

(1) Takayanagi has reviewed his extensive studies on dynamic properties of mats prepared by compression of polymer single crystals^{7,8}. Many other relevant topics are included. These papers serve as an introduction to many subsequent articles by him in the English language technical literature.

(2) Sauer *et al.*⁹ prepared an extensive review on deformation and relaxation behaviour of polymer single crystals, showing in effect that this is a very mature area of study.

(3) McCall¹⁰ published a series of relaxation maps for all key polymers with special emphasis on n.m.r. data.

(4) The work of Heijboer¹¹ on mechanical loss in saturated ring ester of poly(methyl acrylic acid) constitutes a definitive study correlating both temperature and intensity of the group motion with chemical structure of the unsubstituted and substituted rings from C₅ to C₈. The five types of experimental apparatus developed by Heijboer and/or his collaborators to cover the frequency range from $\sim 10^{-4}$ Hz (torsional creep) to $\sim 10^7$ Hz (wave propagation) are described, and typical results presented.

(5) Lamb¹²⁻¹⁴ and his colleagues have approached dyna-

* Presented at the Sixth Biennial Manchester Polymer Symposium, UMIST, Manchester, March 1976.

mic viscoelastic behaviour of liquids and polymers from the viewpoint of electrical circuitry. Analogies with circuit theory have allowed them to analyse and resolve the several key components playing a role in viscoelastic processes. Ultrasonic absorption (up to 1–2 GHz) and dielectric loss (low frequency) apparatus have recently been added.

(6) Simha and his students^{15,16} have measured thermal expansion of amorphous and semi-crystalline polymers, in some cases from 4.2K upwards, and shown in many examples a one to one correspondence between multiple step-jumps in coefficient of linear thermal expansion and peak heights of torsion pendulum loss curves. The latter represent their own data as well as literature data, in some cases on identical samples as, for example, the C₅ to C₈ cycloalkyl methacrylates prepared and measured by Heijboer¹¹.

(7) Ward and collaborators have made a systematic study of the effect of orientation on mechanical relaxation in polyethylene^{17,18} supplementing such studies with dielectric¹⁹ and n.m.r.²⁰ results. Orientation permits a correlation between loss peaks and direction of crystallographic axes, thereby helping to define molecular motion occurring at specific loss peaks. Takayanagi *et al.*²¹ have also reported a systematic study of Rheovibron data on oriented PE.

(8) Illers, in a series of detailed studies on branched and linear polyethylenes^{22–25} has resolved and clarified the detailed nature of the various amorphous and crystalline loss peaks lying in the temperature range between liquid N₂ and the melting point. His conclusions about $T_g = 195–200\text{K}$ for amorphous polyethylene are not universally accepted and the controversy continues. We consider this work definitive and the most sophisticated use yet made of the torsion pendulum in analysing an exceedingly complex problem.

(9) Eisenberg²⁶ has carried out extensive mechanical loss measurements on a new class of polymers, the ionomers, which contain relatively small amounts (usually less than 10%) of metal salts of acrylic or methacrylic or other acids present in the polymer chain.

(10) Several pertinent review papers might be cited, both comparing results from mechanical and other types of relaxation measurements. We refer to book chapters by Roberts and White²⁷ and by North²⁸. The present author has reviewed in some detail special problems related to multiple loss spectra of semi-crystalline polymers²⁹.

(11) Jansson^{30–32} has developed a new viscoelastic function which facilitates frequency or time–temperature transformations, calculation of creep compliance from complex compliance, and separation of viscoelastic mechanisms.

(12) Gisolf has discussed the relationship between the applied mechanical field and the moving groups in the polymer in terms of mechanical–dipole relaxation³³. He concludes that compliance rather than modulus is the proper function to use³⁴. Gray and McCrum³⁵ had earlier stressed the importance of considering the proper viscoelastic function to use for crystalline polymers.

Future trends: the outlook

Any scientific discipline advances in an erratic fashion caused by the unexpected advent of new theories and new techniques; one need only consider the characterization of polymers prior to the advent of light scattering, the laser or gel permeation chromatography. Our personal philosophy is that by reviewing the recent past as above and in refs 2–35, one can draw a tangent to the curve of progress at this moment in time and extrapolate to what might happen in the absence of unpredictable break-throughs. Hence, we

confine ourselves to listing some areas where problems exist and where specific types of studies might be conducted.

THE OUTLOOK FOR DYNAMIC MECHANICAL SPECTROSCOPY

Apparatus

Several trends can be foreseen with considerable confidence based on activities already present in specific laboratories.

Automation of data acquisition and reduction, with plotting either directly on an $X-Y-Y'$ recorder or as a computer printout, is inevitable. Automation of all instrumental techniques is occurring rapidly. Dynamic mechanical testing has seemed to lag in this regard, presumably because of some inherently difficult problems. Gillham has automated his torsional braid analysis equipment to the point that temperature programming is completely controlled in any desired logical sequence while an $X-Y-Y'$ recorder plots out as a function of temperature at ~ 1 Hz log decrement and log (period⁻²), the latter being a measure of relative modulus of rigidity. This has now been described in detail⁴. Since t.b.a. is inherently a torsion pendulum, this means that the technique for automating any torsion pendulum is at hand. In principal, the digital printouts⁴ can be punched onto tape. All viscoelastic functions can be calculated and printed out.

Du Pont has just announced a new type of automated dynamic mechanical analyser, Model 980^{36,37}. It prints out on an $X-Y-Y'$ recorder, X being the temperature scale, the resonant frequency of the specimen, which can be related to modulus, and damping on a decibel scale. Temperature is programmed from -150° to 500°C at various linear rates in heat–cool cycles or isothermal modes. The modulus range is 0 to 10^{11} dyne/cm² so that metals, polymers, and other materials can be studied. While frequency varies along the temperature scale as modulus decreases, the variation is generally in the range from 150 to 3.5 Hz, and in specific instances, such as linear PE, from 20 to 3.5 Hz. The output information from the unit can be fed to various outside data handling devices and computers. In this way modulus can be calculated directly from the frequency–temperature data.

An automated Rheovibron developed by the Monsanto Company has been described by Kenyon^{38,39}. Stress, strain phase angle, sample length and temperature are recorded continuously while the data are fed to an off-line computer to give storage modulus, loss modulus and $\tan \delta$. Tension is controlled with loadings as low as 0.015 g. Such low loading permits going well above T_g . $\tan \delta$ measurements are made to ± 0.001 . Minor transitions and relaxations are now seen in a reproducible fashion.

One automated instrument originally developed by Simpson *et al.*⁴⁰ for mechanical loss in metals deserves consideration for polymers. As originally conceived and used, the driven metal specimen forms one plate of a parallel plate condenser. Electrical circuitry permits plotting of logarithmic decrement and Young's modulus, currently as a function of time, but alternately as a function of temperature. According to Soisin⁴¹, the apparatus works on a polymer sample coated with an electrically conducting paint. Frequencies in the range of 0.1 to 5 kHz can be attained.

Increased experimental sophistication. While a given investigator may use a single dynamic mechanical testing apparatus for general characterization, it is apparent that complete characterization of mechanical spectra requires a range

Figure 1 T_g -molecular weight plot for a polymer such as PS or PMMA. The shaded area above T_g is not normally available for dynamic mechanical tests because of excessive melt flow. The shaded area to the left of molecular weight $\sim 20\,000$ gives, for PS, polymers too weak and brittle to be tested. The inset shows a dynamic loss spectrum at 1 Hz for atactic PS of molecular weight in the range $1-2 \times 10^5$

of instruments^{11,42}, namely: torsional creep for $\sim 10^{-5}$ to $\sim 10^0$ Hz; torsional pendulum for ~ 0.1 to ~ 20 Hz; flexural resonance for $\sim 10^2$ to $\sim 10^4$ Hz; long resonance for $\sim 10^3$ to $\sim 10^5$ Hz; wave propagation for $\sim 10^6$ Hz. The resulting range of 11 decades permits a precise determination of apparent energies of activation, especially for secondary relaxations⁴³.

In general, mechanical relaxation measurements should be supplemented with one or more of the following techniques: dielectric, n.m.r., neutron scattering, and dynamic viscoelasticity. One such multidisciplinary study by Allen *et al.* on the glassy state of polymers containing *para*-phenylene linkages might be cited⁴⁴.

Extension of mechanical relaxation measurements to higher temperatures and to lower molecular weights

The Problem. Figure 1 is a generalized dilatometric, d.s.c. or d.t.a. determined glass temperature-log (molecular weight) plot for an atactic polymer whose limiting T_g , $T_g(\infty)$, is around 400K such as PS or PMMA. The insert is a schematic 1 Hz torsion pendulum loss curve on an atactic PS of molecular weight $\sim 100\,000$. (A schematic curve is used because no single investigator has reported for one specimen the five loss peaks shown.) The dynamic loss curve usually ends at a temperature corresponding to the minimum in $\tan \delta$ just above T_g . Very careful torsion pendulum work by Turley⁴⁵ has revealed on several specimens the $T_{l,l}$ loss peak indicated. In general, dynamic measurements normally must cease slightly above T_g because of excessive melt flow in the specimen. Thus, the shaded region above T_g is inaccessible to torsion pendulum (or Rheovibron) measurements because of viscous flow. However melt flow measurements by Ueberreiter and Orthmann⁴⁶ show some kind of viscoelastic relaxation behaviour above T_g (broken line) for both atactic PS and atactic PMMA. This broken line appears to represent an iso-viscous state associated with the time scale of their instrument. Nevertheless, there have been in the literature enough scattered reports about events in the liquid state above T_g in atactic polymers and above the melt in crystalline polymers to suggest that an *a priori* dismissal of this area is inadvisable.

At the same time, Turley⁴⁵ found it impossible to make coherent moulding of atactic polystyrene at molecular

weights of 20 000 or below. Hence the crosshatched area below the T_g line and to the left of molecular weight $\sim 20\,000$ is inaccessible for measurement by torsion pendulum or Rheovibron as those instruments are normally used. The lower limiting molecular weight will vary from polymer to polymer. In brief, both the liquid state above T_g at all molecular weights and the oligomeric region for T_g and below at less than some critical molecular weight are not available for examination by conventional dynamic mechanical spectroscopy.

We first recognized this situation in about 1969 when trying to prepare a review article on polystyrene⁴⁷. It then became apparent to us that the torsional braid analysis technique being perfected by Gillham⁴ offered the possibility of examining the entire molecular weight range as well as the entire temperature range up to the thermal decomposition temperature. A collaborative study on anionic PS from 600 to 2×10^6 molecular weight and on a fractionated thermal PS over a more limited molecular weight range has been mostly completed, using the temperature range from liquid N_2 to 300°C. Certain parts of the data are in press^{48,49} while other parts are being withheld because of some uncertainties about interpretation. The following summary can be made of both types of data.

(a) A dynamic T_g for anionic PS of molecular weight between 600 and 2×10^6 is available⁴⁸. The points lie consistently above the dilatometric values, as is normal for a dynamic test.

(b) The $T_{l,l}$ loss peak noted by Turley is found on both heating and cooling cycles and is completely reproducible. Below M_c , $T_{l,l}$ (K) $\sim 1.2 T_g$ (K) and $T_{l,l} \sim \bar{M}_n^{-1}$ ^{48,49}. Both facts suggest an iso-free volume state at $T_{l,l}$, which is consistent with an iso-viscous state

(c) The β loss peak is always below T_g being ~ 300 K for molecular weights down to 20 000 and as low as 190K for 600 molecular weight. As normally seen, it is a shoulder on the low temperature side of the T_g loss curve and hence must be approximated. Moreover, it shows marked hysteresis, being much more intense on reheating from liquid N_2 than on cooling below T_g . Since the curves are reproducible on subsequent cooling and heating, Gillham has postulated that crazing occurs at very low temperatures, with crazes being removed on heating back to T_g ⁵⁰. The large free volume existing in craze matter (up to 50%) is presumably responsible for the enhanced loss. The subject of crazes will be discussed later.

(d) The γ peak around 150K is not seen as such at any molecular weight⁵¹. The loss curves start to rise again below the normal γ region for all molecular weights and reach, at the lowest molecular weights, a maximum around 190–200K with height increasing as \bar{M}_n^{-1} . This loss peak might arise from catalyst end-groups, as first suggested by the n.m.r. measurements of Connor⁵² and later clearly assigned to CH_3 -rotation by Crist⁵³. However, a thermal PS fraction of molecular weight 3100 also shows such a low peak but at 100–110K⁵¹. It is also possible that the peak seen is somehow related to the δ loss mechanism normally occurring at 40–50K (1 Hz)¹. Again, because of such uncertainties, this data is being withheld from publication.

Meanwhile, Cowie and McEwen⁵⁴ have reported torsional braid values of T_g on PDMS oligomers. Since this polymer does not appear to have a β peak (see Table 1) and since crystallinity at about $1.2 T_g$ would suppress and/or hide a $T_{l,l}$, only T_g was reported (and presumably was the only peak to be observed). The apparatus used was an earlier non-automated torsional braid equipment.

It is clear then that torsional braid analysis provides one solution to covering both the oligomeric range of molecular weights as well as the liquid region above T_g and/or T_M . While its frequency can be carried by using pendulums with different moments of inertia, the frequency range available is limited. The Rheovibron offers a more extended range of frequencies but cannot use the inextensible Gillham braid⁵⁵. Cowie *et al.*⁵⁶ have demonstrated the use on the Rheovibron of polymer-impregnated strips cut from non-woven glass fibre circles (Watmann GFC) to go above T_g with t.b.a. on some semi-crystalline polymers. The results obtained were similar to those using t.b.a. We used some GFC material supplied by Cowie⁵⁶ to study anionic PS of molecular weight 37 000, but appreciable flow occurred in the Rheovibron just above T_g . Inspired by Cowie, we used woven stainless-steel mesh strips cut at an angle of 45° to the warp and weft directions. This permitted obtaining well defined loss curves at several frequencies, showing T_{β} , T_g and $T_{l,l}$ on anionic PS of molecular weight 37 000^{57a}.

This section will be closed by reviewing two pertinent areas. The first concerns the fact that there have been many successful attempts reported in the literature to measure dynamic mechanical properties of low molecular weight compounds and of oligomeric polymer series. Because of our general interest in this area for reasons cited above, and because such a tabulation might inspire future work, we list in Table 1 the examples readily culled from our files. In all cases the low molecular weight substance is on or within a substrate that can withstand the applied mechanical force over the desired temperature range, while contributing little or no background loss.

The second point is that the scientific community has expressed friendly scepticism about the so-called $T_{l,l}$ transition first named and explained some years ago by us Gillham⁵⁰ and the present author both agree that since the braid may generate an artifact and since the event is not seen by conventional viscoelastic tests, scepticism is deserved until certain key issues are completely resolved, and answers

made available. Since the present author is proposing the liquid region above T_g as a fruitful area for future study, it is important that the joint Gillham-Boyer attitude be clearly stated*. Briefly:

(1) While we do not profess to understand the molecular basis for the t.b.a. observations, it is quite clear how the phenomenon can be observed with t.b.a. at will, and reversibly on heating and cooling, via the use of essentially monodisperse polymers having M_n values $\leq 100\,000$.

(2) The unambiguous dependence of $T_{l,l}$ on M_n^{-1} for molecular weights of narrow polymers and bimodal blends below M_c suggests a basic molecular mechanism, even if an interaction between glass braid and molten polymer is involved.

(3) However, several bodies of systematic data (variation of molecular weight) are now available in the literature on three atactic polymers using four different experimental methods. All agree that something with relaxational character occurs above T_g (Table 2).

(4) In one instance, a fraction of PMMA (25 000 MW) tested by one non-braid method in Germany was furnished to the t.b.a. programme. Essentially identical values were obtained for T_g and $T_{l,l}$ by both techniques, the braid values being slightly higher because of frequency^{57b}.

Table 2 is a summary of these eight systematic bodies of data. We believe that this tabulation should serve to encourage study of dynamic mechanical loss in the region above T_g in amorphous polymers and above T_M in crystalline ones.

Mechanical spectra of rarefied polymers

The mechanical spectra of amorphous and semi-crystalline polymers have been studied as a function of hydrostatic pressure by Zogel⁵⁸ and more recently by Tabor

* A position paper is currently being prepared and will appear as a long abstract in *Polymer Preprints* 1976, 17, (ACS San Francisco Meeting August 1976). This seems to answer all major objections thus far made against $T_{l,l}$ and the t.b.a. method.

Table 2 Systematic evidence for relaxation phenomena above T_g

Polymer (all atactic)	Molecular weight range	Support for polymer	Method	Reference
1 Polystyrene	500–5 x 10 ⁵	Glass plates	Melt fusion under pressure	Ueberreiter and Orthmann ⁴⁶
2 PMMA	1200–1.1 x 10 ⁶	Glass plates	Melt fusion under pressure	Ueberreiter and Orthmann ⁴⁶
3 PMMA	200–1.1 x 10 ⁶	None ^a	Thermal diffusivity	Ueberreiter and Naghizadeh ^{b,c}
4 <i>cis</i> – <i>trans</i> polybutadiene ^d	10 000–3.1 x 10 ⁵	PBD of <i>MW</i> 10 ⁶	Dynamic mechanical loss	Sidorovitch, Marei and Gashtol'd ^e
5 Anionic PS	600–2 x 10 ⁶	Glass braid	t.b.a.	Stadnicki, Gillham and Boyer ⁴⁸
6 Anionic PS		Al pan	d.t.a. ^f	Stadnicki, Gillham and Boyer ⁴⁸
7 Thermal PS fractions	1800–1.1 x 10 ⁵	Glass braid	t.b.a.	Glandt, Toh, Gillham and Boyer ⁴⁹
8 Thermal PS fractions		Al pan	d.t.a. ^f	Glandt, Toh, Gillham and Boyer ⁴⁹

^a Sample in form of a rod. ^b Ueberreiter, K. and Naghizadeh, J. *Kolloid. Z. Z. Polym.* 1972, 250, 927. ^c A fraction of PMMA, molecular weight 25 000 has been tested with t.b.a. Both methods essentially agree concerning T_g and a second event above T_g . ^d ~ 40% *cis*, 40% *trans*, 10% vinyl-1,2. Similar results were obtained but not reported on hevea rubber and a poly(propylene oxide) elastomer. ^e Sidorovitch, E. A., Marei, A. I. and Gashtol'd, N. S. *Rubber Chem. Technol.* 1971, 44, 166. See also *Polym. Sci. USSR* 1974, 16, 993. ^f Seen only on heating cycle of specimens in finely divided form.

It should be recalled that Cox, Isaksen and Mers, *J. Polym. Sci.* 1960, 44, 149 found a minimum in damping lying above T_g but below what we call $T_{1,1}$ which they could not observe. The temperature of this minimum increased with M_n while the magnitude of damping at the minimum decreased. Similar results for PBD are found in the references in footnote e

and his collaborators^{5,6}. Both amorphous and crystalline loss peaks are shifted to higher temperatures, as might be expected because of the decrease in free volume with pressure. Densified polystyrene prepared by the application of hydrostatic pressure in the melt above T_g with subsequent cooling under pressure has been measured at room temperature by Dale and Rogers⁵⁹, as well as by Price *et al.*⁶⁰.

The densification achieved in this latter reference was quite small, being only 1% at 3000 bars. The intensity of a secondary and the T_g peak of atactic polystyrene appeared to be suppressed in intensity by this densification. One cannot be certain if the effect arises from a decrease in free volume alone, or from different ordering parameters, i.e. different isomer content frozen in above T_g or both.

We suggest for the future that there may be some merit in studying polymers whose densities are less than normal and hence, with enhanced free volume. This is achieved to a very limited extent by quenching from above T_g which gives, at least for polystyrene, an enhanced β ($T < T_g$) amorphous loss peak⁶¹. This peak height is suppressed by annealing. We have in mind far greater volume changes than this.

Illers and Jenckel⁶² showed that the β peak in crosslinked styrene–DVB copolymers increased as the divinyl benzene content was raised from zero to 1 to 3 and to 9%. The effect was far greater than that normally achieved by quenching. Subsequent unpublished torsion pendulum results by Turley⁴⁵ on a styrene–1% DVB copolymer confirmed the enhanced β peak.

While one normally expects crosslinking to increase density and decrease free volume, the exact opposite can occur in some instances. For example, Ueberreiter and Otto-Laupenmüehlen⁶³ cast a series of styrene–DVB rods containing 5, 10, and 15% DVB. These cast rods were cooled slowly from 200°C to room temperature at which tempera-

ture densities of 1.047, 1.021 and 1.005 g/cm respectively were measured. Presumably the normal shrinkage, which occurs both during polymerization and subsequent cooling, was inhibited by crosslinks and a substantial decrease in density resulted.

A further but less dramatic indication of this same effect is afforded in the data of Millar⁶⁴ on S–DVB 18–50 mesh beads prepared in suspension. The density goes through a slight minimum at 2 to 4% DVB before starting to climb sharply. This could result from a competition between the shrinkage effect already discussed and the normal tendency of crosslinkers to increase density. This shrinkage effect should be smaller, the smaller the dimensions of the polymerized system.

It might be thought that the presence of physical crosslinks would drastically alter glassy state relaxation processes, and this may in fact prove true. However, with one crosslink every 10 or 20 monomer units, and with the β process involving only one or two monomers along the chain¹, it does not appear too likely that effects other than from free volume will be effective. Takayanagi and coworkers⁶⁵ have clearly shown that high levels of crystallinity (which we consider to act as physical crosslinks) do not appreciably affect either the temperature or the intensity of the β relaxation in poly(ethylene terephthalate).

If one assumes a value of 10% as the effective free volume at T_g , and presumably in the glassy state not too far below T_g then a 5% decrease in density is a 50% increase in free volume. Correspondingly a 1% increase in density by densification means a 10% decrease in free volume.

Further it is known from the studies of Lloyd and Alfrey⁶⁶ that addition of an inert diluent to a styrene–DVB system prior to polymerization, and subsequent removal of the diluent, leads to a control of porosity (and even the shape of the pores depending on amount and type of diluent)

Table 3 Relative intensities of β (local mode)^a amorphous relaxation peaks

Polymer	Crystalline form ^b	Strength of β peak ^c	Reference
Polyethylene	Planar zig-zag	Strong	(l), h
Poly(vinyl fluoride)	Planar zig-zag	Strong	d
Poly(vinylidene fluoride)	Planar zig-zag	Strong	e
	Helical	Weak	e
Isotactic PS	Helical	Weak	f
Atactic PS	Mixed iso-syndio-hetero	Strong	f
Isotactic PMMA	Isotactic	Weak	g
Syndiotactic PMMA	Syndiotactic	Strong	g
Isotactic polypropylene	Helical	Weak	h
Polyisobutylene	Helical	Absent	i, j
PDMS	Helical	Absent	k, l
<i>Cis</i> -polybutadiene	No crankshaft ⁿ	Weak	m
<i>Trans</i> -polybutadiene	Crankshaft ⁿ	Strong	m

^a The β (local mode) loss peak arises in the amorphous phase as well as in crystal defect regions. ^b It is assumed that some tendencies for the indicated conformation will persist in amorphous regions where β peak occurs. ^c Strength of a sub-group relaxation is not well defined. In general, we use whatever measure appears in the literature. See also Figure 2. ^d Osaki, S., Nemura, S. and Ishida, Y. *J. Polym. Sci. (A-2)* 1971, 9, 585; Kawasaki, N. and Hashimoto, J. *J. Polym. Sci. (A-2)* 1971, 9, 2095. ^e Kakutani, H. *J. Polym. Sci. (A-2)* 1970, 8, 1177. ^f Reference 45. ^g Figure 5 of ref 4. ^h Flöcke, H. A. *Kolloid Z.* 1962, 180, 118. Data on PE also appears in this article. ⁱ Morgan, R. J., Nielsen, L. E. and Buchdahl, R. J. *Appl. Phys.* 1971, 42, 4653. There is methyl group rotation below T_g . See Figure 9 of ref 10. ^j It is not known if symmetrical substitution plays some role. As mentioned in the text the β peak may lie under the T_g peak. ^k Figure 34 of ref 10. ^l Symmetrical substitution again. ^m Figure 2 of footnote i. ⁿ Morgan *et al.* (footnote i) above suggest that a slightly imperfect crankshaft is possible in the amorphous phase for the *trans* but not for the *cis* isomer

Small amounts of diluent might be removed from linear polymers by freeze drying techniques although such porosity would almost certainly collapse on heating the specimen near T_g . The porosity induced in crosslinked polymers by diluents is probably much more stable near and above T_g .

We also note that 'popcorn' polymers prepared by proliferous polymerization⁶⁷ as with S-DVB, can naturally attain densities as low as 0.3–0.4 g/cm, with apparently a complete range in densities possible up to ~ 1.05 ⁶⁸.

Finally, controlled crazing offers another technique for introducing microvoids. This crazing may be developed under simple tension on the glassy polymer as was carried out by Maxwell and Rahm⁶⁹ on polystyrene or on a rubber modified glassy polymer such as rubber modified polystyrene, in which crazes developed at each rubber particle on flexing⁷⁰. Such crazes tend to heal themselves and disappear when the specimen is heated above T_g . As indicated earlier crazes induced in PS by deformation at low temperature definitely enhance the intensity of the β peak.

One might rationalize the enhanced β peak with increased free volume as follows: the opportunity for local mode relaxation is probably much greater at the surface than in the interior of a specimen. Generation of large amounts of internal voids would be expected to enhance the intensity of the β peak and possibly to shift its location and/or breadth along the temperature scale.

In summary, we suggest that control of free volume by one or more of the techniques just enumerated offers new opportunities for investigating the nature of relaxation processes in the rarefied glassy state.

Nature of the in-chain β relaxation in addition polymers

The in-chain β relaxation is an amorphous phase process lying below T_g . For addition polymers (vinyl, vinylidene, ring opening, and some self condensing monomers such as 2,6-dimethylphenol) in which the motion about the chain axis must be similar in type but smaller in extent than the motion at T_g , we know from the original finding of Matsuoka and Ishida⁷¹ as later modified and refined by Boyer^{2,29} that:

$$T_{\beta}(100 \text{ Hz}) \equiv (T < T_g)(100 \text{ Hz}) \cong 0.75 T_g(100 \text{ Hz}) \quad (1)$$

for a large number of examples but not all. It seems true for many amorphous and semi-crystalline polymers. The author has interpreted this relationship to imply that the motion occurring at T_{β} is a precursor of that which will occur at T_g ⁷². The presumption here is that the local mode motion (see pp 182–85 of ref 1 for definition) associated with T_{β} occurs in isolated pockets of free volume and that these pockets coalesce at T_g . Moreover Goldstein⁷³ has predicted on theoretical grounds that every T_g should have a $T < T_g$ or T_{β} process.

The key question which remains for the future is: why is this β process missing completely or exceedingly weak in many common polymers? For example, it is missing in PIB, PVDCI, PDMS, isotactic PMMA, isotactic PS, etc. Janssen has concluded^{30,32} that in some cases T_{β} is hidden under the T_g loss peak and can be resolved by suitable data treatment techniques which he has developed. Even so, it would seem that the Goldstein hypothesis, equation (1), and the precursor argument all fail in such instances.

Even though the detailed answers are not available, Table 3 assembles some literature data indicating that both chain geometry as well as chemical structure may play a role in the intensity of the β peak. In pairs of cases where the chemistry is identical, planar zig-zag vs. helical, *trans* vs. *cis* and syndiotactic vs. isotactic appear to be crucial with the first of the two giving a stronger β peak. This is further developed numerically in Table 4 for a few polymers using definitions shown in Figure 2. We show two measures for intensity of the β peak: absolute height on a given loss scale (whatever used by the investigator) and difference between peak height and an assumed background. Heijboer¹¹ has recommended for such weak secondary loss peaks an integration of the area between peak and background vs. $1/T$ but present circumstances do not warrant such detail. Table 4 gives some quantitative feeling for the qualitative statements made in several cases cited in Table 3.

Heijboer⁷⁴ has concluded that apparent activation energies, ΔH_a , for these secondary or β loss peaks are determined by

Figure 2 Two definitions of β peak intensity used in connection with Table 4

local intramolecular barriers to motion about the chain axis. Strong intermolecular steric hindrance decreases the intensity of the loss maxima but leaves ΔH_a unchanged. These conclusions raise several problems. If T_β is indeed a precursor for T_g , a heavy intramolecular component to T_g is implied. This is consistent with the fact that the methyl side group in PMMA raises T_g 100K over the value for poly(methyl acrylate). Heijboer's view is substantiated by the findings of Amrhein *et al.*⁷⁵ that dielectric loss in PMMA solutions still shows the β loss peak because, they conclude, it has an intramolecular origin.

On the other hand, an intense dielectric β peak has been reported for the relatively rigid coplanar molecule, σ -terphenyl⁷⁶. This would appear more in harmony with Goldstein's view of the nature of the glassy state than of Heijboer's internal energy barrier.

Molecular probes for motion in highly crystalline polymers

Introduction. Highly crystalline polymers such as linear PE, POM, isotactic polypropylene, PVF, PVDF etc. are composites consisting of three types of interconnected material in either the chain folded or fringed micelle models: high modulus crystallites; lower modulus crystalline defect regions, amorphous regions with low modulus above T_g , high modulus below T_g . Some amorphous material may be unconnected to the crystallites, or possibly adsorbed on them⁷⁷.

Dynamic mechanical measurements of necessity yield the properties of the composite at any temperature and frequency, with the amount of crystallinity and overall morphology being very important. From an engineering point of view, dynamic properties of the composite are important because they should correlate with end use behaviour. However, this composite structure greatly complicates a thorough understanding of molecular motions in the several regions named above. There are three key problems:

- identification of the phase in which each loss peak occurs;
- effect of fractional crystallinity, χ_c , on the temperature of amorphous and crystalline relaxations and transitions;
- effect of χ_c on the intensities of each relaxation. This in turn assumes knowledge of how to define and measure intensity.

In spite of 20 years or more of efforts to resolve these problems, much controversy still exists, especially in regard to the value of T_g for such highly crystalline polymers (see Figure 1 of ref 29). Therefore, it seems pertinent to review briefly the approaches taken in the past before proposing how one might proceed in the future. The examples deal mainly with PE, POM and PP.

McCrum and his colleagues varied thermal history to control relative amounts of amorphous and crystalline phase, and morphology¹. They were also concerned with the proper mechanical loss function ($\tan \delta$, decrement loss, modulus loss, compliance etc.) to use in describing the dynamic behaviour of crystalline composites as a function of χ_c ³⁵. Recently McCrum has worked with the so-called T jump method⁷⁸, as well as the effect of annealing *versus* quenching on mechanical loss in PE⁷⁹.

Takayanagi and his colleagues extended this work in several directions including modelling, i.e. series models, parallel models and mixed series-parallel models for the two phases; and secondly, study of single crystal mats in which the amorphous phase was extremely small in volume^{7,8,21,65}.

Illers has varied branching, crystallinity, morphology, radiation crosslinking and the use of diluents in studying the relaxation behaviour of polyethylene²²⁻²⁵.

Ward¹⁷⁻²⁰ has studied mechanical spectroscopy, coupled with other techniques, for highly oriented polyethylene. Takayanagi *et al.*²¹ have also used orientation as a tool in studying molecular motion as have Buckley and McCrum.

Kardos and Raison⁸¹ have proposed using very specific models based on analogues with two-component engineering composites. Thus, for the crystalline phase in PE, the spherulite is modelled as a two-dimensional disc whose radius is the lamellar crystal length. The bulk polymer is considered to consist of many such spherulites whose lamellae lengths are oriented principally in one plane of the flat specimen. Observed values of stiffness and thermal expansion vary with crystallinity and morphology in a manner consistent with such a model.

This listing by no means exhausts the names of workers or techniques devoted to mechanical loss in highly crystalline polymers. For example, we have proposed⁸² two simple models to describe respectively the effect of crystallinity on the glass temperature(s) of polymers and the variation in strength of the T_g and $T < T_g$ or T_β relaxations with crystallinity. Dielectric and n.m.r. studies have been reported extensively in the literature as an adjunct to mechanical loss.

However, all of the above considerations convince us that mechanical spectroscopy must be supplemented in the future by one or more techniques not currently in common use. The nature of the problems and the likely origins of the continuing controversy about T_g have been discussed in detail by McCrum⁸³. He concludes *inter alia* that the amorphous forms of linear crystalline polymers are not in all respects identical to the amorphous forms of other polymers and hence one must first define what is meant by the T_g of crystalline polymers.

For purposes of continuing discussion of this problem, we include Figure 3. This Figure shows three types of experimental results. The upper curve is the 0.2 Hz torsion pendulum plot for the T_g of ethylene-propylene copolymers as measured by Tuijman⁸⁴ and further modified in Figure 10.14 of ref 1. To the right of the minimum, as pure PE is approached, T_g is more generally known in the literature as T_β . The lower curve is a plot made by Illers⁸⁵ of dilatometric T_g values for another series of E-P copolymers,

Figure 3 Glass temperatures of ethylene/propylene copolymers as measured by 0.2 Hz torsion pendulum (●)⁸⁴; dilatometry with extrapolation to 100% amorphous PE by the Gordon–Taylor equation (■)⁸⁵; and e.s.r. spin probe technique (▲)^{87–89}

with extrapolation to a value for amorphous PE by the Gordon–Taylor copolymer equation. This places T_g of amorphous PE at Iller's well known value of 196K. The broken straight line is one sometimes found in the literature as the proper extrapolation to a T_g around 150K. We have argued elsewhere⁸⁶ against such a conclusion because the γ relaxation is found independently of T_g in all E–P copolymers for which there is no ambiguity about T_g , as well as in PE for which there is doubt.

The four square points at high ethylene content were obtained by an e.s.r. technique employing a nitroxide probe^{87–89}. We will comment more on this later but suggest for the moment that this probe technique reinforces the Iller's extrapolation via the Gordon–Taylor equation by measuring motion in the amorphous regions over small volume regions.

The main conclusion from Figure 3 is that a dynamic mechanical test on PE gives the T_g of a composite specimen. This T_g is real and is the proper value for such a highly crystalline two phase material. This is the T_g of amorphous material connected to the crystalline material probably at both ends, as in a loop²⁹. It is not the T_g of free (rejected) molecules or of cilia connected at only one end to the chain folded crystal²⁹. It is our belief that the T_g of such amorphous material within a composite semi-crystalline polymer can best be seen only with some type of molecular probe.

Molecular probes. There is nothing novel about proposing molecular probes to study motion in highly crystalline polymers. Bergmann⁹⁰ has demonstrated the power of the n.m.r. technique in revealing the onset of proton mobility in PE and other semi-crystalline polymers; North⁹¹ has recently reviewed the use of luminescence techniques, among which that of Guillet⁹² is prominent. Our own interest is in the use of nitroxide free radical probe molecules to detect the onset of molecular motion in amorphous and semi-crystalline polymers. There are several reasons for this choice: (a) ready availability of a variety of nitroxide probes of different molecular weights and shapes; (b) low level of additive needed (10–50 ppm) because of the extreme sensitivity of the e.s.r. technique; (c) ease of constructing calibration curves between a characteristic e.s.r. signal from a large probe and T_g values of known polymers^{87,89,93,94}; (d) indica-

tions are that smaller probes may be used to calibrate for the onset of motion at secondary relaxations⁹⁵.

A rather sophisticated application of the e.s.r. technique has been reported for PE by Bullock *et al.*⁹⁶ who have used the same nitroxide molecule both as a free probe and as a tag or label chemically bound to the backbone chain. This probe is smaller than any studied by us^{87–89}. It appears from their Figure 6 that this small probe may be responding to the γ relaxation even though the mechanical relaxation peak is normally insensitive to crystallinity variation^{22–25}. However, it may be responding to the amorphous phase T_g around 195K, which is presumably sensitive to crystallinity level. A firm conclusion about T_γ or T_g is not warranted in the absence of a calibration curve for this specific probe.

Finally, it appears from their Figure 5 as if the nitroxide tag is observing the β relaxation, i.e. the T_g of the composite. This would be the case if, for example, the tag were carried on a loop because it has been rejected by the chain folded crystal. It would then follow the motion of the loop, the motion we associate with T_β ²⁹. Bullock *et al.*⁹⁶ appear to believe that this label can rotate freely about the backbone chain, although forced to rotate anisotropically. In our experience, the drop in line width starting at about 250K would be consistent with seeing β motion.

Figure 4 is a schematic plot for PE combining the probe and label data of Bullock *et al.*⁹⁶ with results on two sizes of probes (both larger in size than Bullock's) by Rabold⁹³, as subsequently confirmed by the author and colleagues^{87–89,95}.

Figure 4 is intended to suggest possibilities for understanding complex relaxation spectra in semi-crystalline polymers by using free probes of different size in addition to tags.

Our current experience in using free nitroxide probes in semi-crystalline polymers is not free from problems^{87–89}. Four samples of PE gave T_g values of 201, 201, 220, and 233K, suggesting that probes are not always immune to morphological influences. Experience with POM, PEO and PVF have been satisfactory; that with PVDF is a complete failure for reasons not yet elucidated but probably connected with morphology^{87–89}.

In conclusion, we suggest that the e.s.r. probe and tag techniques will be a valuable adjuncts to, but not replacements for, mechanical spectroscopy. Other probe techniques

Figure 4 Line width vs. temperature by e.s.r. technique in PE for: A, very small probe showing either T_γ or amorphous T_g ⁹⁶; B and C, probes of increasing size showing amorphous T_g ⁹³; D, spin label⁹⁶ which appears to reveal T_β

are not thereby rejected. In fact, the dielectric probe studies of Davies and Edwards⁹⁷ for polystyrene might be cited. Although higher quantities of added probe are required, the essentially spherical molecule, camphor, *MW* 136, lies on a common curve with our nitroxide probes of molecular weight 172 and higher.

It will be suggested later that availability of high molecular weight fractions which are slow to recrystallize will permit examination of PE, PEO, POM and other such polymers by mechanical spectroscopy with no or only minor complications from crystallinity. The work of Illers²² suggests that moderate amounts of crystallinity may have little effect on the loss spectra of PE.

Computer simulation of in-chain sub-group molecular motions for addition polymers

As above, this section is concerned only with cases where the relaxing subgroup is identical in structure to the rest of the chain, as for example in linear PE for which the γ subgroup relaxation at $\sim 150\text{K}$ involves $-(\text{CH}_2)_n-$ where n is a small number, perhaps ≤ 7 . Boyd and Breiting have developed computer techniques involving both intra-chain and inter-chain barriers for simulating the motion of small units in the polymer backbone. This was first demonstrated for PIB only as an exercise in possible backbone chain motions, not in activated relaxation processes⁹⁸.

Such techniques were then extended to a conformational analysis of crankshaft motions in polyethylene⁹⁹⁻¹⁰⁰, namely the γ relaxation. Different proposals for crankshaft motion reported in the literature, such as the Schatzki or the Boyer crankshafts (Figure 5.8 of ref 1) could be examined rigorously. It is possible to calculate the intra-chain energetics and also to simulate the possible effects of the surrounding matrix. Even more recently a simulation has been made for the energetics of kinks in PE, using crystalline arrays of C_{14} , C_{18} and C_{22} linear paraffins¹⁰¹.

These simulation methods would appear to be limited ultimately by computer time and ingenuity in devising computational routines to shorten this time.

We are not concerned here with the important parallel task of devising models for specific sub-group motions such as the glycol unit in PET¹⁰², the phenyl side group in PS¹⁰³ or the generalized local mode motion in addition polymers¹⁰⁴, and analysing such motion either experimentally or theoretically or both.

Structure of the amorphous state and its possible effect on mechanical loss spectra

There is currently considerable world wide interest in the nature of the amorphous state in polymers¹⁰⁵⁻¹⁰⁹. One prevailing opinion, based on recent neutron scattering experiments, is that an amorphous polymer such as atactic PS or PMMA; or the melt of a crystallizable polymer; or an amorphous elastomer consists of an assembly of randomly coiled inter-penetrating molecules with each polymer chain having essentially theta dimensions¹⁰⁵⁻¹⁰⁷. Still uncertain is the extent of short range or local order, such as whether there might be a correlation of molecular orientation among neighbouring chains greater than expected for random coils but still less than will show long range order by scattering of X-rays, electrons or visible light. One study shows PS of *MW* 21 000 to 1.1×10^6 to be random to 10 \AA ¹¹⁰.

Now the mechanical relaxations with which we are concerned (with the possible exception of the $T_{l,1}$ process) involve relatively short sections of a polymer chain i.e. 20-30 monomers at T_g , 1-2 monomers at T_β and less than an

entire monomer unit at T_γ and T_δ . Hence, the question must be whether such local relaxations are sensitive to local order, if such exists.

We have studied on several occasions²⁹ a hypothesis by Bunn¹¹¹ that the empirical rule, $T_g(\text{K}) \cong (2/3)T_M(\text{K})$, is consistent with the presence of short range order in the amorphous phase. While one cannot prove this hypothesis conclusively, a number of facts are in harmony with it.

However as mentioned above, Amrhein *et al.*⁷⁵ have shown that dielectric loss curves of either iso- or syndiotactic PMMA in concentrated solutions (15 and 48%) in toluene occur at lower temperatures but are essentially similar to those of the bulk polymer. They conclude that intra-chain barriers to rotation are playing the dominant role in such motion. This would seem to suggest that the nature of the bulk state in these polymers plays no significant role beyond affecting free volume and hence the temperature at which a relaxation will occur. Presumably the relative intensities are also affected. Regions of demixing occur in the 15 and 40% solutions and act as crosslinks.

Ito and Hatakeyama^{112,113} have attempted to introduce local order into PET¹¹² and into polycarbonate¹¹³ by controlled orientation. Dielectric and mechanical loss do change in a very definite pattern with draw ratio. The frequency of the maximum in dielectric loss changed in the same manner at T_β as at T_g . They consider that the local mode process does reflect the structure of the glassy state. We cite these two papers as indicative of concern about relaxation spectra and structure of the glassy state.

We have attempted¹¹⁴ to explain the extreme breadth of the β relaxation in atactic polystyrene, namely from about 170 to 370K at 1 Hz, as arising from the extremes of variation of free volume in the glassy state. Following an argument of Robertson¹¹⁵, it has been assumed that a random array of matchsticks (polymer chains) will have only about 60% of the density of a regular parallel array, with many polymers showing an amorphous to crystalline density ratio of about 0.9. Therefore, one can visualize a free volume range from 0 to 40% with an average around 10%. An increase in T_g of 500 to 700K per cm^3/g decrease in free volume has also been estimated. We assume similar values might hold for T_β . Thus a range in free volumes from 0 to 40% might correspond to a spread in the β peak of 175-250K, in agreement with the observed value for atactic PS.

Finally it has been noted many low molecular weight glasses show β and T_g relaxations not too dissimilar in overall characteristics from those in polymers. For such glasses there can be only a short range, local liquid-like order with no long range physical connectivity between different parts of the glass, as in the case of polymers. It would appear from these simple considerations that local structure of the amorphous state other than distribution of free volume, may not play a role in glassy state relaxations. However, we mainly pose the problem for the future to answer.

Room temperature impact of glassy polymers in relation to glassy state relaxations

It is now known that the room temperature impact strength of polymers whose T_g is above room temperature may vary by several orders of magnitude. It is also known from the classical work of Bohn and Oberst¹¹⁶, as well as Staverman and Heijboer¹¹⁷, that for certain polymers room temperature impact is higher if a strong $T < T_g$ relaxation, a β peak in amorphous polymers, exists below room temperature (provided this is due to an in-chain and not a side

Figure 5 Tensile impact at room temperature plotted against the estimated frequency of the glassy state β or local mode relaxation at room temperature. The latter can be estimated from relaxation maps in ref 1. They may have torsion pendulum 1 Hz relaxation peaks at very low temperatures, i.e. nylon, 150–160K; PC, 180K. a, Amorphous; sc, slightly crystalline, c, crystalline

chain motion). This general topic has been reviewed both by Heijboer¹¹⁸ and by the present author¹¹⁹.

We have recently tried to refine the basic ideas of Bohn and Oberst with the hypothesis that room temperature impact should correlate with the measured or calculated frequency at room temperature of the most dominant subgroup in-chain motion. This frequency, determined dielectrically and/or mechanically, will be higher the lower is the temperature of the $T < T_g$ relaxation at 1 Hz and the higher its apparent energy of activation. Using scattered data from the literature on Izod, tensile impact and elongation at break, one could observe that high frequency of the subgroup motion at room temperature correlated well with high toughness. These data were presented in tabular form¹²⁰. Figure 5 shows a plot of tensile impact strength against log frequency. The scatter is considerable, which is not unusual in view of the nature of catastrophic tests and their sensitivity to flaws. Moreover, the data came from a variety of investigators.

Manson *et al.*¹²¹, aware of the above correlations, found that one characteristic parameter in fatigue studies, namely fatigue crack sensitivity, FCS , (rate of change of fatigue crack propagation per decade change in test frequency at room temperature) correlated with the room temperature jump frequency of the β process.

Sacher¹²² has shown a good correlation between toughness evaluated from stress-strain curves (Instron) and dynamic $\tan \delta$ (Rheovibron) at 11 Hz and 10°C.

It is evident in the two cases^{121,122} where one investigator(s) collects the data that the correlation found is significantly better than that shown in Figure 5. This clearly points out a future need.

Deformation and rupture processes in tough, glassy polymers pose a number of complex problems. We have enumerated some of them on a prior occasion (pp 342–347 ref 114). There is, however, a simple rationale for behaviour such as that shown in Figure 5. Application of a tensile stress generates a bias favouring rearrangement of bonds by rotation over energy barriers and/or free volume barriers. A high frequency of rotation in the absence of stress presumably facilitates such motion, leading to facile glassy state deformation in the presence of a stress. Argon has treated

the problem of deformation in glassy polymers in some detail (pp 411 ref 114).

There is now a rather dramatic new development in n.m.r. which can have a profound impact on the subject matter of this section. Schaefer *et al.*¹²³ have shown that by use of ¹³C n.m.r. with magic angle spinning, the motion of chemically unique carbon atoms in the main chain and side chain of bulk polymers can be followed in detail. Thus, they have been able to differentiate between the frequencies of motion of the 5 carbon atoms of a monomer residue in the PMMA chain. Each one has a characteristic frequency and some of the frequencies are quite high (especially $-\text{CH}_2-$ and $\text{CH}_3-\text{O}-$ groups) in comparison with the normal 1 Hz mechanical motion associated with the β relaxation. Thus far, such measurements have not been made as a function of temperature¹²⁴.

Schaefer and his associates^{125,126} have now extended this work to obtain a correlation between motions of carbon atoms in a selected group of polymers and notched impact strength. They observe crosspolarization relaxation times, T_{CH} , which contain information in the near zero frequency range; and ¹³C rotating frame relaxation times, $T_{1\rho}$, which contain information about motion in the 10–50 kHz range. An empirical correlation shows that a high ratio of $T_{\text{CH}}/T_{1\rho}$ is associated with high notched impact strength and *vice versa*. It seems clear that a technique such as this which follows motion of individual carbon atoms in bulk polymers can really help to clarify all types of mechanical behaviour problems such as crazing, shear band yielding, creep and impact strength, especially once such measurements are made over a range of temperatures.

Amorphous state of rapidly crystallizing polymers and copolymers

This topic naturally relates to the section on molecular probes for highly crystalline polymers but has been deferred because of required background material in subsequent sections.

We have stated on an earlier occasion²⁹ that certain questions relating to T_g for the amorphous state of highly crystalline polymers such as PE, PEO, POM, etc. will not be answered unambiguously until the amorphous state of such systems is achieved experimentally. Several recent events have revived our interest in this topic as one for much consideration in the future.

The first is that Hendra *et al.*¹²⁷ have reported the preparation via rapid quenching of amorphous PE and its subsequent recrystallization as a function of temperature. I.r. crystalline bands at 720 and 730 cm^{-1} were used as the measure for crystallinity. They conclude from the development of these bands with temperature of subsequent annealing that T_g of amorphous PE must lie below 190K, presumably because recrystallization normally occurs only above T_g . While we accept their experimental findings without reservation, some caution is indicated concerning their conclusion on T_g in view of material produced above especially Figures 3 and 4, and considerations introduced.

Without trying to pre-judge this matter categorically, we suggest that their results are not inconsistent with an amorphous T_g of about 195K for the following reasons.

(1) Order present in the crystalline material is not necessarily completely destroyed by a simple melting regime. Short range order reported by Zachmann¹²⁸ for PE melts could then be preserved in the quenched specimens, predisposing them to recrystallize, especially with the marked undercooling.

(2) Semi-crystalline PE shows²²⁻²⁵ 1 Hz torsion pendulum loss peaks at 108K in the crystalline regions and at 138 and 163K in amorphous regions which may be subject to some restraint by the crystallites. As noted above, especially in regard to Figure 5, 1 Hz loss peaks at low temperature can move much more rapidly at elevated temperatures. Hence frequencies of 10^4 – 10^6 Hz in the region of 180–200K are not unlikely. An e.s.r. spin probe (Figure 6, ref 96) is probably rotating at 10^6 Hz at 190K and 10^8 Hz at 210K. This does not prove, of course, that chain segments are moving this rapidly.

(3) The absence of side groups favours recrystallization.

(4) Their PE specimen is a commercial material and, hence, heterodisperse. Limited evidence above suggests that all glassy transitions decrease in temperature with decreasing molecular weight so that transition temperatures just given may be considerably lower for short chains and effective frequencies at 180–200K higher than estimated.

(5) Nylon-6,6 recrystallizes at temperatures some 80K below its nominal T_g ¹²⁹, which most likely is a result of the prominent 1 Hz γ loss peak in nylons around 150–160K*.

The issues we have raised are amenable to experimental attack but would seem to require a high molecular weight monodisperse PE (a fraction) with a carefully controlled history in the melt.

The other recent development is that MacLaine and Booth¹³⁰ have succeeded in preparing by fractionation amorphous high molecular weight PEO and following its rate of recrystallization. A fraction of MW 1.6×10^6 had a limiting fractional crystallinity of 0.4 when recrystallized at 57°C.

We were able to obtain a small amount of a fraction having MW 1.1×10^6 in order to check T_g by several methods¹³¹. A preliminary d.s.c. run on a Perkin–Elmer II unit by MacDonald¹³² showed no evidence for a T_g but did give a strong endotherm at T_M . It appears that the specimen had become highly crystalline while held at ambient temperature for four months. The maximum rate of recrystallization for PEO occurs at 20°–25°C¹³³, consistent with the d.s.c. observations. Quenching from just above the melt generated a small amount of amorphous material. Other parallel studies of melting for 2½ h at 100°C and for 10 min at 130°C were insufficient to remove all crystallinity. Thus high molecular weight and monodispersity slow down recrystallization and also remelting.

Our experience with e.s.r. at a frequency of 10^7 Hz indicates that since T_{50G} is usually 40°–50°C above T_g , rapid recrystallization may occur during e.s.r. measurements, entrapping the probe molecule and leading to a high estimate of T_g .

At the moment enough has been done to demonstrate the preparation of amorphous PE and PEO. Dynamic mechanical measurements on such amorphous materials remain for the future.

New polymer types

One can predict the appearance of challenging new polymer types without being specific. One need only consider the challenges presented by two-phase polymer systems: block, graft, interpenetrating polymer networks, and poly-

blends. The advent of a class of synthetic polymers with rings in the chain (polycarbonates, poly(phenylene oxides), polysulphones, etc.) generated a new set of problems, especially when considering mechanical properties via a vis relaxation spectra. The ionomers²⁶ were mentioned very briefly above as possibly being at the threshold of some surprising new developments, especially in view of unpublished work by Eisenberg¹³⁴ as, for example, a new peak above T_g which correlates in intensity with ion content.

CONCLUSIONS

The areas chosen as likely candidates for future effort in mechanical spectroscopy cover apparatus, materials and experimental as well as theoretical techniques. Most of them, understandably, are areas in which we have had a strong interest and/or some measure of interaction in the recent past. It is evident that progress made on the mechanical spectroscopy of polystyrene^{48,49}, both above T_g and at low molecular weights, was heavily dependent first on the automation of the t.b.a. equipment⁴ and second on the commercial availability of anionic polystyrenes from 600 to 2×10^6 MW. Many polymers, such as PMMA, are not readily amenable to preparation by living polymer techniques. Until sizeable fractions (1–10 g) of narrow distribution atactic, isotactic and syndiotactic PMMA are available by any means, progress in studying these materials will lag far behind PS. The same can be said of poly(vinyl acetate), poly(isobutylene), polypropylene, PVC and many other polymers. Any simple technique to give high molecular weight fractions of PE, PEO, POM, PVDF, PVF and other rapidly crystallizing polymers will be tremendously important. Therefore, the pace of progress in the near future – five to ten years – will rest heavily on automation of mechanical spectroscopy to simplify acquisition of data; on easy availability of good, relatively monodisperse materials; on new polymer types; and on characterization breakthroughs, in related fields, as in ¹³C n.m.r.^{123–126} and e.s.r.^{87–96}.

Failure to include any results based on dielectric techniques was dictated almost entirely by a need to limit the scope of this article, and not by any lack of appreciation for this powerful tool. If one could cite a single example, it is the dielectric study by Irvine and Work¹³⁵ on copolymers of *para*-methyl- and *para*-chloro-styrenes in order to elucidate the nature of the δ relaxation mechanism in polystyrene. North¹³⁶ has a recent review on dielectric relaxation, with special reference to two phase systems.

* Personal discussions with Hartley and Lord in Manchester in March 1976 reveals that they consider the above results to be based on an artifact. A recent paper, Lord, F. W. (*Polymer* 1974, 15, 42) shows ordering but not recrystallization in the glass state below T_g i.e. from 20°–40°C. Crystallization occurs only some 30°–40°C above T_g . Nylons are dominated by hydrogen bonding which is absent in PE.

Syntheses and conformational studies of poly(*S*-menthyloxycarbonylmethyl L- and D-cysteines)

Tadao Hayakawa, Yoshiyuki Kondo and Masayo Matsuyama

Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda 386, Japan

(Received 14 May 1976)

S-menthyloxycarbonylmethyl L- and D-cysteines were prepared by the reaction of L- or D-cysteine and (–)-menthyl chloroacetate in liquid ammonia and were then polymerized to poly(*S*-menthyloxycarbonylmethyl L- and D-cysteines) by the *N*-carboxyanhydride (NCA) method. From the results obtained by means of infra-red spectra, X-ray diffractions, optical rotatory dispersions (o.r.d.), and circular dichroisms (c.d.), poly(*S*-menthyloxycarbonylmethyl-L-cysteine) was found to be a right-handed α -helix in the solid state and in ethyl ether/chloroform and chloroform solutions. Similarly, poly(*S*-menthyloxycarbonylmethyl-D-cysteine) was a left-handed α -helix. The helix–coil transition of these polymers was observed in the vicinity of 3–4% trifluoroacetic acid (TFA) in chloroform/TFA mixtures.

INTRODUCTION

Considerable interest has recently been shown in the conformation of many synthetic poly(α -amino-acids) and proteins in the solid state and in solution. The conformation of a polypeptide is intrinsically dependent on its amino-acid composition, and it can form an α -helix, a β -structure, or a random coil conformation. It has been reported that polypeptides with a hetero-atom (oxygen or sulphur) attached directly to the β -carbon atom, such as poly(L-cysteine) and poly(L-serine) derivatives form a stable β -structure¹; in coil promoting solvents, such as DCA and TFA, they are in a random coil. However, poly(L-homocysteine) derivatives with a hetero-atom attached to the γ -carbon in the side chains, assume the α -helix conformation^{2,3}.

Poly(*S*-benzylthio-L-cysteine)⁴ and poly(*S*-benzylpenicillamines)⁵ are in the ω -helical conformation due to the steric interference between the side chain and main chain. Since polycysteine derivatives are hardly soluble in most common organic solvents, o.r.d. and c.d. measurements in the far ultra-violet region are very difficult.

In the present study, *S*-menthyloxycarbonylmethyl L- and D-cysteines were prepared by the reaction of L- or D-cysteine with (–)-menthyl chloroacetate and were polymerized to poly(*S*-menthyloxycarbonylmethyl L- and D-cysteines) by the NCA method. The forms of the poly(*S*-menthyloxycarbonylmethyl L- and D-cysteines) are as follows:

The polymers were soluble in many organic solvents, such as chloroform, methylene chloride, benzene, dioxane, DCA and TFA, were slightly soluble in diethyl ether and

n-hexane, and were insoluble in water and alcohols. The conformations of the polymers were studied by o.r.d., c.d., infra-red spectra, and X-ray diffractions, in order to investigate the effect of their side chains with optically active groups on the polypeptide structure.

EXPERIMENTAL

Materials

(–)-Menthyl chloroacetate. 9.45 g of monochloroacetic acid, 15.2 g of (–)-menthol, and 1.88 g of *p*-toluenesulphonic acid monohydrate were mixed with 150 ml of benzene. The mixture was heated under reflux, and the nascent water was removed azeotropically by means of a Dean and Stark distillation apparatus. After the solvent was removed, the residue was distilled under reduced pressure; yield 19.0 g (83.0%); b.p. 140°–144°C at 25 mmHg; $[\alpha]_D^{25^\circ\text{C}} = -112.2$ ($c = 0.13\%$ in EtOH).

S-menthyloxycarbonylmethyl-L-cysteine. 5.7 g of L-cysteine in 150 ml of liquid ammonia were treated with small pieces of metallic sodium, with stirring until a lasting blue colour was obtained. To this solution 10.0 g of (–)-menthyl chloroacetate were slowly added. 4.8 g of ammonium chloride were then added, the solvent was allowed to evaporate, and the residue was taken up in 200 ml of water and brought to pH 6.8 under cooling. The crystals thus precipitated were filtered and dried yielding 9.8 g, and were then recrystallized from methanol and ether; yield 6.5 g (52.2%); m.p. 149°C; $[\alpha]_D^{25^\circ\text{C}} = -64.1$ ($c = 0.55\%$ in MeOH). Calculated for C₁₅H₂₇O₄NS: C = 56.75%; H = 8.57%; N = 4.41%; found: C = 56.31%; H = 8.38%; N = 4.49%.

S-menthyloxycarbonylmethyl-D-cysteine was prepared from the D-cysteine and (–)-menthyl chloroacetate by the same procedure as above; yield 4.38 g (27.6%); m.p. 156°C; $[\alpha]_D^{25^\circ\text{C}} = -27.0$ ($c = 0.56\%$ in MeOH). Calculated for C₁₅H₂₇O₄NS: C = 56.75%; H = 8.57%; N = 4.41%; found:

Figure 1 O.r.d. spectra of poly(*S*-menthyloxycarbonylmethyl *L*- and *D*-cysteines) in an ethyl ether/chloroform, 95/5 (v/v) mixture at 22°C. A, Poly(*S*-menthyloxycarbonylmethyl-*L*-cysteine); B, poly(*S*-menthyloxycarbonylmethyl-*D*-cysteine)

C = 57.27%; H = 8.57%; N = 4.12%.

S-menthyloxycarbonylmethyl-*L*-cysteine NCA. *S*-menthyloxycarbonylmethyl-*L*-cysteine NCA was prepared from the corresponding cysteine derivative and phosgene by the usual procedure; yield 58.2%; m.p. 95.5°C. Calculated for C₁₆H₂₅O₅NS: C = 55.95%; H = 7.33%; N = 4.08%; found: C = 55.87%; H = 7.32%; N = 4.00%. *S*-menthyloxycarbonylmethyl-*D*-cysteine NCA was prepared by the same procedure; yield 83.3%; m.p. 77.0°C. Calculated for C₁₆H₂₅O₅NS: C = 55.95%; H = 7.33%; N = 4.08%; found: C = 55.78%; H = 7.30%; N = 4.03%.

Poly(*S*-menthyloxycarbonylmethyl-*L*-cysteine). The above NCA (1.9 g) was polymerized in benzene with triethylamine as an initiator at NCA/initiator ratios of 50/1; yield 1.02 g (61.9%). Calculated for (C₁₅H₂₅O₃NS)_n:

C = 60.11%; H = 8.35%; N = 4.68%; found: C = 59.78%; H = 8.42%; N = 4.61%. $[\eta] = 0.243$ (in DCA at 25°C ± 0.05°C). N-terminal titration, $MW = 25\,600$ ($DP = 80$). Poly(*S*-menthyloxycarbonylmethyl-*D*-cysteine) was prepared by the same method as mentioned above; yield 54.8%. Calculated for (C₁₅H₂₅O₃NS)_n: C = 60.11%; H = 8.35%; N = 4.68%; found: C = 59.58%; H = 8.65%; N = 4.52%. $[\eta] = 0.213$ (in DCA at 25°C ± 0.05°C). N-terminal titration, $MW = 12\,000$ ($DP = 40$).

Methods

The molecular weights were determined from the titration of the polymer in benzene with HClO₄/acetic acid, using crystal violet as the indicator. The viscosities were measured in DCA at 25°C using an Ubbelohde viscometer. Infra-red spectra were measured with a JASCO Model DS-301 spectrophotometer at 22°C. Infra-red spectra of the solutions of the polymers were measured in a tube of polyethylene film. X-ray diffraction photographs were taken using a Rigaku-Denki Geigerflex with a Cu target. C.d. and o.r.d. were measured with a JASCO ORD/UV-5 spectropolarimeter with a c.d. attachment at 22°C. The c.d. and o.r.d. measurements were performed with 0.1 and 1 mm cells from 260 to 200 nm, and with 10 and 50 mm cells in the visible region. The concentration of the polymers was between 0.1 and 1.0 vol%. The c.d. and o.r.d. were expressed, respectively by the molecular ellipticity, $[\theta]$, and the reduced residual rotation, $[m']$.

Figure 2 C.d. spectra of poly(*S*-menthyloxycarbonylmethyl *L*- and *D*-cysteines) in an ethyl ether/chloroform, 95/5 (v/v) mixture at 22°C. A, Poly(*S*-menthyloxycarbonylmethyl-*D*-cysteine); B, poly(*S*-menthyloxycarbonylmethyl-*L*-cysteine)

RESULTS AND DISCUSSION

Infra-red studies and X-ray analyses

Poly(S-menthyloxycarbonylmethyl L- and D-cysteines) showed infra-red absorption bands characteristic of polypeptides both in the solid state and in chloroform solution (Table 1). Both the L- and D-polymers gave almost the same infra-red spectra. The amide I and the amide II bands were found at about 1660 cm^{-1} and 1550 cm^{-1} , respectively. The X-ray diffraction patterns of the L- and D-polymers indicated the presence of a 13.6 \AA reflection. The marked spacing at 13.6 \AA corresponds to the helix-helix interval of the α -helical polypeptides, as has been reported by Bamford *et al.*⁶ The result of the X-ray diffraction diagram coincides well with that of the infra-red spectra.

Optical rotatory dispersion and circular dichroism

The o.r.d. and c.d. of poly(S-menthyloxycarbonylmethyl L- and D-cysteines) in ethyl ether/chloroform, 95/5 (v/v) were measured. Figure 1 shows the o.r.d. curves of the L- and D-polymers in ethyl ether/chloroform 95/5 (v/v). The L-polymer exhibits a broad trough at 233–235 nm with $[m']_{233} = -14\,500$ degree cm^2/dm , a crossover point of $[m']$ at 224 nm, a strong peak near 204 nm with $[m']_{204} = 49\,000$ and a shoulder near 217 nm with $[m']_{217} = 13\,000$. The c.d. curves are shown in Figure 2. The o.r.d. and the c.d. spectra correspond well with each other. Two negative dichroism bands at 221 nm and

Figure 3 Helix-coil transition of poly(S-menthyloxycarbonylmethyl L- and D-cysteines) in chloroform/TFA mixtures at 22°C . A, Poly(S-menthyloxycarbonylmethyl-D-cysteine); B, poly(S-menthyloxycarbonylmethyl-L-cysteine)

Figure 4 O.r.d. and c.d. spectra of poly(S-menthyloxycarbonylmethyl L- and D-cysteines) in a chloroform/TFA 96/4 (v/v) mixture at 22°C . Poly(S-menthyloxycarbonylmethyl-D-cysteine): A, o.r.d.; B, c.d. Poly(S-menthyloxycarbonylmethyl-L-cysteine): C, c.d.; D, o.r.d.

210 nm, with $[\theta]_{221} = -44\,000$ and $[\theta]_{210} = -43\,000$ and a zero point at 203 nm were observed for the L-polymer; a positive dichroism band below 200 nm can be expected. The polymer gave also similar curves in chloroform solution. From these o.r.d. and c.d. measurements, the L-polymer can be considered to have a right-handed α -helical conformation in an ethyl ether/chloroform mixture and in chloroform solution⁷. On the other hand, the o.r.d. and c.d. curves of the D-polymer have a peak at 233–235 nm with $[m']_{235} = 15\,200$ and the positive dichroism bands at 221 nm and 210 nm, with $[\theta]_{221} = 39\,500$ and $[\theta]_{210} = 35\,100$. This result suggests that the D-polymer can be considered to have a left-handed α -helical conformation in solution⁷. The o.r.d. trough (or peak) at about 233–235 nm, and the magnitude of the negative (or positive) c.d. band of $[\theta]_{210}$, is somewhat different for the L-polymer and the D-polymer. This result signifies that the asymmetry of the (–)-menthyl chromophore in their side chains causes an extraordinary rotational strength. The conformational changes of the L- and D-polymers in chloroform and in a chloroform/TFA mixture have been studied. The plots of the specific rotation $[\alpha]_{400}$ values versus the solvent composition of these

polymers in solution are shown in *Figure 3*. In 100% chloroform, the $[\alpha]_{400}$ of the L-polymer is -190 . When TFA is added to the chloroform solution, its levorotation increases markedly. In a chloroform/TFA mixture 98/2 (v/v), it decreases to a minimum value of -341 , finally reaching the $[\alpha]_{400} = -332$ at about 4% TFA. On the other hand, in 100% chloroform, that of the D-polymer is -78 . With the addition of TFA, it increases to a maximum value of $+46.3$ at 1.5% TFA, finally reaching $+44.0$ at above 2.5% TFA. *Figure 4* shows the o.r.d. and c.d. curves of the L- and D-polymers in a chloroform/TFA mixture 96/4 (v/v), characteristic of the random coil conformation. There is a 237 nm trough (or peak), a 226 nm peak (or trough), and a trough (or peak) below 210 nm in the o.r.d. curves, and a small negative (or positive) dichroism band at 230 nm in the c.d. curves. This means that a small amount of TFA causes a drastic conformational transition from an α -helix to a random coil conformation. However, the absolute magnitude of the $[m']_{237}$ and $[\theta]_{230}$ are larger than those of usual polypeptides^{7,8}, and differ for the L-polymer and the D-polymer. This may be due to the influence of the (-)-menthyl groups in their side chains.

As described above, the o.r.d., c.d., infra-red spectra, and X-ray results suggest that poly(*S*-menthyloxycarbonylmethyl L- and D-cysteines) in helix promoting solvents take the α -helical conformation. This could be interpreted as indicating that these polymers form an α -helix because of the stacking of the menthyl groups in their side chains. In the case of poly(*S*-alkyl cysteine), the steric interference between the side chains and the main chain forms a stable

β -structure⁹⁻¹³, however, it is interesting that poly(*S*-menthyloxycarbonylmethyl L- and D-cysteines) form an α -helix because of the influence of the menthyl groups in their side chains.

Phosphonitrilic chloride : 34. Electrical conductivity of polybisaminophosphazenes

M. Kajiwara and H. Saito

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

(Received 10 May 1976)

The electrical conductivity of polybisaminophosphazenes investigated over a range of temperatures was found to obey the general relation for semi-conductors. The resistivity decreased or increased when a side group having a high inductive effect or bulky group was linked in the polymers. The electrical conductivity of polybisaminophosphazenes containing primary amine, secondary amine and aromatic amine ranged from 1.3×10^{10} to 2.8×10^{10} Ω -cm, 9.3×10^{10} to 8.5×10^{11} Ω -cm and above 9.1×10^{14} Ω -cm, respectively.

INTRODUCTION

Eley and Wills¹ and Reucroft² described the electrical conductivity of single crystals or powdery dichlorocyclophosphazene (NPCl₂)₃ and dichlorocyclophosphazene (NPCl₂)₄. Allcock and Best³ reported electrical conductivity of liquid dichlorocyclophosphazene and thereby explained its polymerization mechanism. Recently, the conductivity of some phosphazene chelating polymers was described by Kajiwara^{4,5}. This paper describes the conductivity of polybisaminophosphazenes.

EXPERIMENTAL

Dichlorocyclophosphazene (NPCl₂)₃ was prepared by a method previously described⁶ and polymerized as described by Gimblet⁷.

Polybis(ethylamino)phosphazene [NP(NHC₂H₅)₂]_n (I), polybis(n-propylamino)phosphazene [NP(n-NHC₃H₇)₂]_n (II), polybis(n-butylamino)phosphazene [NP(n-NHC₄H₉)₂]_n (III), polybis(hexylamino)phosphazene [NP(NHC₆H₁₃)₂]_n (IV), polybis(allylamino)phosphazene [NP(NHCH₂CHCH₂)₂]_n (V), polybis(dimethylamino)phosphazene {NP[N(CH₃)₂]₂]_n (VI), polyaminodiethylaminophosphazene [NP(NH₂)N(C₂H₅)₂]_n (VII) and polybis(phenylamino)phosphazene [NP(NHC₆H₅)₂]_n (VIII) were synthesised by the methods of Allcock^{8,9}.

The electron conductivity of polybisaminophosphazenes

was investigated using the apparatus described by Kajiwara⁴.

The value of the electrical conductivity (ρ) was estimated by equation (1):

$$\rho = RA V/L \quad (1)$$

where R is the electrical resistance, A the plate area (1.3773 cm²), L the sample thickness (cm), and V is the volume fraction. Polybisaminophosphazenes were moulded under pressures 200–300 kg/cm².

Infra-red (i.r.) spectra of the polymers were obtained using the pressed KBr disc technique with a Shimadzu Co. IRG-2 type spectrometer.

RESULTS AND DISCUSSION

Yield and appearance of the polymers formed from the reaction of polydichlorophosphazene (NPCl₂)_n with each amino compound are summarized in Table 1.

The polybisaminophosphazenes were soluble in THF and the P = N frequency in P₃N₃ ring of the polymers appeared in the region of 1200 to 1300 cm⁻¹.

The relationship between the resistivity of the polymers I–V and temperature is shown in Figure 1 and the energy gaps of the polymers calculated from the general relation of semi-conductors are summarized in Table 2.

The glass transition temperature of the polymers I, IV and V appears at about 45°–80°C as shown by the drastic

change of resistivity with increasing temperature. The resistivity at 25°C is decreased since the inductive effect is increased with increasing number of carbon atoms in the pendant group.

The activation energies and the resistivity of secondary

amino phosphazene polymers is lower than the values of primary amino phosphazene polymers, and this may be ascribed to the inductive effect of secondary amine linked in a side group. Furthermore the resistivity of the anilinophosphazene polymer, at room temperature is so high that it is difficult to measure. However, the resistivity decreased on heating and the polymer showed a glass temperature of 91°C. The resistivity of the benzylaminophosphazene polymer was too high to measure even with the heated polymer.

Use of differential scanning calorimetry to study polymer crystallization kinetics

J. N. Hay*, P. A. Fitzgerald† and M. Wiles‡

Department of Chemistry, University of Birmingham, Birmingham B15 2TT, UK

(Received 17 March 1976; revised 1 June 1976)

The use of differential scanning calorimetry to determine accurate crystallization parameters is reconsidered by direct comparison with dilatometry. Two calorimeters are compared: Perkin-Elmer DSC models 1B and 2. Fractions of polyethylene are studied since their rate constants have a marked temperature dependence which enables the accuracy of setting and calibrating the temperature of the calorimeters to be gauged. The resolutions of the calorimeters are compared from their abilities to detect secondary crystallization. The limitations of d.s.c. and the choice of operating conditions are discussed.

INTRODUCTION

In a previous publication¹ the limitations of a differential scanning calorimeter, DSC-1B, in measuring directly isothermal crystallization data were discussed. It was concluded that the d.s.c. was not as sensitive as precision dilatometry in detecting low rates of crystallization, but nevertheless the time dependence of crystallization could be obtained at higher rates with sufficient accuracy to test the validity of rate equations. Care, however, was necessary in setting and calibrating the temperature, as rate variations between repeated isothermal crystallizations were consistent with an error of $\pm 0.3\text{K}$.

Since this report, d.s.c. has been considerably improved with the introduction of the Perkin-Elmer DSC-2. We now report on its use in crystallization kinetics.

EXPERIMENTAL

Materials

Polyethylene (Marlex 60) fractions, supplied by Phillips Petroleum Co. Ltd, were used. Their characteristics are listed in Table 1.

Apparatus

Dilatometry has been described previously². Perkin-Elmer Differential Scanning Calorimeters, models DSC-1B and DSC-2, were used with powder samples (1.0–30.0 mg) weighed to 0.01 mg on a microbalance, and sealed in aluminium sample holders. An empty aluminium sample holder was used as a reference.

DSC-2 could be used at a constant temperature (preset to 0.1K) by heating or cooling from temperatures also preset to 0.1K at rates from 0.312 to 320 K/min. For comparison the DSC-1B rates were from 0.50 to 64 K/min and temperatures set to 1K. The temperature scale of the DSC-2 was calibrated for the effect of sample size and rate of heating from the melting characteristics of zone refined

stearic acid (343.2K) dibenzyl (325.3K) and ultra-pure metals, indium (429.8K) and tin (505.0K). Extrapolation to zero rate of heating was used to calibrate constant temperature. Over this range (340–500K) temperature corrections were linear with temperature. This was a considerable improvement over that of the DSC-1B, which exhibited pronounced curvature¹. For calibration, the heat of fusion of indium was taken as 28.45 J/g.

Analysis of the crystallization isotherms

The crystallization–time dependence was analysed by means of the Avrami equation:

$$(X_{\infty} - X_t)/(X_{\infty}) = \exp(-Z_1 t^n) \quad (1)$$

where X_t and X_{∞} are the weight fraction of crystallized material at time t , and ∞ ; Z_1 is the rate constant and n the exponent.

Accordingly,

$$\log\{\ln[(X_{\infty})/(X_{\infty} - X_t)]\} = n \log t + \log Z_1 \quad (2)$$

and

$$n = -t(dX_t/dt)/\{(X_{\infty} - X_t) \ln[(X_{\infty} - X_t)/(X_{\infty})]\} \quad (3)$$

The rate constant Z_1 was calculated from the half life, $t_{1/2}$, and the average value of n , since:

$$Z_1 = \ln(2)/t_{1/2}^n \quad (4)$$

D.s.c. measures the rate of evolution of the enthalpy of

crystallization (dH_t/dt) as a function of time. The rate curves were processed by integrating to determine the relative extent of crystallization as a function of time, i.e. by assuming:

$$X_t/X_\infty = \frac{\int_0^t (dH_t/dt) \cdot dt}{\int_0^\infty (dH_t/dt) \cdot dt} \quad (5)$$

RESULTS AND DISCUSSION

Primary crystallization

Rate measurements were restricted by the sensitivity of the calorimeter (0.4–8.5 μJ/sec), sample size (up to 30 mg), and the enthalpy of crystallization (300 J/g). For polyethylene this limited the study to crystallization with half lives between 2–200 min, and to a range of 5–7K. With polymers which crystallize less readily than polyethylene, these restrictions severely limit their study. Dilatometry is not so restricted since it measures the extent of crystallization directly rather than the rate.

The isothermal extent of crystallization–time plots obtained with the DSC-2 was similar in most details to those obtained with DSC-1B and by dilatometry (see Figure 1 of ref 1). The reproducibility of the plots, however, was improved compared with those obtained with the DSC-1B, since the automatic temperature control enabled the temperature to be reproduced to 0.1K. Figure 1 exhibits the

effect of varying the temperature of crystallization by ±0.1K at 396.0K (sample B). The crystallization at 396.0K was repeated 10 times and the scatter in the superimposed rate curves used as a measure of the error in setting the temperature. This was ±0.025K. The method must be considered a maximum error since it attributes all variations, recorder speed and setting the initial onset of crystallization, to an error in temperature.

Analysis of the crystallization rate–time dependences by equations (1) to (5) indicated that two processes were present² which could be separated on a time scale. Following Banks *et al.*³, X_∞ for the primary stage was used as an adjustable parameter and a value was selected which gave a constant value of *n* over most of the primary process. Rate constants, Z_1 , and values of *n* obtained in this way are listed in Table 2. Dilatometry and both DSC's gave similar rate constants with the same temperature dependence, indicating that the primary process was being measured to a similar extent by the methods.

Variations in the rate constants were considered to be due to errors in the procedures adopted for calibrating and setting temperature (0.3K in DSC-1B). This can be seen by directly comparing the crystallization rate curves. For this purpose the time interval between attainment of constant temperature and maximum crystallization rate, t_{max} , was selected as an experimental parameter independent of the choice of X_∞ and the analyses procedure adopted. No sample size dependence was observed with the DSC-2 in the weight range (1–30 mg), (see Figure 2) and all three methods exhibited the same temperature dependence.

Figure 2 Sample size effects: ●, 15.0 mg; ▲, 10.0 mg; ○, 5.2 mg

Figure 3 Reproducibility of crystallization characteristics within the methods: ●, DSC-1B; ○, DSC-2; □, dilatometry

Figure 4 Analysis of crystallization isotherms for sample B from equation (2). ●, 398.8K; △, 399.3K; ■, 399.8K; ●, 400.8K

Assumption of an error of 0.3K in the DSC-1B temperature calibration alone was sufficient to superimpose all the data, (see Figure 3).

It would also appear that t_{max} might be a more accurate means of calibrating constant temperature of the calorimeters than linear extrapolation of the melting points of zone-refined materials determined at various rates of heating to zero rate.

Secondary crystallization

It was observed previously¹ that differences existed between the integrated DSC-1B and dilatometric crystalliza-

tion extent-time plots, in that the slow increase in crystallinity with time attributed to secondary crystallization was not present in the calorimeter determined plots. Despite this, analyses of the DSC-2 determined plots by equation (2) indicated that there was a change in mechanism at about 85–95% of the measured crystallinity in that the exponent changed from 2.5–3.0 to about 1.0, (see Figure 4). The lower rates, inherent in secondary crystallization, meant that the process could only be followed over a limited time period and also a limited temperature range. The rate parameters, obtained from equations (2) and (4) using $n = 1.0$, are listed in Table 3. Apparently conflicting results were

		401.5	1.0	0.0021

* Assuming $n = 1.0$

Figure 5 Secondary crystallization for sample B. A, 399.8K; B, 398.8K; C, 397.5K

obtained, in that with sample B, both dilatometric and calorimetric measured rate constants are very similar, and with sample C, very different values were obtained. However, dilatometry indicates that the secondary process of sample C is much slower than that of B, to such an extent that it would not be detected to any appreciable conversion by DSC-2. Furthermore, it is unlikely that it could be separated from the final traces of the primary process.

The sensitivity of the calorimeter required to determine the primary process severely restricted the use of the calorimeter to detect secondary crystallization, and no faith could be placed on the rate parameters determined. An alternative procedure was adopted by which the crystallization was followed to 80–90% apparent completion, and then the sensitivity of the calorimeter increased to a maximum ($0.4 \mu\text{J}/\text{sec}$). The remaining rates of crystallization were followed to completion at this increased sensitivity. As before, the increased crystallinity was obtained by integrating [from the arbitrary initial point (X_∞) to the experimental point (X_c, t)]. An increase in crystallinity with logarithmic time was observed with sample B which closely paralleled the dilatometric observation² (see *Figure 5*) and indicated that secondary crystallization was present but its extent limited by the calorimeter sensitivity.

CONCLUSIONS

DSC-2 can be applied to the study of isothermal crystallization kinetics provided the rate is sufficiently large. Rates can be measured to lower values ($\times 0.1$) than can be measured by DSC-1B.

The isothermal crystallization–time curves are more reproducible with DSC-2 because of the improved temperature setting (to 0.1K), and the maximum variation in temperature setting is $\pm 0.025\text{K}$.

Despite the improved sensitivity of DSC-2, it is more restricted than dilatometry in measuring low rate of crystallinity. This severely limits its use in studying secondary crystallization processes. Its main advantages, however, are in the speed and accuracy of use, and also the small samples required (1–2 mg). This has obvious advantages in characterizing the crystallization behaviour of polymer fractions for which small samples may only be available.

There may also be some advantage in using the crystallization rate characteristics of standard polymer samples to calibrate the temperature of the calorimeter.

Contributions to the proton relaxation of poly(ethylene oxide) in benzene solutions

F. Heatley and I. Walton

Chemistry Department, University of Manchester, Manchester M13 9PL, UK
(Received 27 May)

It is clear from recent studies of polymer motion in solution using nuclear magnetic relaxation¹⁻³ that the auto-correlation functions for reorientation of internuclear vectors are often far from exponential, and full characterization of the motion requires the measurement of several relaxation parameters. Because of the simplicity of interpretation, ¹³C spin-lattice relaxation times (T_1) and nuclear Overhauser enhancements (NOE) are extremely valuable for this purpose^{1,3}, but it has been shown³ that further data is required to distinguish between various models of the reorientation process. An obvious source of such data is ¹H relaxation, since almost all synthetic polymers contain ¹H nuclei and general application is possible. However whereas ¹³C relaxation is practically entirely intramolecular in origin, ¹H relaxation may also have substantial intermolecular contributions from interactions with solvent, polymer and dissolved oxygen. Each of these contributions must either be removed or determined separately in order to isolate the intramolecular contribution which is the significant quantity in studying chain dynamics. The interaction with dissolved oxygen is easily eliminated by vacuum degassing, but the interactions with other molecules can only be removed by expensive deuteration of both polymer and solvent. In order to determine whether intermolecular interactions are sufficiently important to require the use of the deuteration technique, we have measured the ¹H relaxation times of poly(ethylene oxide) in benzene solutions of concentrations from 5 to 30% w/w.

Three series of solutions were run: (a) fully protonated polymer (PEOH) in C₆H₆; (b) PEOH in C₆D₆; (c) C₆H₆ solutions of polymer consisting of 20% PEOH and 80% fully deuterated polymer (PEOD). The PEOD available had a fairly wide molecular weight distribu-

tion ($M_n = 3500, M_w = 7000$). To ensure that replacing PEOH by PEOD left the solution properties unchanged, the PEOH employed was a mixture of sharp fractions which reproduced the PEOD distribution. All solutions were degassed and the polymer and solvent ¹H relaxation times measured on a Varian Associates HA-100 spectrometer using the adiabatic rapid passage with sampling technique⁴. The results are presented in Table 1.

It is clear that the polymer ¹H relaxation times are affected very little by deuteration of either solvent or polymer, and are therefore determined almost entirely by intramolecular interactions. As expected the largest increase in T_1 is observed on replacing C₆H₆ by C₆D₆ for the 5% solution, but the increase is small and not far outside the combined experimental errors. The smallness of the polymer-solvent contribution is also shown by the minor increase in the solvent T_1 on deuteration of the polymer. The largest increase is shown by the 30% solution. Using the formula:

$$\left(\frac{1}{T_1}\right)_{\text{PS}} = \left(\frac{1}{T_1}\right)_{\text{S,PEOH}} - \left(\frac{1}{T_1}\right)_{\text{S,PEOD}}$$

where $(T_1)_{\text{PS}}$ is the polymer-solvent contribution and $(T_1)_{\text{S,PEOH}}$ and $(T_1)_{\text{S,PEOD}}$ are the solvent relaxation

times for the PEOH and PEOH/PEOD solutions respectively, we calculate a value of 70 ± 30 sec for $(T_1)_{\text{PS}}$ in the 30% solution. Such a contribution would lead to a change of only 0.08 sec in the polymer T_1 of about 1.5 sec, which is well within the experimental error. The effect on the polymer relaxation in the more dilute solution would be even smaller. The insignificance of solvent-polymer interactions in polymer relaxation is in accord with earlier measurements⁵ on aqueous PEO solutions.

The conclusion drawn from these results is that in PEO solutions, ¹H relaxation arises almost entirely from intramolecular causes, and is therefore an accurate indicator of the chain motion. This data may thus be combined with ¹³C relaxation data to define the nature of the motion more precisely. We have measured the ¹³C T_1 of PEOH in C₆D₆ at 30°C and 25.14 MHz using a Varian Associates XL-100 spectrometer. The results are given in Table 2, together with correlation times, τ_c , obtained using

$$\frac{1}{T_{1C}} = \frac{2\gamma_H^2\gamma_C^2\hbar^2}{r_{CH}^6} \times \tau_c \quad (1)$$

where r_{CH} is the C-H bond length (0.11 nm). This equation assumes isotropic motion in the extreme narrowing limit. ¹H relaxation times were then calculated using the equation:

$$\frac{1}{T_{1H}} = \frac{3}{2} \gamma_H^4 \hbar^2 \tau_c \left[\frac{1}{r_m^6} + P_T \times \left(\frac{1}{r_t^6} + \frac{1}{r_g^6} \right) + \frac{P_G}{2} \left(\frac{1}{r_t^6} + \frac{3}{r_g^6} \right) \right] \quad (2)$$

^aError in $T_{1\text{C}} \pm 10\%$

where P_T and P_G are the relative populations of the rotational isomers of the C—C bond with the oxygen atoms *trans* and *gauche* respectively, and r_m , r_t and r_g are distances between protons in respectively *geminal*, *trans* vicinal and *gauche* vicinal orientations. $T_{1\text{H}}$ is in fact dominated by the *geminal* interaction, and the uncertainty in assuming equal weighting of the isomers ($P_T = P_G/2 = 1/3$) amounts to only 2.5%. A comparison of calculated and experimental values of $T_{1\text{H}}$ is also made in Table 2.

The correspondence between the two sets of values is quite close, apparently justifying the isotropic rotational model used to derive equations (1) and

(2). It is known¹⁻³ however that polymer motion is often better represented by a distribution of correlation times, and τ_{C} should be interpreted as an average correlation time. The conclusion to be drawn is that the C—H interactions causing the ^{13}C relaxation, and the H—H interactions causing the ^1H relaxation have the same average correlation time and presumably also the same autocorrelation function.

In PEO, the major contribution to ^1H relaxation arises from mutual interaction of *geminal* protons separated by 0.18 nm. It is therefore highly probable that one can ignore intermolecular contributions to the relaxation of CH_2 groups in other polymers. However, relaxation of methine protons is due to vicinal interactions over distances of 0.25 nm or more, which are at least 10 fold less effective. In a vinyl polymer $(-\text{CH}_2-\text{CHX}-)_n$, each CH proton has four vicinal neighbours, so its relaxation time should be about 3 or 4 times greater than the CH_2 relaxation time. In a hypothetical vinyl polymer with the same motional properties as PEO, the methine $T_{1\text{H}}$ would therefore be about 5 sec. The polymer—solvent contribution of 70 sec estimated above would cause a significant decrease of 7% from 5 to 4.67 sec. However, vinyl

polymers are generally much less flexible than PEO, so that at the same temperature the relaxation times in vinyl polymers would be much less than in PEO and therefore the effect of intermolecular interactions would be as insignificant for CH protons as it is for CH_2 .

Finally, it is worth noting that the relaxation times presented here are in agreement with previous studies⁵⁻⁷ of polymer motion, which showed that the polymer motions causing n.m.r. relaxation are independent of concentration until monomer/solvent mole ratios of about 5 are reached^{5,6}, and that the motions of solvent molecules are essentially unaffected by the presence of polymer up to quite high concentrations of 20–30%⁷.

Preparation and reactions of polymeric Grignard compounds

F. J. Burgess and D. H. Richards

Explosives Research and Development Establishment, Ministry of Defence, Waltham Abbey, Essex EN9 1BP, UK

(Received 14 June 1976)

INTRODUCTION

The synthesis of mono- and difunctional living polymers was first described in full by Szwarc^{1,2} in 1956, although the idea of terminationless polymerization systems had been proposed by Ziegler³⁻⁵ in the 1930s. In recent years academic and commercial interest in these anionic techniques has developed rapidly; in particular the methods have allowed the synthesis of terminally functional polymers of narrow molecular weight distributions. Polymeric carbanions have been reacted with carbon dioxide to give carboxy end groups, and with ethylene oxide to give hydroxy end groups (equation 1)⁶. This approach

has been particularly valuable in the preparation of di-terminally functional (telechelic) liquid polybutadienes⁷, which may be subsequently chain extended and crosslinked by the addition of suitable reagents.

Other methods, which rely on the reaction of living polymers with an excess of a difunctional reagent, have been developed to prepare terminally functional polymers. Thus epoxy terminated polymer has been synthesised by reaction with excess epoxy resin⁸ and, perhaps more importantly, bromine terminated polymer has been prepared by reaction with excess bromine or with excess of an α,α' -dibromoxylene⁹ (equation 2). However, in both the latter cases the resulting mate-

rial contained appreciable quantities of non-functional polymer, the maximum yield of brominated chain ends never exceeding 75%. It was shown that when monofunctional living polystyrene was used, the non-brominated material was double the molecular weight of that brominated, and so it was concluded that the efficiency of the reaction was limited by the prevalence of the Wurtz condensation reaction, as represented generally by equation (3).

The latter process appears to be so rapid that attempts to reduce its contribution by rapid stirring or increase in the halide excess all failed.

Clearly this high rate of reaction is controlled by the extreme reactivity of the organometallic end group and, if this could be reduced, it should result in a corresponding decrease in the rate of coupling. Further, if this rate were lowered to a point where the reagents could be efficiently mixed be-

(2). It is known¹⁻³ however that polymer motion is often better represented by a distribution of correlation times, and τ_c should be interpreted as an average correlation time. The conclusion to be drawn is that the C—H interactions causing the ^{13}C relaxation, and the H—H interactions causing the ^1H relaxation have the same average correlation time and presumably also the same autocorrelation function.

In PEO, the major contribution to ^1H relaxation arises from mutual interaction of *geminal* protons separated by 0.18 nm. It is therefore highly probable that one can ignore intermolecular contributions to the relaxation of CH_2 groups in other polymers. However, relaxation of methine protons is due to vicinal interactions over distances of 0.25 nm or more, which are at least 10 fold less effective. In a vinyl polymer $(-\text{CH}_2-\text{CHX}-)_n$, each CH proton has four vicinal neighbours, so its relaxation time should be about 3 or 4 times greater than the CH_2 relaxation time. In a hypothetical vinyl polymer with the same motional properties as PEO, the methine $T_{1\text{H}}$ would therefore be about 5 sec. The polymer—solvent contribution of 70 sec estimated above would cause a significant decrease of 7% from 5 to 4.67 sec. However, vinyl

polymers are generally much less flexible than PEO, so that at the same temperature the relaxation times in vinyl polymers would be much less than in PEO and therefore the effect of intermolecular interactions would be as insignificant for CH protons as it is for CH_2 .

Finally, it is worth noting that the relaxation times presented here are in agreement with previous studies⁵⁻⁷ of polymer motion, which showed that the polymer motions causing n.m.r. relaxation are independent of concentration until monomer/solvent mole ratios of about 5 are reached^{5,6}, and that the motions of solvent molecules are essentially unaffected by the presence of polymer up to quite high concentrations of 20–30%⁷.

Preparation and reactions of polymeric Grignard compounds

F. J. Burgess and D. H. Richards

Explosives Research and Development Establishment, Ministry of Defence, Waltham Abbey, Essex EN9 1BP, UK

(Received 14 June 1976)

INTRODUCTION

The synthesis of mono- and difunctional living polymers was first described in full by Szwarc^{1,2} in 1956, although the idea of terminationless polymerization systems had been proposed by Ziegler³⁻⁵ in the 1930s. In recent years academic and commercial interest in these anionic techniques has developed rapidly; in particular the methods have allowed the synthesis of terminally functional polymers of narrow molecular weight distributions. Polymeric carbanions have been reacted with carbon dioxide to give carboxy end groups, and with ethylene oxide to give hydroxy end groups (equation 1)⁶. This approach

has been particularly valuable in the preparation of di-terminally functional (telechelic) liquid polybutadienes⁷, which may be subsequently chain extended and crosslinked by the addition of suitable reagents.

Other methods, which rely on the reaction of living polymers with an excess of a difunctional reagent, have been developed to prepare terminally functional polymers. Thus epoxy terminated polymer has been synthesised by reaction with excess epoxy resin⁸ and, perhaps more importantly, bromine terminated polymer has been prepared by reaction with excess bromine or with excess of an α,α' -dibromoxylene⁹ (equation 2). However, in both the latter cases the resulting mate-

rial contained appreciable quantities of non-functional polymer, the maximum yield of brominated chain ends never exceeding 75%. It was shown that when monofunctional living polystyrene was used, the non-brominated material was double the molecular weight of that brominated, and so it was concluded that the efficiency of the reaction was limited by the prevalence of the Wurtz condensation reaction, as represented generally by equation (3).

The latter process appears to be so rapid that attempts to reduce its contribution by rapid stirring or increase in the halide excess all failed.

Clearly this high rate of reaction is controlled by the extreme reactivity of the organometallic end group and, if this could be reduced, it should result in a corresponding decrease in the rate of coupling. Further, if this rate were lowered to a point where the reagents could be efficiently mixed be-

fore significant reaction occurred, then the effect of the excess halide would be maximized as would the yield of brominated product.

We have previously shown that living polymers react smoothly with metal halides such as triethyl lead chloride¹⁰, and mercuric bromide¹¹ to give the corresponding polymeric adducts, and so it was expected that a similar reaction would occur with excess magnesium bromide to form a polymeric Grignard compound (equation 4). By analogy with the behaviour of small molecule Grignard compounds, these species should be very much less reactive than their parent living polymers but still retain sufficient activity to react clearly with the reagents cited¹². It is the results of such experiments which are the subject of this communication.

EXPERIMENTAL

The preparation of benzene/THF solution of 2000 molecular weight monofunctional polystyryl lithium was carried out under nitrogen, and is an adaptation of a high vacuum technique described by Altares *et al.*¹³. This adaptation has been described previously⁹, as has the reaction of aliquots of the living polymer with ten-fold excess bromine and with ten-fold excess α,α' -dibromoxylene.

The preparation of the polystyrene Grignard has not been previously re-

ported and is briefly outlined here.

The reaction scheme shown in equation (4) requires that an anhydrous solution of magnesium bromide be prepared, preferably in THF so that the final Grignard reaction is carried out in the presence of an ethereal solvent. The most convenient method of preparing this is by the reaction of 1,2-dibromoethane with magnesium turnings in THF, which goes quantitatively by equation (5)¹⁴.

Typically, 37 g (0.2 mol) of 1,2-dibromoethane was added gradually to 6 g (0.25 mol) of magnesium turnings in 350 ml of refluxing THF. Reaction was carried out under nitrogen with rapid stirring to prevent uncontrolled frothing. After completing the addition the mixture was further refluxed for half an hour before filtering through a porosity 3 sinter whilst just below the boiling point of THF. The filtered solution was clear and colourless, but much magnesium bromide crystallized out on cooling to room temperature. Its solubility was determined as being ~ 0.25 M at 25°C (titration with 0.1 N silver nitrate using phenosafranine as indicator¹⁵).

A known volume of the polystyryl lithium solution was transferred into an appropriate container fitted with a septum, and through which nitrogen was passing. A quantity of saturated magnesium bromide solution in slight excess of that required to react with the carbanion ends according to equa-

tion (4) was added with a syringe, and this resulted in the immediate and total loss of the characteristic red colour of the living ends.

The reaction of polystyrene Grignard both with excess bromine and with excess α,α' -dibromoxylene was conducted in a manner identical to that previously described for the analogous reactions with living polymer⁹, and will therefore not be described again here.

RESULTS AND DISCUSSION

Living polystyrene of about 2000 molecular weight with one active end per chain was prepared. A sample of this solution was protonated with methanol, and examination of the polymer by g.p.c. showed it to be of the anticipated molecular weight, and to possess a narrow molecular weight distribution ($M_w/M_n \approx 1.05$) (Figure 1).

The remaining solution was divided into three parts, two being of equal volume and half the volume of the third. This largest sample was then reacted with magnesium bromide before again dividing into two equal parts.

One of the living polymer solutions was added slowly to a rapidly stirred solution containing ten-fold excess bromine, and the other was added similarly to a solution containing the same excess of α,α' -dibromo-*m*-xylene. These operations were repeated under identical conditions using the two polymeric Grignard solutions, and the four polymers were then isolated and examined by g.p.c. The traces of the two polymers resulting from the direct bromination reaction are compared

Figure 1 G.l.c. trace of protonated polystyryl lithium

in Figure 2, and those of the two produced by reaction with α,α' -dibromo-*m*-xylene are illustrated in Figure 3. The traces are all typical of a number of repeat experiments carried out under these conditions.

All the four traces in Figures 2 and 3 show the presence of coupled polystyrene of 4000 molecular weight. This is in contrast to the protonated material (Figure 1) which exhibits a single sharp peak at 2000 molecular weight. Thus the coupling must have resulted from the bromination reactions employed.

The degree of coupling has been very much reduced, however, in both reactions when the Grignard reagent is employed. In the direct bromination reaction the percentage of bromine terminated polystyrene is increased from about 58 to 93% by this means. Similarly, with α,α' -dibromo-*m*-xylene the percentage is increased from 25 to 77%. Undoubtedly the bromine content can be increased fur-

Figure 2 G.I.c. traces of products of (a) polystyryl lithium and (b) polystyryl Grignard reaction with ten-fold excess bromine

ther by a more refined technique of addition and so these figures are not meant to represent an upper limit for bromination. These increases do, however, illustrate the principle of reducing reactivity in order to improve selectivity.

It is at first sight somewhat surprising that the degree of coupling with either polymeric reagent should be much more pronounced when α,α' -dibromo-*m*-xylene is used than in the direct bromination reaction. This trend may perhaps be explained in the following manner. The initial bromination reaction is expected to be appreciably faster with bromine than with the dihalide and in both cases the polymeric bromides formed are benzylic in character and therefore should be of comparable intrinsic reactivities. The product from direct bromination should react less readily with further living polymer, however, because it is more shielded initially and on coupling produces a more sterically hindered bond (equations 6 and 7).

This idea of reducing reactivity of the polymer end groups to a required level may have much wider application than that listed here. Preliminary experiments in our laboratories indicate that the reaction of polybutadiene dianions with carbon dioxide or with ethylene oxide to produce telechelic carboxy or hydroxy liquid polymers (equation 1) may benefit by prior reaction to form Grignard analogues. Under these conditions we have found that the polymer may be mixed at room tem-

Figure 3 G.I.c. traces of products of (a) polystyryl lithium and of (b) polystyryl Grignard reaction with ten-fold excess α,α' -dibromo-*m*-xylene

perature with ethylene oxide without significant reaction occurring. Reaction takes place at elevated temperatures¹⁶ as evinced by the gelling of the solution due to alkoxide ion pair association⁶, and this may be subsequently destroyed by hydrolysis. When living polymer is mixed directly with ethylene oxide immediate reaction occurs and the resulting gel delays completion of the reaction for hours or days. The efficiency of the Grignard-ethylene oxide reaction has not as yet been studied.

Similarly, in the reaction with carbon dioxide it is very probable that the prior formation of the polymeric Grignard would reduce the production of ketone groups by the unwanted side reaction shown in equation (8).

Of course, living polymers may be reacted with other metallic salts, either in excess or stoichiometrically, to generate organometallic terminal groups possessing a variety of reactivities and properties. We have prepared end groups of the Grignard type such as $-\text{HgX}$, $-\text{CdX}$, $-\text{ZnX}$ etc, and have also prepared the dipolymeric derivatives of metals such as these. We are currently investigating the behaviour of such species, and we have already shown

that high yields of bromine terminated polymer may be obtained by reacting the mercury derivatives directly with bromine.

Another intriguing possibility is that of preparing polydiketone systems by reacting polymeric cadmium¹⁷ or copper complexes¹⁸ with diacylchlorides (neither of these species are reactive toward ketones) as illustrated in equation (9).

It appears that this approach of generating polymers with end groups of controlled reactivity allows a much greater freedom in the choice of subsequent reactions to produce new polymers and copolymers of well defined structure.

ACKNOWLEDGEMENT

We wish to thank Mr R. J. Pace for the gel permeation chromatographic measurements.

Book Review

Synthetic Paper from Fibers and Films

M. G. Halpern

Noyes Data Corporation, Park Ridge, New Jersey, 1975, \$36.00

This volume is essentially a summary of the content of 122 US Patents issued during the period 1957–1974. Paraphrasing the author's words, 'legal jargon and juristic phraseology have been eliminated' giving a book that is much more readable by the average scientist than would be the original patents.

Perhaps inevitably the book title does not adequately describe its contents. Basic information on both polymer technology and papermaking is lacking. Patents issued prior to 1957 have apparently been ignored and no account has been taken of information available from other sources such as technical journals and trade literature. A number of highly important recent developments in both materials and processes are not at present covered by patents, in some cases possibly because the innovators are not prepared to meet the Patent Office requirement of 'sufficient disclosure' or because the innovation is not considered sufficient to warrant the issue of a patent, and these are not referred to. Admittedly, the Foreword makes it clear that the volume is effectively a patent review covering a limited period of time, but this is not clear from the title.

Although this is still the subject of some controversy, the author's description of paper in the Introduction as a nonwoven fabric can be criticized. Furthermore, his statement of the advantages of synthetic papers, also given in the Introduction, must be regarded as an over-simplification. For instance, not all synthetic fibres have good chemical durability and the dimensional stability of synthetic fibres is sometimes much worse than that of cellulose fibres. It is suspected that the author was here referring primarily to moisture effects, but paper is also subjected to heat (during manufacture, conversion and usage) and the dimensional stability of cellulose fibres to heat is much better than that of some synthetic fibres and other materials.

There must also be some reservation with regard to the use by the author of the term 'synthetic paper'. Agreed terminology in

this field is inadequate. However, the current internationally accepted definition of paper requires that the material should be produced from fibres (thus disqualifying those paper-like materials manufactured in film form), but permits the use of synthetic fibres in any quantity. Rigid application of these criteria would require a complete change in the title of the book, but the reviewer has encountered the same terminology problems himself when preparing technical papers on this subject and cannot suggest a better title.

The patent field covered by the author includes the use of chemical derivatives of cellulose (in both fibrous and non-fibrous forms) and of chemically modified natural cellulose fibres in papermaking. It also includes the papermaking use of fibres manufactured from polymers such as polyolefins, polyamides and polyacrylonitriles, and the manufacture of non-fibrous synthetic papers from polyolefins and other polymers.

The patents described in the text will obviously vary considerably in their importance. Some have been exploited commercially and in a few cases the reviewer, from personal knowledge of products manufactured using the process described, is satisfied that the information given would be very useful to interested scientists and technologists. Others might be considered to be of very doubtful merit but, bearing in mind the constantly changing technological requirements for paper and paper products and the state of flux in the availability and relative costs of materials, more critical selection of the patents included would have been very difficult.

The descriptions of the patents are clear and concise although in some cases the terminology used is somewhat unorthodox. Adequate diagrams are included and the amount of tabulated numerical data given is gratifyingly greater than might have been expected. It is interesting to note, however, the wide variety of test methods and units for expression of results used by the different workers. For instance, no fewer than 15 different units are used for tensile strength, apart from several patents where numerical values for this property are given without units. This must be viewed as a criticism not of the author of this book, but of the original workers and of the lack of progress towards standardization.

Although not without its limitations, this book is considered to be a very useful addition to the available literature, most particularly for papermakers, but also for polymer and textile technologists. Its publication at this stage of the development of synthetic pulps and papers is particularly well timed. Technical papers in this area have tended to concentrate on the properties and performance of these materials and have usually ignored the basic production technologies. This gap has now at least partially been filled.

F. D. Munday

Conference Announcement

Polymer Processing

Massachusetts Institute of Technology, Cambridge, Massachusetts, USA, 15–18 August 1977

An international conference on 'Polymer Processing' will be held at M.I.T., Cambridge, Massachusetts, 15–18 August, 1977. The purpose of the conference is to establish the state of fundamental knowledge in polymer processing and to assess the nature of major problems to be solved in the field. The topics to be covered are: basic considerations in polymer processing, polymer melt processing, liquid reaction processing, processing of composites, processing of foamed plastics, processing related to surface phenomena, polymers for non-traditional applications, recent advances in polymer processing, characterization and properties of polymers, quality control and accelerated testing and needs and opportunities in polymer processing. Those interested in presenting papers are invited to submit abstracts of not more than 500 words on subjects related to one of the topics above. Abstracts should be sent by 30 November, 1976 to: Professor Nam P. Suh, Conference Chairman, Massachusetts Institute of Technology, Room 34–134, Cambridge, Massachusetts 02139, USA.

Conference Announcement

Polymer Surfaces Symposium

University of Durham, 21–24 March 1977

The Macromolecular Group of the Chemical Society are organizing the symposium 'Polymer Surfaces' to be held at the University of Durham, 21–24 March 1976. Particular emphasis is being placed on plenary and keynote lectures to review and highlight work of both an applied and academic nature. The topics to be discussed include the formation; chemical, physical, electrical and mechanical properties and modifications thereof; characterization and uses of polymer surfaces. Contributed papers are solicited and abstracts are requested by the end of November 1976. Further details may be obtained from: Dr W. J. Feast, Department of Chemistry, University of Durham, South Road, Durham DH1 3LE.

Configuration of cellulose trinitrate in solution

C. Holt*, W. Mackie and D. B. Sellen

Astbury Department of Biophysics, University of Leeds, Leeds LS2 9JT, UK

(Received 1 March 1976; revised 19 May 1976)

Cellulose trinitrate was prepared from cotton (*Deltapine*) under a variety of conditions and investigated in solution with ethyl acetate as solvent using the techniques of light scattering, osmometry and viscometry. The more mildly nitrated samples (e.g. 1 h at 20°C) exhibited downward curvature in the Zimm plots and a fractional precipitation experiment showed that this was due to the presence of large gel-like aggregates. Light scattering, viscometry, infra-red and ultracentrifuge measurements were made on the fraction of gel-like material and the effect of further nitration investigated. The possible nature of the aggregates is discussed. Light scattering measurements made on a mildly nitrated sample with this fraction removed yielded a straight line Zimm plot from which chain statistics similar to those found by other authors could be deduced. Samples obtained by more extensive nitration (2–25 h at 20°C) were considerably degraded but yielded straight line Zimm plots and osmotic pressure measurements showed the polydispersities to be low ($DP_w/DP_n \sim 1.3$). Values of effective bond length, b , calculated from these Zimm plots (4.6 to 5.6 nm) were much larger than those found for the more mildly nitrated samples and those found by other authors. Also, in contrast to the results of other authors, second virial coefficients obtained by light scattering and osmotic pressure were found to be in fair agreement. The effect of gel-like material on measured second virial coefficients is discussed. It is suggested that the discrepancy in b arises because gel-like material remains in more mildly nitrated samples even after the larger aggregates have been removed by fractional precipitation. This material consists of particles denser than the single coils but of comparable or smaller size so that values obtained for the effective bond length are too low. The results of previous investigations on all the cellulosic polymers which have been investigated are discussed in the light of the present work with particular reference to the effect of gel-like material. It is suggested that the apparent disagreement between the conformational analysis of cellulose and experimental results arises from the presence of gel-like material in solutions rather than any fault in the molecular model.

INTRODUCTION

Although the degree of polymerization and polydispersity of native cellulose has been investigated by a number of workers over many years, the nature of native cellulose in this respect remains a matter for speculation. An extensive re-investigation of this problem has therefore been carried out in this department¹ and a brief report of the results obtained has already been published². During this investigation, cellulose trinitrate was prepared from cotton cellulose and investigated in solution with ethyl acetate as solvent, using the techniques of light scattering, osmometry and viscometry. The chain statistics of cellulose trinitrate, calculated from the results of the experiments, were similar to those obtained by other authors^{3–6}, when similar procedures of nitration and fractionation were adopted, and similar assumptions made about polydispersity. However it was discovered that direct nitration of cotton for periods of from 2 to 25 h at 20°C yielded samples of low polydispersity with $M_w/M_n \sim 1.3$ and the chain statistics calculated from the results of experiments on these samples indicated a much stiffer chain. It is this aspect of the work which forms the subject of the present paper. The biological aspects of the work will be discussed elsewhere. Gel permeation chromatography measurements were also made

on the cellulose trinitrate solution but in view of the complex behaviour discovered these also will be the subject of a separate publication.

EXPERIMENTAL

Preparation of cellulose trinitrate solutions

In all the work to be discussed in the present paper, cotton (*Deltapine*) was obtained from freshly opened bolls and was air dried prior to nitration with the mixture of Alexander and Mitchell⁷. Stock solutions of the nitrate were made up in redistilled ethyl acetate at concentrations of $\sim 1 \text{ kg/m}^3$. The good solvent ethyl acetate was used for three reasons (a) microgel formation is less likely in a good solvent, (b) for instrumental reasons osmotic pressure measurements were not possible in acetone and (c) gel permeation chromatography measurements were made concurrently with this investigation and a good solvent was found to be necessary for this technique. The solutions were made up by slowly agitating for 24 h and then centrifuging for 1 h at $30\,000 \times g$ to remove any undissolved material. The time of nitration required to achieve complete solubility was found to be a function of temperature and was approximately 20 min at 20°C, 1 h at 0°C and 24 h at –20°C. The nitrogen content of all the fully soluble samples was found by a semi-micro Kjeldahl method to be

* Present address: The Hannah Research Institute, Ayr, Scotland KA6 5HL, UK.

13.8 ± 0.1% (14.1% represents full substitution). The nitrogen content of the soluble components of samples obtained by nitration for shorter periods was also 13.8 ± 0.1% whilst the insoluble components had a nitrogen content ranging from 1 to 12%.

Light scattering measurements

Light scattering measurements were made by using a semi-cylindrical cell in an Aminco apparatus (American Instrument Co. Inc., Silver Spring, Maryland, USA). The apparatus was tested and calibrated as already described⁶ except that the Ludox calibration was checked by measurements on the pure liquids carbon tetrachloride, benzene and carbon disulphide. Assuming the Rayleigh ratios for these liquids based on a literature survey by Kratochvil *et al.*⁸ and making the usual correction for the refractive index of the liquids^{9,10} the Ludox calibration was confirmed to be correct within experimental error (±5%).

An adequate degree of clarification prior to light scattering measurements is especially difficult to achieve with solutions of cellulose derivatives because centrifugation is the only effective means of removing dust and because the low refractive index increment and high dissymmetry of scatter make it necessary to work at concentrations where the solute scatter is sometimes less than that due to the solvent. In this work solutions were centrifuged for 2 h at 30 000 × g and the top 20% of each volume used for light scattering measurements. Both the syringe used for transferring the solution to the light scattering cell and the cell itself were rinsed in a stream of condensing distilled ethyl acetate immediately before use. In this way an adequate degree of clarification was achieved once in every three attempts. The solute concentration was determined after each set of light scattering measurements by taking a 2 ml volume of solution from the light scattering cell and evaporating to dryness.

Zimm plots were made in the usual way. It was found however that repeated experiments at a given concentration yielded KC/R_θ against $\sin^2\theta/2 + kC$ plots (where the symbols have their usual meaning) in which the slope at high angles varied by about 10% although constant intercepts at $\theta = 0$ were obtained. Higher slopes were obtained more frequently at the lower concentrations. The Zimm plots presented in this paper were constructed by taking at each concentration the set of measurements yielding the highest slopes at high angles. This procedure was found to yield self-consistent Zimm plots with linear extrapolation to zero concentration. A justification of this procedure will be given in the Results and Discussion section of this paper.

The refractive index increment dn/dC was measured using a 10 mm cell in a Rayleigh differential refractometer. The cellulose trinitrate sample used for this purpose was one obtained by nitration for 1 h at 20°C. This was divided into three fractions by precipitation from solution in ethyl acetate with n-hexane and the middle fraction used for refractive index measurements. This was done to ensure that measurements were made on cellulose trinitrate chains and not upon microgel or low molecular weight material. It was found that due to it being slightly hygroscopic the refractive index of ethyl acetate could vary by several parts in 10⁵. The errors resulting from this can be minimized by using ethyl acetate from the same distillation batch both for making up the solution and as reference solvent. In this way dn/dC was found to be 0.105 ± 0.001 ml/g at both 546 and 436 nm. This is in good agreement with the values found by Holtzer *et al.*³ and Huque *et al.*⁵ but 5% lower than that found by Penzel and Schulz¹¹.

Membrane osmometry

Osmotic pressure measurements were made in a Mechrolab apparatus (model 503 Hewlett-Packard Ltd, Slough, UK) at 25°C using type 08 membranes. In this apparatus a negative pressure head of solvent is applied with the aid of a servo-mechanism so as just to counteract the flow of solvent through the membrane. Solvent flow is detected by means of a photocell which is set to receive light passing through an air bubble. The apparatus was found usually to reach equilibrium within 5 min and no permeation of the membrane by the solute was observed. By continuously recording the pressure with the aid of a pen recorder until 15 min after equilibrium had been reached, it was found possible to integrate out purely random fluctuations (thermal and instrumental) and to obtain osmotic pressures correct to 0.05 mm of ethyl acetate. Prior to making measurements the stock solutions were centrifuged for 2 h at 100 000 × g and decanted.

Viscometry

Viscosity measurements were made at 20°C using two Cannon-Fenske viscometers each with two bulks thus giving four rates of shear in the range 900 to 3000 sec⁻¹. In each case the reduced specific viscosity was extrapolated first to zero rate of shear and then to zero concentration in the manner previously described¹².

RESULTS AND DISCUSSION

* Assuming a Schulz-Zimm distribution for the single coils with $DP_w/DP_n = 1.3$ (see text)

Figure 1 Zimm plot for cellulose trinitrate derived from cotton (Deltapine), sample III (Table 1). $\lambda_0 = 436$ nm; solvent, ethyl acetate

ing light scattering experiments on samples which had been obtained by nitration for relatively short periods, i.e. long enough to yield a high proportion of soluble material, (sample II was 84% soluble), without severe degradation. A representative Zimm plot is shown in Figure 1. All the Zimm plots exhibited downward curvature at low angles and Table 1 shows their interpretation in terms of the theory of Benoit *et al.*¹³ for a polydisperse solution of Gaussian coils. This interpretation indicates highly polydisperse material with weight-average degrees of polymerization in the range 10 000 to 14 000. b is given by $b^2 = r^2/DP$, where r^2 is the mean square end to end distance of the cellulose chain. The mean value of b obtained, 3.3 ± 0.3 nm (calculated from the asymptotic slopes⁶) agrees well with that found by Hunt *et al.*⁴ for cellulose trinitrate in ethyl acetate and other authors for cellulose trinitrate in acetone. It is somewhat lower than that found by Huque *et al.*⁵ for cellulose trinitrate in ethyl acetate (4.3 nm).

The interpretation of the Zimm plots as representing a polydisperse solution of Gaussian coils does not however stand up to close inspection. The number-average degrees of polymerization so derived are about 3000. Systematic errors arising because the Zimm plots are not truly asymptotic at high angles would make these higher than the true values. Thus the number-average degrees of polymerization should be low enough to be determined by osmotic pressure measurements. An attempt to make such a measurement on one of the samples showed that the number-average degree of polymerization was much higher than 3000. It could not be determined with any accuracy because solutions at concentration greater than 1 kg/m^3 could not be conveniently handled owing to their high viscosity.

An alternative explanation of the downward curvature in the Zimm plots is that the solutions contained supermolecular aggregates or gel-like material. In order to ascertain whether this was so, fractional precipitation experiments were carried out. A series of fractions was obtained by adding *n*-hexane to a 0.1% solution of sample I. Precipitates were removed by centrifugation at $3000 \times g$ after sufficient *n*-hexane had been added to produce a permanent cloudiness. In order to avoid local excesses of precipitant, and hence obtain a narrower fraction, the cloudy solutions were raised 5°C above ambient temperature for 24 h and then allowed to cool prior to centrifugation. On heating, the

cloudiness disappeared for all the fractions except the first. All the fractions were completely resolvable in ethyl acetate except the first which was only 68% soluble. The first fraction had a lower intrinsic viscosity than the second, (Table 2), indicating the presence of denser particles and Figure 2 shows the corresponding Zimm plot. The virtually zero second virial coefficient indicates a high density particle, and the form of the reciprocal particles scattering factor indicates some sort of supermolecular aggregate, with molecular weight and polar radius of gyration $\geq 10^4 \text{ kg/mol}$ and $\geq 200 \text{ nm}$ respectively. It was thought unlikely that the solution consisted entirely of aggregates however and an attempt was made to separate aggregates from single chains by centrifuging for 4 h at $100\,000 \times g$. This resulted in the removal of $\sim 15\%$ of the material from solution. Light scattering measurements on the supernatant however yielded a qualitatively similar Zimm plot to that obtained previously although the molecular weight and polar radius of gyration fell to $4 \times 10^3 \text{ kg/mol}$ and 150 nm respectively. An experiment with the first fraction using an analytical centrifuge running at $100\,000 \times g$ confirmed that there was no separation into two components. A single sharp Schlieren peak was obtained and the sedimentation constant increased markedly with decreasing concentration in a manner characteristic of single cellulose chains; the extrapolated value at infinite dilution ($S \sim 2 \times 10^{-12} \text{ sec}$) corresponding to a degree of polymerization of ~ 7000 on the

Table 2 Fractionation of cellulose trinitrate derived from cotton (Deltapine), sample I (see Table 1)

Fraction number	Intrinsic viscosity (m^3/kg)	Huggin's constant	Weight fraction
1	3.6	1.08	0.17
2	5.8	0.71	0.09
3	4.5	0.50	0.28

5	2.3	0.33	0.13
6	1.1	0.38	0.05
7	0.54	0.30	0.03

Figure 2 Zimm plot for cellulose trinitrate derived from cotton (Deltapine), sample I (Table 1), fraction 1 (Table 2). $\lambda_0 = 436$ nm; solvent, ethyl acetate

Figure 3 Infra-red spectrum for cellulose trinitrate derived from cotton (Deltapine), sample I (Table 1) fraction 1 (Table 2) before (A) and after (B) renitration

basis of the relationship given by Hunt *et al.*⁴. A possible explanation of this is that the aggregates are *like* branched polymers, rather than swollen gel particles, with just a few *effective* branch points, each formed by a number of inter-chain hydrogen bonds acting cooperatively. In this case the sedimentation constant of the aggregates might not differ greatly from that of their constituent chains and if single chains were also present the difference would be diminished due to the Johnston–Ogston effect¹⁴. The nitrogen content of the first fraction, 13.2%, indicated incomplete substitution, and the infra-red spectrum (Figure 3) showed high absorption in the range characteristic of hydrogen bonded hydroxyl groups. After precipitating with *n*-hexane, drying and renitration for 1 h at 20°C, the nitrogen content rose to 13.9% and the absorption characteristic of hydrogen bonds disappeared (Figure 3). On redissolving in ethyl acetate and centrifuging at $100\,000 \times g$ for 30 min to remove a small amount of insoluble material, the intrinsic viscosity was found to have risen to $3.9 \text{ m}^3/\text{kg}$, the Huggins constant to have fallen to 0.59, and a straight line Zimm plot (Figure 4) was obtained consistent with single cellulose chains of low polydispersity having weight-average degree of polymerization 4500 and polar radius of gyration, $[(\bar{S}^2)_z]^{1/2}$, 130 nm. The second virial coefficient was $8.5 \times 10^4 \text{ mol m}^3/\text{kg}$. Thus the properties of the gel fraction after renitration are consistent with the model proposed above, the aggregates breaking down into single chains.

Light scattering measurements were also made upon sample I with the first fraction removed. The fractional precipitation experiment was repeated, the first fraction in this case representing 14% by weight of the material. The remaining solute was precipitated with *n*-hexane, air dried and heated *in vacuo* at 50°C for 4 h to remove all traces of hydrocarbon. It was then redissolved in ethyl acetate, centrifuged at $100\,000 \times g$ for 1 h and decanted. Figure 5 shows the Zimm plot obtained from this sample. It exhibits no downward curvature and yields the data $DP_w = 5800$, $B = 9.2 \times 10^{-4} \text{ mol m}^3/\text{kg}^2$, $[(S^2)_z]^{1/2} = 140 \text{ nm}$. The way in which this sample was prepared is similar to the way in which most authors have obtained their highest molecular weight fraction. In the case of straight line Zimm plots it is common practice to assume a Schulz–Zimm distribution with $DP_z : DP_w : DP_n = 3 : 2 : 1$ as theory predicts a straight line in this case³. If this is assumed a value of $b = 3.8 \text{ nm}$ is obtained. This is in agreement with other

authors, as is the intrinsic viscosity of this sample, $4.4 \text{ m}^3/\text{kg}$, which corresponds to degrees of polymerization of 5300 and 6700 according to the expressions given by Hunt *et al.*⁷ and Huque *et al.*⁵ respectively. A similar agreement may be obtained with the results for the renitrated first fraction. However Kratochvil¹⁶ has shown that reciprocal particle scattering factors are in practice indistinguishable from straight lines over a very wide range of polydispersities. The data of Table 2, yield $DP_w/DP_n = 1.1$ if each fraction is assumed to be monodisperse. The true value is therefore much less than 2 and it will be shown in the next section that $1.3 > DP_w/DP_n > 1.1$, yielding $4.5 \text{ nm} > b > 4.2 \text{ nm}$.

Figures 2 and 5 show that at high angles the scattered intensity per unit concentration due to aggregates is of the same order as that due to single coils. In the unfractionated sample the weight fraction of aggregates is small. As a result values of degree of polymerization and radius of gyration obtained by ignoring the downward curvature in Figure 1 and extrapolating high angle data to zero angle differ little from those obtained from Figure 5. Table 1 shows values for the coil component, DP_c and S_c calculated in this way for all three samples, together with values for the radius of gyration of the aggregates, S_g , found using the relation:

$$S_g^2 \sim \frac{(\bar{S}^2)_z M_w - S_c^2 M_c}{M_w - M_c} \quad (1)$$

$(\bar{S}^2)_z$ and M_w relate to the whole sample and are found from the low angle data in the usual way. In all cases squares of radii of gyration are *z* averages and molecular weights weight-averages. The definition of the aggregates is here somewhat arbitrary however. Whereas there appears to be a fairly well defined fraction of gel-like material, the Huggins constants shown in Table 2 decrease continuously with fraction number and only for low molecular weights approach the value of 0.3 characteristic of polymers in a good solvent¹⁷. Thus it is likely that the Zimm plot of Figure 5 contains a contribution from residual gel-like material, the particles of which are not large enough to cause any downward curvature. The extent to which the

Figure 4 Zimm plot for cellulose trinitrate derived from cotton (Deltapine), sample I (Table 1), fraction 1 (Table 2), after renitration. $\lambda_0 = 436 \text{ nm}$; solvent, ethyl acetate

parameters calculated for the coil component (DP_c, M_c, S_c, b) are thereby in error depends upon the distribution of sizes of the residual gel-like particles. It will be argued later that S_c and b are seriously affected but M_c and DP_c much less so.

More extensively nitrated samples

Table 3 shows data derived from Zimm plots representing light scattering measurements on samples which had been obtained by nitration for longer periods. These samples were considerably degraded. Their Zimm plots (e.g. Figure 6) however, exhibited no downward curvature indicating the absence of large aggregates. There are probably two reasons for this. First, aggregates were broken down into single chains after longer periods of nitration and second, any remaining aggregates were more easily removed during the light scattering clarification procedure due to the lower solution viscosity. After 25 h of nitration some downward curvature reappeared in the Zimm plot although this was easily removed by centrifuging the sample for 4 h at $100\,000 \times g$ and decanting. Still longer periods of nitra-

tion, however, produced even greater downward curvature and the material causing this is clearly different in origin from the aggregates in the mildly nitrated samples. It is likely that all the samples contain some very dense particles which are highly resistant to nitration but are normally easily removed during the light scattering clarification procedure. Very long periods of nitration however turn these into swollen gel particles which are not so easily removed. It is thought that the two types of gel-like material arise from different components of the cell wall and the biological significance of this will be discussed elsewhere.

Table 3 and Figure 7 show the results of osmotic pressure measurements. These were made possible by virtue of the lower degrees of polymerization and the fact that the lower solution viscosities enabled higher concentrations to be used. The polydispersities are low with $DP_w/DP_n \sim 1.3$. It is very unlikely therefore that the coil components of the more mildly nitrated samples had a higher polydispersity than this. Values of b calculated for the more extensively nitrated samples are considerably greater than those found for the more mildly nitrated samples and those found by other authors. This cannot be explained

in terms of experimental errors (the calculation of b depends only on the square root of the slope of the Zimm plot and the square root of the estimate of polydispersity). The intrinsic viscosities are also higher than those found by other authors and the dispersity in intrinsic viscosity may be correlated with the disparity in b . The second virial coefficients obtained by light scattering (B_{ls}) and osmometry (B_{op}) are in fair agreement in contrast to the results of other authors who have usually obtained much lower values for B_{ls} comparable to the values obtained in the present work for the unfractionated mildly nitrated samples. All of these discrepancies may be explained in terms of residual gel-like material in the mildly nitrated samples and the samples of other authors. The general effects of the presence of gel-like material will now be discussed.

Effects of the presence of gel-like material on the solution properties of cellulose trinitrate

Particle scattering factors. Numerical calculations using particle scattering factors similar to that obtained from Figure 2 show that the presence of small numbers of large aggregates not only causes downward curvature in the Zimm plot at low angles of scatter, but also produces a slight decrease in the slope at high angles. This decrease is due to the fact that the aggregates are denser than the coils and is mitigated by the downward curvature at low angles resulting from the large disparity in size between coil and aggregate. Gel-like material comprised of smaller particles would not necessarily cause downward curvature and when this is the case a greater decrease in the slope of the Zimm plot would be expected. This decrease could be considerable if a significant proportion of the gel-like material were comprised of particles comparable in size to or smaller than the single coils. If this sort of material remained in sample I after the larger aggregates had been removed by fractional precipitation, as in fact the viscosity measurements on the fractions

(Table 2) have already suggested, then this would account for the discrepancy in the values of b calculated for the mildly and more extensively nitrated samples. On this basis the highest value of b obtained is nearest the true value, i.e. $b \geq 5.6$ nm, showing that the flexibility of the cellulose trinitrate chain has been overestimated by other workers. The optimum period of nitration from the point of view of investigating chain statistics appears to be in the range 2 to 6 h. After very long periods of nitration additional gel-like material becomes soluble leading once again to lower apparent values of b .

It is the contention of the authors that the variability observed in the high angle slopes of plots of KC/R_θ against $\sin^2\theta/2 + kC$ for given concentrations is entirely due to the removal of varying amounts of gel-like material during the light scattering clarification procedure. It is on the basis of the above discussion that data yielding the highest slopes were selected to construct Zimm plots. However the observed variability would in any case affect the calculated values of b by only $\pm 5\%$.

Second virial coefficients. An analysis of the effect of polydispersity on the second virial coefficients as determined by light scattering and osmometry is given in the Appendix. B_{ls} and B_{op} should be the same for a solution of single coils unless the polydispersity is very high. It is also shown that when gel-like material is present:

$$\frac{B_{ls}}{B_{op}} \sim \frac{M_c}{M_w} \quad (2)$$

where M_c is the true weight-average molecular weight of the coil component and M_w is that for the whole sample.

In practice B_{ls} may be even lower due to the fact that less gel-like material is removed at the higher concentrations during the light scattering clarification procedure. In either case serious disagreement between B_{ls} and B_{op} is a sure indication that the results are affected by the presence of a gel-like component, quite apart from whether or not downward curvature in the Zimm plot is observed. Agreement between B_{ls} and B_{op} however merely indicates that $M_c \sim M_w$ showing that any gel-like material present does not contain sufficient heavy particles to affect the measured molecular weight. The high value of B_{ls} obtained for sample I with the first fraction removed would indicate that the value for DP_c obtained is reliable. However as already argued the value of b obtained from the slope of the Zimm plot is not correct.

Intrinsic viscosity and diffusion constants. Intrinsic viscosity is a measure of effective partial specific volume. For a given sample molecular weight therefore, the effect of the presence of a gel-like component is to lower the intrinsic viscosity as well as lowering the experimentally determined value of b . The observed correlation in Table 3 is therefore to be expected.

A diffusion constant is an inverse measure of effective hydrodynamic diameter so that for a given sample molecular weight the effect of the presence of a gel-like component is to increase the diffusion constant. The straight line which best fits a double logarithmic plot of diffusion constant against degree of polymerization obtained from data in Table 3 has a slope somewhat less than -1^{18} . It is likely that this arises from a systematic variation in the amount of gel-like material present, the diffusion constants for the lower degrees of polymerization being too high.

Comparison of the experimentally determined chain statistics of cellulosic polymers in general with conformational analysis

In order to compare experimental results with the results of conformational analysis it is necessary to correct experimental data so as to obtain the value of b , b_0 corresponding to the unperturbed chain statistics. In the present work the only method available is to apply the expression of Orofino and Flory¹⁹, which, by taking account of excluded volume, gives the expansion factor, α , in terms of the second virial coefficient. For the sample yielding the highest value of b (5.6 nm) α can be calculated in this way to be 1.04. In view of the experimental errors involved, this correction is not considered to be significant.

No detailed theoretical work has been carried out on the conformation of cellulose derivatives. Cellulose itself has been investigated. The results however depend very much on the value, τ , assumed for the angle at the bridge oxygen atom and also on the type of potential energy function and the associated parameters used to estimate the permitted degrees of rotation about the C—O bonds. Assuming free rotation, b_0 varies from 0.89 nm for $\tau = 118^\circ$ to 0.77 nm for $\tau = 110^\circ$ ^{20,21}. Using Lennard—Jones potentials and Van der Waals radii obtained from crystallographic data to take account of hindered rotation, Cleland²¹ obtained $b_0 = 2.1$ nm for $\tau = 118^\circ$ and $b_0 = 4.3$ nm for $\tau = 110^\circ$. However by increasing the Van der Waals radii by 0.02 nm (which Cleland considers more realistic) the values $b_0 = 4.6$ nm for $\tau = 118^\circ$ and $b_0 = 4.8$ nm for $\tau = 110^\circ$ are obtained. Using Kitaigorodsky potentials Yathindra and Rao²⁰ have obtained $b_0 = 3.8$ nm for $\tau = 118^\circ$ and $b_0 = 5.2$ nm for $\tau = 110^\circ$, Cleland obtaining $b_0 = 3.5$ nm for the former figure. Yathindra and Rao have suggested that τ could be different in different solvents.

The solution properties of cellulose have been investigated in cadoxen^{22,23} and iron sodium tartrate²⁴. Numerous investigations of the solution properties of various derivatives have also been made viz. the hydroxyethyl,^{25,26} hydroxypropyl-²⁷, ethyl(hydroxyethyl)-^{28,29}, methyl-³⁰, ethyl-^{31,32}, sodium (carboxymethyl)-^{33,34} derivatives, and also the acetate^{35–37}, tricaproate³⁸, tricarbanilate^{39–44}, tributrylate⁴⁵, tricaprilate⁴⁵ and trinitrate^{2–6,11}. An extensive review of these publications has been given elsewhere¹. Values of b_0 range from 1.5 to 4.5 nm but in general agreement between different authors for the same derivative is not good, and only the values for cellulose trinitrate (excluding those presented in the present paper) consistently fall within the range predicted by the conformational analysis for cellulose. Most other work has suggested that cellulose and its derivatives are highly flexible polymers. Brown, Henley and coworkers for instance have obtained results for cellulose and the hydroxyethyl-, ethyl(hydroxyethyl)- and sodium (carboxymethyl)- derivatives which indicate that all have the same flexibility with a persistence length equal to about four monomer units, comparable in fact to synthetic polymers such as polystyrene.

Previously reported experimental data is therefore clearly at variance with conformational analysis and Brant and Goebel⁴⁶ have suggested that this might result from a fault in the molecular model, in that glucose residues in the cellulose chain might occasionally adopt conformations other than C1. It is the contention of the present authors however that nearly all previously reported values of b_0 are too low and that the true values of b_0 for cellulose and many derivatives probably lie within the range predicted

by the conformational analysis of cellulose, whilst the true value for cellulose trinitrate is somewhat higher.

The above assertions are based on the authors' belief in the light of experience gained in the present work, that gel-like material in the samples investigated by most other authors has seriously affected their results. Second virial coefficients as determined by light scattering and osmometry have nearly always been in serious disagreement (by factors as much as three²⁵), B_{12} often varying widely and at random with molecular weight. B_{12} can often be correlated with the biological source of material, a fact never commented on by the authors concerned which can only be explained by the presence of varying amounts of gel-like material, and in one case B_{12} has been correlated with the degree of nitration⁵. It might be expected that using a low value for B_{12} in the Orofino—Flory equation would lead to an underestimate of α and thus tend to compensate for the effect of a gel-like component on the measured value of b . However the form of the Orofino—Flory equation is such that substitution of a too low value for the radius of gyration tends to counteract this. Huggins constants reported for cellulosic polymers are often very high, again indicating the presence of gel-like material. Nevertheless it might be expected that chain statistics calculated from viscosity measurements would be less affected by the presence of a gel-like component than those calculated from Zimm plots. In fact values of b_0 calculated from the former tend to be even lower than those calculated from the latter. This arises because the various methods used to calculate b_0 ^{47–50} involve the extrapolation of intrinsic viscosity data to zero molecular weight, i.e. into a region where the theories themselves do not apply and in which the effective value of b_0 would be lower than the true value.

Finally it must be mentioned that the work of Mackie and Sellen on the nitrates of mannan and xylan^{12,51} is open to all the criticisms levelled here against other authors. The purely relative conclusions of these publications that the chain statistics of the trinitrate of β -1,4 linked mannan are similar to those of cellulose trinitrate whilst the dinitrate of β -1,3 linked xylan is a much more flexible polymer still stand. The absolute values of b quoted are however almost certainly much too low.

CONCLUSIONS

The results of solution experiments on cellulose trinitrate obtained by mild nitration procedures are very much affected by the presence of gel-like material even when the larger aggregates are removed by fractional precipitation so as to yield straight line Zimm plots. Gel-like material remaining consists of particles denser than the single coils but of comparable or smaller size so that values obtained for the effective bond length are too low. Experiments on more extensively nitrated samples indicate that the effective bond length is at least 5.6 nm. It is suggested that all previous investigations of cellulosic polymers have yielded too low values for the effective bond length and that this has led to the apparent disagreement with conformational analysis.

APPENDIX

It is not possible to obtain general expressions which relate the values of B obtained from light scattering and osmotic pressure measurements to the values which would be obtained for constituent components if each were in solution alone⁵²⁻⁵⁴. B_{op} and B_{ls} are in fact given by:

$$B_{op} = \frac{\sum_i \sum_j C_i C_j B_{ij}}{\sum_i \sum_j C_i C_j}, \quad B_{ls} = \frac{\sum_i \sum_j C_i C_j M_i M_j B_{ij}}{\sum_i \sum_j C_i C_j M_i M_j} \quad (A1)$$

If $B_{ij} = (B_i + B_j)/2$, an assumption which will not lead to appreciable error if B_i and B_j are not too different*, then $B_{op} = B_w$ and $B_{ls} = B_z$. B is not expected to vary greatly with molecular weight for single chain polymers and unless the polydispersity is very high, values of B obtained by the two methods should agree. This is not the case when a gel-like component is present however. Equation (A1) may be written:

$$\frac{B_{ls}}{B_{op}} = \frac{1}{M_w^2} \frac{\sum_i \sum_j C_i C_j M_i M_j B_{ij}}{\sum_i \sum_j C_i C_j B_{ij}} \quad (A2)$$

If the second virial coefficients corresponding to all mutual interactions between gel-like particles are assumed to be zero due to their high density and/or low solubility, and if the polydispersity of the coil component is low enough for all mutual coil interactions to be characterized by a single value B_c then:

$$\frac{B_{ls}}{B_{op}} = \frac{M_c (w_c M_c B_c + 2w_g M_g B_{cg})}{M_w^2 (w_c B_c + 2w_g B_{cg})} \quad (A3)$$

where w indicates weight fraction. This formula is oversimplified since B_{cg} will be different for each gel-coil interaction and there are no real criteria for saying what the effective value of B_{cg} in equation (A3) is, as in this case the second virial coefficients of the two components are very different. However, crude calculations made on data obtained from *Figures 2* and *5* by adopting a hard sphere model in which the equivalent radius is proportional to the radius of gyration, indicate that the foregoing assumption is still approximately true, i.e. $B_{cg} \sim B_c/2$. Substituting this in equation (A3) yields equation 2†.

* For a hard sphere model in which the radius of the equivalent hard sphere is assumed to be proportional to $(r^2)^{1/2}$ and in which r^2 is proportional to molecular weight:

$$B_{ij} = \frac{3}{8} (B_i + B_j) + \frac{1}{8} \left(\frac{B_i^2}{B_j} + \frac{B_j^2}{B_i} \right)$$

† A more rigorous but less useful expression may be obtained by putting $B_{cg} > 0$ which yields $B_{ls}/B_{op} > (M_c/M_w)^2$.

Dynamics of solutions of entangled polymers

D. A. Maclnnes

Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow G1 1XL, UK

(Received 22 March 1976)

A simple network model for the relaxation dynamics of entangled polymer fluids is presented. It has been assumed that entanglement friction is the principal dissipative mechanism for all but the longest wavelength modes in the entanglement region, and this gives rise to a peak in the relaxation spectrum. This model is shown to predict viscoelastic response functions whose qualitative features agree well with those observed experimentally, and in particular the well-known, 'C²' effect of entanglement coupling is derived in a natural manner.

INTRODUCTION

The phenomenon of entanglement coupling in polymer fluids is well known and has been studied many times¹. Most of the work has concentrated on explaining the response in terms of a spectrum of relaxation modes and the experimental indications are that the major portion of the response derives from a relatively narrow region, known as the terminal region, of the spectrum.

The purpose of this paper is to propose a very simple model, for the dynamics of an entangled polymer fluid, which reproduces some of the major features of the response in a physically transparent manner. This work depends greatly on the work of Edwards², Edwards and Grant³ and de Gennes⁴. The standard assumption is made that the normal relaxational modes of the fluid can be separated into two groups – single chain modes and entanglement modes – and that with the transition between these groups a characteristic relaxation time T_c can be associated. It is further assumed that there is a disentanglement time⁴ T_d such that for motion on a time scale $t \gg T_d$ the polymer fluid will simply flow showing no elasticity. The primary concern in the present study is with modes with relaxation times τ such that $T_d < \tau < T_c$ i.e. the terminal spectrum. It is assumed that there are no relaxation modes with $\tau > T_d$. The spectrum and response of single chain modes (i.e. those with relaxation times $< T_c$) have already been studied⁵⁻⁷, and given certain assumptions it has been shown that the relaxation spectrum contains a peak. The present study shows that the terminal spectrum should show a similar peak, and that this feature is crucial in the interpretation of the experimental data.

DYNAMICS OF THE TERMINAL REGION

For $T_d > \tau > T_c$ (i.e. for relaxation in the terminal region) the motion of the polymer fluid is taken to be that of an elastic network with two dissipative mechanisms: polymer–polymer (entanglement) friction and polymer–solvent friction. The equation of motion is assumed to be:

$$\zeta \frac{\partial \mathbf{u}(\mathbf{r}t)}{\partial t} - \zeta_e \frac{\partial}{\partial t} \nabla_{\mathbf{r}}^2 \mathbf{u}(\mathbf{r}t) - \epsilon \nabla_{\mathbf{r}}^2 \mathbf{u}(\mathbf{r}t) = \phi(\mathbf{r}t) \quad (1)$$

where $\mathbf{u}(\mathbf{r}t)$ is the position vector of the network element labelled \mathbf{r} ; ζ is the polymer–solvent friction constant; ζ_e is the entanglement friction; ϵ is the 'elastic constant' of the network and $\phi(\mathbf{r}t)$ is a random force such that:

$$\langle \phi(\mathbf{r}t) \phi(\mathbf{r}'t') \rangle = f(\mathbf{r} - \mathbf{r}') \delta(t - t') \quad (2)$$

where $f(\mathbf{r})$ is an unknown function and $\delta(y)$ is the Dirac delta function. The average is over an equilibrium ensemble. To find the relaxation times implicit in equation (1) the author has followed the procedure of Edwards² and Edwards and Grant³ in calculating the second moment:

$$\langle [\mathbf{u}(\mathbf{r}t) - \mathbf{u}(\mathbf{r}'t')]^2 \rangle$$

Writing

$$\mathbf{u}(\mathbf{r}t) = \iint \bar{\mathbf{u}}(\mathbf{k}\omega) \exp [i(\mathbf{k} \cdot \mathbf{r} + \omega t)] d\mathbf{k} d\omega$$

gives

$$\langle [\mathbf{u}(\mathbf{r}t) - \mathbf{u}(\mathbf{r}'t')]^2 \rangle = 2 \iint \langle \bar{\mathbf{u}}(\mathbf{k}\omega) \bar{\mathbf{u}}^*(\mathbf{k}\omega) \rangle \times \{1 - \cos[\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}') + \omega(t - t')]\} d\mathbf{k} d\omega \quad (3)$$

(unimportant normalization constants are omitted throughout). This is obtained by observing that:

$$\iint \exp(i\mathbf{k} \cdot \mathbf{r}) \exp(i\mathbf{k}' \cdot \mathbf{r}') d\mathbf{k} d\mathbf{k}' \propto \cos[\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')]$$

Carrying out a Fourier transform on equation (1) gives:

$$\zeta i\omega \bar{\mathbf{u}}(\mathbf{k}\omega) + \zeta_e i\omega k^2 \bar{\mathbf{u}}(\mathbf{k}\omega) + \epsilon k^2 \bar{\mathbf{u}}(\mathbf{k}\omega) = \bar{\phi}(\mathbf{k}\omega) \quad (4)$$

so

$$\bar{\mathbf{u}}(\mathbf{k}\omega) = \bar{\phi}(\mathbf{k}\omega) / [i\omega(\zeta + \zeta_e k^2) + \epsilon k^2] \quad (5)$$

Inserting equation (5) into equation (2) gives:

$$\langle [\mathbf{u}(rt) - \mathbf{u}(r't')]^2 \rangle = 2 \iint \frac{\langle \bar{\phi}(\mathbf{k}\omega) \bar{\phi}^*(\mathbf{k}\omega) \rangle \{1 - \cos [k \cdot (r - r') + \omega(t - t')]\}}{\omega^2(\zeta + \zeta_e k^2)^2 + \epsilon^2 k^4} d\mathbf{k} d\omega$$

Now equation (2) implies:

$$\langle \bar{\phi}(\mathbf{k}\omega) \bar{\phi}^*(\mathbf{k}\omega) \rangle = \bar{f}(\mathbf{k}) \quad (7)$$

so equation (5) becomes:

$$\begin{aligned} \langle [\mathbf{u}(rt) - \mathbf{u}(r't')]^2 \rangle &= 2 \iint \frac{\bar{f}(\mathbf{k}) \{1 - \cos [\omega(t - t')]\}}{\omega^2(\zeta + \zeta_e k^2)^2 + \epsilon^2 k^4} d\mathbf{k} d\omega \\ &= \frac{1}{2\pi} \int \frac{\bar{f}(\mathbf{k})}{k^2(\zeta + \zeta_e k^2)} \left\{ 1 - \exp \left[-\frac{\epsilon k^2}{\zeta + \zeta_e k^2} |t - t'| \right] \right\} d\mathbf{k} \end{aligned} \quad (8)$$

The integration over ω is carried out by complex variable methods⁸ and the result is standard. Thus it is clear from equation (8) that the dispersion relation of the terminal spectrum is:

$$\tau(k) = \zeta + \zeta_e k^2 / \epsilon k^2 \quad (9)$$

Equation (9) is the principal result of this section.

SPECTRUM OF RELAXATION TIMES

The spectrum is assumed to be divided into three separate regions: (a) $\tau > T_d$; (b) $T_d > \tau > T_c$ and (c) $T_c > \tau$.

Region (c) has already been discussed⁵⁻⁷, and has been shown, given certain conditions, to contain a peak (at $\tau \equiv \omega_s^{-1}$).

Region (a) is of little interest, since it is assumed that there are no relaxation modes in this region.

Region (b) is the terminal region with dispersion relation given by equation (9). The entanglement friction is taken to be the dominant resistance for almost all the motion in the terminal region. This implies $\zeta_e k^2 \gg \zeta$ for most values of k such that $\tau(k) < T_d$ which gives a peak in the relaxation spectrum at $\tau \approx \zeta_e / \epsilon$. To obtain an estimate of the number, N , of modes in the peak it is assumed that nearly all of the modes of the network which cannot be described by single chain dynamics are concentrated round $\tau \approx \zeta_e / \epsilon$. By following Graessley¹ it is found that N is the number of modes in the 'shifted Rouse' spectrum i.e. $N \sim C^2 M^0$, or by following de Gennes⁴ by means of essentially the same procedure but with excluded volume taken into account, it is found that $N \sim C^{2.25} M^0$. In the present study we have taken $N \sim C^{2\alpha}$ where $0 < \alpha < 1$.

Thus the predominant features of the spectrum are two peaks, one with $\tau > T_c$ and one with $\tau < T_c$.

VISCOELASTIC RESPONSE

To calculate the response it is necessary to know the visco-

elastic weighting factor of a normal mode. The author has shown this to be proportional to the relaxation time of the normal mode for the principal viscoelastic modes in single chain dynamics⁷, and has assumed it to be so for network dynamics. An argument is given to support this claim but this has been relegated to an appendix, for two reasons: (a) the result is what we would intuitively expect; (b) the argument contains features which, although plausible on physical grounds, will require further analysis to become totally justified.

The zero frequency response will come almost entirely from the terminal peak. This will give for the steady-state viscosity, η_0 , and the equilibrium compliance, J_e :

$$\eta_0 = \sum_{k=1}^N \tau(k) \approx N\tau_0 \quad (\tau_0 \equiv \zeta_e / \epsilon)$$

and

$$\begin{aligned} J_e &= \lim_{\omega \rightarrow 0} \{G'(\omega) / [G''(\omega)]^2\} \\ &\approx N\tau_0^2 / N^2\tau_0^2 \\ &= N^{-1} \end{aligned}$$

Thus

$$\eta_0 \sim C^{2\alpha} \tau_0$$

and

$$J_e \sim C^{-2\alpha} \quad (10)$$

Equation (10) compares well with similar expressions quoted by Graessley¹.

The principal features of the dynamical response can be seen from $G'(\omega)$ and $G''(\omega)$

$$\left\{ G'(\omega) = \sum_k \frac{\omega^2 \tau(k)^2}{1 + \omega^2 \tau(k)^2}; G''(\omega) = \sum_k \frac{\omega \tau(k)}{1 + \omega^2 \tau(k)^2} \right\}$$

$G'(\omega)$ will clearly have a plateau stretching from $\omega \approx \epsilon / \zeta_e$ to $\omega = \omega_s$ and the magnitude of the plateau modulus will be proportional to N i.e. to $C^{2\alpha} M^0$. $G''(\omega)$ will appear to contain a separate relaxation region at $\omega = \epsilon / \zeta_e$. These results bear close resemblance to those quoted by Graessley¹ and those reported by Riande *et al.*⁹. The magnitude of the maximum in $G''(\omega)$ at $\omega = \epsilon / \zeta_e$ should be proportional to N i.e. to $C^{2\alpha} M^0$. The author is unaware of any experimental results against which to test this prediction.

CONCLUSION

A simple model for the dynamics of a fluid of entangled polymers has been proposed, and it has been shown how this model predicts a viscoelastic response whose qualitative features agree well with experiment, in particular the 'C²' effect attributed to entanglement coupling occurs naturally and is a result of a peak in the relaxation spectrum.

The principal features lacking in the model are considered to be: (a) Mathematical rigour—many assumptions

are introduced with only physical intuition as a guide. (b) The quantities ϵ , ζ and ζ_e are introduced as parameters. To obtain the full theory of the viscoelastic response (i.e. the molecular weight dependence) it will probably be necessary to relate equation (1) to a more detailed molecular theory.

It is felt that these omissions are justified in that the present work is only a first step. The analysis of (a) and (b) would seem to contain very difficult but perhaps not intractable mathematical difficulties.

To obtain an idea of the M dependence of the response we need to know the M dependence of τ_0 . It would be consistent with the present analysis to assume $\tau_0 \sim T_d$. de Gennes found $T_d \sim M^3$ which would give $\tau_0 \sim M^3$ in close agreement with experiment. However this feature is grafted on to the present model rather than occurs naturally, and should not be taken too seriously.

ACKNOWLEDGEMENT

It is a pleasure to acknowledge receipt of financial support from the Science Research Council as part of the programme concerning molecular motion in polymers currently under study at Strathclyde University.

APPENDIX

Response of the entangled network

The purpose of this Appendix is to give justification to the claim that each viscoelastic mode is weighted according to its relaxation time. The argument is not rigorous, rather it is carried out by analogy with those in refs 7 and 10.

The viscosity is taken as:

$$\eta = - \left\langle \int_v \mathbf{u}_y(\mathbf{r}t) \mathbf{F}_x(\mathbf{r}t) d\mathbf{r} \right\rangle \quad (\text{A1})$$

where $\mathbf{F}_x(\mathbf{r}t)$ is the elastic force on the element of network labelled \mathbf{r} at time t . The average is over the non-equilibrium distribution of the network, in a shear field, given by the function ψ which is determined by a diffusion equation. The secular force in a shear field $\mathbf{V}_0(\mathbf{r}t)$ on an element of network is taken as:

$$\zeta \left[\frac{\partial \mathbf{u}(\mathbf{r}t)}{\partial t} - \mathbf{V}_0(\mathbf{r}t) \right] - \zeta_e \left[\frac{\partial}{\partial t} \nabla_{\mathbf{r}}^2 \mathbf{u}(\mathbf{r}t) - \nabla_{\mathbf{r}}^2 \mathbf{V}_0(\mathbf{r}t) \right] - \epsilon \nabla_{\mathbf{r}}^2 \mathbf{u}(\mathbf{r}t) \equiv f_s(\mathbf{r}t) \quad (\text{A2})$$

where $\nabla_{\mathbf{r}}$ is the gradient with respect to \mathbf{r} .

The principal difference between equations (A2) and (1) is that in equation (A2) velocities are taken relative to the local shear velocity. We have no proof that this is the correct procedure but adopt it by analogy with ref 7. If $\mathbf{V}_0(\mathbf{r}t)$ is omitted in the entanglement resistance term there would appear, in a manner identical to ref 11, a non-relaxing component of the fluid viscosity and this is taken to be unphysical.

The diffusion equation for the network is:

$$\frac{\partial \psi}{\partial t} = - \int \nabla_{\mathbf{u}(\mathbf{r}t)} \cdot \left[\psi \frac{\partial \mathbf{u}(\mathbf{r}t)}{\partial t} \right] d\mathbf{r} \quad (\text{A3})$$

Fourier transform the $\mathbf{u}(\mathbf{r}t)$, $\mathbf{V}_0(\mathbf{r}t)$ and $\nabla_{\mathbf{u}(\mathbf{r}t)}$ to normal coordinates by writing:

$$\mathbf{u}(\mathbf{r}t) = \int \cos(\mathbf{k} \cdot \mathbf{r}) \bar{u}_c(\mathbf{k}t) d\mathbf{k} + \int \sin(\mathbf{k} \cdot \mathbf{r}) \bar{u}_s(\mathbf{k}t) d\mathbf{k}$$

Similarly for $\mathbf{V}_0(\mathbf{r}t)$ and:

$$\nabla_{\mathbf{u}(\mathbf{r}t)} = \int \cos(\mathbf{k} \cdot \mathbf{r}) \nabla_{\bar{u}_c(\mathbf{k}t)} d\mathbf{k} + \int \sin(\mathbf{k} \cdot \mathbf{r}) \nabla_{\bar{u}_s(\mathbf{k}t)} d\mathbf{k}$$

where the bar, $\bar{\quad}$ denotes 'transformed function'. Unimportant normalization factors are omitted throughout.

Thus in normal coordinates the diffusion equation becomes:

$$\frac{\partial \psi}{\partial t} = - \sum_{\alpha} \int \nabla_{\bar{u}_{\alpha}(\mathbf{k}t)} \left\{ \psi \left[\bar{V}_{0\alpha}(\mathbf{k}t) - \frac{\epsilon k^2}{\zeta + \zeta_e k^2} \bar{u}_{\alpha}(\mathbf{k}t) \right] - \frac{k_B T}{\zeta + \zeta_e k^2} \nabla_{\bar{u}_{\alpha}(\mathbf{k}t)} \psi \right\} d\mathbf{k} \quad (\text{A4})$$

where α represents c or s . Take

$$\bar{V}_{0\alpha}(\mathbf{k}t) \equiv (g \bar{u}_{y\alpha}(\mathbf{k}t), 0, 0)$$

The viscosity

$$\eta = - \left\langle \int \mathbf{u}_y(\mathbf{r}t) \mathbf{F}_x(\mathbf{r}t) d\mathbf{r} \right\rangle = \sum_{\alpha} \int \epsilon k^2 \langle \bar{u}_{y\alpha}(\mathbf{k}t) \bar{u}_{x\alpha}(\mathbf{k}t) \rangle d\mathbf{k}. \quad (\text{A5})$$

The $\langle \bar{u}_{y\alpha}(\mathbf{k}t) \bar{u}_{x\alpha}(\mathbf{k}t) \rangle$ can be found in a manner similar to that given by Yamakawa¹⁰, i.e. by the construction from equation (A4) of a closed set of first order linear differential equations. This is carried out as follows:

$$\begin{aligned} \frac{\partial}{\partial t} \langle \bar{u}_{y\alpha}(kt) \bar{u}_{x\alpha}(kt) \rangle &= - \sum_{\beta} \int dk' \langle g \bar{u}_{y\beta}(kt) \times \\ &\frac{\partial \psi}{\partial \bar{u}_{x\beta}(k't)} \bar{u}_{y\alpha}(kt) \bar{u}_{x\alpha}(kt) - \frac{\epsilon k'^2}{(\zeta + \zeta_e k'^2)} \bar{u}_{y\alpha}(kt) \times \\ &\bar{u}_{x\alpha}(kt) \nabla_{\bar{u}_{\beta}(k't)} \cdot \{ \bar{u}_{\beta}(k't) \psi \} - \\ &\frac{k_B T}{(\zeta + \zeta_e k^2)} \bar{u}_{y\alpha}(kt) \bar{u}_{x\alpha}(kt) \nabla_{\bar{u}_{\beta}(k't)}^2 \psi \rangle \\ &= g \langle \bar{u}_{y\alpha}^2(kt) \rangle - \frac{2\epsilon k^2}{(\zeta + \zeta_e k^2)} \langle \bar{u}_{y\alpha}(kt) \bar{u}_{x\alpha}(kt) \rangle \end{aligned} \quad (A6)$$

where β is summed over c and s .

This results, as in ref 10, by the application of boundary conditions on ψ and by the independence of the normal coordinates.

Similarly

$$\begin{aligned} \frac{\partial}{\partial t} \langle \bar{u}_{y\alpha}^2(kt) \rangle &= - 2 \frac{\epsilon k^2}{(\zeta + \zeta_e k^2)} \langle \bar{u}_{y\alpha}^2(kt) \rangle + \\ &2 \frac{k_B T}{(\zeta + \zeta_e k^2)} \end{aligned} \quad (A7)$$

The equations (A5), (A6) and (A7) are identical in form to those of Yamakawa¹⁰ apart from the replacement of the ordinary friction constant ζ by an effective friction constant $(\zeta + \zeta_e k^2)$. Thus the expression for the viscosity will have the same form as in ref 10 i.e.

$$\eta(\omega)_{\alpha} \sum_k \left[\frac{\tau(k)}{1 + i\omega\tau(k)} \right]$$

where $\tau(k) = \zeta + \zeta_e k^2 / \epsilon k^2$ giving that the viscoelastic weighting factor of each mode is the relaxation time of that mode.

Effect of macromolecular length on anisotropic scattering of light in an electric field*

M. Dębska-Kotłowska and S. Kielich

Nonlinear Optics Division, Institute of Physics, A. Mickiewicz University, 60-780 Poznań,

Grunwaldzka 6, Poland

(Received 9 April 1976)

Light scattering by monodisperse solutions of rigid rod-like anisotropic macromolecules, with linear dimensions l of the order of incident wavelength λ , oriented in an external d.c. electric field, E has been analysed. The relative variations δV_v^E , δH_v^E , δV_h^E , δH_h^E of the scattered light components are discussed for the three values $[l/\lambda] = 1, 0.5, 2$, and various reorientation parameters, $p = [\mu E/kT]$ of the permanent dipole moment μ and $q = [(\alpha_3 - \alpha_1)E^2/2kT]$ of the moment induced by the principal polarizabilities $\alpha_1 = \alpha_2 \neq \alpha_3$. The saturation orientation field strength has been calculated for certain macromolecules with the aim of determining their optical anisotropy numerically.

INTRODUCTION

Relative intensity variations of the components of light scattered by monodisperse solutions of macromolecules, oriented in an external d.c. electric field, are a source of abundant data concerning their optical, electric and geometrical properties¹. The field effect has been considered for large macromolecules, of linear dimensions comparable with the incident light wavelength, for particular cases of the Rayleigh-Debye-Gans approximation^{2,3}. Wippler and Benoit⁴ analysed theoretically the influence of a d.c. electric field on the particle interference scattering factor, $P(\theta)$, with an accuracy to the square of the field strength E . Stoylov^{5,6} extended their analysis to intense fields, including electric saturation. Ravey⁷ gave a description of the effect of arbitrary orientations of macromolecules having the shape of spheres, rods, discs and Gaussian chains in a d.c. electric field, acting in the direction of the external bisector of the observation angle.

In the present study, on the basis of previous theory^{8,9}, we give an analysis of the relative variations δV_v^E , δH_v^E , δV_h^E and δH_h^E of the respective components of light scattered by solutions of large rod-like macromolecules, oriented by a d.c. electric field applied perpendicularly to the plane of observed scattered light. Our results are obtained by numerical computer calculation of the relative variations for the three values $[l/\lambda] = 1, 0.5$ and 2 , and for various values of the reorientation parameters of the permanent dipole moments and polarizability ellipsoids.

THEORY

Consider dilute, monodisperse solutions of rigid, aniso-

tropic, non-absorbing macromolecules in the shape of rods, of rotation-ellipsoidal symmetry. We have assumed that the symmetry axis of their electric and optical properties coincides with their geometrical axis. Thus, the principal electric polarizability, α_3 , and optical polarizability, a_3 , are parallel to the symmetry axis, the principal 3-axis of the macromolecule, whereas the principal polarizabilities $\alpha_1 = \alpha_2$ and $a_1 = a_2$ are perpendicular. The permanent dipole moment is also assumed to lie along the symmetry axis.

Relative variations in scattered light intensity can be defined as follows^{5,6}:

$$\delta I^E = \frac{I^E - I^0}{I^0} \quad (1)$$

where I^E and I^0 represent the intensity of light scattered in the presence and absence of the d.c. field E . Considering the experimental arrangement shown in Figure 1, and taking into account equation (1) and the expression for I^E and I^0 proposed by Kielich⁹ and Horn², respectively, one can write the relative variations of the vertical (V) and horizontal (H) components of scattered light when the incident light beam is polarized vertically (v), or horizontally (h), as follows:

$$\delta V_v^E = \frac{1}{V_v^0} \times \left[\int_0^\pi \int_0^{2\pi} [1 + 2\kappa(3 \cos^2 \nu - 1) + \kappa^2(9 \cos^4 \nu - 6 \cos^2 \nu + 1)] |R(\nu, \phi)|^2 \times \exp(p \cos \nu + q \cos^2 \nu) \sin \nu d\nu d\phi \right] - 1$$

$$\frac{2\pi \int_0^\pi \exp(p \cos \nu + q \cos^2 \nu) \sin \nu d\nu}{0} \quad (2)$$

* Reported in part at the International Symposium on Electro-optical Properties of Macromolecular Solutions, Liège, September 1974.

Figure 1 The light beam is incident in the Y-direction with its electric vector $\vec{E}(\omega)$ vibrating in the XZ-plane (the direction of the electric vector vibrations defines the light polarization direction: ν , vertical; h horizontal). The scattered light is observed in the x-direction (observation angle $\Theta = 90^\circ$), with the vertical and horizontal component of scattered light denoted by V and H , respectively. θ is the angle between the Z-axis and the macromolecular symmetry axis \vec{n} , whereas ϕ is the azimuth of \vec{n} . The orienting electric field \vec{E} is directed along Z

$$\delta V_h^E = \frac{1}{V_h^0} \times \frac{9\kappa^2 \int_0^\pi \int_0^\pi \cos^2 \nu \sin^2 \nu \cos^2 \phi |R(\nu, \phi)|^2 \times \exp(p \cos \nu + q \cos^2 \nu) \sin \nu d\nu d\phi}{2\pi \int_0^\pi \exp(p \cos \nu + q \cos^2 \nu) \sin \nu d\nu} - 1 \quad (3)$$

$$\delta H_v^E = \frac{1}{H_v^0} \times \frac{9\kappa^2 \int_0^\pi \int_0^\pi \cos^2 \nu \sin^2 \nu \sin^2 \phi |R(\nu, \phi)|^2 \times \exp(p \cos \nu + q \cos^2 \nu) \sin \nu d\nu d\phi}{2\pi \int_0^\pi \exp(p \cos \nu + q \cos^2 \nu) \sin \nu d\nu} - 1 \quad (4)$$

$$\delta H_h^E = \frac{1}{H_h^0} \times \frac{9\kappa^2 \int_0^\pi \int_0^\pi \sin^4 \nu \cos^2 \phi \sin^2 \phi |R(\nu, \phi)|^2 \times \exp(p \cos \nu + q \cos^2 \nu) \sin \nu d\nu d\phi}{2\pi \int_0^\pi \exp(p \cos \nu + q \cos^2 \nu) \sin \nu d\nu} - 1 \quad (5)$$

where²:

$$V_v^0 = (1 - \kappa)^2 \left[\frac{Si(2K)}{K} - \left(\frac{\sin K}{K} \right)^2 \right] + 3\kappa(1 - \kappa) \left[\frac{Si(2K)}{K} + \frac{\sin 2K}{4K^3} - \frac{1}{K^2} + \frac{\cos 2K}{2K^2} \right] + \frac{27}{8} \kappa^2 \left[\frac{Si(2K)}{K} - \frac{4}{3K^2} - \frac{\cos 2K}{4K^4} - \frac{\sin 2K}{4K^3} + \frac{\cos 2K}{2K^2} + \frac{\sin 2K}{8K^5} \right] \quad (6)$$

$$V_h^0 = H_v^0 = 9\kappa^2 \left[\frac{Si(2K)}{16K} + \frac{\cos 2K}{32K^2} + \frac{\sin 2K}{64K^3} + \frac{3 \cos 2K}{64K^4} - \frac{3 \sin 2K}{128K^5} \right] \quad (7)$$

$$H_h^0 = 9\kappa^2 \left[\frac{3Si(2K)}{32K} - \frac{1}{6K^2} + \frac{3 \cos 2K}{64K^2} - \frac{5 \sin 2K}{128K^3} - \frac{19 \cos 2K}{128K^4} + \frac{19 \sin 2K}{256K^5} \right] \quad (8)$$

where,

$$\kappa = \frac{a_3 - a_1}{a_3 + 2a_1} \quad (9)$$

defines the optical anisotropy of the macromolecule, whereas

$$p = \frac{\mu E}{kT} \text{ and } q = \frac{(\alpha_3 - \alpha_1)}{2kT} E^2 \quad (10)$$

are dimensionless reorientation parameters of the permanent dipole moment, μ , and electric polarizability ellipsoid; k is Boltzmann's constant and T the absolute temperature. For rod-like macromolecules, in the Rayleigh-Debye-Gans approximation, the function $R(\theta, \phi)$ is of the form³:

$$R(\theta, \phi) = \frac{\sin \left[K \sin \theta \cos \left(\phi + \frac{\Theta}{2} \right) \right]}{K \sin \theta \cos \left(\phi + \frac{\Theta}{2} \right)} \quad (11)$$

where $K = [(2\pi l \sin \Theta / 2) / \lambda]$ is a parameter dependent on the length l of the object, the observation angle, Θ and the wavelength, λ , of incident light.

DISCUSSION

In the case of small macromolecules, the component variations, equations (2)–(5) can be expressed in the variables p and q in terms of generalized Langevin functions⁹. In the case under consideration, which is that of large macromolecules, it is more simple to proceed by way of numerical computer calculations of $\delta H_v^E = \delta V_h^E$, δH_h^E and δV_v^E in the integral form of equations (2)–(5) versus the reorientation parameters q and p , for $[l/\lambda] = 1, 0.5, 2$.

As can be seen from Figures 2–11, $\delta H_v^E = \delta V_h^E$ (Figures 2 and 3) is negative for almost all the positive q values; δH_h^E (Figures 4 and 5) is negative for all $q > 0$; whereas δV_v^E (Figures 6–11) is positive at practically all $q > 0$. This is because the orienting field, here, is applied perpendicularly to the plane of observation causing a weakening

Figure 2 The relative variation $[-\delta H_v^E]$ as a function of the reorientation parameter q , at $p = 0$. A, $l < (1/20)\lambda$; B, $l = \lambda/2$; C, $l = \lambda$; D, $l = 2\lambda$

Figure 3 The relative variation $[-\delta H_v^E]$ versus the reorientation parameter q , at $p = 4\sqrt{q}$. A, $l = \lambda/2$; B, $l = \lambda$; C, $l = 2\lambda$

Figure 4 The relative variation $[-\delta H_h^E]$ versus the reorientation parameter q , at $p = 0$. A, $l < (1/20)\lambda$; B, $l = \lambda$; C, $l = 2\lambda$

of the horizontal scattered light components and an enhancement of the vertical ones.

The relative variations $\delta V_h^E = \delta H_h^E$ and δV_v^E (Figures 2, 3, 6–11) are strongly dependent on the macromolecular length l . The longer the macromolecule, the larger are the variations, because the scattered light intensity undergoes a weakening due to intramolecular interferences. The weakening is considerably larger if scattered light is observed in the absence of a reorienting field. The depen-

dence on l is less strong in the case of δH_h^E (Figures 4 and 5) since δH_h^E is very small in comparison with δH_h^0 even for macromolecules with $l = 2\lambda$; at very low field strengths, some influence of l on δH_h^E is still apparent, but as E increases δH_h^E very rapidly attains a constant value ($\delta H_h^E \rightarrow -1$), which is now independent of the length of the macromolecule.

With increasing q (i.e. with growing field strength), all relative variations, equations (2)–(5) tend to a finite value when saturation sets in. The saturation phenomenon consists of the complete ordering of the macromolecules in the

Figure 5 The relative variation $[-\delta H_h^E]$ versus the reorientation parameter q , at $p = 4\sqrt{q}$

Figure 7 The relative variation $[\delta V_v^E]$ versus the reorientation parameter q , at $p = 0$ and $\kappa = 0$. A, $l = 2\lambda$; B, $l = \lambda$; C, $l = \lambda/2$

Figure 8 The relative variation $[\delta V_v^E]$ vs. the reorientation parameter q , at $p = 0$ and $\kappa = -0.1$. A, $l = 2\lambda$; B, $l = \lambda$; C, $l = \lambda/2$

Figure 11 The relative variation $[\delta V_v^E]$ vs. q , at $p = 4\sqrt{q}$ and $\kappa = -0.1$. A, $l = 2\lambda$; B, $l = \lambda$; C, $l = \lambda/2$

Figure 9 The relative variation $[\delta V_v^E]$ vs. the reorientation parameter q , at $p = 4\sqrt{q}$ and $\kappa = 0.1$. A, $l = 2\lambda$; B, $l = \lambda$; C, $l = \lambda/2$

Figure 10 The relative variation $[\delta V_v^E]$ vs. the reorientation parameter q , at $p = 4\sqrt{q}$ and $\kappa = 0$. A, $l = 2\lambda$; B, $l = \lambda$; C, $l = \lambda/2$

external orienting field. At a given temperature T , macromolecules with a given value of electric anisotropy, $(\alpha_3 - \alpha_1)$, attain the completely ordered state more readily the smaller their length l .

In calculating the electric field strength when saturation occurs, the incident wavelength, λ , as well as the electric anisotropy value, $(\alpha_3 - \alpha_1)$, plays a highly essential role. For example, in the case of collagen at a wavelength of the order of 5600 Å the relative variation $\delta H_h^E = \delta V_v^E$ attains the value corresponding to saturation in a field of 30 e.s.u.

whereas δH_h^E attains its saturation value at a field strength of 17 e.s.u.

It is also worth stating that, in absolute values, $|\delta V_v^E| = |\delta H_h^E|$, $|\delta V_v^E|$ and $|\delta H_h^E|$ are always largest for macromolecules possessing a permanent electric dipole moment.

The numerical analysis of the components (equations 2–4) is also applicable to the reorientation of macromolecules by the electric field of laser light, of intensity I_L and frequency ω ¹⁰, when $p = 0$ and $q(\omega) = [(\alpha_3 - \alpha_1)I_L/2kT]$. Optical molecular reorientation in polymers¹¹ and liquid crystals^{11–14} has, in fact, successfully been observed a short time ago.

Studies of this kind are of considerable importance for the determination of the optical anisotropy of macromolecules, since the relevant formulae involve relative variations, defined by the phenomenon of electric and optical saturation^{9,15}.

In recent years, electric light scattering observations in synthetic and biological polymers^{16,17} as well as liquid crystals¹⁸ have provided abundant, interesting data on the dipole moments of macromolecules and their polarizability anisotropies. Lately, first observations have been reported¹⁹ of the effect of electric fields on the depolarization ratio of light, scattered by molecular liquids.

Thermal degradation of poly(butylene terephthalate)

V. Passalacqua, F. Pilati, V. Zamboni*, B. Fortunato and P. Manaresi
Istituto Chimico della Facoltà di Ingegneria, Università di Bologna, Bologna, Italy
(Received 6 July 1976)

The thermal degradation of poly(butylene terephthalate) between 240° and 280°C has been studied by measurements of intrinsic viscosity, carboxyl end groups and weight loss. A first-order mechanism of fission, followed by elimination of butadiene, is proposed. The values of the kinetic constant and activation energy are in good agreement with those obtained for simple esters and poly(ethylene terephthalate).

INTRODUCTION

Among the linear polyesters of terephthalic acid with aliphatic diols, poly(butylene terephthalate) (PBT) has found applications in recent times, especially in the field of thermoplastics for injection moulding and films. At the temperatures of processing (250° to 280°C) various degradation effects (thermal, oxidative and hydrolytic) may occur, and while for poly(ethylene terephthalate) (PET) such phenomena have been studied extensively¹⁻¹¹, nothing on this subject has appeared in the literature, to our knowledge, for PBT. Therefore, we have studied the mechanism of the thermal degradation of PBT, between 240° and 280°C. The study was carried out by measurements of viscosity, weight loss and number of carboxyl end groups.

EXPERIMENTAL

Samples were commercial or laboratory products. They were obtained according to the well known technique of condensation of aromatic polyesters¹², i.e. by transesterification of dimethyl terephthalate with 1,4-butanediol at 180°C in the presence of titanium tetrabutyltitanate as catalyst, and subsequent polycondensation in the molten state, at 260°C *in vacuo*.

All samples were free from additives and stabilizers, and the ash content was less than 200 ppm.

The products were of different molecular weights; their properties are shown collectively in *Table 1*. All samples were ground and dried *in vacuo* at 120°C for 6 h before each experiment; under these conditions moisture was reduced to less than 400 ppm.

Degradation technique

Dried samples of PBT were placed in glass tubes, 6 mm i.d., which were placed horizontally in an electrically heated furnace. The variance of the sample temperature was controlled by means of a Philips 'Plastomatic' system, and kept to within $\pm 0.5^\circ\text{C}$.

The temperature difference between the centre and the ends was $\sim 1^\circ\text{C}$.

Degradation was carried out at various temperatures, and special care was taken to prevent the effect of oxygen:

Table 1 Properties of various PBT

* Calculated from $[\eta] = 4.3 \times 10^{-4} \bar{M}_n^{0.76}$

† Values obtained after degradation in a flow of nitrogen for 1 h at 260°C

some preliminary tests were carried out at 260°C in a slight flow of preheated nitrogen; a second group of tests was carried out on tubes which had been repeatedly filled with nitrogen and evacuated, and eventually sealed under vacuum.

Identification of the products

In order to identify the gaseous degradation products the tube was connected to an evacuated gas cell, optical path length 70 mm, in which gases were collected at room temperature. Those degradation products which were liquid and solid at room temperature were generally recovered on the cold wall of the tube out of the furnace; the infra-red spectra were recorded on capillary films or nujol mulls. N.m.r. measurements of the liquid and solid degradation products were performed in CDCl_3 solutions.

Viscosity measurements

Viscosity measurements were carried out using Ubbelohde viscometers on solutions in the solvent mixture phenol/s-tetrachloroethane (50:50 by wt) at $30^\circ \pm 0.05^\circ\text{C}$.

End group analysis

Carboxyl content was determined according to the method of Pohl¹³, using freshly distilled aniline instead of benzyl alcohol as solvent.

An attempt was made also to identify and evaluate quantitatively the -OH end groups by means of infra-red spectroscopy, since the absorption band at 3620 cm^{-1}

* Montedison Spa, Centro Ricerche Bollate, Milan, Italy.

corresponds to the stretching vibration of the free -OH group. However, this method can yield only indicative data, because of experimental difficulties and of the small concentration of the -OH groups.

Weight loss determinations

A Perkin-Elmer thermogravimetric balance model TGS-1 was used for weight loss measurements. These isothermal tests were carried out in nitrogen on small samples (a few mg); special care was taken to avoid losses of those degradation products which are solid or liquid at room temperature. The temperature was calibrated with the Curie points of some selected magnetic materials.

RESULTS

Some preliminary tests, made on different samples in a flow of preheated nitrogen, showed that at 260°C PBT undergoes significant degradation. We found that $[\eta]$ decreases, and also that the ratio $\Delta[\eta]/[\eta]$, after 1 h, varies between 0.124 and 0.164, and does not depend upon the initial value of $[\eta]$ (Table 1); moreover, it seems irrespective of the preparation method.

For a more complete study of the mechanism and kinetics of decomposition we have taken into consideration the sample L₁.

During the degradation tests, volatile products are evolved and some discoloration of PBT occurs. The gas collected up to 280°C was essentially butadiene. The products condensed on the tube wall appeared to be a mixture of two solids and one liquid. One of the solids proved to be terephthalic acid, the other showed a m.p. of 124°C. The liquid distilled at reduced pressure (K_{p5} , 184°C). The i.r. and n.m.r. spectra support the suggestion that the last two are unsaturated esters of terephthalic acid. The elemental analysis and spectral data are reported in Table 2.

In order to ascertain that these degradation products are terephthalic acid mono-3-butenyl (I) and di 3-butenyl-(II) esters, the latter have been prepared by reacting 1-buten-4-ol and terephthalic acid dichloride in the correct

proportions. The spectra of these compounds coincided with those of the degradation products.

Tables 3 and 4 list respectively the viscosity data and the -COOH group content, obtained from samples degraded under vacuum. The \bar{M}_n values were calculated from the relationship¹⁴: $[\eta] = 4.3 \times 10^{-4} \bar{M}_n^{0.76}$.

By thin layer chromatography low molecular weight and volatile products were recognized to be present in the polymer bulk. Viscosity measurements and carboxyl determinations were performed without any previous extraction of these substances.

Table 5 lists the weight losses at various temperatures; the weight losses were transferred into butadiene moles per mole of repeat unit: it was assumed that all gas was butadiene and that all butadiene was in the gaseous phase, because of its low solubility in the polymer¹⁵.

DISCUSSION

The presence of unsaturated esters and butadiene among the degradation products suggests that fission takes place at the ester linkage, as found for carboxylic esters^{16–24} and for the first step of PET degradation^{1–11}.

On the basis of the experimental data the most likely mechanism can be outlined as follows:

Once it is assumed, as is usual, that fissions occur randomly, for the proposed mechanism we obtain:

$$-\frac{d(N \text{ ester linkages})}{dt} = k_1(N \text{ ester linkages}) \quad (3)$$

$$\frac{d[N(-\text{COOH})]}{dt} = k_1(N \text{ ester linkages}) + k_2[N(\text{III})] \quad (4)$$

Table 5 Weight loss data for sample L1

Temperature (°C)	Time (min)	Weight loss %, $\frac{\Delta\rho}{\rho} \times 100$	Butadiene evolution $\times 10^3$ (moles/mole of repeat unit)
260	60	0.2	8.2
260	120	0.3	12.2
260	180	0.35	14.3
260	240	0.4	16.3
280	60	0.3	12.2
280	120	0.7	28.5
280	180	1.1	44.9
300	60	1.1	44.9
300	120	3.0	122.4
300	180	5.7	232.5

$$\frac{d[N(\text{III})]}{dt} = k_1(N \text{ ester linkages}) - k_2[N(\text{III})] \quad (5)$$

$$\frac{d(N \text{ butadiene})}{dt} = k_2[N(\text{III})] \quad (6)$$

where: (*N* ester linkages) = moles of ester linkages/moles of repeat units; [*N*(—COOH)] = moles of —COOH end groups/moles of repeat units; [*N*(III)] = moles of 3-butenyl ester end groups/moles of repeat units; [*N* butadiene] = moles of butadiene/moles of repeat units. According to this mechanism, only the first-order reaction (1) is the rate-controlling step with respect to the degree of polymerization.

This reaction can be described by a kinetic treatment of the Tuckett type²⁴ which results in a linear relationship between $1/\bar{x}_n$ and *t*, if $\bar{x}_n \gg 1$ (where \bar{x}_n is the number-average degree of polymerization). Figure 1 shows the experimental data.

The splitting of butadiene from the unsaturated end groups occurs, according to reaction (2), via a cyclic intermediate contiguous to a double bond.

This reaction may be favoured by resonance with the double bond, and takes place at a higher rate than the primary fission. In this way it is reasonable to apply the steady-state hypothesis to equation (5). Then, from equation (4), the initial rate of formation of butadiene is constant up to 280°C, as shown in Figure 2.

According to this hypothesis, the number of —COOH end groups must also be found linearly increasing with time. This is verified in Figure 3. The steady-state approximation yields:

$$\frac{d[N(\text{III})]}{dt} = 0; k_1(N \text{ ester linkages}) = k_2[N(\text{III})] \quad (7)$$

from which we obtain

$$\begin{aligned}
 \frac{d[N(-\text{COOH})]}{dt} &= \frac{d(N \text{ butadiene})}{dt} \\
 &= -\frac{d(N \text{ ester linkages})}{dt} = \frac{d(1/\bar{x}_n)}{dt} \\
 &= k_1(N \text{ ester linkages}) \quad (8)
 \end{aligned}$$

The values of *k*₁, the kinetic constant, calculated from Figures 1–3, are listed in Table 6; the data obtained from the different methods of measurements are fairly consis-

tent for temperatures between 240° and 280° C.

The calculated Arrhenius activation energy is $E = 41$ kcal/mol in good agreement with the values reported for PET²⁻⁴ and carboxylic esters¹⁸⁻¹⁹ under analogous conditions. Some tests at higher temperatures (300° C or more) suggest

that side reactions or different mechanisms are possible. This can be inferred from the weight loss data and from the presence of carbonyl compounds and small quantities of water and tetrahydrofuran in the gaseous degradation products.

CONCLUSIONS

In the temperature range of processing, the thermal degradation of PBT takes place by ester-linkage fission, as is the case for carboxylic esters and for the first step of the PET degradation; the value of the activation energy is also in good agreement with those reported for these.

The chain fissions of PBT are followed by an evolution of butadiene, while carboxyl end groups increase and unsaturated terminal groups disappear. This justifies the absence of those secondary reactions which take place in PET, where unsaturated compounds are more stable and acetaldehyde more soluble in the polymer bulk.

The presence of carboxyl end groups, as well as of other reactive fragments in degraded PBT might favour contamination by metal traces due to corrosion, and affect reactivity towards additives and fillers, added for the fabrication stage (stabilizers, flame-retardants and reinforcing

Glass transition temperature in nylons

R. Greco and L. Nicolais*

Laboratorio di Ricerche su Tecnologia dei Polimeri e Reologia del CNR, Arco Felice (Napoli), Italy

(Received 24 May 1976; revised 12 July 1976)

The determination of the glass transition temperature of semi-crystalline polymers is a controversial problem in the literature, because of the complexity of the phenomenon and of the different methods used for its measurement. In this work the glass transition temperatures of five commercial nylons (nylon-6, nylon-6,6, nylon-6,10, nylon-11, nylon-12) have been measured by both thermal and mechanical methods. The behaviour observed during thermal measurements is analogous to that observed by Gordon, who found that the transition detected in the heating cycle disappeared in the subsequent cooling cycle and appeared again only after a sufficient rest period of the samples, and at a temperature different from the initially measured one. He attributed this behaviour to the structure of the amorphous regions of the material, where the hydrogen bonding groups form an irregular network. The delay in reforming the above mentioned network is the main cause of the dependency of the observed transition on the thermal history imposed on the samples. Mechanical measurements give results that are quite insensitive to the thermal treatment of the materials, and thus provide very reproducible values of the transition. This feature allows the possibility of attributing to the transition obtained the character of a true glass transition where the main cause of the phenomenon is the increased mobility of the chain backbone in the amorphous regions of the materials with increasing temperature. This character was also confirmed by dilatometry, with results in agreement with Boyer's criteria for a true glass transition temperature.

INTRODUCTION

The glass transition is a well known phenomenon, especially to people working in the area of polymer science and technology, even though it occurs in several other classes of materials. It has a multidimensional character, i.e. once certain critical conditions have been achieved, it is possible, keeping all the variables constant but one to define many critical variables, such as glass transition temperature, glass transition pressure, molecular weight, frequency, and so on. The most technologically important is the glass transition temperature (T_g), which will be analysed here focusing our attention on a particular class of semi-crystalline polymers, the nylons.

It is known that going through such a transition a large number of properties of the material undergo a more or less drastic change, due to the onset of motions of the chain backbone involving long sequences of carbon atoms¹. Step changes in properties such as the coefficient of thermal expansion, specific heat, compressibility, modulus of elasticity, etc. give the glass transition the apparent behaviour of a second order thermodynamic transition, but its kinetic character is clearly shown by the dependency on time², dependency on rate of heating or cooling, hysteresis phenomena³, etc. Among all these properties, T_g has been analysed by two thermal techniques: differential thermal analysis (d.t.a.) and differential scanning calorimetry (d.s.c.), and two mechanical methods: volume dilatometry and the so-called 'Tobolsky method'^{4,5}.

In d.t.a. measurements^{6,7} a differential temperature between the sample and a reference material is recorded at steadily increasing temperature. The temperatures are determined by means of two thermocouples embedded one

in the sample and the other in the reference material and it is not very easy to relate the differential temperature to the step change in the specific heat of the polymer.

In d.s.c.^{6,7}, it is the differential heat flowing from the sample and from the reference, individually controlled and kept at the same temperature, while the temperature of the entire system is steadily increased, that is essentially measured.

In volume dilatometry a plot of specific volume vs. temperature shows a breakpoint indicating the value of T_g . Sometimes there is a region of smooth curvature and the value of T_g is taken at the intersection of two limiting straight lines, the lower one representing glass-like and the upper one rubber-like behaviour.

In the so-called 'Tobolsky method' a log-log plot of the elastic isochronal shear (tensile) modulus is plotted against temperature and the glass transition temperature is defined as the temperature corresponding to the following value of the modulus:

$$\log G(K) = \frac{\log G_1 + \log G_2}{2} \quad (1)$$

where G_1 and G_2 are the values of the modulus corresponding to the glassy and the rubbery plateau, respectively and K is a fixed time after starting the experiment. Generally K is equal to 10 sec as suggested by Tobolsky and the glass transition temperature is represented by T_i^{10} . It is possible to show, by applying the Boltzmann superposition principle and the WLF superposition procedure⁸, that the T_g obtained by volumetric measurements, and T_i^{10} obtained by the Tobolsky method, are closely related by⁹:

$$T_i(10) = T_g + 4^\circ\text{C} \quad (2)$$

* Also with the Istituto di Principi di Ingegneria Chimica, University of Naples, Italy.

The above relation is only approximate as the values of the coefficients have been calculated from average values obtained on different polymers, and different techniques.

In the case of semi-crystalline polymers and in particular nylons, some authors¹⁰ suggest the occurrence of T_g at -65°C , based on penetrometer studies and on crystallization kinetics considerations, whereas other authors¹⁰ accept the transition occurring in the range of $40^\circ\text{--}50^\circ\text{C}$, as satisfying most of the criteria for T_g , even though some unusual behaviour seems to be associated with it.

EXPERIMENTAL

The materials used were commercial samples of nylon-6 (Renyl B/V, produced by Montedison) nylon-6,6 (produced by Rhodiatocce), nylon-6,10, nylon-11 and nylon-12 (produced by BASF). The crystallinity of the samples was calculated by measuring the peak areas of the melting zone

Table 1 Crystallinities and melting temperatures for nylons investigated

Materials	H_f	H_f^0 (kJ/kg)	Crystallinity (%)	T_f
Nylon-6	51.7	193	27	224
Nylon-6,6	52.8	193	27	265
Nylon-6,10	31.5	165	19	225
Nylon-11	41.2	222	19	184
Nylon-12	58.7	225	26	172

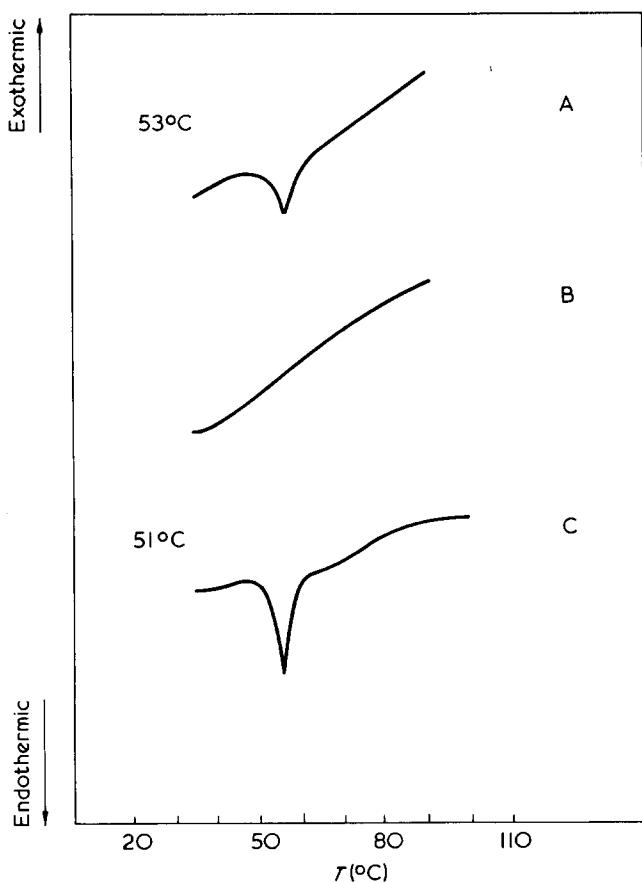

Figure 1 D.s.c. measurements on nylon-6: A, first run; B, immediate rerun; C, rerun after one week of rest

obtained by means of a previously calibrated Perkin-Elmer DSC-2 apparatus. The values of H_f (Table 1) so obtained were divided by the enthalpy of fusion H_f^0 relative to samples with 100% crystallinity. The latter values were calculated by the group contribution method¹¹. In the same Table the melting temperatures are also shown in the last column.

Thermal measurements have been made on a Perkin-Elmer DSC-2 (Figure 1) and the results are very similar to the ones obtained by Gordon on a d.t.a. apparatus¹². The transition present in the initial heating cycle, disappeared in the subsequent cooling and also in an immediate rerun; it began to reappear only after few hours rest of the samples, but at a lower temperature than the initial one. Only after about a weeks rest did the transition appear again at the initial temperature. This behaviour was similar for all the nylons studied. Another feature was the shift of the observed transition towards higher temperature due to the annealing of the samples. Furthermore in an infra-red spectrum the absorption band attributable to unbonded NH groups disappeared after heating the samples at 85°C for 15 min. This behaviour cannot be explained in terms of the classical understanding of T_g . In fact if the transition is due to the onset of motion of long segments of the chain backbone, the disappearance of the transition on cooling and also the other effects mentioned should not occur. In fact in the case of polystyrene in spite of a little hysteresis due to the kinetic character inherent in the T_g , the transition is still present in the cooling cycle and never disappears¹². Therefore Gordon postulated the existence of an irregular network formed in the amorphous region of the polymer by hydrogen bonding groups. Since bonding sites occur at a certain distance along the chain, there are some steric factors which hinder the formation of the network, and this can explain the long delay in reforming the network. The shifting on annealing is due to the formation of a new network, which is stable at higher temperatures, and the disappearance of the absorption band for unbonded NH groups is also due to the formation of the network at a temperature of 85°C . Even though this explanation seems very plausible, we found different results by performing mechanical measurements with a Clash-Berg creep torsional tester. The apparatus is very simple and very easy to use; it consists of a torsion drum to which two weights are suspended. A push button releases the weights applying to the sample a certain torque, at the start of the experiment. After a fixed time, generally 10 sec, the creeping of the sample is stopped and the angle of torsion is measured. Changing weights with decreasing modulus (at increasing temperature) allowed us to maintain torsion angles to within $20\text{--}30^\circ$ and hence to restrict, the experiments within the range of linear viscoelasticity.

The samples were obtained by compression moulding at a temperature of 20°C above the corresponding melting temperature and at a pressure of 100 kg/cm^2 . The plates of the moulding machine were water cooled. The results for nylon-6 and nylon-6,6 are shown in Figures 2 and 3 for samples subjected to heating and cooling cycles. It can be seen that the transition is very well reproduced. Furthermore since the thermal measurements (d.s.c.) are made at faster speeds, we increased the heating rate by immersing the sample of nylon-6,6, at room temperature, into a bath at 87°C , and then quenching to room temperature, therefore obtaining a very high cooling rate. Also in this case the points fall on the curve showing no dependency of the observed transition on thermal histories.

RESULTS AND DISCUSSION

The shape of the curves shown in Figures 2 and 3 is similar to that obtained in the case of non-crystalline polymers¹³, i.e. a glassy plateau, a transition zone, a rubbery plateau and a liquid-like terminal zone. The only difference is that the rubbery modulus has a value of 2–3 orders of magnitude higher than the corresponding value for a non-crystalline polymer, but this is clearly due to the presence of crystalline regions that stiffen the polymer making it leathery rather than rubbery. However it seems clear that the observed transition is due to the onset of motions of the chain backbone in the amorphous region of the material.

The independence of the transition from thermal treatments can also be seen from the dilatometric measurements shown in Figure 4 where the transition is present in both the heating and the cooling cycle.

To judge the character of the above observed transition we will apply Boyer's criteria for a true glass transition in the case of non-crystalline polymers¹⁴:

$$\alpha_e T_g = 0.16$$

$$\Delta\alpha T_g = 0.113 \quad (3)$$

$$\alpha_g = 2 \times 10^{-4} \text{ (degree}^{-1}\text{)}$$

where α_e is the expansion coefficient of the rubbery-like liquid:

$$\alpha_e = \frac{1}{V_g} \left(\frac{dV}{dT} \right)_e \quad (4)$$

α_g is the expansion coefficient of the glassy solid:

$$\alpha_g = \frac{1}{V_g} \left(\frac{dV}{dT} \right)_g \quad (5)$$

and

$$\Delta\alpha = \alpha_e - \alpha_g \quad (6)$$

These criteria are based on the concept that the glass transition is an iso-free-volume state.

In Table 2 the parameters given previously for Boyer's criteria are reported for the nylons analysed. It is clear that $\Delta\alpha T_g < 0.113$; $\alpha_e T_g < 0.16$ and $\alpha_g > 2 \times 10^{-4}$ degree⁻¹ and therefore we fall into case IV as described by Boyer¹⁵ for semi-crystalline polymers: in fact $\alpha_e T_g$ is lower than 0.16 because of the presence of crystallinity; α_g is larger than 2×10^{-4} degree⁻¹ because of the existence of secondary relaxation at temperature lower than T_g . Hence $\Delta\alpha$ must

Table 2 Physical parameters of the nylons tested

Materials	T_i	T_g (data from literature)	$\alpha_e T_g$	$\Delta\alpha T_g$	α_g	T_g (d.s.c.)

Nylon-12	40	37	0.118*	0.022*	3.8×10^{-4} *	43

* Data from Champetier, G. and Pied, J. P. *Makromol. Chem.* 1961, 44, 64 where T_i is the glass transition temperature detected by means of the Tobolsky method; T_g is the glass transition temperature detected by differential thermal analysis; α_e and α_g are the expansion coefficients of the rubbery-like liquid and the glassy solid respectively; $\Delta\alpha = \alpha_e - \alpha_g$

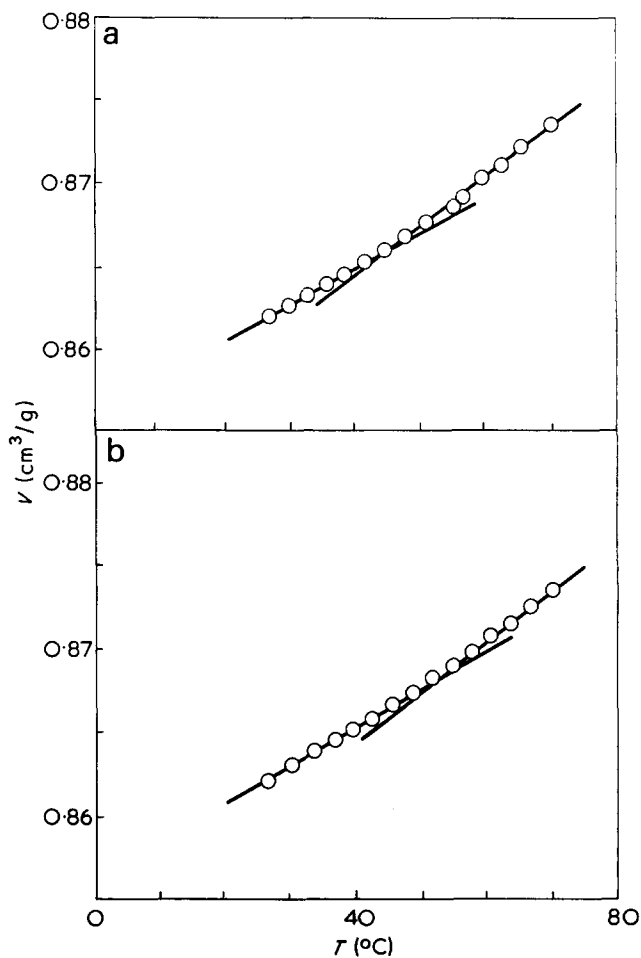

Figure 4 Plot of specific volume vs. temperature for (a) heating and (b) cooling cycles for nylon-6. \circ , Heating; \blacksquare , cooling; \bullet , quenching

Figure 5 Plot of $G(10)$ vs. temperature for nylon-6,10. The points are obtained after annealing at 150°C for 2 h and subsequent quenching of the sample at -10°C . \circ , Heating; \blacksquare , cooling

be lower than the indicated value valid in the case of amorphous polymers. Therefore it is confirmed also from dilatometric data that the transition lying in the region of $40^\circ\text{--}50^\circ\text{C}$ is a true glass transition in its classical meaning. In Figures 5–7 the isochronal curves obtained with the Clash–Berg apparatus for nylon 6,10, nylon-11 and nylon-12

are shown. The behaviour is very similar to that already discussed for nylon-6 and nylon-6,6. Of course, this technique does not have the necessary sensitivity to detect the existence of multiple glass transition as suggested by Boyer¹⁶ and it can only give an average glass transition temperature. However if there is a change in crystallinity, some shift in the transition can occur, as qualitatively shown in the Figures 5–7. In these the full symbols are relative to the cooling cycle made on specimens maintained at temperatures very close to the melting temperatures (nylon-11 and nylon-12) for at least 10 h. It would be possible, in principle at least, to see how the change in crystallinity affects the change in the glass transition temperature, but so far this can be only a very rough, indirect and qualitative evi-

Figure 6 Plots of $G(10)$ vs. temperature for nylon-11. The cooling curve shows a variation in the value of T_g due to a change in crystallinity

Figure 7 Plot of $G(10)$ vs. temperature for nylon-12 showing variation of T_g with increasing crystallinity. \circ , Heating; \blacksquare , cooling

dence of the presence of multiple glass transitions in nylons.

In conclusion, we have seen that transition of nylons lying in the range of 40°–50°C is a glass transition in its classical meaning, where the amorphous regions of the polymer undergo a glassy–rubbery change. Furthermore the reliability of mechanical measurements compared to the thermal techniques has been shown, at least in cases where hydrogen bonding groups are present. We have also shown that the Tobolsky method is a very convenient method, from a technological point of view, providing the T_g and also the two glassy and rubbery values of the modulus whose difference tells the importance of the glassy transition for that particular polymer.

Rheological behaviour of blends of narrow molecular weight distribution polystyrenes in the molten state: dynamic viscoelastic properties in the terminal zone

J. P. Montfort

Laboratoire de Thermodynamique, Université de Pau, 64016-Pau, France

(Received 12 May 1976)

Narrow molecular weight distribution polystyrenes and their blends, with molecular weights exceeding M_c , have been measured in the molten state by means of a Contraves–Kepes balance rheometer. The vertical and the horizontal shift factors are the same for the fractions and their blends. In the terminal zone, the effect of blending on the complex viscosity η^* and its imaginary part η'' results in the appearance of two fields representing the respective contributions of both components to the blend. The importance of the coupling between both fields as a function of the weight ratio of both components is discussed. The zero-shear viscosity η_0 is equal to that of a narrow molecular weight distribution polystyrene having the same weight-average molecular weight M_w , measured at the same temperature.

INTRODUCTION

Many investigations have revealed that the viscoelastic properties of amorphous polymers, in the terminal and plateau zones, are strongly affected by the molecular weight distribution.

This effect can be studied, for example, using binary blends of the same species of polymers having different molecular weights: blends of poly(methyl methacrylates)¹, monodisperse polystyrenes^{2–4}, poly(vinyl acetates)⁵, polyethylenes⁶. The studies dealing with the binary blends of monodisperse polystyrenes have shown that, in the terminal zone, the storage shear modulus G' and loss modulus G'' undergo only a mere translation. On the other hand, Masuda and his collaborators⁴ have shown that, if the weight ratio of the two components is high enough – higher than about four – in the rubbery zone, the curves G' of the blends show a two-step plateau and the curves G'' show two peaks seeming to correspond to those of the components. This behaviour is also found in the aspect of the relaxation spectrum which, under the same conditions as G' and G'' , can present two maxima. The peak on the long time side seems to be shifted slightly to the short time side; the other peak, on the short time side, is shifted to the long time side.

In the present study, we will show a similar behaviour with binary blends of monodisperse polystyrenes of weight-average molecular weight higher than M_c , in the terminal zone. For this purpose we have used a directly measurable viscoelastic function: the complex viscosity η^* .

EXPERIMENTAL

Materials

Narrow molecular weight distribution polystyrenes obtained by anionic polymerization and manufactured by the Waters Associates Corporation were used. The polydisper-

^a ϕ is the weight fraction of the component with the highest molecular weight

sity, determined by gel permeation chromatography, was lower than 1.1. Table 1 shows the weight-average molecular weights of the fractions used.

The blending of components was carried out by dissolving a suitable mixture of narrow molecular weight distribution polystyrenes in benzene. The solvent was then removed by freeze-drying and the blends obtained were dried in a vacuum oven at 60°C over two days. Features of the blends are given in Table 2.

Measurements

The dynamic measurements were achieved with a Contraves–Kepes balance rheometer. Complex viscosity η^* was measured at four temperatures: 156°, 166°, 176° and

Figure 1 Temperature dependence of terminal relaxation time τ_0 (●) and zero-shear viscosity (+) for the narrow molecular weight distribution polystyrene samples: A, PS 40; B, PS 20; C, PS 11. ($T_\infty = 50^\circ\text{C}$)⁹

186°C for all samples. Frequencies varied from 10^{-4} to 20 Hz.

Superposition time-temperature

The variations of the complex viscosity η^* as a function of frequency at the various temperatures of measurement can be shown in the form of some master curves.

In fact, Marin⁷ and Labaig⁸ have shown that the analytical expression of complex viscosity can be written in the form:

$$\eta = \eta_0 z(\omega\tau_0, h) \quad (1)$$

where z is a complex function such that $z(0, h) = 1$; h is a parameter independent of time and temperature, but possibly dependent on the nature of the polymer; η_0 is the zero-shear viscosity such that $\eta_0 = \lim_{\omega \rightarrow 0} \eta^*$; and τ_0 is a terminal relaxation time as defined by $\tau_0 = 1/\omega_m$, ω_m being the pulsation corresponding to the maximum of η'' .

Therefore, for the fractions of polystyrene, the parameter h will be the same and the use of the reduced variables η/η_0 and $\omega\tau_0$ will permit the superposition of the curves relating to various temperatures.

Figure 1 shows that the thermal variations of η_0 and τ_0 follow a Vogel-type law:

$$\log \eta_0 = a_1 + \frac{b}{T - T_\infty}$$

$$\log \tau_0 = a_2 + \frac{b}{T - T_\infty}$$

where $b = 715^\circ\text{C}$ is independent of M_w , and $T_\infty = 50^\circ\text{C}$ ⁹.

If we want to bring back the variations of the reduced complex viscosity η^*/η_0 from the measuring temperature T to a reference temperature T_0 , the measuring pulsation ω_T will have to be assorted with a shift factor $a_T = (\tau_{0T}/\tau_{0T_0})$.

By using the law of thermal variation of τ_0 , it can be shown that:

$$\begin{aligned} \log a_T &= \log \tau_{0T} - \log \tau_{0T_0} \\ &= b \cdot \frac{T_0 - T}{(T - T_\infty)(T_0 - T_\infty)} \end{aligned}$$

The WLF equation is actually confirmed if we put

$$c_1^0 = -\frac{b}{T_0 - T_\infty}$$

Thus, if the reference temperature is $T_0 = 186^\circ\text{C}$, the shift factors a_T are determined by $\log a_{176} = 0.42$; $\log a_{166} = 0.91$ and $\log a_{156} = 1.49$. All the master curves are obtained using these values.

The vertical shift factor b_T will be such that $b_T = \eta_{0T_0}/\eta_{0T}$. Now, the laws of thermal variation of η_0 and τ_0 show that, in the temperature range studied:

$$\frac{\eta_{0T_0}}{\eta_{0T}} = \frac{\tau_{0T_0}}{\tau_{0T}}$$

Thus,

$$b_T = \frac{1}{a_T}$$

We notice that the same shift factors can be applied to the fraction and to their binary blends.

RESULTS AND DISCUSSION

Effect of weight ratio

Figure 2a shows the development of the curves in the complex plane, representing the points with the affix η^*/η_0 .

For the pure components (PS 11 and PS 40), the curves can be assimilated to arcs of circles, where the centre is located below the x -axis¹⁰. The location of the centre is the same for all three fractions studied.

For the binary blends of PS 11 and PS 40, the curves reveal two fields. The field corresponding to the lower frequencies increases as the weight fraction ϕ of the component with the highest molecular weight increases, while the field corresponding to the higher frequencies decreases. The coupling between both fields is sufficiently important to ensure that whatever the pulsation ω and the weight fraction ϕ may be, the curve does not present a minimum separating both fields.

This notion of coupling between the contributions of each component to the properties of the blend is also noticeable in Figure 2b, which shows the variations of the imaginary part η''/η_0 of the reduced complex viscosity.

Figure 2 (a) Master curves of reduced complex viscosity and (b) reduced imaginary part for binary blends of PS 11 and PS 40 with values of ϕ : A, 0; B, 0.5; C, 0.10; D, 0.15; E, 0.25; F, 0.50; G, 1.00. ($T_0 = 186^\circ\text{C}$)

As ϕ increases, we can observe: for $\phi = 0$, a maximum at the higher frequencies; for $0 < \phi < 1$, the high frequency maximum decreases and shifts towards the lower frequencies, at the same time as a second maximum appears which increases and also shift towards the lower frequencies; or for $\phi = 1$, a maximum at the lower frequencies.

The development of the curves corresponding to the blend M 112030 (Figure 3) shows that the coupling is all the closer as the weight ratio—hence the ratio of the zero-shear viscosities and of the terminal relaxation times τ_0 —of both components is lower.

The variations of the real part η'/η_0 as a function of ϕ

show a gradual distortion of the curves as well as a shift of all points together towards the lower frequencies (Figure 4).

It should be noted that for blends, it is impossible to determine a relaxation time τ_0 having the same definition as that of fractions. In fact, τ_0 has been defined as the inverse of the pulsation ω_m corresponding to the maximum of η'' . It can be determined accurately when the curve can be assimilated to the arc of a circle^{7,8}. However, for the blends studied, the complex viscosity cannot be represented by the arc of a circle and, if the weights of the components are sufficiently distant, the distribution of ter-

Figure 3 (a) Master curves of reduced complex viscosity and (b) reduced imaginary part for: A, PS 11; B, M 112030; C, PS 20; reduced to 186°C

Figure 4 Master curves of reduced dynamic viscosity for the same samples as Figure 2

minimal relaxation time is a bimodal one, and a more probable relaxation time cannot be defined.

Effect of temperature and molecular weight

Figure 5 shows that the variations of η_0 as a function of temperature are the same for the pure fractions and their binary blends. This is connected with the fact that the vertical shift factor b_T is the same for the fractions and their blends. The same applies for the variations of η_0 as a function of the weight-average molecular weight M_w . The molecular weight M_w of the blends is calculated by means of the following equation:

$$M_w = (1 - \phi)M_1 + \phi M_2 \quad (2)$$

since each component presents a polydispersity very close to 1.

In equation (2), ϕ and M_2 represent the weight fraction and the molecular weight of the component with the highest weight, respectively and M_1 represents the molecular weight of the component with the lower weight.

The points relating to the blends are precisely located on the line of the points relating to the fractions (Figure 5). Therefore, the zero-shear viscosity η_{0b} of the blends obeys the law:

$$\eta_{0b} = kM_w^{3.4} \quad (3)$$

where k depends on temperature.

Thus, we notice that, as has been shown by Friedman and Porter¹¹, viscosity depends only upon the weight-average molecular weight and no other moment.

So the variations of a zero-shear viscosity of the fractions of linear atactic polystyrene and of their binary blends in the molten state, with a molecular weight higher than M_c can be represented by the expression:

$$\log \eta_0 = 3.4 \log M_w + \frac{715}{T - T_\infty} - 17.73 \quad (4)$$

The blending law on zero-shear viscosity can be easily inferred from relations (1) and (2) in the form:

$$\eta_{0b} = [(1 - \phi)\eta_{01}^{1/3.4} + \phi\eta_{02}^{1/3.4}]^{3.4} \quad (5)$$

An extension of this blending law to the complex viscosity of the blend may be contemplated in the general form:

$$\eta_{0b} = [(1 - \phi)\eta_{01}^{1/3.4} f_1(z_1, z_2, z_b) + \phi\eta_{02}^{1/3.4} f_2(z_1, z_2, z_b)]^{3.4} \quad (6)$$

Figure 5 Temperature dependence of zero-shear viscosity for the same samples as Figures 2 and 4

where z_1 , z_2 and z_b are the reduced complex viscosities of the components 1 and 2 and the blend, respectively as defined in relation (1); f_1 and f_2 are two functions of z_1 , z_2 and z_b such that they obey the following relations:

$$\lim_{\omega \rightarrow 0} f_i = 1$$

$$f_1(z_1, z_2) = f_2(z_2, z_1)$$

Thus, relation (6) is compatible with relation (5), in that it obeys the principle of superposition time-temperature and takes into account the symmetric part of the two components.

CONCLUSIONS

We have shown that the binary blends of narrow molecular weight distribution of linear atactic polystyrene with a molecular weight higher than the critical weight M_c , in the molten state, presented an interesting rheological behaviour in the terminal zone when the variations of the complex viscosity were examined.

We have observed that, in the complex plane, the arc of a circle characteristic of the pure fractions, became distorted when these were blended and that the contribution of each component to the blend could be identified. The coupling between the two corresponding fields becomes closer as the molecular weights of the elements are nearer.

The identification of all parameters conditioning this coupling and particularly the expression of the functions f_1 and f_2 in relation (6) could provide a better knowledge of the nature of entanglements between molecular chains and of the effect of the polydispersity affecting the viscoelastic properties in the plateau and terminal zones.

X-ray studies of surface melting in single crystals of linear polyethylene

K. Suehiro*, H. Tanizaki and M. Takayanagi

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan
(Received 8 December 1975; revised 5 July 1976)

X-ray diffraction by annealed single crystal mats of linear polyethylene was studied as a function of temperature. The intensity of small-angle scattering changed reversibly with temperature, but the long-period remained constant. The crystal thickness along the molecular chain, which was evaluated from the line width of the wide-angle 002 reflection, began to decrease in the vicinity of 60°C. The change in the intensity of the 002 reflection also indicated the decrease in the number of crystal lattices. From these facts surface melting of the crystal was inferred.

INTRODUCTION

Variation of small-angle X-ray scattering intensity above room temperature has been studied for many polymers such as polyethylene¹⁻⁶, polypropylene², nylon-6^{2,8}, polyoxymethylene^{8,9}, and others^{7,8}. According to these investigations, the intensity of the small-angle X-ray scattering changes reversibly with temperature so long as the measuring temperature does not exceed the crystallization or annealing temperature. In addition, the long-period varies reversibly in bulk and oriented polymers^{2,7,8}, but such a phenomenon has not been observed in the case of single crystals except for branched polyethylene⁵. The reversible change of the intensities has been interpreted mainly by a concept of reversible change in the ratio of the crystalline and amorphous regions due to the surface melting of the crystal.

In this paper the temperature dependence of wide-angle as well as small-angle X-ray scattering was investigated over a range of temperatures from room temperature to the melting point for annealed single crystal mats of linear polyethylene to obtain further evidence of the surface melting of the crystal lamellae.

EXPERIMENTAL

Sample preparation

The sample used in this study was a commercial grade high density linear polyethylene, Hizex 1200J, provided by Mitsui Petro-Chemical Industries Co. Ltd with a viscosity-average molecular weight (\bar{M}_v) of 30 800 and a degree of branching of 2 CH₃/1000 CH₂.

Single crystals were prepared by the following method. A hot concentrated xylene solution of polyethylene was gradually dropped into xylene, which was kept at the crystallization temperature of 80°C, to obtain finally a 0.05% solution. The solution was maintained at 80°C for more than 24 h. The precipitated single crystals were then filtered and formed into oriented mats with thickness of 0.2 mm. After drying they were annealed at 125°C for 24 h *in vacuo*.

Measurements

X-ray diffraction diagrams were obtained with Ni-filtered CuK α radiation using a counter technique. The small-angle X-ray scattering was measured over the temperature range 16°–120°C. The specimen was heated in a Rigaku–Denki hot stage. The diffraction profile from the (002) plane was measured by the reflection method using a diffractometer.

The infra-red absorption spectra were also taken in order to estimate crystallinity by using a Japan Spectroscopic Company heating cell at various temperatures from room temperature to 120°C.

Data analysis

If the single crystal mat consists of alternating crystalline and amorphous layers with no intermediate transition regions, the peak intensity of the n th order small-angle X-ray scattering is given by¹²:

$$I_n = K(\Delta\rho)^2 \sin^2(\pi nd/L) / (\pi n/L)^2 \quad (1)$$

where K is a constant, $\Delta\rho$ is the electron density difference between two layers, d is the thickness of the amorphous layer and L is the long-period. Providing that the amorphous regions are mainly located adjacent to the lamellar surfaces and those not are considered negligible, d/L may be substituted for χ , because the crystalline and amorphous regions are interchangeable as far as X-ray diffraction is concerned. Equation (1) can be written thus:

$$I_n = K(\Delta\rho)^2 \sin^2(\pi n\chi) / (\pi n/L)^2 \quad (2)$$

When the long-period does not change with temperature, the following relation can be derived from equation (2):

$$\frac{I_2(T)}{I_2(T_0)} \bigg/ \frac{I_1(T)}{I_1(T_0)} = \frac{\cos^2\pi\chi(T)}{\cos^2\pi\chi(T_0)} \quad (3)$$

where T_0 represents a standard temperature. Therefore, if $\chi(T_0)$ is known, the crystallinity at a temperature T can be evaluated⁴.

The long-periods were calculated directly applying Bragg's law to the position of the maximum intensity of the first order small-angle scattering.

The sizes of the crystalline layers along the molecular

* Present address: Department of Industrial Chemistry, Faculty of Science and Engineering, Saga University, Saga 840, Japan.

chain axis, D_{001} , were estimated from the integral line width of the 002 reflection by use of Scherrer's formula:

$$D_{001} = K\lambda/(\beta \cos \theta) \quad (4)$$

where λ is the wavelength; β is the true line width corrected for broadening due to the instrument and the $K\alpha_1$ and $K\alpha_2$ radiations; θ is the Bragg angle for the 002 reflection. The shape factor K was taken as equal to unity. The method of correction for spectral broadening was principally based on the Jones procedure¹¹. Quartz powder was used as an instrumental standard. A diffraction diagram of the 002 reflection of polyethylene is shown in Figure 1. The foot of the peak is superimposed on the 231, 511, and 112 reflections. This effect was subtracted for convenience by a straight line which was in contact with reflection curve at $\sim 73^\circ$ and 76° in 2θ . As the diffraction line profiles of polyethylene and quartz were nearer to a Gaussian rather than a Cauchy distribution, the Gaussian profile was assumed for both line shape. The true line width β is given by¹⁴:

$$\beta = (B^2 - b^2)^{1/2} \quad (5)$$

where B and b are the line widths of the specimen and quartz corrected for the spectral broadening, respectively.

The crystallinity was also determined from infra-red absorption spectra. One crystalline band, 1894 cm^{-1} , and two amorphous bands, 1352 and 1368 cm^{-1} , were used according to the method proposed by Okada and Mandelkern¹⁰ to evaluate the crystallinity of a thick polyethylene sample.

RESULTS AND DISCUSSION

The relative intensities of the first and second order peaks of the small-angle X-ray scattering are plotted against measuring temperatures in Figure 2. Both intensities increased with increasing temperature, but the degree of change in the second order scattering was less than that in the first. They decreased reversibly to their initial values on cooling from a maximum temperature of 117.5°C which did not exceed the annealing temperature of the specimen.

Figure 1 Diagram of the 002 reflection of polyethylene. Region below the straight line represents background

Figure 2 Variation in the peak intensities of A, the first (I_1) and B, second (I_2) order small-angle X-ray scattering with temperature: \circ , heating; \bullet , cooling

According to equation (2), the scattering intensities depend upon the density difference between the crystalline and amorphous layers and upon the volume crystallinity. The ratio of $I_1(117.5)$ to $I_1(16)$ was as large as 1.99. On the other hand, $[\Delta\rho(117.5)/\Delta\rho(16)]^2$ was found to be 1.48 by using the specific volumes of the crystalline (\bar{v}_c) and amorphous (\bar{v}_a) polyethylene, which were determined by Richardson *et al.*¹³:

$$\bar{v}_c = 0.993 + 3.0 \times 10^{-4}T$$

$$\bar{v}_a = 1.152 + 8.8 \times 10^{-4}T$$

where $T(^{\circ}\text{C})$ is the temperature. Therefore, as indicated first by Nukushina *et al.*¹, the increase of the scattering intensities can not be explained by the increase of the electron density difference alone, but is also concerned with the change in the crystallinity.

The volume crystallinity determined from density at 16°C was 0.792. By substituting this value into equation (3) as $\chi(T_0)$, the volume crystallinities at other temperatures were calculated. The results are shown in Figure 3 together with those evaluated by the infra-red method. They were in good agreement with each other. As a matter of course, these crystallinities decreased with increasing temperature. Long-period, L , was nearly constant at 418 \AA throughout a heating and cooling cycle as shown in Figure 4, although reversible changes of long-period with temperature have been observed for many bulk polymers^{2,7,8} and single crystal mats of branched polyethylene⁵. The constancy of the long-period and the decrease of the crystallinities indicate that the thickness of the amorphous layers increased. Indeed, the crystalline size along the molecular chain, D_{001} , changed reversibly with temperature decreasing gradually, increasing as the temperature was raised. The values of the ratio D_{001}/L are markedly lower

Figure 3 Crystallinities determined by A, infra-red (i.r.); B, small-angle X-ray scattering (SAXS), and C, D_{001}/L vs. temperature: □, heating; ■, cooling

Figure 4 Temperature dependence of A, the long-period (L) and B, the crystal thickness (D_{001}) in the direction of the c -axis: ○, heating; ●, cooling

than those of SAXS and i.r. crystallinities. If any transition region of ~ 80 Å thick is assumed between the amorphous and crystalline layers which is regarded as crystalline by the infra-red and small-angle X-ray scattering measurements, those three sets of values agree fairly well.

Another reason for the discrepancy is the following. The line broadening is not corrected precisely, because the line profiles are not necessarily exactly Gaussian. Consequently, the values of D_{001} in Figure 4 may be apparent ones and the true values larger.

Furthermore, the intensity change of the 002 reflection was investigated to make sure the change of the crystallinity with temperature. The observed integrated intensities of the 002 reflection are plotted against the temperatures in Figure 5. Decrease in the intensity was observed

Figure 5 Relative intensity of 002 reflection vs. temperature. The corrected intensity is determined by multiplying the observed one by $[\exp 8\pi^2 U_{cc}(\sin\theta/\lambda)^2]^2$. A, Corrected; B, observed

from room temperature. Two factors may be considered as the cause: decrease in the number of crystal lattices and thermal vibration of the atoms in the crystal. The observed intensities were multiplied by $[\exp 8\pi^2 U_{cc}(\sin\theta/\lambda)^2]^2$ to eliminate the effect of the thermal vibration of the atoms. U_{cc} gives the amplitude of atomic displacement in the direction of c -axis and $8\pi^2 U_{cc}$ represents the temperature factor. The values determined by Iohara *et al.*¹⁵ were used for U_{cc} . The corrected intensities decreased markedly from the temperature in the vicinity of 60°C as shown in Figure 5. Premelting of the crystal seems to begin at this temperature.

Bergmann and Navotki separated broadline n.m.r. spectra of polyethylene samples into three components, i.e. narrow, intermediate, and broad, and they have proposed a three phase model for polyethylene¹⁶. The intermediate component is considered to originate from a boundary region where the crystal changes to the amorphous part. The molecular chains in the intermediate region must be more irregular than those in the crystal. According to the potential energy calculation of the fold conformation given by Oyama *et al.*¹⁷, the internal rotation angles of eight bonds succeeding to the fold part deviated somewhat from precise *trans* conformation. This region will correspond to the intermediate region suggested by Bergmann and Nawotki¹⁶. Intermolecular forces in the intermediate region especially with approach to the fold part are weaker than those in the crystal so that the chains in the intermediate region are relatively easy to move. On heating they will melt before those in the crystal. This fact results in the melting of the crystal from the lamellar surface to the interior.

Deformation mechanism of 'hard elastic polyethylene films'

Takeji Hashimoto, Kikuo Nagatoshi[†], Akira Todo[‡], and Hiromichi Kawai

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606, Japan

(Received 23 February 1976)

Film specimens were prepared from extra-high molecular weight linear polyethylene (commercial grade, Sholex super 5551 H and 4551 H) as well as ordinary high and medium molecular weight polyethylenes (commercial grade, Hizex 7000 F and Sholex 4002) by using a calender manufacturing method, which involves the important processing problem of crystallization from a stressed polymer melt. The films crystallized from the extra-high molecular weight polyethylene, as compared with those crystallized from the lower molecular weight polyethylene, underwent a large elastic deformation on stretching along the machine direction, characteristic of the specific morphology of the so-called 'row structure' or 'hard elastic structure'. Deformation mechanism of the submicroscopic crystalline superstructure of the hard elastic films was investigated by means of small- and wide-angle X-ray scattering and diffraction, as well as electron microscopy.

INTRODUCTION

There have been many reports on the morphology and crystallization of polyethylene crystallized from stressed polymer melts and solutions. Pennings *et al.* crystallized polyethylene from stirred polyethylene solutions¹⁻³. Andrews *et al.*^{4,5} crystallized polyethylene after cooling stretched crosslinked polymer melts below their melting points. The crystallization was also achieved by applying shear stress to the polymer melts in between two plates followed by cooling below their melting points^{2,6}, and by applying tubular extrusion (blown film)^{2,7} or injection moulding to the polymer melts.

Polyethylene crystallized from stirred solutions produces the row-nucleated shish-kebab structures which contain irregular lamellar platelets held together by a central fibre. The shear stress produces the fibre acting as row nuclei on which lamellar overgrowth occurs to result in the formation of the usual lamellar crystal.

Crystallization from a stressed melt similarly produces stacks of oriented lamellae, their plane normals being parallel to the machine direction⁴⁻⁹. In order to explain the particular morphology, Keller and Machin demonstrated the row structure²; nucleation occurred from 'rows' of nucleating points, and as with crystallization from stirred solutions, growth was restricted only to the plane perpendicular to the row of nucleating points. The row nuclei were considered to be fibres formed as a result of the shear stress. Characteristics of row structure such as number of row nucleating lines, crystal and lamellar orientations were also shown to be a function of shear stress²; e.g. crystal *a*- and *c*-axes preferentially orient along the machine direction when the films are crystallized under low and high shear stresses, respectively.

On the other hand, Kobayashi¹⁰ suggested that the stacking of oriented lamellae in the machine direction results from numerous spiral growths of lamellae. The angle between the axes of the spiral and the machine direction, which varies with film preparation conditions affects crystal orientations with respect to the machine direction. Drawing the films along the machine direction has been shown to result in a pulling apart of the spiral growths in a fashion similar to that which occurs when a helical spring is stretched.

It has been found, recently, that several polymers form, under specific conditions of crystallization, highly crystalline fibres or films which exhibit markedly elastic behaviour, the so-called 'hard elastic' property, i.e. a high degree of length recovery from large extensions and additional unusual properties such as a marked reduction of apparent density, and generation of very large amounts of internal volume and surface area on stretching along the machine direction^{9,11-16}. These polymers are polypropylene, poly(3-methylbutene-1) and some of its 1-olefin copolymers, and acetal copolymer, Celcon, in particular specimens of nylon-6, nylon-6,6, polyethylene, poly(4-methylpentene-1), and poly(ethylene sulphide). The elastic nature of these polymers results from a specific morphology produced by crystallization from sheared polymer melts, i.e. the stacks of oriented lamellae, their normals being parallel to the machine directions.

It is not fully understood what the criteria are in terms of morphology or crystallization conditions for a given polymer leading to such unusual long range elasticity. The morphological studies on the 'hard elastic' fibres or films, however, indicated that the tilting and splaying apart of the lamellar network result in creating the void and surface area on stretching and that the bending of lamellae between the links in a manner analogous to a leaf spring¹¹ is related to the long range elasticity which is non-rubber-like, i.e. energetic but not entropic in origin^{9,11,14}.

In this work we adopted a calender manufacturing method to prepare high density polyethylene films as a method of crystallization from stressed melts. The method is efficient especially in moulding extra-high molecular

weight polyethylene compared with conventional blowing (tubular extrusion) technique. Under a given film preparing condition, the films crystallized from the extra-high molecular weight polyethylenes showed crystal *c*-axis preferentially oriented along the machine direction (*MD*) and exhibited unusually long range elasticity (hard elastic property) of the type described above, whereas those crystallized from polyethylenes having conventional molecular weights showed crystal *a*-axis preferentially oriented along the *MD* and exhibited usual mechanical properties accompanied by necking and low degree of length recovery from large extensions. In order to understand this phenomenon, we investigated the crystalline superstructure of these films in submicroscopic scales by using various techniques such as wide-angle X-ray diffraction, small-angle X-ray scattering, and electron microscopy.

TEST SPECIMENS

Four kinds of linear polyethylenes were calendered under different conditions as shown in Table 1. Series of HMW1 and HMW2 specimens have extra-high molecular weights, while those of MMW and LMW have ordinary molecular weights. Polyethylene pellets were fed into a bumbury mixer where the pellets were melted for about 4 min. The melt, with a temperature $\sim 150^{\circ}$ to 170°C at the exit of the mixer was fed into a mixing roll controlled at 150°C . The melt was then calendered into sheets as schematically shown in Figure 1. Temperatures of the first to the fourth rolls were controlled as in Table 1, while those of the other rolls were at ambient temperature.

The friction ratios of the rolls were set so that the ratio of surface velocities of the first to the fourth rolls were 1:1.25:1.30:1.32. The surface velocity of the fourth roll

was set 5 m/min, and the films were taken up at velocity of 6 m/min. Under this condition, the whitening of the specimens due to crystallization was visible immediately after the fourth roll. The ratio of the surface velocities of the first to the fourth rolls as well as the velocities themselves are important factors which decide the shear rate of the melt.

EXPERIMENTAL

Stress–strain behaviour was measured at 20°C and at a rate of 100% elongation/min with a tensile tester, Shimadzu autograph type IM 100.

Wide-angle X-ray diffraction (WAXD) patterns were obtained at 40 kV and 20 mA, using nickel filtered $\text{CuK}\alpha$ radiation. Small-angle X-ray scattering (SAXS) patterns were obtained with nickel filtered $\text{CuK}\alpha$ radiation at 50 kV and 100 mA using a Rotaflex RU-100 PL (Rigaku–Denki) and with a point focusing system under the following collimating conditions: distances of the second pinhole, specimen and photographic films are 250, 310 and 610 mm from the first pinhole, respectively, and the size of the first and second pinholes are 0.5 and 0.2 mm in diameter, respectively.

The SAXS patterns were recorded from three directions: 'end' patterns taken with the incident X-ray beam parallel to the *MD* (machine direction); 'through' patterns with the beam normal to the film surface, and 'edge' patterns with the beam normal to the *MD* but parallel to the film surface. The end scattering was very weak and usually required a long exposure time (~ 10 h), six to seven times longer than the through and edge scattering patterns under equivalent conditions. Since the film specimen is thin, about 100 to 200 μm , the patterns were taken after stacking the specimens to an appropriate thickness (about 1 mm). In the edge and end patterns, the incident radiation is nearly parallel to the film surfaces. This situation often produces a sharp streak-like scattering in a direction parallel to the film normal due to total reflection of the X-rays at sample–air interfaces as pointed out by Hashimoto *et al.*¹⁷. In order to reduce the extra scattering arising from the reflection, the stack of specimens were immersed in liquid paraffin which replaces sample–air interfaces by sample–liquid paraffin interfaces¹⁷.

Figure 2 The stress-strain diagram of the HMW2-L specimens. A, A', 0°; B, B', 45°; C, C', 90°

The SAXS intensity distributions were measured along the meridional direction, i.e. a direction parallel to the machine direction (*MD*) with line focusing under the following collimating system: the second slit, the third slit, the specimen and the receiving slit were placed at 250, 290, 310, and 610 mm from the first slit, respectively, and the sizes of the first, second, solar, and receiving slits were 0.1×10 , 0.05×10 , 0.1×15 , and 0.05×15 mm², respectively. The length direction of the slit was set normal to the *MD*, i.e. parallel to the stack of lamellae. The intensity was measured with a scintillation counter and a Rigaku-Denki Rotaflex RU-100PL generator at 50 kV and 100 mA, and with nickel filtered ($21 \mu\text{m}$ thick) $\text{CuK}\alpha$ radiation and pulse height analyser.

The second order orientation factors of crystal *a*, *b* and *c* axes (f_a , f_b , and f_c , respectively) were evaluated by measuring the azimuthal angle dependence of integrated intensities under diffraction peaks corresponding to (110), (200), and (020) crystal planes. The intensity distributions were measured with a scintillation counter and a Rigaku-Denki Rotaflex RU-100PL at 50 kV and 100 mA. The intensity was measured with point focusing and with Ni-filtered $\text{CuK}\alpha$ radiation and pulse height analyser. The intensity was corrected according to the conventional method for air scattering, polarization factor and amorphous scattering.

RESULTS

Mechanical studies

Figures 2 and 3 demonstrate typical stress-strain behaviour of the extra-high molecular weight linear polyethylenes (HMW2-L) and polyethylenes having conventional molecular weights (LMW-L) specimens, respectively, where curves A, B and C in Figures 2 and 3 show the behaviour at small strain. The stress in the ordinate is the so-called nominal stress and is measured as a function of the angle between the *MD* and stretching direction. Under the same moulding conditions, HMW1 and HMW2 series show greater mechanical anisotropy than MMW and LMW polyethylenes in terms of Young's modulus, yield stress, ultimate strength, and ultimate elongation as is clearly seen by comparing Figures 2 and 3. The HMW1 and HMW2 series exhibit, in general, somewhat smaller ultimate elon-

gations at a given stretching direction than the MMW and LMW series. The yield strengths and ultimate strengths of the HMW1 and HMW2 are higher than those of the MMW and LMW series.

On stretching the HMW1 and HMW2 series along the *MD*, the film specimens start to whiten uniformly at $\sim 10\%$ elongation and the whitening is completed at $\sim 20\%$. On further stretching, the specimens exhibit no trace of macroscopic necking to result in a break at $\sim 75\%$. On releasing the tension, the whitening disappears almost completely unless the initial elongation is larger than 20% . At initial elongations greater than 20% , the whitening remains to some extent, although only a little. On the other hand, on stretching the MMW and LMW series, the film specimens exhibit a clear macroscopic necking where the whitening is localized.

Length recovery of the HMW1 and HMW2 series is extremely good compared with the MMW and LMW series. Figure 4 shows typical stress-strain behaviours under a cyclic tensile loading mode for the HMW1 and HMW2 series. The solid lines correspond to the specimens crystallized under calender moulding, while the broken lines correspond to the specimens crystallized from the isotropic melt.

Figure 4 The stress-strain behaviours under cyclic tensile loading the specimens moulded by the calender method (—) and the specimens crystallized from isotropic melt of the same polymer grade (---). The elongation rate was 100%/min and measuring temperature was 25°C. The tensile loading is applied parallel to the machine direction

Figure 5 Typical electron micrograph of the HMW2 series. Surface replica. The arrow in the micrograph indicates the MD

The elongation rate and measuring temperature were 100% min. and 25°C, respectively. As is shown in the Figure the stress-strain behaviour of the calender films stretched parallel to the machine direction (MD) showed considerably large length recovery compared with the isotropic films. The stress-strain behaviour of MMW and LMW series along the MD are roughly similar to that of the isotropic films shown in Figure 4.

The unusual mechanical properties as observed in the HMW1 and HMW2 series are apparently similar to those found by Clark *et al.*^{9,11}, and Quynn *et al.*¹²⁻¹⁶ for 'hard elastic' films or fibres.

Morphology of as-prepared calender films

Electron microscopic studies. Figure 5 shows a typical electron micrograph of the free surface of the HMW1 and HMW2 series. As is typical for film crystallized from oriented melts, the stack of crystal lamellae are seen to highly orient with their normals parallel to the MD. The orientation of the lamellae corresponds to the two-point SAXS patterns (Figures 6 and 7) and a high degree of negative *b*-axis orientation (Figure 14) as will be discussed later. Therefore the surface structure is considered to be representative of the bulk. Some degree of lamellar twisting is shown in the micrograph, which is also important in explaining the observed degree of crystal *c*-axis orientation (Figure 14) and the preliminary results of dynamic birefringence (Figure 15). Similar but more distorted arrays of lamellae were observed on the electron micrographs of free surfaces of the MMW and LMW series.

X-ray studies. In Figures 6 and 7 are shown typical WAXD and SAXS patterns for HMW1 and HMW2 series and LMW and MMW series, respectively. In these Figures the through and edge patterns are identical, and the end

patterns are cylindrically symmetrical with respect to the incident beam axis. This indicates that orientation of both crystallites and lamellar crystals are uniaxially symmetric with respect to the MD in these specimens. The SAXS patterns for all these specimens show a typical two-point pattern, indicating that the crystalline texture is essentially the stacks of oriented lamellae, their normals being parallel to the MD. The WAXD and SAXS patterns of the other HMW1 and HMW2 series and those of the HMW-H specimens were almost identical to those of the HMW1-L and LMW-L specimens, respectively, so that their patterns are not included in this paper. The end patterns in SAXS patterns did not exhibit any appreciable distinct scattering maxima for all the specimens. This is probably because only a few lamellar edges are emerging parallel to the MD and/or lamellae having this type of orientation are stacked less regularly compared with those having their normals parallel to the MD.

The orientation of crystallites for the HMW1 and HMW2 series is, however, quite different from that for the MMW and LMW series. The former shows a preferential *c*-axis orientation along the MD, while the latter shows crystal *a*-axis orientation (Figures 6 and 7). The second order orientation factors of crystal *b*-axis, $f_b = (3\langle \cos^2 \theta_b \rangle_{av} - 1)/2$ (θ_b being the angle between the crystal *b*-axis and the MD), are close to -0.5 for all these specimens, indicating that the crystal *b*-axis orients almost perfectly normal to the MD. This is in accordance with a high degree of lamellar orientation with their normals being parallel to the MD and thus with the observed two-point SAXS patterns. The difference of the crystal *a*- or *c*-axis orientation may be therefore interpreted in terms of the difference in degree of rotation of crystal *a*- and *c*-axes around *b*-axis, i.e. a degree of lamellar twisting around its axis. For the HMW1 and HMW2 series the rotation of lamellae around their axes (i.e. *b*-axes) occurs less to give positive and negative *c*- and *a*-axis orientation, respectively, while for the MMW and LMW series it occurs much more than the HMW1 and HMW2 to give positive *c*- and *a*-axis orientations, although *a*-axis orientation factor is larger than *c*-axis orientation factor¹⁸.

Keller and Machin² demonstrated that the manner of lamellar orientation or degree of twisting of lamellae grown from the row nuclei depends upon shear stress in the melt: crystallization under high shear stress giving rise to the preferential *c*-axis orientation, while that under low shear stress gives rise to the preferential *a*-axis orientation.

According to the above result, the crystal orientation of the extra-high molecular weight HMW1 and HMW2 series is typical of that resulting from crystallization under high shear stress, while that of the MMW and LMW series is typical of that resulting from crystallization under low shear stress. This is quite reasonable because under a given manufacturing condition with a fixed temperature and shear rate, the higher molecular weight series are subjected to a greater shear stress due to a greater viscosity. The degree of crystal *c*-axis orientation, or the degree of lamellar twisting is apparently related to the 'hard elastic' properties.

Deformation mechanism along the MD

In this study, a particular specimen designated as HMW2-L was used as a test specimen having the hard elastic property. Deformation behaviour of the superstructure was again investigated by means of wide-angle X-ray diffraction, small-angle X-ray scattering, and electron microscopy techniques.

Figure 6 (a), (b), (c), WAXD and (d), (e), (f) SAXS patterns for the HMW1-L specimens. The machine direction is vertical for the through and edge patterns. (a), (d), Through; (b), (e), edge; (c), (f), end

Electron microscopy. Figure 8 shows electron micrographs of the surface replica of the specimen stretched along the MD, this particular specimen also shows increased tendencies of splaying apart, tilting and bending of the lamellar network of the type which is reported for other typical elastic hard fibres and films¹¹⁻¹⁶.

Small-angle X-ray scattering. The deformation of the lamellar network can be quantitatively investigated by detecting the change of SAXS patterns and intensity distributions during the stretching process. In Figures 9a-g and 10 the change of SAXS patterns upon stretching along the MD, which is in the vertical direction of the Figures are shown. The patterns in Figure 9 are for dry specimens, while those in Figure 10 are for specimens stretched by a given percentage and then immersed in liquid paraffin (SG, 0.855).

On increasing the stretching, the following changes in the lamellar network may be seen from Figure 9: (a) increase of interlamellar spacing, which is associated with shifting the position ($2\theta_{\max}$) of the meridional SAXS intensity maximum to a lower scattering angle; (b) increase of interlamellar void formation as a consequence of the

process (a), which is associated with increase of the SAXS intensity especially at lower angles than $2\theta_{\max}$; (c) increasing degree of lamellar bending and irregular deformation of lamellae, which is associated with increase of the lateral breadth of two-point SAXS patterns. The increase of the SAXS intensity and the appearance of the equatorial streak at large elongations are related to a phenomenon of whitening of specimen as pointed out earlier.

In Figure 10 the SAXS patterns after immersing the stretched specimens in the liquid paraffin are shown. As shown in the Figure, the SAXS intensity decreases due to a reduction in scattering arising from the void as a consequence of the penetration of the liquid paraffin into the interlamellar void region. Therefore the mechanisms (a) and (c) described above can be more clearly seen in the immersed specimens.

Figures 11a and 11b show changes of the meridional SAXS intensity distributions upon stretching for dry specimens and for specimens stretched and then immersed in the liquid paraffin, respectively. Each scattering curve shows the first and the second order scattering maxima (or shoulders). On stretching, positions of the scattering maxi-

Figure 7 (a), (b), (c), WAXD and (d), (e), (f) SAXS patterns for the LMW-L specimens. The machine direction is vertical for the through and edge patterns. (a), (d), Through; (b), (e), edge; (c), (f), end

ma are seen to shift to lower angles, and the scattering intensity is seen to increase tremendously at scattering angles smaller than $\sim 20^\circ$ (Figure 11a).

The extra-intensity that appeared at the lower angles disappears upon immersing the specimens in the liquid paraffin. This is ascribed to the large interlamellar void which is accessible to the liquid paraffin. A small decrease in intensity at small angles on immersing in the liquid paraffin is also observed for unstretched specimens, which indicates that the interlamellar void exists even for unstretched specimens, though its amount is less compared with the stretched specimens. It should be noted that the peak positions themselves do not change before and after immersion, indicating that the liquid paraffin does not swell the specimens at all and thus does not affect the morphology.

Figure 12 shows change of long spacing as a function of elongation. The long spacings are evaluated from peak positions of the first and second order scattering maxima in Figure 11b by using Bragg's law. As shown in the Figure, the long spacing observed from the first maximum is greater than that observed from the second maximum. The ratio P_2/P_1 of the second to first peak positions is also plotted

in Figure 12 as a function of elongation. The ratio is seen to be greater than 2 and to increase slightly with increasing elongation. The discrepancy of the two long spacings or deviation of the ratio from 2 may be interpreted in terms of an asymmetric distribution of the interlamellar distances as proposed by Reinhold, Fischer and Peterlin²³. According to their model, the results in Figure 12 may be interpreted in terms of the positively skewed distribution of interlamellar distances. The width parameter γ corresponds to ~ 0.4 for unstretched specimens and tends to increase upon further stretching. This is partly associated with the lamellar bending.

Figure 13 shows elongation of the long spacing calculated from the position of the first meridional SAXS maximum and residual strain of the bulk specimens as a function of bulk elongation. As seen in the Figure, the deformation of submicroscopic structure as observed from the change of the spacing affinely occurs with the bulk deformation at elongations less than $\sim 10\%$. However at larger elongations, the increase in the spacing is much retarded to the bulk elongations, indicating that the submicroscopic deformation becomes increasingly heterogeneous and localized.

Figure 8 The change of surface structure of the specimens as a function of elongation (surface replica). Arrows indicate the stretching direction which is parallel to the MD. (a) 10%; (b) 40%

This is closely related to the whitening of the stretched specimens, and to the increasing SAXS power at the low angles (Figures 9a, 9c, 9e, 9g).

Wide-angle X-ray diffraction. Figure 14 shows the second order orientation factors of crystal a , b , and c axes as a function of elongation. The orientation factor of the i th axis is defined by $f_i = (3\langle \cos^2 \theta_i \rangle_{av} - 1)/2$, where θ_i is the angle between the stretching direction and the i th crystal axis. The orientation factors were measured both for stretched specimens and for specimens stretched and then relaxed. For the relaxed specimens, the orientation factors were plotted as a function of residual elongation. The arrows in the upper part of Figure 14 indicate changes of f_c upon relaxing the specimens from given elongations. The relationship between the residual and initial elongation is shown in Figure 13.

As is shown in Figure 14, the original unstretched specimens show almost perfect orientation of the crystal b -axis perpendicular to the MD, i.e. $f_b \cong -0.5$. This corresponds to an orientation of lamellar axes normal to the MD, which is in good agreement with evidence from electron microscopy (Figure 5) and SAXS (Figure 6) studies. On the other hand, the a - and c -axis orientations are less perfect, which is associated with some degree of lamellar twisting, i.e. rotation of crystal a - and c -axes with respect to the b -axis.

On stretching, the orientation factor f_c increases while f_a decreases, indicating that crystal c - and a -axes orient towards the stretching direction (SD) and the direction perpendicular to the SD (TD), respectively. On the other hand the orientation factor f_b changes only a little compared with f_a and f_c . These changes of the orientation factors should result primarily from a lamellar detwisting process which gives rise to rotation of crystal a - and c -axes around the crystal b -axis (lamellar axis). The detwisting (or so called interlamellar slip) makes the crystal c - and a -axes orient more towards the SD and TD, respectively.

A minor change of f_b occurs in that f_b slightly increases with increasing elongation. The increase of f_b may be attributed to a process of lamellar bending between tie links of the type as described in Figure 9 of ref 11 which may give rise to rotation of crystal c - and b -axes around crystal a -axis in a way that the c - and b -axes (originally oriented along SD and TD, respectively) tend to orient toward TD and SD directions, respectively. Therefore the entire change of orientation factors can be well interpreted in terms of the two processes, lamellar detwisting (interlamellar shearing) and lamellar bending (intralamellar shearing of mosaic blocks constituting lamellae or intralamellar chain slip). The contribution of the former to the orientation factors is greater than that of the latter, at least for the static deformation. We will discuss briefly the time-dependence of the relative contribution, later.

Recoverability of deformation of structure upon releasing the strain. The recoverability of deformation upon releasing the applied strain was investigated in terms of (a) deformation of interlamellar spacing (see Figure 13) and (b) orientation of crystallographic axes (see Figure 14). The recoverability of deformation of the interlamellar spacing is considerably high even at large elongations. The residual strain involved in the interlamellar spacing is approximately equal to the residual strain involved in the bulk. Thus in this sense the residual strain in the bulk is interpreted in terms of irreversible deformation of the submicroscopic structure, i.e. lamellae.

Figure 9 (b)–(h) change of WAXD and (a)–(g) change SAXS patterns upon stretching the specimens along the MD. The stretching direction is vertical. (a), (b) 10%; (c), (d) 20%; (e), (f) 40%; (g), (h) 60%

Figure 10 The change of SAXS patterns upon stretching the specimens along the *MD*. The patterns were taken for the specimens stretched by a given elongation and then immersed by liquid paraffin (*SG* 0.855). (a) 0%; (b) 20%; (c) 30%; (d) 50%

As a possible mechanism of irreversible lamellar deformation, one may consider a chain slip within the lamellae of the type as described in Figure 10 of ref 11, lamellar destruction, and destruction of interlamellar tied links. All these processes are irreversible and increasingly important with increasing bulk elongations. At large elongations, the submicroscopic residual strain is slightly smaller than the bulk residual strain. This must be associated with an irreversible deformation process involved on a much larger scale than in the interlamellar spacing. In our subsequent papers, we have discussed its origin¹⁹.

Figure 14 also shows recoverability of orientation of

the crystal *a*, *b*, and *c* axes upon releasing the applied stress. The degree of residual crystal orientation again corresponds to the bulk residual strain. Thus the lamellar bending and interlamellar slip processes involve plastic deformation of crystal such as chain slip of the type [001] (100)^{21,22}, which becomes increasingly important with elongations and is closely related to the irreversible deformation of interlamellar spacing.

Time-dependence of deformation

In the preceding sections, we discussed the static deformation mechanism of the hard elastic polyethylene films

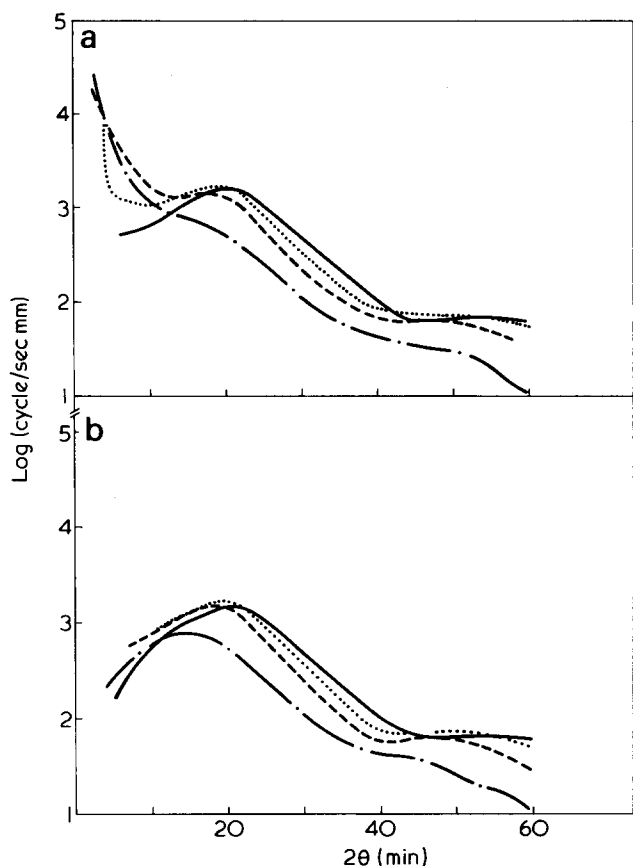

Figure 11 The meridional SAXS intensity distributions for specimens stretched by various elongations. (a) Dry specimens; (b) the specimens immersed by liquid paraffin. —, Unstretched; ····, 10% stretched; ---, 20% stretched; - · - ·, 50% stretched

Figure 12 The change of long spacing upon stretching the specimens along the MD. The long spacings are estimated from the first and second order scattering maxima. P_2/P_1 is the ratio of the second to first peak position

along the MD. Relative contributions of the various deformation processes involved are expected to be time-dependent. The analysis of the time-dependence is very important in understanding its dynamic mechanical properties.

Figure 15 shows a preliminary result of dynamic birefringence experiments where master curves of real ($K' + P_T$) and imaginary parts ($-K'' - P_T$) of strain-optical coefficient were plotted as a function of a reduced frequency f_0T .

In order to obtain the master curves a slight vertical shift (shift factor P_T) was necessary as well as the conventional horizontal shift (shift factor o_T).

Static strain 3.3% and dynamic strain 0.25% were imposed on the specimens along the MD²⁴⁻²⁶. The strain-optical coefficient is defined as the ratio of dynamic variation of birefringence to applied dynamic strain amplitude. As seen in the Figure the real part of the strain-optical coefficient increases from negative to positive value with decreasing frequency or increasing temperature. The transition of the coefficient from negative to positive values is related to the change of molecular orientation mechanism, i.e. negative to positive molecular orientation.

As discussed earlier, the negative molecular orientation is associated with the lamellar bending process, while the positive molecular orientation is associated with the lamellar detwisting process. The frequency or temperature dependence of the coefficient is then interpreted qualitatively in terms of the frequency or temperature dependence of a

Figure 13 The deformation of the submicroscopic structure, $(L - L_0)/L_0$, as a function of bulk elongation (O). ●, Corresponds to its residual deformation when the applied stress is released. The Figure also indicates a relationship between applied bulk elongation and residual elongation in bulk

Figure 14 The second order orientation factors of crystal a, b, and c axes as a function of elongation. For the specimens stretched and then released, the orientation factors were plotted as a function of residual elongation. Stretched: ●, f_a ; △, f_b ; ○, f_c . Relaxed: ◆, f_a ; □, f_b ; ◇, f_c .

Figure 15 The master curve of the real ($K' + P_T$) and imaginary parts $-(K'' - P_T)$ of the strain-optical coefficients when static (3.3%) and dynamic strains (0.25%) were applied along the MD . The quantities σ_T and P_T are horizontal and vertical shift factors, respectively. The reference temperature is set at 50°C. ●, $-(K'' - P_T)$; ○, $(K' + P_T)$

relative contribution of the two deformation processes. In a more quantitative discussion one must take into account contributions of amorphous orientation and form birefringence to the total birefringence, the discussion of which is beyond the scope of this paper.

In other words, at high frequency or at low temperature, the lamellar bending is activated but the lamellar detwisting is not, and so the contribution of the former is greater compared with the latter. Consequently the coefficient is negative. On the other hand with decreasing frequency or increasing temperature, the lamellar detwisting is increasingly activated, and so the contribution of the latter becomes predominant to the former. Therefore the coefficient becomes positive.

The lamellar bending process is accompanied by only a small amount of negative imaginary part, and thus the phase difference between the dynamic birefringence and applied strain is very small, indicating that the process is elastic in nature. On the other hand the detwisting process is accompanied by a relatively large phase lag to the applied strain as seen in a large phase lag between the dynamic birefringence and strain at low values of $f_0 T$, indicating that the process is viscous in nature and time-dependent.

More detailed discussion including dynamic birefringence in other directions and dynamic mechanical spectra is reported elsewhere²⁰.

CONCLUSIONS

(1) High density polyethylene films crystallized by a calender processing method exhibit a submicroscopic structure typical of that found for films crystallized from oriented polymer melts. Stacks of crystal lamellae are oriented with their normals parallel to the MD . Corresponding to this, the SAXS patterns show a two-point pattern, and the second order orientation factor for the crystal b -axis is close to $-1/2$.

(2) Under a given moulding condition with fixed temperature and shear rate, the films prepared from extra-high molecular weight polyethylenes and from high and medium molecular weight polyethylenes showed a preferential c - and a -axis orientation, respectively. In either case crystal b -axis orients almost perpendicular to the MD . The differ-

ence of the orientation may be attributed to a difference of shear stress in polymer melt. The proposal by Keller and Machin² that the c - and a -axis orientation result, respectively, from crystallization under high and low shear stresses turned out to be applicable also to our system.

(3) The manner of crystal orientation is apparently related to the mechanical properties of bulk specimens. Specimens having preferential c -axis orientation exhibit the hard elastic properties, while the specimens having preferential a -axis orientation do not show such unusual elasticity but exhibit usual yielding and necking, and a relatively small degree of length recovery from large extensions. This may occur partly because the interlamellar slip process involves a plastic deformation of the type $[001] (100)$ chain slip. The interlamellar slip process which orients crystal c -axis towards the SD occurs more extensively for the specimens having a -axis orientation than for those having c -axis orientation.

(4) The deformation of specimens along the MD involves lamellar bending and interlamellar slip processes. The bending process opens up interlamellar spacing to generate voids. The expansion of the interlamellar spacing affinely occurs with bulk elongation at small elongations. At larger elongations the increase of the spacing is less than that expected for the affine deformation due to increasing localization of interlamellar deformation which is associated partly with beginning of the sample whitening.

(5) The interlamellar slip involves rotation of crystal c - and a -axes around crystal b -axis (lamellar axis) towards the stretching direction (MD) and direction normal to the stretching direction (TD), respectively. The lamellar bending, on the other hand, involves rotation of crystal b and c axes around crystal a axis towards the SD and TD , respectively.

(6) Time-dependence of the two orientation mechanisms i.e. lamellar bending and interlamellar slip were studied by means of dynamic birefringence. The results indicated that the former mechanism is associated with a small phase difference to the applied strain, and is elastic in nature, while the latter mechanism is accompanied by a large phase lag to the strain, and is viscous in nature and time-dependent.

(7) Recoverability of deformation of the lamellar network, and crystal orientation was also studied. The results indicated that the lamellar bending and interlamellar slip processes involves, to some extent, a plastic deformation of crystals (irreversible intralamellar chain slip).

Superstructure of high density polyethylene film crystallized from stressed polymer melts as observed by small-angle light scattering

Takeji Hashimoto, Kikuo Nagatoshi*, Akira Todo† and Hiromichi Kawai

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606, Japan
(Received 23 February 1976)

The crystalline superstructure of high density polyethylene films prepared by a calender manufacturing method was investigated by means of polarizing light micrographs and light scattering patterns. Results show that optically anisotropic rod-like units exist which orient at preferential angles $+\alpha_0$ and $-\alpha_0$ with respect to the machine direction to form a network type superstructure. The rod-like unit is considered to be a row-nucleated cylindrite or a parallel assembly of them. The angle α_0 is associated with a preferred orientation of axes of the cylindrites with respect to the machine direction, and found to be dependent upon manufacturing condition. Existence of such a super-structure was shown to be important in accounting for whitening of the specimens on stretching along the machine direction and for deformation behaviour of the specimens.

INTRODUCTION

In a previous paper¹, we prepared various high density polyethylene films by a calender manufacturing process which involved crystallization from stressed polymer melts. Morphology and deformation mechanism of the submicroscopic structures were studied by means of small-angle X-ray scattering, wide-angle X-ray diffraction, and electron microscopy.

The X-ray data and electron micrographs were in agreement with general concepts obtained for tubular extruded^{2,3}, injected and hard elastic material⁴⁻⁸, and other material crystallized from oriented melts^{9,10}. For example, the submicroscopic structure consists of stacks of oriented lamellae, their plane normals being parallel to the machine direction (*MD*), which gives rise to two-point low-angle X-ray scattering patterns and the second order orientation factor of the crystal *b*-axis nearly equal to $-1/2$.

Under given manufacturing conditions with a fixed temperature, shear rate etc., the polyethylenes with higher molecular weights (e.g. HMW1 and HMW2 series in ref 1) result in a texture giving rise to preferential *c*-axis orientation, while those with lower molecular weights (e.g. LMW and MMW series in ref 1) result in a texture giving rise to *a*-axis orientation. This again is in agreement with the general concepts of material crystallized from oriented melt, because the material with higher molecular weights are subjected to a greater shear stress (due to greater viscosity) than those with lower molecular weights under the given conditions. The difference in the manner of crystal orientation can be interpreted in terms of the differences in number of row nuclei and in the degree of lamellar twisting overgrowth on the nuclei².

The polyethylene with higher molecular weights exhibited so-called 'hard elastic' properties⁸, i.e. a high degree of length recovery from large extensions, a marked reduction of apparent density, generation of very large amounts of internal volume and surface area on stretching along the *MD*, etc. The results obtained for our polyethylene films of morphology, deformation mechanism, and mechanical properties etc. are again in agreement with the general concepts of other hard elastic films or fibres⁴⁻⁸. The elasticity is energetically driven due to a bending type deformation of lamellae (see Figure 9 of ref 5). However in the case of polyethylene, the degree of lamellar twisting is large and thus the deformation mechanism associated with it (e.g. interlamellar slip) is markedly involved compared with poly(α -olefin). This makes the hard elasticity of polyethylene less pronounced, because the deformation will probably involve some irreversible chain slip of the type (100) [001]^{11,12} within the lamellae.

In this paper we have extended our study further, from the submicroscopic scale to the microscopic scale to investigate superstructure of the lamellae, if any, by means of polarizing microscope and light scattering. This work also should be of importance in investigating clarity of film specimens as-prepared and stretched, and to understand the deformation mechanism of the bulk specimens. It is one of our purposes in this work to study how the superstructure of the lamellae of these particular specimens is reconciled with our X-ray data and electron micrographs described in the previous paper¹ and with the concept of row-nucleated cylindrites proposed by Keller and Machin², and other workers.

TEST SPECIMENS

In this study, we used a particular linear polyethylene film designated as HMW2-L in our previous paper¹. The polyethylene (commercial grade, Sholex Super 4551H supplied

* On leave from present address, the Central Research Laboratory, Idemitsu Kosan Co. Ltd, Sodegaura-cho, Kimitsu-gun, Chiba-ken, Japan.

† On leave from the Research Center, Mitsui Petrochemical Industries Ltd, Waki-cho, Kuga-gun, Yamaguchi-ken, Japan

from Japan Olefin Chemical Ind. Ltd, and prepared by the Philips method) has weight-average molecular weight 2.9×10^5 by light scattering (measured in α -chloronaphthalene solution at 125°C), and a melt index of 5.0 at 190°C and 21.6 kg.

The film specimens were prepared by a calender processing method as described in detail in the previous paper¹. Temperatures of the first to third drums were kept at 145°C and that of the fourth drum was at 130°C (see Figure 1 of ref 1). Crystallization took place immediately after the fourth drum. The ratio of take-up to extruded velocities was controlled to 6/5. The density of the films thus prepared was 0.940 g/cm^3 (measured in methanol-water system at 25°C with a density gradient tube). The volume-average crystallinity evaluated was 59.5% by assuming densities of crystal and amorphous to be 1.000 and 0.852 g/cm^3 , respectively. Other specimens prepared from the HMW1 and HMW2 polyethylenes as described in the previous paper¹ showed a similar trend to the HMW2-L specimens.

EXPERIMENTAL

Light scattering patterns were obtained with a 1 mW He-Ne gas laser as a light source. Diffuse surface scattering was avoided by sandwiching the specimens in between the microcover glasses with silicone oil as an immersion fluid having an appropriate refractive index. The scattering patterns were taken with H_V and V_V polarizations where the polarization directions of the analyser were set horizontally and vertically, respectively, under a vertically polarized incident beam as well as with H_H polarization where both polarizer and analyser were set horizontally. The machine direction of the specimens was always set vertically. Typical exposure times were 1/30 to 1/8 sec for H_V , and 1/60 to 1/25 sec for V_V and H_H patterns.

Particular care was taken in obtaining the patterns, since as was shown in the previous paper, the specimen begins to whiten at elongations greater than $\sim 10\%$, when the specimen is stretched along the MD ¹. At these elongations the sample transparency becomes poor, in general, and as a consequence scattering patterns will be distorted due to a multiple scattering effect¹³. In order to minimize this effect the specimen stretched by a given elongation was immersed in a silicone oil (whose refractive index was matched to the average refractive index of the specimen) for at least a week prior to obtaining the patterns. Upon immersing the specimen into the silicone oil, the transparency of the stretched specimen became as high as that of the undrawn specimen. It should be noted that it takes a few hours, at least, before the stretched specimen becomes transparent after immersion in silicone oil.

Texture of the film specimens was also studied by means of polarizing light and electron microscopy.

RESULTS AND DISCUSSIONS

Polarizing light micrographs

Figure 1 shows a typical light micrograph observed under crossed polaroids. Close observation of the micrograph suggests that the texture is composed of rod-like units a few microns in diameter. These units are oriented at a particular angle of $\sim \pm 22.5^\circ$ with respect to the MD to form a network structure. It should be noted that the network structure composed of the anisotropic rod-like units

can be distinguished from the submicroscopic network structure composed of a stack of oriented lamellae linked by tie molecules of relatively short length. The deformation of the latter network was discussed by Hashimoto et al.¹ in relation to the hard elastic properties of bulk specimens. When the specimens were rotated between crossed polaroids, the brightness and the retardation colour of the units varied in such a way as to indicate that the average orientation of the optical axes of the rod-like units was parallel to the MD . The network structure was preserved and rotated. The angle that the rod-like units make to each other was also kept constant at $\sim 45^\circ$.

When the specimens are stretched parallel to the MD , the rod-like units orient toward the stretching direction (SD) and thus the angle between the units decreases from 45° . With a further increase in elongation identification of the units becomes increasingly difficult; this is associated with decreasing continuity or integrity of the units with elongations.

The observations under polarizing light microscope seem to suggest that the rod-like units reflect some morphological detail existing in the interior of the specimens. As will be discussed below, we consider that these units correspond to a single row-nucleated cylindrite or an assembly of them (see Figure 13). Although the axes of the cylindrites are usually found or considered to orient parallel to the MD , the axes orient at $\pm 22.5^\circ$ with the MD in these particular films. The boundaries between the adjacent cylindrites become a part of amorphous phase having zero birefringence similar to a volume-filling spherulitic system.

It should be noted that the network structure could also result from surface structure which is nothing to do with the morphological entity in the interior of the specimen. The surface structure causes variation of sample thickness which, in turn, gives rise to variation of retardation to result in the network structure under crossed polaroids. However, we can rule out this possibility for the light scattering data as will be discussed below.

Light scattering patterns

We consider the light scattering experiments to be very important and useful in studying the origin of the rod-like units or the network as observed under the polarizing light microscope. By treating the film specimens with silicone oils whose refractive indices are matched with the specimens, we can effectively avoid the surface scattering.

Figure 1 A typical polarizing light micrograph of the specimens

Figure 2 (a) H_V ; (b) V_V , and (c) H_H light scattering patterns of the specimens. The scale indicates the scattering angle

Therefore the scattering patterns are considered to be representative of the interior superstructure. The scattering patterns under crossed polaroids are particularly insensitive to the surface scattering.

In Figure 2 typical low-angle H_V , V_V , and H_H light scattering patterns are shown. It is observed that the patterns for other specimens (the HMW1 and HMW2 series) are essentially the same and consequently essentially identi-

cal crystalline superstructures are formed in these films. In all these patterns the scattered intensity at a given azimuthal angle continuously decreases with increasing scattering angle. In this regard the patterns are those typical of an oriented assembly of anisotropic rods¹⁴⁻¹⁶ as will be discussed below, but are not those typical of spherulitic texture.

The H_V scattering depends upon anisotropy and orientation of the rods, while the V_V and H_H scattering also depend upon density fluctuation between or within the rods and their surrounding medium. Since the scattering arising from the density fluctuation is isotropic in origin, it therefore does not depend upon a polarization direction under parallel nicols. Hence H_H and V_V scattering patterns are equivalent, if the scattering arises purely from the density fluctuations. The difference in the two patterns suggests that the orientation and anisotropy contributions are predominant in the density fluctuation. In the case of the V_V scattering the polarization direction is parallel to the MD and therefore to the molecular chain axis¹, so that the orientation and anisotropy contributions to the scattering are maximized, while in case of the H_H scattering these contributions are minimized and the scattering predominantly arises from the density fluctuation. The cylindrically symmetric H_H scattering intensity distribution with respect to the incident beam axis indicates that density fluctuation is isotropic. Therefore the density fluctuation between the rods and their boundary region turns out to be small, because if the fluctuation is large, then the H_H pattern becomes anisotropic in shape as in the V_V pattern. On the other hand the strong azimuthal angle dependence of H_V and V_V scattering arises from anisotropic orientation and anisotropy fluctuations as will be discussed later.

The angle that the H_V and V_V scattering lobes make with respect to the equator is $\sim 22.5^\circ$ and is apparently related to the angle that the optically anisotropic rod-like units make with respect to the MD . Therefore from the light scattering patterns also we can show that there exists an anisotropic rod-like entity oriented at a particular angle with respect to the MD as an internal superstructure of the film specimens. The rod-like entity giving rise to the scattering patterns should be essentially identical to the units observed under the polarizing microscope. We will discuss later a relationship between the units and the scattering patterns in a more quantitative manner by model calculation of the scattering patterns.

Orientation of the optical axis within the rod-like units may be qualitatively determined by observing the change in H_V scattering patterns upon rotation of the MD as shown in Figure 3. On rotating the MD of the specimens while keeping the polarization directions constant as in the Figure, the pattern also rotated through the angle α , since orientation of the rod-like units is changed by the angle α . An additional change is also seen in the intensity distributions in the rotated patterns. This arises from two factors which are mutually interrelated: (a) change of induced dipole moment which affects an absolute intensity, the intensity being maximum at $\alpha = 45^\circ$ because of the preferential c -axis orientation as shown in the previous paper¹, and (b) change of birefringence effect on light scattering¹⁵, the effect being maximized at $\alpha = 45^\circ$.

The fact that four lobes of the pattern change in an equivalent manner upon rotating the MD through an angle α demonstrates that the two rod-like units having $+\alpha_0$ and $-\alpha_0$ ($\alpha_0 \cong 22.5^\circ$) orientation with respect to MD have equivalent optical condition for all values of α under the given polarization condition. This may rule out the pos-

Figure 3 The change of H_V light scattering patterns upon rotating the MD by the angle α under crossed nicols. The polarization directions of polarizer (P) and analyser (A) are set in vertical and horizontal positions, respectively. (a) 0° ; (b) 22.5° ; (c) 45°

sibility that the orientation of the principal optical axis is parallel to the longitudinal direction of the rod-like units. This fact together with the preferential c -axis orientation

suggests that the optical axis is preferentially oriented along the MD , and therefore it makes an angle $\alpha_0 (= 22.5^\circ)$ or $-\alpha_0$ with respect to the longitudinal direction of the rod-like units as schematically shown in Figure 13b. Moreover the two-point SAXS patterns as described in the previous paper¹ demonstrate that the rod-like unit is composed of a stack of lamellae with their normals making also the angle $+\alpha_0$ or $-\alpha_0$ with respect to the longitudinal direction.

Integrity of the anisotropic rod-like units

Continuity or integrity of the anisotropic rod-like units which are now considered to exist as an internal superstructure were investigated by observing the change of the scattering patterns on treating the specimens with fuming nitric acid and on stretching the specimens.

Figure 4 shows the change of H_V , V_V , and H_H light scattering patterns of the specimens on treating with fuming nitric acid. Approximately 1 g of the polyethylene films was treated with 100 cm^3 of a fuming nitric acid ($SG 1.54$) for 4 and 8 h at $80^\circ \pm 2^\circ\text{C}$. The specimens were then washed with water and put into acetone for a day and subsequently dried. The film specimens obtained were brittle and opaque. On increasing the time of the treatment, the H_H pattern becomes angularly dependent with respect to the azimuthal angle and becomes similar to the V_V pattern, indicating that the density contribution becomes predominant to those of orientation and anisotropy. The change of V_V and H_H patterns indicates that the treatment increases the density difference between the rod-like units and their surrounding medium. This occurs because nitric acid first attacks boundaries between the rod-like units. On the other hand the H_V patterns of the treated specimens are essentially identical to that of the untreated original specimens. This demonstrates that the integrity or continuity of the rod-like unit itself is maintained even after the treatment. This result again suggests existence of the network superstructure which is built up from the anisotropic rod-like units as an internal superstructure of the film specimens.

As mentioned earlier in this paper and also in a previous paper, the specimen uniformly whitens during the course of stretching and becomes opaque at elongations greater than $\sim 10\%$. The stretched specimens were, therefore, treated with a silicone oil for a certain period of time prior to recording their scattering. The silicone oil acts in two ways; (a) to avoid surface scattering, and (b) to increase the transparency of specimens as a result of penetration of oil into the internal void region responsible for the whitening. For the specimens stretched by an amount smaller than 20%, the patterns were taken immediately after immersing the stretched specimens in silicone oil, so that the silicone oil essentially minimized surface diffuse scattering only. On the other hand for the specimens stretched by an amount greater than or equal to 20%, the patterns were taken after the specimens had been immersed in silicone oil for a few weeks. Thus in this case the silicone oil minimized both the surface diffuse scattering and the internal void scattering.

Figure 5 shows the change of H_V , V_V , and H_H scattering patterns on treating the specimens stretched by 20% with the silicone oil. The patterns in Figures 5a, 5b and 5c were taken immediately after the specimens had been treated with silicone oil, while Figures 5d, 5e and 5f were taken after treating the specimens with silicone oil for a few weeks. As seen in Figures 5b and 5c, V_V and H_H

Figure 4 The change of H_V , V_V , and H_H light scattering patterns of the specimens treated with fuming nitric acid for 4 h (a, b, c) and 8 h (d, e, f). (a), (d) H_V ; (b), (e), V_V ; (c), (f), H_H

(a), (d), H_V ; (b), (e), V_V ; (c), (f), H_H

patterns are essentially identical, indicating that the scattering arises primarily from density fluctuation, since the scattering from density fluctuation is independent of polarization directions in parallel polarizers. The density fluctuation, in turn, arises from density lowering or void formation at the interrod region, i.e. at boundaries between adjacent row-nucleated cylindrites.

Upon immersing the stretched specimens in the silicone oil for a sufficient time, the silicone oil penetrates into the void region and decreases the density fluctuation along the interrod region. This results in increased transparency of the specimens and in the patterns shown in *Figures 5d, 5e* and *5f*. The difference in V_V and H_H patterns suggests that the orientation contribution is now predominant to the density fluctuation. Thus the V_V pattern is primarily dependent upon anisotropy of the rod-like units and orientation distribution of the units with respect to the MD as in the H_V pattern. On the other hand the H_H pattern primarily depends on the density fluctuation, as polarization directions of polarizer and analyser are perpendicular to molecular chain axes. The circular type of H_H pattern suggests that the density fluctuation is spherically symmetric in contrast to the pattern in *Figure 5c* where the fluctuation occurs preferentially along the interrod region. Therefore the whitening of the specimens arises primarily from the void formation at boundaries between the cylindrites and from a long range correlation of fluctuations produced by interlamellar void formation. The generation of the interlamellar voids was discussed in detail in the previous paper¹. The H_V pattern in *Figure 5a* is diffuse compared with that in *Figure 5d* due to a multiple scattering effect¹³, but is essentially identical before and after immersion, suggesting that the silicone oil does not affect the morphology except for the fact that it interpenetrates the void region.

Figure 6 shows the change of H_V , V_V , and H_H patterns on stretching the specimens along the MD . With increasing elongation the H_V scattering lobes orient towards the equatorial direction. This results from orientation of anisotropic rod-like units towards the SD as discussed previously.

On increasing the elongation, the density difference between the rod-like units and their surrounding medium increases. Consequently, the anisotropic H_H pattern appears, and the V_V and H_H patterns become identical as shown in *Figure 6* for the specimens stretched by 7, and 14% and in *Figures 5b* and *c* for the specimens stretched by 20%. The disappearance of the anisotropic V_V lobes which is especially remarkable at elongations greater than $\sim 30\%$ may be associated with a decrease of continuity or integrity of the rod-like units. The tendency is also seen in H_V patterns in that the intensity distribution becomes sufficiently broader, and in polarized light micrographs the identification of the rod-like units becomes increasingly harder.

Figure 7 shows recoverability of the H_V scattering patterns upon releasing strain from given elongation percentages. It is seen that the patterns are almost completely recoverable if the initial elongations are less than $\sim 30\%$. However at larger elongations recovery of the pattern was not complete as seen typically in the pattern released from 50% elongation. This can be associated with decreasing continuity or integrity of the rod-like unit is considerably high.

Figure 8 shows the relationship between bulk elongation and elongation of the microscopic structural units i.e. the rod-like units. The angles between the MD and the rod-like units α_0 and α before and after stretching were evaluated by measuring the angles between the equator and one of

the H_V scattering lobes. The solid line indicates the change of the $(\alpha_0 - \alpha)/\alpha_0$ if the unit affinely orients toward the SD . From the Figure the units turned out to orient affinely even at relatively large elongations. At large elongations greater than $\sim 40\%$, the deformation of the microscopic structure is retarded to the bulk elongations. This is related to some localization of strain, especially at the interrod amorphous region, which may be followed by a disruption of integrity or continuity of the rod-like units as suggested from the change of the light scattering patterns.

Hashimoto *et al.*¹ previously investigated the residual strain, i.e. the strain which is observed even after the stress applied to the specimens is released as a function of initial elongations. At low initial elongations, the residual strain in bulk turned out to be identical to the submicroscopic residual strain which is analysed in terms of the long spacings measured by low-angle X-ray scattering. At large initial elongations greater than $\sim 40\%$, the bulk residual strain cannot be uniquely interpreted in terms of the submicroscopic residual strain. The former is shown to be appreciably greater than the latter. The excess residual strain in bulk can be associated with an irreversible deformation process involved on a much larger scale than the interlamellar spacing. The irreversible deformation, in turn, may occur due to the localization of strain at the interrod amorphous region described above.

At elongations greater than 40%, $(\alpha_0 - \alpha)/\alpha_0 \cong 0.4$ thus α is approximately 10° . By taking the orientation distribution of the rod-like units into account, the interrod void is considered to exist virtually parallel to the MD , and therefore it partly accounts for the equatorial streak-like scattering in the SAXS patterns as shown in *Figure 9* of the previous paper¹. The change of the orientation of the unit α with elongations is qualitatively in agreement with that observed directly under polarizing microscope. This again confirms that the network structure of the rod-like units observed under the microscope reflects a morphological detail existing in the interior of the specimens.

Origin of anisotropic rod-like units

In order to obtain better microscopic evidence showing existence of the rod-like units as crystalline superstructure of the film specimens, we investigated electron micrographs of the free surface. The typical micrographs obtained were shown in *Figure 5* in the previous paper¹. No micrographs were obtained which showed clearly boundaries between adjacent rod-like units. This may be due to the small density difference between the rod-like units and their boundaries as predicted by the circular type H_H scattering pattern.

Since it is well known that there are anisotropic rod-like units oriented at $\sim \pm 22.5^\circ$ with the MD , our problem is now to understand the origin of the superstructure. There may be two ways to approach this problem: (a) the superstructure is essentially formed as a consequence of crystallization from oriented melts, and (b) the superstructure is eventually formed by stress exerted to crystallized texture when the films are taken up. The latter may be less probable since for this particular manufacturing condition the stress should not be so large as to change texture which has been already crystallized (probably spherulitic in nature) into the network of the oriented rod-like units. The continuity or integrity of the units also may support the fact that the former is more probable than the latter. Therefore the oriented melts are considered to be crystallized into the network of the oriented rod-like units which are followed

Figure 8 The change of the angle between the MD and the rod-like unit as a function of elongation

by a minor deformation by the stress exerted when the films are taken up.

The anisotropic rod-like units as observed by the scattering patterns and the light micrographs should then correspond to a row-nucleated cylindrite or parallel assembly of them. However, the axes of the cylindrites which are found or considered to be usually parallel to the MD are now inclined by angles of $\sim \pm 22.5^\circ$ with respect to the MD , though there should be some orientation distribution around the

Figure 9 The model of an anisotropic rod-like unit as a scattering entity

preferred direction. It is not clearly understood at present why the axes should be inclined to the MD . A possible interpretation may be drawn by assuming that the row nuclei are formed in the preferred direction due to a particular mode of flow involved in this manufacturing method.

In fact the angle of $\sim \pm 22.5^\circ$ turned out to coincide roughly with flow directions of polymer melt by adding intentionally lower molecular weight impurity (dye) to the melt and observing its flow line.

The angle of 22.5° was found to vary with processing conditions adopted in this work. For example the angle turned out to be 15° and 20° for the HMW2-H1 and the HMW2-H2 specimens designated in the previous paper¹, respectively.

Model calculation of light scattering patterns

In order to confirm further that the scattering patterns shown in Figures 2 to 7 arise from anisotropic rod-like units observed under polarizing microscope (Figure 1), we made calculations on the scattering patterns based upon a simplified model of an oriented assembly of anisotropic cylindrical units (Figure 9).

The coordinate $oxyz$ is a cartesian coordinate where oz is parallel to the MD and ox is the film normal along which the incident beam is irradiated. The vectors $i, j,$ and k are the unit vectors along ox, oy and $oz,$ respectively, and s_0 and s' are those along propagation directions of incident and scattered light beams, respectively. The scattered light is observed as a function of the scattering angle θ and azimuthal angle μ . The axis of cylinder (unit vector r) having length L and radius R is oriented at angles α and β with respect to the coordinate. The cylinder is assumed to be composed of uniaxially anisotropic scattering element with polarizabilities α_{\parallel} and α_{\perp} parallel and perpendicular to the optical axis, respectively. The optical axis whose unit vector is given by d makes a polar angle ω_0 with respect to r .

In our special case, the orientation distribution function $N(\alpha, \beta)$ of the rod axes r has maximum values at α equal to $\alpha_0, \pi - \alpha_0, \pi + \alpha_0,$ and $2\pi - \alpha_0,$ and the value of ω_0 is nearly equal to α_0 . The radius R is roughly 0.5 to $1 \mu\text{m}$.

Some assumptions were introduced in order to simplify the calculation: (a) the radius R is negligibly small compared with length L ; (b) the distribution function $N(\alpha, \beta)$ is uniaxially symmetric with oz axis, i.e. independent of β ; (c) the angle ω_0 is zero, and (d) interrod interference is negligible, and the rod-like unit is dispersed in an isotropic medium having polarizability α_s .

The assumption (a) turned out to be reasonable from the light micrograph (Figure 1). Moreover the lateral size of the rod-like unit was previously shown to affect the pattern only in a quantitative manner^{17,18}. The assumption (b) may be reasonable from experimental evidences of uniaxially symmetric orientations of crystallographic axes and lamellar crystals¹. The assumptions (c) and (d) will be legitimate only if the qualitative shape of the patterns is of importance.

Under these assumptions, H_V and V_V scattering intensities I_{H_V} and I_{V_V} are given by

$$\begin{pmatrix} I_{H_V} \\ I_{V_V} \end{pmatrix} = C \int_{\beta=0}^{2\pi} \int_{\alpha=0}^{\pi} N(\alpha) \begin{pmatrix} E_{H_V}^2 \\ E_{V_V}^2 \end{pmatrix} \sin\alpha d\alpha d\beta \quad (1)$$

where C is a proportional constant related to the absolute intensity, and $N(\alpha)$ is an orientation distribution of the vector r . E_{H_V} and E_{V_V} are amplitudes of H_V and V_V scattering given by:

$$\begin{pmatrix} E_{H_V} \\ E_{V_V} \end{pmatrix} = \begin{pmatrix} (\mathbf{M} \cdot \mathbf{O})_{H_V} \\ (\mathbf{M} \cdot \mathbf{O})_{V_V} \end{pmatrix} F(L; \alpha, \beta) \quad (2)$$

where $(\mathbf{M} \cdot \mathbf{O})_{H_V}$ is an induced dipole moment under H_V polarization condition given by:

$$(\mathbf{M} \cdot \mathbf{O})_{H_V} = E_0(b_r - b_t) \sin\alpha \cos\alpha \cos\beta \quad (3a)$$

similarly

$$(\mathbf{M} \cdot \mathbf{O})_{V_V} = E_0[(b_r - b_t) \cos^2\alpha + b_t] \quad (3b)$$

E_0 is the amplitude of incident light, and b_r and b_t are polarizability differences defined by:

$$b_r = \alpha_{\parallel} - \alpha_s, \quad b_t = \alpha_{\perp} - \alpha_s \quad (4)$$

Now the function F is the structure amplitude of an isolated, homogeneous rod of length L having infinitesimally thin lateral dimension oriented at a given direction and is given by:

$$F(L; \alpha, \beta) = \int_{-L/2}^{L/2} \cos k(\mathbf{r}_1 \cdot \mathbf{s}) d\mathbf{r}_1 = \frac{\sin UW}{UW} \quad (5)$$

where $k = 2\pi/\lambda'$, s is so called scattering vector, and \mathbf{r}_1 is a displacement vector indicating position of a scattering element in the rod. The variables U and W are defined by:

$$U = 4\pi(L/\lambda') \sin(\theta/2) \quad (6)$$

$$W = \sin\alpha \sin\beta \sin(\theta/2) - \sin\alpha \cos\beta \cos(\theta/2) \sin\mu - \cos\alpha \cos(\theta/2) \cos\mu \quad (7)$$

The quantity λ' is a wavelength of light in the medium.

The scattered intensities can be numerically calculated by using equations (1) to (7), if a functional form $N(\alpha)$ is known. In this work $N(\alpha)$ is assumed to be:

$$N(\alpha) = \exp[-\sigma^2(|\sin\alpha| - \sin\alpha_0)^2] \quad (8)$$

where α_0 is related to a peak position and σ to a sharpness of the orientaton distribution. Figure 10 shows the typical

Figure 10 Assumed orientation distribution $N(\alpha)$ for a set of parameters: $\sigma = 5.0$ and $\alpha_0 = 22.5^\circ$ (—); $\sigma = 3.0$ and $\alpha_0 = 12.25^\circ$ (-----)

Figure 11 (a) Calculated H_V and (b) calculated V_V scattering patterns for a set of parameters: $\sigma = 5.0$, $\alpha_0 = 22.5^\circ$, $L/\lambda' = 40$, and $p = b_t/(b_r - b_t) = -0.27$

behaviour of $N(\alpha)$ for a set of parameters, ($\sigma = 5.0$, $\alpha_0 = 22.5^\circ$; solid line) and ($\sigma = 3.0$, $\alpha_0 = 12.25^\circ$; broken line).

Figure 11 shows the typical result of calculated H_V and V_V contour patterns for $\sigma = 5.0$, $\alpha_0 = 22.5^\circ$, $L/\lambda' = 40$, and $p = b_t/(b_r - b_t) = -0.27$. The intensity of the calculated H_V patterns passes through a maximum value at $\mu = 65^\circ$, which is in good agreement with that experimentally observed. The relative contribution of density and orientation fluctuations to the V_V scattering pattern is determined by a parameter $p (= -0.27)$, the value of which roughly corresponds to a case where the orientation contribution is predominant to the density contribution. Although splitting of the lobes of the calculated V_V pattern is less than that of the experimental patterns, agreement of the calculated and experimental patterns is fairly good. The intensity of the calculated V_V pattern passes through a maximum value at $\mu = 75^\circ$, which is in agreement with that of the experimental pattern. The difference in the values of μ where the H_V and V_V intensities are maximized is clearly understood by comparing $(\mathbf{M} \cdot \mathbf{O})_{H_V}$ and $(\mathbf{M} \cdot \mathbf{O})_{V_V}$ in equation (3). The deviation between the calculated and

experimental patterns in terms of the splitting of the lobes may arise from an interrod interference effect which is neglected in the present calculation.

Figure 12a shows the calculated H_V pattern for another set of parameters, $\sigma = 3$ and $\alpha_0 = 12.25^\circ$. Although the pattern well agrees with the experimental pattern, the fit of the V_V pattern is less satisfactory compared with the case of $\sigma = 5$ and $\alpha_0 = 22.5^\circ$. Figure 12b shows the calculated H_V pattern for a slightly modified model where $N(\alpha)$ linearly increases from 0 to 1 with increasing α from 0° to α_0° , and decreases according to equation (8) upon further increase of α . The pattern was calculated for a set of parameters, $\alpha_0 = 22.5^\circ$ and $\sigma = 5$ as in the previous case (Figure 11a). Upon modifying the function $N(\alpha)$, the calculated pattern at large W is shown to be slightly skewed towards the equator, the tendency of which is in better agreement with the experimental patterns.

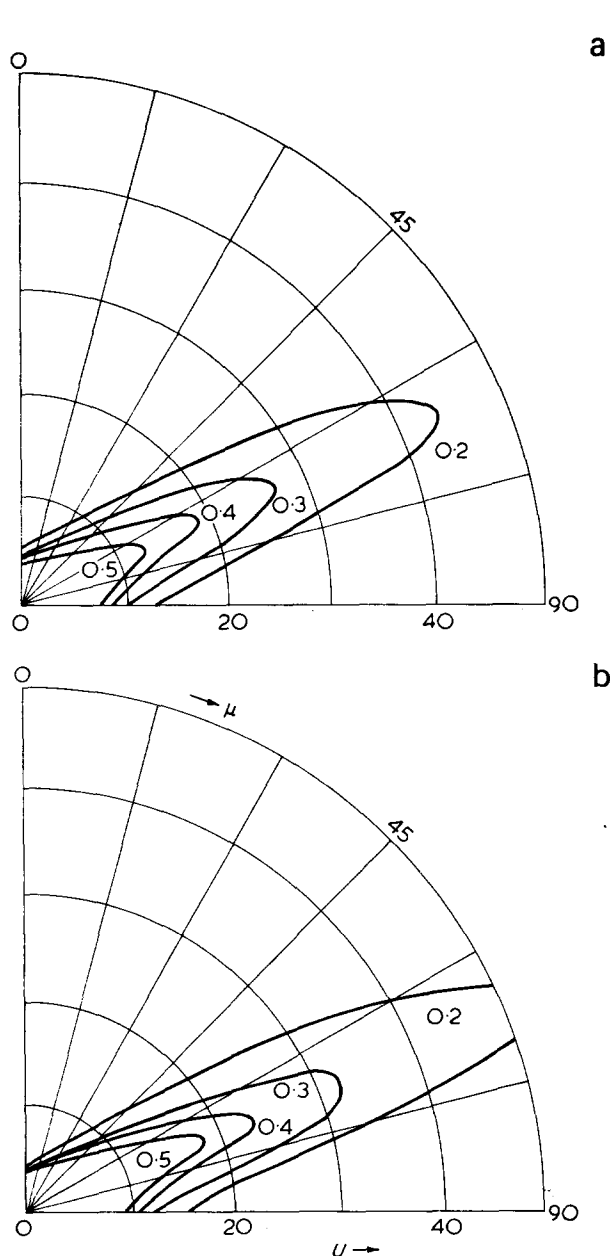

Figure 12 The calculated H_V scattering patterns: (a) $\sigma = 3$, $\alpha_0 = 12.25^\circ$, and $L/\lambda' = 40$, and (b) $N(\alpha)$ being linearly increasing from 0 to 1 with increasing α from 0° to α_0° , and decreasing according to equation (8) for a set of parameter $\alpha_0 = 22.5^\circ$, $\sigma = 5$, and $L/\lambda' = 40$

Figure 13 Schematic diagram of the network (a) composed of optically anisotropic rod-like units. The units is composed of a row-nucleated cylindrites or a parallel assembly of them. The axes of the cylindrites or the units (vector r_1) are oriented on average at angles $\pm\alpha_0$ with respect to the machine direction (MD) as in (b), while the average orientations of the chain axis and lamellar normal (vector c) are parallel to the MD

CONCLUSIONS

The high density polyethylene films crystallized by a calendar processing method exhibit a submicroscopic structure typical of that found for films crystallized from oriented melt; stack of crystal lamellae oriented with their normals parallel to the MD , giving rise to a two-point small-angle X-ray scattering patterns and to the second-order orientation factors of the crystal b -axis close to $-1/2$. Simultaneous observations of the light scattering patterns and polarized light micrographs revealed existence of a microscopic structure, i.e. a superstructure of the lamellae (Figure 13). The superstructure is composed of optically anisotropic rod-like units whose axes are preferentially oriented at angle of $\pm\alpha_0$ (22°) with respect to the MD to result in a sort of network structure as schematically shown in Figure 13a.

The rod-like unit is considered to be composed of a row-nucleated cylindrite or a parallel assembly of them. The axes of the cylindrites which are usually found to be

parallel to the MD are inclined with respect to the MD by $\sim\pm 22^\circ$ in this particular processing condition. The average orientations of the chain axis and lamellar normal is parallel to the MD and thus make angles of $\sim\pm 22^\circ$ with respect to the axes of cylindrites as shown in Figure 13b. The angle α_0 is dependent upon manufacturing conditions such as temperatures of the first to the fourth drums and the ratio of extruded and taken-up velocities. The existence of such superstructure plays an important role in the deformation behaviour of specimens and to their mechanical properties, especially at large deformation. It is also important in accounting for whitening of the specimens when they are stretched parallel to the MD .

Studies of the chemical degradation of polysiloxanes by hydrofluoric acid: 1. Poly(tetramethyl-*p*-silphenylene siloxane)

N. Okui and J. H. Magill*

Metallurgical and Materials Engineering, University of Pittsburgh, Pittsburgh, Pennsylvania 15261, USA

(Received 1 June 1976)

Hydrofluoric acid solution selectively degrades poly(tetramethyl-*p*-silphenylene siloxane) (TMpS) through scission of the Si—O bonds. The crystallinity of self-seeded single crystals of TMpS is significantly enhanced on degradation as the fold surfaces are removed. For 48% HF at 30°C the crystallinity change is from 73 to 95%. This corresponds to removal of two or more monomeric units from each crystal surface. Acid concentration and treatment temperature are very significant factors in the degradation reactions. The observed molecular weight change with time also depends on these details. The molecular weight distribution of a fraction at first broadens and then narrows with degradation time. At relatively long reaction times, the molecular weight (by g.p.c.) is reduced by more than an order of magnitude over that of the starting polymer fraction. In the early stages of chemical degradation the reaction is heterogeneous presumably because of poor wetting of the siloxane polymer by the HF reagent.

INTRODUCTION

Many years ago chemical etching techniques were first used in the analysis of cellulose by acid hydrolysis in water or ethanol¹³. Since then numerous studies using chemical degradation methods have been used to investigate the nature of the crystal surface structure of polymers. Examples are the degradation of polyethylene with nitric acid¹⁻³ or ozone^{4,5}, isotactic polypropylene with nitric acid^{6,7} and poly(hexamethylene adipamide) with sodium hydroxide⁸ as well as the degradation of cellulose by acid hydrolysis⁹ or poly(ethylene terephthalate) with monoethylamine^{10,11,23} or water vapour¹². Over the last decade polyethylene in particular, has been the subject of very intense investigations, but the precise details of the crystal surface and the mode of chain-folding is still not well understood. However, very recent work on the chemical etching of solution grown polyethylene has provided further insight into the extent of fold region and of the crystalline core^{14,15}. From all studies made to date it is clear that there is a real need to use definitive etching techniques which have a minimum of side reactions in such studies. Recent studies¹⁶ of the surface topography of polyoxymethylene single crystals suggest that they may have an absorbed layer of 'amorphous' material which may have far reaching implications¹⁷ with regard to many solution grown polymer crystals.

It has already been established¹⁸ that TMpS and related siloxanes selectively degrade thermally through Si—O bond cleavage. More recently it has been demonstrated that HF has (a) the ability to selectively cleave Si—O bonds of siloxanes, and (b) the ability to preferentially attack, under certain conditions, the non-crystalline regions of the polymeric solid. From this vantage point the polysiloxanes are amenable to investigation by chemical degradation in a way that will provide useful information about the topography of the chain-fold surface in solution grown crystals.

* Present address: Department of Physics, University of Bristol, Bristol BS8 1TL, UK.

EXPERIMENTAL

Solution grown crystals of poly(tetramethyl-*p*-silphenylene siloxane) (TMpS), molecular weight $M_w = 6.20 \times 10^4$, were crystallized from 0.1% solution in a mixture ethyl acetate and methanol (volume ratio 2:1) using the self-seeding procedure²⁰. The single crystal nature of these samples was confirmed by electron microscopy. The crystalline samples so obtained were then dried overnight *in vacuo* at room temperature. Selective chemical degradation was carried out subsequently by treatment with hydrofluoric acid to which a few drops of a solution of an anionic dispersing agent were added to facilitate wetting of the crystal surfaces. The reaction was carried out in polyethylene vessels which are not attacked by HF. Degradation experiments were conducted at several HF concentrations, at three different temperatures and for various reaction times.

The degraded polymer was carefully washed, first with distilled water and then with methanol in which it was insoluble. Complete removal of HF from the crystals was affected by an overnight soaking and further washing in an excess of methanol. Samples were later dried to constant weight *in vacuo* at room temperature.

Molecular weights and molecular weight distributions were obtained from conventional g.p.c. analysis. A Water Associates G.P.C. was used with tetrahydrofuran as solvent. Aliquots of 0.5 ml of 0.25 wt % polymer solution in tetrahydrofuran were injected into a series arrangement of four columns having porosity ratings of 3×10^6 , 1.5×10^5 , 10^4 , 10^3 Å. The melting temperature and heat of fusion were obtained on degraded and original polymer by Perkin—Elmer (d.s.c.) calorimetry. X-ray small-angle scattering (Rigaku—Denki) was used for determining the crystalline long spacing.

RESULTS

Figure 1 shows the weight loss of poly(TMpS) as a function

Figure 1 Weight loss (%) of poly (TMpS) on etching with 48% HF at three different temperatures: ○, 20°; ●, 30°; □, 50°C

Figure 2 Weight loss (%) of poly (TMpS) on etching at 30°C with three different HF concentrations: ○, 28%; ●, 32%; □, 48%

of time when it was selectively degraded with 48% HF at three different temperatures (20°, 30°, 50°C). It was found that at 50°C, the crystals were etched away very quickly and were completely destroyed in less than 80 h of treatment. At 20° and 30°C, the reaction was less rapid and the weight loss curves show a levelling off after the first few hours of reaction. Figure 2 illustrates how the HF concentration affects the weight loss of poly(TMpS) at 30°C. These curves clearly show that weight loss is very sensitive to both the concentration of the HF and the treatment temperature. Polymer treated with 24% HF at 30°C for 100 h showed no measurable evidence of reaction since the molecular weight and specimen melting point changed very little by this treatment. However, upon etching with 28 and 32% HF at 30°C, there was some loss in weight, but no appreciable change in molecular weight or melting point was detected under these conditions. Contrast, however, the drastic molecular weight decrease with the time during degradation with 48% HF (see Figure 3) where saturation levels are rapidly reached at relatively shorter reaction times.

Typical g.p.c. traces (Figure 4) of the degraded samples show only a single peak. The molecular weight distribution was ascertained from the spread of the g.p.c. peaks for different extents of reaction. In Figure 5, the molecular weight distributions (M_w/M_n) of the resultant g.p.c. curves are plotted vs. the square root of time. At first the molecular weight of the polymer fraction broadens with the time of the reaction in the early stages, after a few polymer

Figure 3 Time dependence of the g.p.c. molecular weight on etching with 48% HF at three different temperatures: ○, 20°; ●, 30°; □, 50°C

Figure 4 G.p.c. traces of poly(TMpS) degraded with 48% HF at 30°C for various periods of time: A, 100 h; B, 16 h; C, 5 h; D, 1 h; E, 0 h

Figure 5 Plot of the molecular weight distribution (M_w/M_n) against the treatment time for poly(TMpS) degraded with HF under the conditions: \circ , 20°C, 48% HF; \bullet , 30°C, 48% HF; \square , 50°C, 48% HF; \triangle , 30°C, 28% HF; \times , 30°C, 32% HF

chains have been cut. For this reason M_w/M_n initially rises as the molecular distribution broadens as observed for 20°C, 48% HF and 30°C, 28% HF treatment conditions. For the 48% HF at 30° and 50°C, and 32% at 30°C specimens, where the degradation is faster, similar M_w/M_n rises are expected (but not measured) as much shorter reaction times (see Figure 5, broken line) are suggested. The molecular weight distribution then narrows as the treatment time and temperature are increased.

Crystal stem lengths determined by small-angle X-ray scattering, make as a function of treatment conditions, are shown in Figure 6. Little change in the long period was found at short etching times using 48% HF. However, beyond a certain reaction time for a given temperature, the crystals were rapidly attacked by HF and solution (i.e. the fold surface was readily removed by HF) and the small-angle long period decreased by about 6~13% approaching constant values at long times of reaction.

DISCUSSION

The increase in the molecular weight distribution, invariance in the molecular weight and the relatively small weight loss change during etching with 28 or 32% HF at 30°C can be explained by the relatively mild reaction conditions that all the surfaces of the aggregations of the single crystals were not equally exposed simultaneously to the etchant. This behaviour is not exclusive to these mild conditions. At very long reaction times when the HF etchant can penetrate more deeply a significant weight loss occurs. Clearly degradation must be incomplete within the reaction times investigated under mild conditions of treatment where the rate is slower and only the readily accessible surfaces of the crystals in the aggregations will be etched with HF. Under such circumstances, a somewhat superficial levelling-off of the weight loss is noted with time because of the slow rate of degradation. A model depicting this type of mechanism of degradation is given in Figure 7. Molecular weight measurements indicate as a function of degradation time that the molecular weight of the specimens changes (increases) only

slightly when the chemical attack occurs at the surfaces of the aggregates of crystals. Support for this behaviour follows from the fact that both the melting point and X-ray long spacing of the samples did not change significantly, supporting the idea of the inaccessibility of the chemical reagent to the crystal surfaces.

The somewhat unexpected trends in behaviour have been noted in other polymer systems too. The dependence of the treatment temperature, degradation reagent and specimen history have all featured in the weight loss (and/or the molecular weight changes) reported for polyethylene [solution grown crystal^{13,21,22}, bulk crystal^{1,2,23}, high oriented²⁴ and copolymers^{25,26}, isotactic polypropylene^{6,7}, poly(ethylene terephthalate)^{11,27} and cellulose⁹]. For instance in the early stages of acid treatment, a negative weight loss was observed for polyethylene crystals due to the addition of heavy chemical groups through the oxidation reaction with HNO_3 ^{21,24}. However, this gain in weight is found to be dependent on the treatment condition²³ (i.e. temperature or acid concentration). Polyethylene crystals etched with HNO_3 show a much more drastic molecular weight change for a few per cent weight loss, because the chain scission occurred mainly on the folded lamellae surface. Degradation varies with sample history because of the extent to which the acid can diffuse or penetrate into the amorphous or more disordered parts of the crystals²³.

Figure 6 Time dependence of X-ray long spacing on etching with 48% HF at temperatures: \circ , 20°; \square , 30°; \triangle , 50°C

Figure 7 Model depicting the mode of attack of HF on TMpS single crystal clusters. Initially HF attacks accessible peripheral areas (arrowed), later permeating to the 'shielded' interior

Selective chain scission of polyethylene single crystal gave g.p.c. multiple peaks corresponding to the single stem traverse, double traverses and triple traverses of the lamellae²⁸. This evidence is supportive of a chain-folded morphology with a lamella texture. However, it was found that the multiple g.p.c. peaks were ill-defined for the fibrillar crystals^{9,24,29,30} and for branched polymers²⁶. Here degraded residues have inherently broad distributions because of (a) a wider distribution of crystalline lengths than in the lamellar crystal and (b) geometrical constraints associated with accessibility to the etchant.

In poly(TMpS) the molecular weight of unfractionated material is narrow ($M_w/M_n \sim 2.2$) relative to polyethylene ($M_w/M_n \sim 40$) so that the polydispersity of polyethylene usually improves with the acid treatment time tending towards a most probable distribution independent of the original chain length distribution^{31,32}. This trend is illustrated in a theoretical analysis polymer chain scission by Kothiar³³.

Figure 8 summarizes some aspects of the degradation of TMpS by HF. The molecular weight and the crystallinity variations are small until the sample weight loss reaches about 25%. Beyond this point the molecular weight and the crystallinity exhibit a drastic 25% weight loss (as indicated by the broken lines). From here on the molecular weight decrease is small but the crystallinity decrease is still comparatively large. This pattern of behaviour before the weight loss reached 25%, is attributed to limited ingress of HF where diffusion of the etchant is intimately connected with both geometrical (surface area) and wettability considerations. Later in the degradation process, the surface of the single crystals (particularly fold surfaces) are selectively cut very quickly by HF with relatively small weight loss (as indicated by the broken lines in Figure 8 about the 25% level). After the HF has removed most of the fold surface, the acid can then penetrate and attack the crystalline core and progressively remove monomer units from the crystal surfaces causing a further weight loss and crystallinity change.

Crystallinity assessed by d.s.c. from heat of fusion data

Figure 8 Plot of the molecular weight against the weight loss of the degraded poly(TMpS) under the conditions: ○, 20°C, 48% HF; ●, 30°C, 48% HF; □, 50°C, 48% HF. Plot of the degree of crystallinity against weight loss of the degraded poly(TMpS) under the conditions: ○, 20°C, 48% HF; △, 30°C, 48% HF; ▲, 50°C, 48% HF

reaches levels of 95% after selective degradation with 48% HF at 30°C for 50 h. Originally poly(TMpS) crystals have approximately 73% crystallinity and a 71 Å long period. It was found from long period measurements (Figure 6), that the crystalline core is about 52 Å (consisting of 6 monomer units) with an amorphous fold surface estimated at 9.5 Å (comprised of 2 monomer units). At this point little can be said about the unevenness of the surfaces or indeed if there are adsorbed chains on the crystal surfaces¹⁷. However it is clear that HF removes this surface resulting in a 25% loss of weight—a fact which is consistent with the proposed model and is in good agreement with the measured weight loss, molecular weight measurements and degree of crystallinity (Figure 8).

Still, in all chemical degradative studies it seems that the physical dimensions of the surface actually accessible to the acid must feature somehow in assessing the degradation rate. To date the role of geometrical factors stemming from different morphologies have largely been ignored in the literature. However it is worth mentioning that fibres and bulk crystallized specimens are naturally expected to have less accessible amorphous regions than single crystals or well dispersed aggregates of crystals. At this point the type of crystal must also be important (i.e. whether the morphology is platelet, axialite, hedrite or terraced) within a given specimen. The diffusion or penetration rate of etchant²², as well as sample area vulnerable to attack, deserves further consideration. Some of these problems will be tackled in later papers on the degradation of polysiloxanes. Highly drawn fibres will undoubtedly be more receptive to etchants than unoriented fibres because of the higher sorption and diffusion transverse to the draw direction, that is a consequence of a more open microfibrillar morphology consisting of taut tie molecules³⁴.

CONCLUSIONS

All results can be explained by assuming that aqueous HF preferentially attacks the less ordered surface layer of the crystalline material and removes it through severing selectively the Si—O bonds of poly(TMpS)¹⁹. The molecular weight decreases by 10 ~ 14 times compared to the original specimens. However, current g.p.c. curves did not show multiple peaks corresponding to single, double or triple chain traverses. This may be due to limited g.p.c. resolution or to the presence of degraded molecular fragments having broad distributions. Further investigations are aimed at this problem.

ACKNOWLEDGEMENTS

This work was supported in part by the National Science Foundation under contract GH 32581. The authors are grateful to Professor G. C. Berry of the Mellon Institute of Science for kindly placing his g.p.c. facilities at their disposal. They also wish to thank Dr J. Stejny, University of Bristol, for his helpful comments on the manuscript.

Confirmation of the role of radicals in energy transfer resulting in induced phosphorescence of irradiated doped poly(methyl methacrylate)

C. S. Bilen and D. J. Morantz

London College of Printing, London SE1, UK

(Received 10 June 1976)

Transient species, in irradiated doped poly(methyl methacrylate) (PMMA), enhance the transfer of energy to the triplet state of the dopant. Production of these transients enables a strong, induced, phosphorescence to occur even at room temperature. This is inhibited by the use of a radical scavenger or the presence of oxygen, which results in reduction of the phosphorescence intensity in the post-irradiation period. E.s.r. analysis of u.v. and X-ray irradiated doped PMMA samples, showing induced phosphorescence, identifies such transients as PMMA radicals. The correlation between induced phosphorescence and thermoluminescence, previously reported, is extended by a further correlation between induced phosphorescence and e.s.r. measurements. It is concluded that the PMMA radicals are involved in the induced phosphorescence as well as the thermoluminescence.

INTRODUCTION

The presence of radicals in irradiated polymers is well established^{1,2}. However, there has been some controversy^{3,4} as to whether, in irradiated PMMA samples, there is only one type of radical with the same decay rate for various e.s.r. lines (5th and 7th lines are generally used for these arguments) or whether more than one kind of radical is present having different decay rates for the 5th and 7th lines. More recent studies⁵ indicate that various types of radical may be produced under different irradiation conditions, however, at room temperature one type only of propagation radical predominates over other types. This radical is characterized by a strong (so-called 9 line) e.s.r. spectrum. We have studied the luminescence of doped PMMA which has been irradiated by X-ray, u.v. light and visible laser light respectively and also by prolonged heating, at 473K, of this system in the absence of air. In each case this results in *induced phosphorescence*^{6,7}, emitted by the affected regions of these samples.

We have demonstrated⁶ the role of transient species as providing an alternative route for the transfer of energy to the triplet state. Other studies⁸ correlated the thermoluminescence and induced phosphorescence of the irradiated systems and helped to narrow the possible range of transient species responsible for these two effects. Our present findings concerning the reaction of transient species with atmospheric oxygen yields an estimate of the activation energy for oxygen sensitized decay of phosphorescence which is not inconsistent with the reported value⁹ for radical recombination. Furthermore, inhibition of the induced phosphorescence, through the use of a radical scavenger (diphenylamine) during u.v. irradiation, also indicates the presence of radicals in the irradiated regions. Although radicals have been demonstrated in u.v. and X-ray irradiated PMMA using e.s.r. spectroscopy, such studies did not relate to the effects of induced phosphorescence or

thermoluminescence. The present paper reports direct, e.s.r., evidence which confirms that PMMA radicals (propagation type) occur in u.v. and X-ray irradiated samples exhibiting induced phosphorescence and we find a strong correlation between the induced phosphorescence intensity and the e.s.r. signals for the u.v. irradiated samples.

EXPERIMENTAL

PMMA (BDH) was of low molecular weight and average particle size, 170 μm . Triphenylene (purity 98%) and dibenzothiophene (95%) dopants were obtained from Ralph N. Emanuel Ltd. The diphenylamine radical scavenger was laboratory reagent grade from BDH. The samples were prepared as described elsewhere⁶ and the radical scavenger, diphenylamine powder, was mixed with the doped or undoped PMMA by a similar method. Details of the emission spectrophotometer have also been mentioned in earlier papers⁸. X-ray irradiation of samples was undertaken in a steel irradiation chamber fixed at a point focus window of an Elliot Automation Cu target tube (type no. 315/Tx/6 Cu). This was generally operated using an accelerating potential of 30 kV at 16 mA beam current. X-ray spots of about 8 mm diameter were produced. U.v. irradiation of doped PMMA samples was carried out using an unfiltered high pressure mercury lamp with quartz windows (MED Mazda, powdered by an a.c. supply) at a distance of about 10 cm. Irradiations were of 5–10 min intervals, the total exposure being up to ~ 130 min.

E.s.r. analysis was undertaken at room temperature in air using a Varian E-12 X-band spectrometer and scans were carried out immediately after the completion of each u.v. irradiation period. The emission spectra for induced phosphorescence were also recorded using the same u.v. lamp in a similar arrangement.

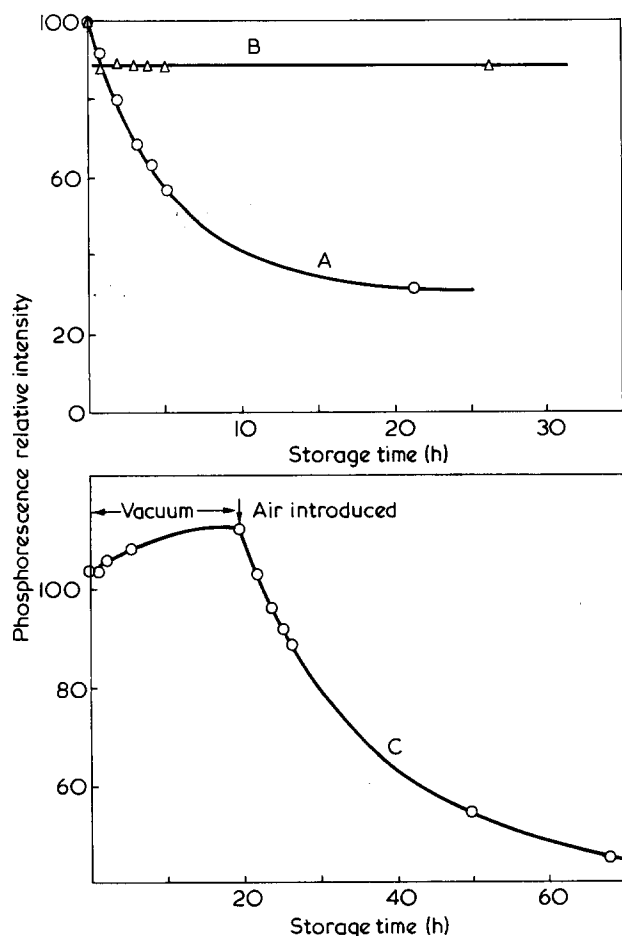

Figure 1 Effect of air on phosphorescence decay ratios. Curves A and B are for X-ray irradiated dibenzothiophene doped PMMA samples during the post irradiation period. A, Sample stored in air; B, sample stored in nitrogen; C, shows phosphorescence intensity changes of a u.v. irradiated triphenylene doped PMMA sample stored in vacuum and after the introduction of air

RESULTS

Figure 1 shows the sensitivity of the induced phosphorescence to the oxygen of the air. The intensity (curve A) falls, after 20 h, to about 30% of the value obtained immediately after the X-ray irradiation. The induced phosphorescence intensity remains high, however, when the irradiated samples are stored in oxygen-free nitrogen gas (curve B) or in a vacuum (curve C). Curve C again emphasizes how the induced phosphorescence is affected by the introduction of air to the storage dessicator. We believe that the induced phosphorescence intensity decreases when oxygen reacts with the transient species to form peroxides. The sensitivity towards oxygen of the transient species is also indicated by our observation that the induced phosphorescence in doped PMMA samples is only generated when the air (oxygen) is excluded from these samples during prolonged heating. Furthermore in u.v. irradiated samples the induced phosphorescence effect is restricted to surface layers as opposed to X-ray irradiation where the effect is in the whole thickness of the sample. The surface layers (u.v. irradiated) show a much faster decrease with storage in air, than do the thicker, bulk, (X-ray irradiated) samples.

The radical character of the transient species is further supported by the results shown in Figure 2. Curves A and B (Figure 2a) show the emission from a triphenylene doped

PMMA sample before and after u.v. irradiation. Note the development of an emission peak at 460 nm in curve B, corresponding to induced phosphorescence of the dopant in addition to the normal fluorescence peaks in the region of 360 nm. Curves C and D (Figure 2b) show the emission of triphenylene doped PMMA sample also containing a radical scavenger diphenylamine, before and after irradiation respectively. Before irradiation, the scavenger slightly reduces the fluorescence emission and suppresses the vibrational structure corresponding to triphenylene. After the u.v. irradiation (similar exposure to that in the case of curve B above) the sample does not show induced phosphorescence but does give a strong fluorescence peak in the region of 400 nm. The curves E and F show the emissions of PMMA samples containing only the radical scavenger compound diphenylamine before and after u.v. irradiation. Noting the similarity of emission after u.v. irradiation, and bearing in mind that no such emission takes place when the PMMA sample is without any additive and irradiated with u.v. light, one can only conclude that these emission bands (at 400 nm) are related to the radical scavenger diphenylamine dopant when it interacts with the transient species in PMMA. Furthermore the presence of primary dopant triphenylene does not affect this interaction.

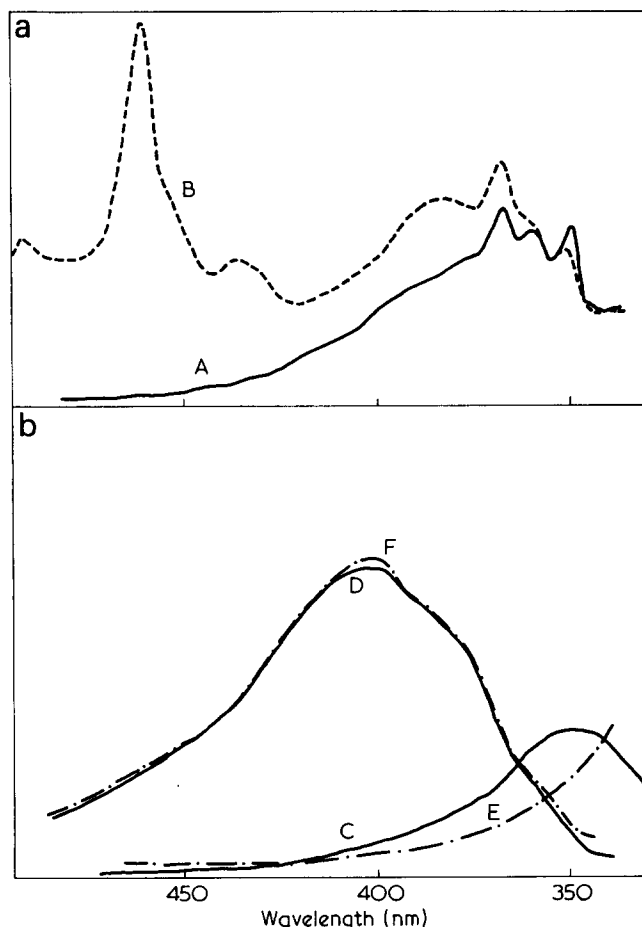

Figure 2 (a) Emission spectra of triphenylene doped PMMA sample before (A) and after u.v. irradiation (B). (b) Emission spectra of triphenylene doped PMMA sample also containing diphenylamine radical scavenger (—) before (C) and after u.v. irradiation (D); emission spectra of PMMA sample without triphenylene but containing radical scavenger (- · - ·) before (E) and after u.v. irradiation (F).

Figure 3 A, E.s.r. spectrum of X-ray irradiated dibenzothiophene doped PMMA sample scanned after 5½ h storage in air; B, e.s.r. spectrum of dibenzothiophene doped PMMA sample u.v. irradiated for 40 min and scanned immediately after irradiation

Curve A of Figure 3 shows the e.s.r. spectrum obtained, when dibenzothiophene doped PMMA, showing induced phosphorescence under u.v. inspection, was placed in the Varian E-13 cavity. This sample was irradiated, with the X-ray beam (16 mA at 30 kV accelerating potential) from a Cu target for 1 h; the sample was, however, left in air for 5½ h. As a result of this long exposure to air and because the X-ray beam spot only covered about 1/10 of the cavity area, the e.s.r. signal is relatively weak. Curve B shows the typical sharp e.s.r. spectrum, immediately after a 40 min period of u.v. irradiation for a dibenzothiophene doped PMMA sample. This spectrum is similar to those obtained by Wong¹⁰ for u.v. irradiation of evacuated PMMA films and X-ray and γ -irradiated PMMA samples^{3,5}. The line attributed to a signal from the quartz container¹⁰ did not appear in our scan, as solid samples without quartz containers were used.

Figure 4, curve A shows the variation of the e.s.r. signal, for a dibenzothiophene doped PMMA sample, with increasing u.v. irradiation. The curve shows a linear increase at first, followed after a maximum by a non-linear fall. A corresponding induced phosphorescence intensity behaviour is shown by curve B. The curves have similar shapes but with a slight shift in the relative position of the peaks for the two curves. We recall that such shifts were also present when induced phosphorescence and thermoluminescence curves were compared in our earlier studies⁸.

DISCUSSION

The results shown in Figures 1 and 2 clearly indicate that the transient species responsible for induced phosphorescence in doped PMMA are sensitive to both oxygen and radical scavengers. This points strongly to the possibility that the transients are radicals derived from the PMMA matrix. Moreover, we have estimated the activation energy for the decay, caused by oxygen, of induced phosphore-

scence (from the decay rates at 295K, 307K and 314K). The value obtained, 16.6 kcal, may be compared with half of the reported values (which range from 28–32 kcal) for PMMA radical pair recombination reported by Ohnishi and Nitta⁹. In the latter case two radicals need to be detrapped (in the absence of oxygen) compared with one only in our case in the presence of oxygen. This strengthens our earlier conclusions that the transient species are the PMMA radicals, which predominate at room temperature, of the type:

The e.s.r. spectra of Figure 3 for X-ray and u.v. irradiated doped PMMA samples clearly identify the transients as the above mentioned species of PMMA radicals by their characteristic line spectrum. The spectrum for the X-ray irradiated sample corresponds to a low signal, however, and probably for the reasons previously mentioned, namely small spot size and long exposure to air. Nevertheless there remained sufficient signal to identify it as belonging to PMMA radical. This scan of the X-ray sample, however, does not show the central line (indicated by the broken line). This has been nullified by the cavity signal. This effect is also seen in the reduction of the amplitude of the same central line for the stronger signal, in the case of the u.v. irradiated samples (Figure 3, curve B).

The strong similarity of the curves in Figure 4 supports the argument that these radicals, measured by the e.s.r. signal, play an essential role in induced phosphorescence. The slight shift in the peak positions for the two curves in Figure 4 may be explained as follows: the induced phosphorescence emission is recorded using a weak excitation source (312 line) which only affects the topmost layers of the irradiated regions near the surface of the irradiated samples. The e.s.r. signal and this would be the case as well for thermoluminescence (we have reported, elsewhere⁸, the correlation of thermoluminescence and induced phosphorescence) is derived from all the affected layers including deeper layers. Thus the weighted average for the e.s.r. signal (and for thermoluminescence) would reach saturation after a small time lag as compared with the induced phosphorescence measurements.

Figure 4 Comparison of e.s.r. signal amplitude (A) and induced phosphorescence intensity (B) for increasing u.v. irradiation periods

Our conclusion concerning the role of PMMA radicals in energy transfer is further supported by the anomalous thermal behaviour of induced phosphorescence. Such energy transfer as well as induced phosphorescence was reduced drastically as the irradiated doped PMMA sample was cooled below the γ -transition of PMMA. Below this transition the rotational freedom of the ester group¹² is reduced and we believe that loss of such freedom affects the energy transfer of these radicals. However, other types of radicals of PMMA origin may also be produced under other conditions⁵, and their role and participation in energy transfer processes were quite different⁸ from those of the PMMA radicals now identified by the sharp line spectra in *Figure 3*. The evidence for the role of PMMA radicals in energy transfer to the triplet state of the dopant, is we believe, quite conclusive.

Some aspects of flame retardancy in high density polyethylene*

S. C. Sheat and J. P. Berry

Department of Polymer and Fibre Science, University of Manchester Institute of Science and Technology, Manchester, UK

(Received 9 June 1976; revised 1 July 1976)

The influence of the flame retardant agents, antimony trioxide and a chlorinated hydrocarbon, on the mechanical and flammability properties of high density polyethylene has been studied. Flammability was assessed by means of the limiting oxygen index test, whilst mechanical properties were measured in the tensile mode on compression moulded samples. An optimum in terms of flame resistance was found at a Sb:Cl mole ratio of 1:3 which tends to confirm that the actual flame retardant is the volatile antimony trichloride. The modulus, yield and drawing behaviour, and ultimate properties of the unoriented samples did not show significant change (< 10%) until the combined level of additive exceeded 25% by wt. Above this level it was found that the samples could not be oriented and that the elongation to break decreased markedly. Alumina trihydrate was studied as an alternative flame retardant but was found to be unsuitable for use in HDPE, since to obtain an adequate level of fire retardancy a high concentration (40%) of additive was required, which resulted in a significant deterioration in the mechanical properties.

INTRODUCTION

In the study of fire retardant additives it is desirable to include the effect of these substances on other properties, notably mechanical, as these determine to a large extent the end use to which a particular formulation can be put. It is the purpose of this paper to apply these ideas to the antimony/chlorine system and to alumina trihydrate, using high density polyethylene (HDPE) as the matrix.

Although well known, the antimony/halogen synergism is highly controversial in terms of optimum ratios of antimony to halogen. Little¹ in 1947 made what is considered to be the first attempt at explaining this synergism. He claimed that hydrogen chloride was evolved from the chlorinated hydrocarbon which reacted with antimony trioxide to yield antimony oxychloride (SbOCl) *in situ*. This implies an optimum flame retardancy when the mole ratio of Sb:Cl is close to 1:1, according to the following simplified reaction:

More recently^{2,3} claims were made implying an optimum at ~28% (w/w) Sb₂O₃ and ~15% chlorinated hydrocarbon, while Raff and Allison⁴ claimed that 6% chlorinated hydrocarbon is sufficient. Pitts⁵ reviewed recent evidence and while conceding that the oxychlorides of antimony (SbOCl and Sb₄O₅Cl₂) are powerful flame retardants, suggested that the real flame retardant is the volatile antimony trichloride (SbCl₃) according to the following simplified reaction:

In 1966 Fenimore and Martin^{6,7} reported saturation in terms of oxygen index above certain mole ratios of Sb:Cl in polyethylene. Unfortunately their results are somewhat difficult to interpret and it was the purpose of the work reported in this paper to repeat their results.

Regarding alumina trihydrate, which has gained popularity as a fire retardant, in recent years, owing largely to its relatively low cost, this has been described by Hopkins⁸ and functions by the endothermic release of water at temperatures above 180°C resulting in flame cooling.

EXPERIMENTAL

Materials

Commercial grade materials were used throughout this investigation and their properties are shown in *Table 1*, the data being taken from the manufacturers' information sheets.

Sample preparation

To ensure good dispersion of the flame retardant a two-stage mixer process was adopted. The polyethylene was heated to 145°C in a Banbury mixer, the additives added over a period of 4 min and mixing continued for another 4 min at 125 rev/min. After discharging, the hot blend was rapidly transferred to a two-roll hot mill and intensively mixed for another 5 min before sheeting off, a differential speed of 1:1.14 was used to ensure shear in the nip, and roller temperatures were set at 145°C front, and 127°C rear.

Sheets moulded from 100% HDPE subjected to the above conditions showed no significant difference in tensile and flammability properties to those of sheets produced under identical moulding conditions from virgin polymer chips. On the basis of this it was assumed that no significant degrada-

tion of the HDPE occurred during the blending and moulding cycles.

Compression moulded sheets of nominal thickness, 0.8 mm, were produced at 190°C and slowly cooled to room temperature over a period of 8 min. Moulded sheets were not annealed following the experience of Anderton and Treloar⁹ who found that annealing HDPE sheets gave poor drawing characteristics.

In view of its reproducibility it was decided to use the limiting oxygen index test for flammability as originally proposed by Fenimore and Martin¹⁰. Basically this test measures the concentration of oxygen (by volume) in an oxygen/nitrogen atmosphere to just sustain combustion and is interpreted on the basis of air containing ~21% oxygen. Thus, materials with an oxygen index (OI) less than 21 can be expected to burn in air, while materials with a higher OI will generally be self-extinguishing.

Samples cut from the compression moulded sheets were subjected to this test as per ASTM D2863-74 with one modification. This specification recommends that for material in the form of thin sheet the criterion for sustained combustion shall be the burning of a sample of length 100 mm. In view of the size of the compression moulded sheets (150 × 150 mm) it was decided to adopt the criterion for a rod, which is burning for a length of 50 mm or 3 min, whichever occurs first. This enabled more samples to be tested from one moulded sheet. Consequently while OI results quoted here are comparative with each other they will be slightly low when compared with results obtained by other authors. Results indicate the mean and range of five samples.

Dumbbell shaped specimens 80 mm long were used for the tensile tests, thickness being measured at three points along the length of the parallel section. Five samples per variable were tested at a clamp separation rate of 50 mm/min and an initial strain rate of 100% per min. The tests were conducted at room temperature (19°–23° C) and all samples except those at 40% additive level necked and drew. Since dumbbell specimens were used it was decided to use a

corrected initial length of 35 mm in the calculation of mechanical properties in an attempt to overcome the problems posed by this shape. Accordingly results are comparative only.

Theoretical boundary conditions, corresponding to uniform stress and uniform strain were calculated as detailed by Broutman and Krock¹¹, assuming moduli for antimony trioxide and the chlorinated hydrocarbon of 2×10^{10} Pa and 2×10^9 Pa respectively. The iso-stress modulus is calculated from:

$$1/E = \sum \frac{V_i}{E_i}$$

where E is the composite modulus; E_i is the modulus of components; V_i is the volume fraction of components: while the iso-strain modulus is obtained from:

$$E = \sum V_i E_i$$

DISCUSSION

Regarding the antimony/chlorine system it is convenient to plot results as a function of mole fraction of chlorine. This has the advantage of indicating the effects of different total concentrations on the same graph, however the graphs become somewhat compressed in that a Sb:Cl ratio of 1:3 is shown as a mole fraction of chlorine of 0.750 while a Sb:Cl ratio of 1:30 becomes 0.968.

Results for 10% and 20% total additive concentrations are shown in Figure 1 and considering these graphs it would appear that two discontinuous regions exist, corresponding to undiluted antimony trioxide and chlorinated hydrocarbon respectively. Some synergism can be seen to exist in that the oxygen index obtained in a blend is higher than that obtainable by the individual components, antimony trioxide and chlorinated hydrocarbon. It can be seen that this synergism is relatively small; an effect which has been ascribed to the relatively high degree of crystallinity of the base polymer¹².

In view of this synergism it would appear logical to consider the points at 100% Sb₂O₃ and 100% chlorinated hydrocarbon as not belonging to these curves, because of the lack of synergism at these two points. Both curves, at 10% and 20% total additive concentration, show points of inflection at mole ratios Sb:Cl of just greater than 1:3 which tends to confirm that the actual flame retardant is

Figure 1 Oxygen index vs. amount of chlorine at different total additive levels: □, 10% total additive; ○, 20%, total additive

Figure 2 Comparison of different flame retardants. \circ , Sb:Cl of 1:3; \square , alumina trihydrate

Figure 3 Modulus as a function of amount of flame retardant at Sb:Cl of 1:3

the antimony trichloride (SbCl_3). It was found that in the range Sb:Cl of 1:3 to Sb:Cl of 1:30 saturation occurred in that the oxygen index levelled off, which confirms the findings of Fenimore and Martin. The reason for this saturation is not however known at this stage.

On the basis of Figure 1 an optimum could be selected at a Sb:Cl ratio of 1:3. Figure 2 shows the effect of varying the total additive concentration at this fixed mole ratio. It is apparent from this Figure that a vast improvement of flame retardancy is not possible owing to the low efficiency as previously mentioned. From these results it can be seen that at 40% additive the OI is still fairly low at ~25. Consequently it is thought that in a real fire situation HDPE so stabilized will burn and that protection is only afforded against the dropped cigarette end etc. This can be ascribed to the fact that in a real fire situation high temperatures will be encountered, resulting in a decrease in the oxygen index as has been previously described^{13,14}. It is thought that this decrease may be sufficient to reduce the value of the oxygen index to below 21 in which case it can be expected to burn. Experimental evidence regarding the size of this oxygen index reduction with increasing temperature, in HDPE stabilized with antimony/chlorine, is not available as yet.

It was found that the oxygen index of unstabilized HDPE was 16.8 and as explained earlier this figure is expected to be low. Most authors¹⁵⁻¹⁸ quote figures for polyethylene of ~17.4.

Regarding the mechanical properties the effect on modulus and elongation to break are shown in Figures 3 and 4 respectively. It was found that an increase in the amount of additive caused an increase in modulus and a decrease in ultimate strain. Boundary conditions, corresponding to uniform strain and uniform stress are shown by the broken lines and it can be seen that the results obtained are fairly close to the iso-stress boundary, indicating that this is the controlling parameter. As a result of this close proximity to iso-stress, this condition can be used as a practical basis to determine theoretical moduli to within 10%. Above 25% total additive the elongation to break decreased markedly and it is thought that this would represent a maximum flame retardant loading for a commercial plastic.

Alumina trihydrate was compared with the antimony/chlorine system and results are shown in Figure 2. It can be seen that the antimony/chlorine system is far more efficient compared to alumina trihydrate, in HDPE. To achieve an oxygen index of 21 with the latter additive concentrations of ~40% are required, however the elongation to break decreases above levels of ~25% as shown in Figure 4. The effect of alumina trihydrate on modulus is shown in Figure 5; as before results are close to the iso-stress boundary.

CONCLUSIONS

From the available results it can be inferred that the opti-

Figure 4 Elongation at break as a function of amount of flame retardant. \circ , Sb:Cl of 1:3; \square , alumina trihydrate

Figure 5 Modulus as a function of amount of alumina trihydrate

mum ratio of Sb:Cl is 1:3, which tends to confirm that the significant flame retardant in this system is the volatile antimony trichloride (SbCl₃). The synergistic effect of antimony/chlorine was found to be small in HDPE and it is thought that this may be due to the high crystallinity of the base polymer. In a real fire situation, even at high levels of additive (~40%) the material could be expected to burn vigorously with the evolution of dense black smoke which would cause (toxicological) problems. In practice this high level of additive could not be used since the mechanical properties (notably elongation at break and ultimate stress) showed a marked decrease at concentrations above 25%.

Alumina trihydrate, studied as an alternative to antimony/chlorine was found to have poor flame retardancy compared to the Sb:Cl system in HDPE.

Impact yielding of high density polyethylene

B. J. Briscoe and I. M. Hutchings

Physics and Chemistry of Solids, Cavendish Laboratory, University of Cambridge, Cambridge CB3 0HE, UK

(Received 14 May 1976; revised 23 July 1976)

We have used a projectile impact method to estimate the flow stress of high density polyethylene at a strain rate of $\sim 3 \times 10^3 \text{ sec}^{-1}$. The technique was developed initially by Taylor and applied successfully by Whiffin and others to ductile metals. The data from this experiment have been compared with data obtained in more conventional compression and drop hammer tests at lower strain rates at 20°C and 100°C. The flow stress of high density polyethylene deduced from the impact test at 20°C is significantly higher than that anticipated from a simple extrapolation of the low strain rate data at 20°C. The data at 100°C are however in good agreement. The technique has also been used to estimate the flow stress of high density polyethylene as a function of temperature over the range -20° to $+105^\circ\text{C}$. These data indicate that the discrepancy in the data for 20°C arises from a real discontinuity in the response of the polymer rather than from an inadequacy in the theoretical analysis of the impact experiment as applied to polymeric solids. We conclude that the impact method described is a useful technique for estimating the flow stress of polymers. It is however limited to a relatively narrow range of strain rates.

INTRODUCTION

A deformable cylinder (*Figure 1a*) impacted axially against a rigid plane at a high velocity will suffer permanent deformation. In the case of an ideal rigid-plastic material the deformation is of the form shown in *Figure 1b*. For this case Taylor¹ showed that the yield stress, σ , of the material may be estimated from the geometry of the impacted specimen, using the following formula:

$$\sigma \approx \frac{\rho V^2(L_0 - X)}{2(L_0 - L) \ln(L_0/X)} \quad (1)$$

where (*Figure 1*) ρ is the density of the specimen; V is the impact velocity; L_0 is the original length of the cylinder; L is the final length and X is the length of the undeformed portion of the cylinder. The mean rate of strain, $\dot{\epsilon}$, during the impact was shown¹ to be

$$\dot{\epsilon} \approx V/2(L_0 - X) \quad (2)$$

Equation (1) has been used successfully by Whiffin² and others to estimate the flow stress of metals at high strain rates. Taylor's analysis was based on a momentum exchange calculation for an ideal rigid-plastic material; more recent treatments^{3,4} which take account of strain hardening and elastic deformation predict yield stresses which differ only slightly from the value given by equation (1).

We have used Taylor's method to estimate the yield stress of high density polyethylene at a mean strain rate of about $3 \times 10^3 \text{ sec}^{-1}$ *. The result is compared with mea-

surements obtained by uniaxial compression in conventional compression tests and drop-weight impact tests at lower strain rates (up to $3 \times 10^2 \text{ sec}^{-1}$). The projectile impact experiment gives a yield stress significantly higher than that anticipated from a simple Eyring extrapolation of the lower strain rate data. The reason for this anomaly is uncertain; it may be due either to a real change in yield properties of the polymer at these high rates of strain or to an inadequacy in the interpretation of the impact response of polymers using the Taylor method.

This impact method has also been used to study the apparent yield stress of high density polyethylene over the temperature range -20° to $+105^\circ\text{C}$. While the yield strength decreases rapidly with temperature the variation cannot be simply explained using an Eyring flow model.

EXPERIMENTAL

Taylor impact method

A commercial grade of high density polyethylene (Rigidex 075-65) was used in the form of 16 mm diameter rod (density 953 kg/m^3). Plane-ended cylindrical specimens ~ 40 mm in length were accelerated using a compressed-gas gun⁵ and allowed to impact axially against a massive smooth-faced steel anvil. Two high speed photographic sequences are shown in *Figure 2*. *Figure 2a* shows the impact for a typical velocity (120 m/sec) at 100°C and thus corresponds to the maximum observed deformation of the cylinder. The surface of the cylinder was lubricated with MoS₂ grease to reduce frictional losses during impact. The impact velocity was about 110 m/sec and was measured to within 1% by timing the interruption of two light beams crossing the barrel⁶.

The polymer specimens could be heated before impact by means of an electrical heating element around the breech of the gun. The temperature of the barrel surface immed-

* Although in principle the strain rate may be readily varied by changing the impact velocity, in practice at low velocities the deformation is too small for accurate measurement, and at high velocities it is too gross for the theoretical assumptions to be valid. The usefulness of the method is therefore restricted to strain rates of around $3 \times 10^3 \text{ sec}^{-1}$ for high density polyethylene.

Figure 1 Projectiles used for the Taylor impact experiment: (a) before impact; (b) after impact; (c) shows the concavity which forms after impact at 100°C. This concavity is less pronounced at lower temperatures

ately above the specimen was measured by means of a thermocouple; the reading of this thermocouple was compared in a series of calibration experiments with the temperature measured by a thermocouple at the centre of a dummy polyethylene cylinder in the barrel when a steady-state temperature had been achieved. In all experiments at elevated temperatures the specimen was allowed to reach thermal equilibrium in the heated breech for 15 min before firing; we estimate that with these precautions the quoted temperatures are accurate to $\pm 2\text{K}$ and that the maximum non-uniformity of temperature is of a similar order. A few experiments were performed at below room temperature, in which specimens were cooled in a refrigerator before firing; the estimated temperature of -20°C is accurate to $\pm 10\text{K}$.

In some experiments the rebound velocity was measured by a similar photoelectric timing method to the one described above; the rebound velocity was found to be $30 \pm 2 \text{ m/sec}$ and to be essentially independent of specimen temperature and impact velocity over the range -20°C

to $+100^\circ\text{C}$ and 90 to 125 m/sec. The rebound energy was therefore $\sim 7\%$ of the initial kinetic energy of the projectile†.

The final dimensions of the specimens were measured with a micrometer screw gauge. The impacted specimens showed various degrees of concavity on the impacted surface. This is shown schematically in Figure 1c. In all cases the length L was measured along the axis of the cylinder.

The concavity becomes more extreme at the highest impact temperature where $\Delta L/(L_0 - L)$ approached 0.8. Figure 2b shows the rebound of a specimen impacted at 100°C and at a velocity of 170 m/sec. The deformation of the cylinder is extremely pronounced and indeed much greater than observed in cylinders where yield stress measurements were made. At this velocity the concavity of the specimen end is accentuated. The photographs indicate that this concavity, ΔL , is produced as the cylinder rebounds from the anvil; the axial length L remains sensibly constant during rebound. It is not clear why this post-impact deformation occurs but it may be due to a combination of factors including momentum effects, hydrostatic effects and elastic recovery.

The mean flow stress and the mean rate of strain were calculated from equations (1) and (2). After impact several specimens were cut along their axes and sections of the cylinder were microtomed. These sections were examined for stress birefringence and local tensile failure.

Hammer impact method

The instrumented drop-weight apparatus described by Heavens and Field⁷ was used. The measurements were carried out at 20°C and the mean calculated strain rate was

† No correction was made for this effect in the data quoted below. At present the theoretical treatment of such a correction is unclear. However a simple argument suggests that the calculated values of σ (equation 1) might be reduced by up to 7%.

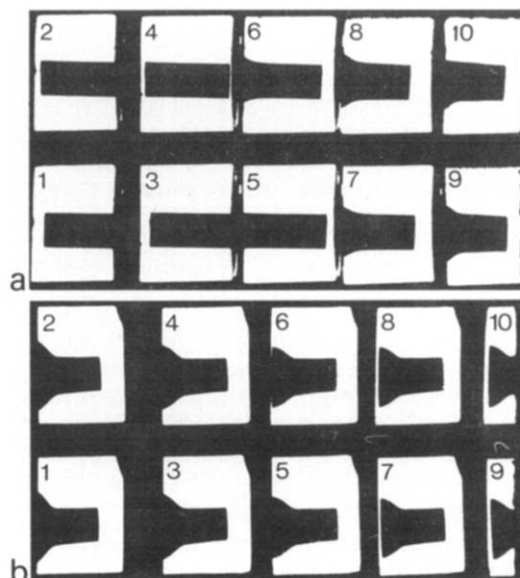

Figure 2 Two sequences of high speed photographs; interframe time 19 μsec . Frames are numbered sequentially. Initial impact is from right to left. (a) Impact of a HDPE cylinder at 100°C and 120 m/sec. Cylinder diameter 16 mm. (b) Rebound of an HDPE cylinder after impact at 100°C and 170 m/sec. Elastic recovery and formation of the concavity on the impacted face occur between frames 1 and 5; the projectile breaks contact between frames 5 and 6. Rebound velocity 30 m/sec

Figure 3 Flow stress of high density polyethylene measured by several techniques, plotted against log (strain rate) for two different temperatures: A, 20°C; B, 100°C. Note the sudden increase in flow stress at 20°C above $\dot{\epsilon} \approx 3 \times 10^2$, which does not appear in the results at 100°C. This work: \square , uniaxial compression; ∇ , drop-weight; \circ , Taylor impact uniaxial compression; \bullet , Amuzu and Briscoe¹¹; \blacksquare Bowden and Jukes⁸

$\sim 3 \times 10^2 \text{ sec}^{-1}$. The specimens were cylindrical and somewhat smaller than those used in the impact tests (diameter 6 mm, length 6 mm) and a certain amount of barrelling was detected in the deformed specimens.

Low strain rate tests

Low strain rate compressive tests were carried out using a commercial testing machine (Instron) in the range 10^{-3} to 1 sec^{-1} . The yield stress was taken to correspond to 10% strain following Bowden and Jukes⁸.

EXPERIMENTAL DATA AND DISCUSSION

Figure 3 shows our data and that of other workers for the influence of strain rate, $\dot{\epsilon}$, on the compressive flow stress, σ , of various grades of high density polyethylene at 20°C and 100°C. Following the classical analysis based on the high stress limit of an Eyring-type stress-modified thermally activated flow process^{9,10} we have plotted $\log_{10} \dot{\epsilon}$ against σ . With the exception of one data point, that for Taylor impact at 20°C, the data for each temperature show a similar monotonic increase in the value of σ with increasing values of $\log_{10} \dot{\epsilon}$. It appears that the Taylor impact technique gives a reasonable value of σ at 100°C. However the value of σ calculated from the impact technique at 20°C is at least twice that anticipated from the linear extrapolation of the low strain rate data. This discrepancy seems to arise from a change in the mode of deformation of the polymer at strain rates above about $3 \times 10^2 \text{ sec}^{-1}$ at 20°C. There is evidence for this in the stress birefringence of the sections of polymer cut from the impacted specimen. At 20°C the impact specimen shows a diffuse region of deformation which penetrates into the cylinder to a depth of the order of one quarter of the diameter of the cylinder. At 100°C however the deformation is more localized in a region close to the impact surface and penetrates to a depth of only about one eighth of the diameter. In addition these specimens show evidence of gross tensile rupture close to the impact surface. The deformation observed at 100°C was with the exception of the gross failure region very similar to that obtained in the slip region during conventional compression tests at both 20°C and 100°C.

A change in the mode of deformation at the high impact strain rates is also indicated by a marked difference in the temperature dependence of the flow stress at high and low strain rates. In **Figure 4** we show our data for the temperature dependence of the flow stress at two strain rates. In both cases the flow stress decreases linearly with temperature. However the temperature dependence at the high strain rate is about three times greater than at the low strain rate. In **Figure 4** we show low strain rate data for $\dot{\epsilon} = 20 \text{ sec}^{-1}$. Similar temperature dependences have been observed at strain rates down to 1 sec^{-1} ¹¹. At about 100°C the higher strain rate data (by the impact technique) are very similar to the lower strain rate uniaxial compression data. It is not clear from the present data whether the results at the two strain rates become coincident or cross over at about 100°C. The data obtained from the impact technique become very inaccurate above 120°C due to excessive concavity in the impacted specimens and thus this question cannot be answered using Taylor's method. However these data do indicate that the discontinuity in the $\log_{10} \dot{\epsilon}$ against σ plot at 20°C (**Figure 3**) is due to a change in the physical properties of the polymer rather than to an artefact inherent in the impact technique. We have no unequivocal explanation for the discontinuity or for the different temperature dependences. The onset of crystallite melting occurs at about 100°C in high density polyethylene. It therefore seems that these effects are associated with the crystalline nature of high density polyethylene. In the absence of data at higher strain rates and temperatures it is probably not sensible to speculate on their origin. Nevertheless the data do indicate that the Taylor impact technique forms a useful method for estimating the flow stress of polymers, although unfortunately limited to a very narrow range of strain rates.

ACKNOWLEDGEMENTS

We thank Professor D. Tabor for his support and encouragement during the course of this study. We are also grateful for the award of Research Fellowships from the Oppenheimer Fund (B. J. B.) and St. John's College, Cambridge (I.M.H.).

Notes to the Editor

Cooling of a polymer sheet

R. Pollard* and J. D. Perkins

Department of Chemical Engineering, University of Cambridge, Pembroke Street, Cambridge CB2 3RA, UK

(Received 20 November 1975; revised 17 June 1976)

This Note presents some results from a digital simulation study of one typical polymer processing operation (see *Figure 1*). Molten polymer sheet cools by heat transfer to metal rollers and to the atmosphere, and as it cools it crystallizes. The crystallization process liberates heat which is removed by both conduction through the sheet and heat transfer at the surface. By a suitable choice of processing conditions it is possible to affect the final state of the polymer sheet.

Heat transfer through the sheet may be represented by:

$$\frac{\partial}{\partial t} \left(\frac{cT}{V} \right) = \frac{\partial}{\partial z} \left(k \frac{\partial T}{\partial z} \right) + \frac{L}{V} \frac{\partial X}{\partial t} \quad (1)$$

Neither heat conduction in the flow direction nor end effects due to finite sheet width have been included.

For polymer surfaces in contact with air, a suitable boundary condition for equation (1) is:

$$\left(\frac{\partial T}{\partial z} \right)_S = \frac{-h}{k} (T_S - T_A) \quad (2)$$

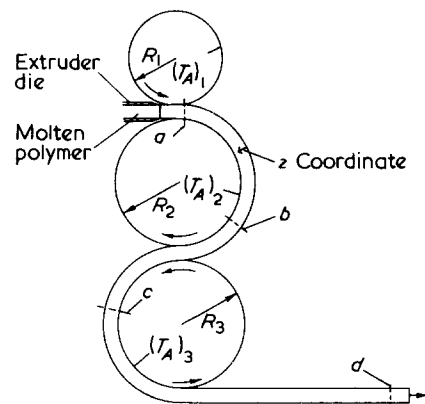

Figure 1 Schematic diagram of a common crystallization process (cross-section). Typical system parameters: $T_0 = 473.2\text{K}$; $(T_A)_1 = 368.2\text{K}$; $(T_A)_2 = 373.2\text{K}$; $(T_A)_3 = 378.2\text{K}$; $R_1 = 0.1\text{ m}$; $R_2 = R_3 = 0.15\text{ m}$; $n = 3$; $A = 0.9$; $B = -2.5$; $C = 408.2\text{K}$

* Present address: Department of Chemical Engineering, University of California, Berkeley, California 94720, USA.

Local heat transfer coefficients have been evaluated from standard correlations where heat transfer results from both free and forced convection¹.

Different correlations are used to calculate point-value heat transfer coefficients in cylindrical and flat regions. For polymer surfaces in contact with rollers, perfect thermal contact has been assumed:

$$T_S = T_A \quad (3)$$

The Avrami analysis² has been extended to predict the kinetics of the non-isothermal crystallization process³. The relative crystallinity, x , may be obtained from:

$$1 - x = \exp \left[- \left(\int_0^t K(\tau) d\tau \right)^n \right] \quad (4)$$

where $x = X/X_\infty$.

Previous workers^{3,4} have neglected X_∞ and have computed x directly. With this approach the latent heat is defined as heat released per unit mass of polymer. This quantity would seem to be a function of temperature and crystallinity, and not the constant which both Sifleet and Nakamura assume. It seems better to work in terms of the absolute crystallinity, X ; then L has the standard definition of heat released per unit mass of polymer crystallized. An empirical expression has been used to predict the temperature dependence of X_∞ ($T < C$):

$$X_\infty = A \exp \left(\frac{B}{T - C} \right) \quad (5)$$

Some evidence suggests that X_∞ is also dependent on cooling conditions⁵, but quantitative predictions are not available. The choice of parameters A , B , and C for a particular process should be made to reflect dependence on cooling rate. A linear relationship was employed to describe the dependence of

polymer properties on the temperature, and a linear mixing law of the type:

$$P = P_M(1 - X) + P_C X \quad (6)$$

was used to describe the dependence on crystallinity. Data for the polyethylene MARLEX 50 were used in this study (*Table 1*).

Estimation of the parameters in equation (4) presents difficulties: only isothermal data are readily available and generally the experiments are performed at slow rates of crystallization for ease of measurement. Thus, extrapolation is necessary to predict fast rates of crystallization common in industrial processes. *Figure 2* shows experimental half-life results⁶ and two equations fitted to these data. Both equations are of a form normally used to represent kinetic data but they lead to greatly different rate predictions in the temperature range of interest in this study. To assess the importance of this uncertainty, simulations were performed with both the fitted equations which are referred to below as 'slow' and 'fast' kinetic models.

The non-linearities in equation (1) make numerical techniques the only feasible method of solution. An explicit finite difference scheme⁷ has been used in a computer program that performs steps in time, computing new polymer temperature profiles at each step. (For constant polymer speeds,

Table 1 Physical properties for MARLEX 50

Polymer property	Temperature dependence (e.g. $C_M = q + rT$)	
	q	r
V_M	9.12×10^{-4}	8.80×10^{-7}
k_M	4.61×10^{-2}	5.02×10^{-4}
c_M	3.22×10^3	0.0
V_C	9.11×10^{-4}	3.00×10^{-7}

L	2.41×10^5	0.0
V_m	1.20×10^{-3}	0.0
k_m	0.30	0.0
c_m	2.70×10^3	0.0

Figure 2 Temperature dependence of crystallization half-life for MARLEX 50: Data points⁶: A, 'slow' kinetic model: $t_{1/2} = 0.690 \exp[611.7/(410.7 - T)^2]$ min; B, 'fast' kinetic model: $t_{1/2} = 0.015 \exp[96.4/(410.7 - T)]$ min

the time variable, t , and the distance coordinate, y , are directly related). Also crystallinity profiles within the polymer are computed from equations (4) and (5), using successive applications of Simpson's rule to calculate the integral in equation (4). The step sizes were decreased until negligible change (<0.1 K) was observed in computed temperatures. It was found that a time step of 5.0×10^{-3} sec and a step length in z of 6.25×10^{-5} m were sufficient. All computations were performed on a PDP 11/45 computer in single-precision.

RESULTS AND DISCUSSION

The processing conditions that were simulated are shown in Figure 1, together with values for the constants in equations (4) and (5) used in this study. The linear sheet velocity is 5 cm/sec and its thickness is 2.5 mm. The calculated temperature profiles at the labeled points in Figure 1 are shown in Figure 3, for the slow kinetic model. The effect of the kinetic model on the predicted temperature profiles was found to be very small for the processing conditions chosen. There was negligible difference between the 'slow' and 'fast' temperature profiles until after the end of the rollers, when the fast model permits more crystallization. It was found that the final, essentially uniform, sheet temperature was about 5K higher for the fast kinetics than for the slow.

The final degree of crystallinity predicted by the two kinetic models is shown in Figure 4. It can be seen that

the slow model predicts negligible crystallization. The order of magnitude difference in crystallinity predicted by the fast model results in a small difference in calculated temperature profiles. The latent heat released during crystallization does not appear to be an important factor in this heat transfer problem.

Previous workers^{3,4} have assumed that polymer physical properties are independent of temperature and degree of crystallinity. To test the validity of this assumption for the process under consideration, constant mean values of the physical properties (Table I) were used in the computer program. The predicted temperature profiles never differed from the variable properties solution by more than 5K for either kinetic model. Thus it seems that the assumption of constant physical properties is reasonable for this process.

Consequently it seems admissible to simplify the equations used to describe the process. By neglecting the latent heat term in equation (1) and assuming constant physical properties, we have:

$$\frac{\partial T}{\partial t} = \frac{kV}{c} \frac{\partial^2 T}{\partial z^2} \quad (7)$$

for which analytical solutions are easily obtainable provided the boundary conditions are linear⁸. However, the boundary condition for polymer-air contact is non-linear because of the dependence of the heat transfer coefficient on the temperature difference, $T_S - T_A$. Detailed examination of the predicted temperature profiles shows that the temperature gradient, $\partial T/\partial z$, at a polymer-air interface is always small, which suggests that little heat is transferred to the air. Therefore, in this case, it is reasonable to omit the contribution of air cooling; this results in the boundary condition:

Figure 3 Temperature profiles at different points in process simulated with equation (1) and 'slow' kinetic model. Time (sec) after start of process: A, 1; B, 7; C, 15; D, 30

$$\left(\frac{\partial T}{\partial z}\right)_S = 0 \quad (8)$$

for polymer-air contact. A dimensionless form of equation (7) may be readily solved analytically with boundary conditions of the form of equations (3) and (8). The resulting temperature profile predictions are shown in Figure 5. By comparison with Figure 3, it can be seen that the simplified description of the process approximates the full description reasonably well; errors are always less than 5K.

With the simpler model it is easy to make preliminary estimates of the process configuration and roller temperatures needed to obtain a specified product. However, the detailed model should always be used to check the validity of the initial results because the simplified approach might not be acceptable for other sets of processing conditions.

Uncertainties in the data can be overcome to some extent by using a sensitivity approach. For example, the range of possible predicted rates of crystallization could be accounted for by using a 'slow' and a 'fast' model

Figure 4 Variation in volume fraction of crystalline material across sheet at end of process. —, 'Slow' kinetic model; ---, 'fast' kinetic model

Figure 5 Temperature profiles at different points in process simulated with equation (7) and 'slow' kinetic model. Time (sec) after start of process: A, 1; B, 7; C, 15; D, 30

for the kinetics and comparing the results. In some circumstances the representation of the kinetic data will not influence the results significantly. However, in general, there is no substitute for better data. In this context, it seems that more effort should be concentrated on non-isothermal crystallization kinetics and on the measurement of higher rates of crystallization of the type usually found in industry.

Conformational study of poly(O-carbobenzoxy-L-tyrosine) in solution

Hiroyuki Yamamoto

Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda 386, Japan
(Received 23 June 1976)

The conformational properties of polypeptides having aromatic side-chain chromophores in organic solvents have been investigated by many workers; poly(L-phenylalanine)¹, poly(L-benzyl-L-histidine)², poly(L-tryptophan)³⁻⁶ and poly(O-carbobenzoxy-L-tyrosine) (PCLT)⁷⁻⁹. In most cases, the interpretation of optical rotatory dispersion and circular dichroism (c.d.) spectra in terms of conformation is rather difficult since there are overlapping contributions to the total activity both from the peptide chromophores and from the side-chain chromophores. PCLT has been shown to have a right-handed α -helical conformation from the change of b_0 with copolymer composition⁷, the c.d. spectrum in solution^{8,9} and the X-ray diffraction pattern in the solid state¹⁰. These studies, however, did not include recent improvements in apparatus and new sol-

vents which are transparent to below 200 nm. The actual conformation of PCLT in various solvents remains unresolved. The author wishes to report here the detailed conformational features and the helix-coil transition of PCLT in pure or mixed solvents.

EXPERIMENTAL

PCLT was prepared by the method described in previous papers¹¹⁻¹³; $[\eta] = 0.62$ dl/g in dichloroacetic acid (DCA) at 25°C. The molecular weight was estimated to be 95 000 (degree of polymerization = 320) from an empirical equation⁷;

$$[\eta] = 3.2 \times 10^{-2} M_w^{0.66}$$

in DCA at 25°C. The rotation properties were measured at 25°C on a Jasco

ORD/UV-5 spectropolarimeter with a c.d. attachment, using cells with light paths of between 0.1 and 10 mm (polypeptide concentration, 0.20-0.60%).

for the kinetics and comparing the results. In some circumstances the representation of the kinetic data will not influence the results significantly. However, in general, there is no substitute for better data. In this context, it seems that more effort should be concentrated on non-isothermal crystallization kinetics and on the measurement of higher rates of crystallization of the type usually found in industry.

NOMENCLATURE

A	} parameters in equation (5)
B	
C	
c	specific heat of polymer (J/kg K)
h	heat transfer coefficient for polymer-air contact (W/m ² K)
K	modified crystallization kinetic rate constant
k	thermal conductivity of polymer (W/m K)
L	latent heat of crystallization of polymer (J/kg)

n	Avrami index
P	polymer physical property
R	radius of cylindrical roller
T	temperature of polymer
t	residence time of polymer in process
V	specific volume of polymer (m ³ /kg)
X	fractional crystallinity of polymer
X_{∞}	final fractional crystallinity of polymer
x	fraction of final crystallinity of polymer
y	distance coordinate (measured from extruder head along polymer sheet)
z	thickness coordinate
τ	time-like integration variable

Subscripts

A	in cooling medium
C	of crystallized polymer
M	of uncrystallized polymer
m	mean value

O	at start of process
S	at surface of polymer

Conformational study of poly(O-carbobenzoxy-L-tyrosine) in solution

Hiroyuki Yamamoto

Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda 386, Japan
(Received 23 June 1976)

The conformational properties of polypeptides having aromatic side-chain chromophores in organic solvents have been investigated by many workers; poly(L-phenylalanine)¹, poly(L-benzyl-L-histidine)², poly(L-tryptophan)³⁻⁶ and poly(O-carbobenzoxy-L-tyrosine) (PCLT)⁷⁻⁹. In most cases, the interpretation of optical rotatory dispersion and circular dichroism (c.d.) spectra in terms of conformation is rather difficult since there are overlapping contributions to the total activity both from the peptide chromophores and from the side-chain chromophores. PCLT has been shown to have a right-handed α -helical conformation from the change of b_0 with copolymer composition⁷, the c.d. spectrum in solution^{8,9} and the X-ray diffraction pattern in the solid state¹⁰. These studies, however, did not include recent improvements in apparatus and new sol-

vents which are transparent to below 200 nm. The actual conformation of PCLT in various solvents remains unresolved. The author wishes to report here the detailed conformational features and the helix-coil transition of PCLT in pure or mixed solvents.

EXPERIMENTAL

PCLT was prepared by the method described in previous papers¹¹⁻¹³; $[\eta] = 0.62$ dl/g in dichloroacetic acid (DCA) at 25°C. The molecular weight was estimated to be 95 000 (degree of polymerization = 320) from an empirical equation⁷;

$$[\eta] = 3.2 \times 10^{-2} M_w^{0.66}$$

in DCA at 25°C. The rotation properties were measured at 25°C on a Jasco

ORD/UV-5 spectropolarimeter with a c.d. attachment, using cells with light paths of between 0.1 and 10 mm (polypeptide concentration, 0.20-0.60%).

Figure 1 C.d. spectra of PCLT in the ultraviolet region at 25°C: ○, in chloroform; □, in dioxane; ●, in TFA; X, in hexafluoroacetone sesquihydrate; △, in hexamethylphosphoramide

The dimension of $[\theta]$ is degree cm^2/dmol . The nuclear magnetic resonance (n.m.r.) spectra were recorded on a Jeol 60-MHz JNM-c-60HL spectrometer and peak positions were measured relative to the internal tetramethylsilane (polypeptide concentration, 5%).

RESULTS AND DISCUSSION

Figure 1 shows the c.d. spectra of PCLT in five solvents at 25°C. PCLT has a right-handed α -helix conformation in chloroform or dioxane. Approximately the same c.d. spectrum to 200 nm is obtained in trimethylphosphate, 2-chloroethanol or 1,1,1,3,3,3-hexafluoro-2-propanol. The polypeptide has a random coil structure in trifluoroacetic acid (TFA), hexamethylphosphoramide or hexafluoroacetone sesquihydrate. As shown in Table 1, the molar ellipticity values are $-6000 \sim -8700$ (at 229–231 nm) in helix-promoting solvents and less than -700 (at 237 nm) in coil-promoting solvents. The assignment of the two Cotton effects, the first negative and centred at ~ 230 nm, the second positive at 218 nm, have been discussed by Goodman *et al.*⁸ PCLT is insoluble in 2,2,2-trifluoroethanol, *N,N*-dimethylformamide, dimethyl sulphoxide, formic acid and methylsulphonic acid.

Figure 2 shows the helix-coil transition of PCLT in chloroform/DCA (or TFA) or dioxane/DCA (or TFA) mixed solvents at 25°C with midpoint at 8% (or 4%) or 62% (or $\sim 35\%$) DCA (or TFA), respectively. This suggests that the right-handed helix of PCLT is more stable in dioxane/DCA (or TFA) mixed solvents than in chloroform/DCA (or TFA) mixed solvents and less TFA is necessary to destroy the helical conformation than DCA. The author was partly unable to measure the transition since the solubility of PCLT decreased and precipitated at solvent compositions between 35 and 88% TFA in dioxane.

Figure 3 shows the behaviour of the chemical shift and b_0 values for PCLT with change of solvent composition in chloroform/TFA mixed solvents at 25°C. The b_0 value was calculated from the optical rotatory dispersion curve using $\lambda_0 = 212 \text{ nm}$ ^{7,14} and is between 150 and 175 in chloroform or dioxane. Vollmer and Spach reported a larger b_0 value in a methylene dichloride/DCA (1%) mixed solvent (no c.d. data)⁷. As for the specific rotation, $[\alpha]_{546}^{25} = 200$ in dioxane

Figure 2 Helix-coil transition of PCLT with change of solvent composition at 25°C. (a): \circ , In chloroform/DCA mixed solvents; \bullet , in chloroform/TFA mixed solvents. (b): \square , In dioxane/DCA mixed solvents; \blacksquare , in dioxane/TFA mixed solvents

Figure 3 α -CH chemical shift (Δ) and b_0 values (\circ) of PCLT in chloroform (or chloroform- d_1)/TFA mixed solvents at 25°C

and $[\alpha]_{546}^{25} = 167$ in a chloroform/DCA (1%) mixed solvent are obtained and these values agree with a specific rotation reported by Vollmer and Spach ($[\alpha]_{500} = 165$ in a methylene dichloride/DCA (1%) mixture)⁷. Addition of 4% TFA to the chloroform solution causes a sudden drop in the value of b_0 to zero. In DCA or TFA the b_0 value is zero (random coil). In chloroform- d_1 , the α -CH resonance of PCLT

Table 1 Residue ellipticities and chemical shifts for PCLT

Solvent	$[\theta]^a$ (degree cm^2/dmol)	α -CH (ppm)
Chloroform	-8700 (231)	4.10 ^b
Dioxane	-8400 (231)	4.05 ^b
Trimethylphosphate	-7100 (230) ^c	
2-Chloroethanol	-6000 (230)	
Pyridine		4.06 ^b
1,1,1,3,3,3-Hexafluoro-2-propanol	-6000 (229)	
TFA		4.75
Hexafluoroacetone sesquihydrate	-700 (237)	4.60 ^b
1,3-Dichlorotetrafluoroacetone 2,5 hydrate	-560 (237)	

^aValues in parentheses show a trough position (nm); ^bmeasured in deuterated solvent; ^c $[\theta]_{232} \sim -7000$ was reported in ref 8

appears at 4.10 ppm (helix), whereas in TFA this proton appears at 4.75 ppm (random coil). 4% TFA changes the chemical shift from 4.10 to 4.55 ppm (Figure 3). Thus, the conformational relationship between the α -CH resonance and the rotation properties

is clearly demonstrated. As summarized in *Table 1*, the conformation of PCLT is a right-handed α -helix in chloroform, dioxane, trimethylphosphate, 2-chloroethanol, pyridine or 1,1,1,3,3,3-hexafluoro-2-propanol and a random coil in DCA, TFA, hexamethylphosphoramide, hexafluoroacetone sesquihydrate or 1,3-dichlorotetrafluoroacetone 2,5 hydrate.

Crown ether catalysed modification of partly chloromethylated polystyrene

J. E. L. Roovers

Division of Chemistry, National Research Council of Canada, Ottawa K1A 0R9, Canada
(Received 11 June 1976)

In the course of the preparation of well characterized narrow molecular weight distribution poly(styrene-*g*-isoprenes) partly chloromethylated polystyrene had to be converted to poly(vinylbenzyl acetate-styrene) random copolymer¹. The published method^{2,3}, using potassium acetate in dimethyl sulphoxide gave variable reaction yields and broadening of the molecular weight distribution. The former observation can be accounted for by the heterogeneity of the reaction medium, the latter is ascribed to the presence of oxidation products of dimethyl sulphoxide. Therefore, a new method using crown ethers to solubilize and activate potassium acetate in non-polar solvents⁴ was adapted to the acetylation of partly chloromethylated polystyrene.

Typically, 1 g anionically prepared⁵ and chloromethylated⁶ polystyrene containing 0.37 mmol chlorine is dissolved in 20 ml of a 50/50 (v/v) mixture of benzene and acetonitrile. To this, 135 mg dicyclohexyl-18-crown-6 (Aldrich) and 365 mg potassium acetate (3.7 mmol) are added. The mixture is magnetically stirred at 75°C. The reaction is quenched by cooling and the addition of benzene. The mixture is filtered and the polymer precipitated in excess methanol. The carbonyl absorption band at 1740 cm⁻¹ is used to monitor the acetylation. (Figure 1). The final acetate content of the polymer agrees with X-ray fluo-

Figure 1 Progress of the substitution reaction of chlorine in partly chloromethylated polystyrene. For the reaction conditions, see the text. O, Substitution by acetate; Δ, substitution by one-ended poly(styrene carboxylate)

rescence analysis of chlorine in the original polymer, indicating that the substitution reaction goes to completion^{4,7}.

The 50/50 mixture of benzene and acetonitrile constitutes a near θ -solvent for polystyrene at room temperature. The reaction is quite slow in pure benzene at 70°C. Dibenzo-18-crown-6 is only about half as efficient as dicyclohexyl-18-crown-6. *Table 1* illustrates the generality of the substitution reaction with the same chloromethylated polystyrene. Gel permeation chromatograms indicate that the substituted polystyrenes retain the origi-

nal narrow molecular weight distribution. The substitution of chlorine by stearate is slower than by acetate, presumably because the large amount of stearate lowers the dielectric constant of the reaction medium. When potassium *p*-(2-chloroethyl) benzoate is the substituent the chloroethyl group is available for further substitution by benzoate. An average of three ester links were formed per polymer chlorine. Neither potassium 2,4-dinitrophenolate nor potassium phenolate reacted under these reaction conditions.

The reaction of chloromethylated polystyrene with potassium 1-phenyl propionate is a prototype for the reaction with one ended potassium carboxylated polystyrene. As an example of crown ether catalysed grafting, 0.30 g chloromethylated polystyrene (0.11 mmol Cl, $M_n = 143\ 000$, $M_w = 157\ 000$) is reacted with 0.655 g of polystyrene capped with one potassium carboxylate group* (0.218 mmol

* The one-ended polystyrene-COOK is prepared with sec-butyllithium in benzene. The living polymer is terminated under vacuum in the presence of 1.5 equivalent tetramethylethylenediamine with a large excess of solid carbon dioxide. The benzene solution of the polymer is acidified with aqueous hydrogen chloride, washed repeatedly with distilled water and freeze dried. The polystyrene is redissolved in benzene and the acid groups are neutralized with potassium methoxide in benzene-methanol (5:1) using the thymol blue end point⁸. The polymer is then recovered by freeze drying. During carboxylation a variable amount of polymer (less than 10%) dimerizes⁹, but this fraction does not interfere in the subsequent coupling reaction.

is clearly demonstrated. As summarized in *Table 1*, the conformation of PCLT is a right-handed α -helix in chloroform, dioxane, trimethylphosphate, 2-chloroethanol, pyridine or 1,1,1,3,3,3-hexafluoro-2-propanol and a random coil in DCA, TFA, hexamethylphosphoramide, hexafluoroacetone sesquihydrate or 1,3-dichlorotetrafluoroacetone 2,5 hydrate.

Grafting on to poly(vinyl alcohol): a new spectral method to estimate the extent of grafting*

T. Vasudevan[†], H. Kothandaraman and M. Santappa

Department of Physical Chemistry, University of Madras, Madras 600025, India
(Received 29 March 1976; revised 27 April 1976)

Studies of grafting onto polymer backbones are numerous¹⁻⁵. In most cases, the grafting rates are obtained by gravimetric procedures; the complete precipitation, filtering and drying to constant weight is a cumbersome procedure, in which it is very difficult to eliminate experimental error. The use of spectral techniques obviates such a gravimetric procedure, once a correlation is established between gravimetric and spectral techniques. Though much

work has been carried out on spectroscopic investigations of vinyl copolymerizations, the method has been applied for graft polymers in only a few cases^{6,7}. In this work, grafting is carried out in a homogeneous solution under both thermal and photochemical conditions.

EXPERIMENTAL

Materials

Poly(vinyl Alcohol) (PVA) ($DP = 1000$) supplied by BDH Laboratories was used as received. Acrylamide (LR BDH) was purified by recrystallizing it from AR Chloroform twice. Ferric chloride (AR BDH) and ceric ammonium sulphate (AR BDH) were used as received without further puri-

fication. The PVA solution and other solutions used in the spectroscopic investigations were prepared according to the procedure reported in a previous paper⁸. A typical absorption spectrum of the PVA/boric acid/iodine complex was recorded using a SPECORD UV-VIS Spectrophotometer (Figure 1).

Figure 1 Typical absorption spectrum of the PVA/boric acid/iodine complex

Grafting on to poly(vinyl alcohol): a new spectral method to estimate the extent of grafting*

T. Vasudevan[†], H. Kothandaraman and M. Santappa

Department of Physical Chemistry, University of Madras, Madras 600025, India
(Received 29 March 1976; revised 27 April 1976)

Studies of grafting onto polymer backbones are numerous¹⁻⁵. In most cases, the grafting rates are obtained by gravimetric procedures; the complete precipitation, filtering and drying to constant weight is a cumbersome procedure, in which it is very difficult to eliminate experimental error. The use of spectral techniques obviates such a gravimetric procedure, once a correlation is established between gravimetric and spectral techniques. Though much

work has been carried out on spectroscopic investigations of vinyl copolymerizations, the method has been applied for graft polymers in only a few cases^{6,7}. In this work, grafting is carried out in a homogeneous solution under both thermal and photochemical conditions.

EXPERIMENTAL

Materials

Poly(vinyl Alcohol) (PVA) ($DP = 1000$) supplied by BDH Laboratories was used as received. Acrylamide (LR BDH) was purified by recrystallizing it from AR Chloroform twice. Ferric chloride (AR BDH) and ceric ammonium sulphate (AR BDH) were used as received without further puri-

fication. The PVA solution and other solutions used in the spectroscopic investigations were prepared according to the procedure reported in a previous paper⁸. A typical absorption spectrum of the PVA/boric acid/iodine complex was recorded using a SPECORD UV-VIS Spectrophotometer (Figure 1).

Figure 1 Typical absorption spectrum of the PVA/boric acid/iodine complex

* This work was presented at the Chemistry Symposium, Indian Institute of Technology, Madras, March 1976.

[†] Present address: Central Laboratory, Bharath Heavy Electricals Ltd, Tiruchivappalli - 620 014, India.

$$\text{Percentage grafting} = \frac{100 \times \text{Weight of grafted polymer} - \text{Weight of backbone polymer}}{\text{Weight of backbone polymer}} \quad (1)$$

Grafting procedure

Thermal. Grafting of acrylamide onto PVA was carried out in a reaction vessel having an inlet and outlet, in an atmosphere of nitrogen at a constant temperature of $50 \pm 0.1^\circ\text{C}$ using ceric ammonium sulphate as initiator. After a definite period of the reaction, the monomer concentration was estimated by bromometry. AR methanol was added to an aliquot of the solution to precipitate the PVA which was then filtered through a G₄ sintered glass crucible, washed with 2% ice cold boric acid solution and dried at 60°C , to constant weight. The percentage of grafting is calculated by equation (1).

Photochemical. The grafting of acrylamide onto PVA was carried out in an all quartz cylindrical cell under an atmosphere of nitrogen, at a constant temperature of $30 \pm 0.1^\circ\text{C}$ using ferric chloride as a photoredox initiator. A high pressure mercury vapour lamp was used for irradiation. The percentage grafting was determined using the same method as for thermal grafting. Samples with varying extents of grafting were prepared by varying the time and concentration of the initiator.

Spectral estimation

To an aliquot of the solution (5 ml) after the reaction was complete, boric acid (0.129 M) was added followed by iodine ($3.565 \times 10^{-4}\text{M}$) solution. The total volume was made up to 25 ml. The visible absorption spectrum was measured in the wavelength region $17\,000\text{--}13\,000\text{ cm}^{-1}$. The absorbance maximum occurred at $14\,500\text{ cm}^{-1}$, and was measured for the various reaction mixtures after the reaction (Figure 2). A plot of these absorbance values against the gravimetrically estimated percentage graftings is given in Figure 3.

RESULTS

Samples of varying extents of grafting were analysed spectroscopically and gravimetrically. Figure 3 represents the correlation between the percentage grafting on initial weight against absorbance, in the case of cerium (IV) and in the case of iron (III) as initiators; these values were checked against the gravimetric values using samples up to 30% grafting and the agreement was excellent.

DISCUSSION

In the PVA/boric acid/iodine complex, the function of boric acid is to wind the linear PVA in a radical conformation^{9,10} i.e. the -OH groups of PVA are held in this conformation by electrostatic interaction with boric acid and not by any covalent type of bond formation as suggested by Finch¹¹. This becomes clear from the high salting out constants of the multiply charged anions such as sulphate, citrate, borate etc.¹¹. The molecular weight and the extinction coefficient of the complex were found to be 106 000 and 55 550 respectively. The stability constant of the complex was found to be $\log k = 7.66$. In a trial study, it has been found that two different grades of PVA at the same concentration, one with no acetyl content and the other with 20% acetyl content,

Figure 2 Absorption spectra for the complexes formed by PVA with different extents of grafting: A, 14% grafted; B, 19.4% grafted; C, 23.25% grafted; D, 26.8% grafted; E, 31.25% grafted

Figure 3 Relation between the optical density of the complexes and extent of grafting. (A) Thermal; initiator: ceric ammonium sulphate; (B) photochemical; initiator: ferric chloride

under identical conditions gave different absorbances, the latter having a lower absorbance than the former, in proportion to the acetyl content for the complex formed with boric acid and iodine. Thus the number of -OH sites in PVA is proportional to the absorbance. Any change in the absorbance is thus related to the number of -OH groups in PVA.

The mechanism of oxidation of secondary alcohols and that of grafting can be compared fairly well. In both cases a hydrogen atom is first abstracted. Since the latter is a polymerization reaction, the hydrogen abstraction is by a radical mechanism. The mechanism generally accepted for grafting onto PVA is that it forms a complex with the initiator which decomposes to give a radical site on the backbone polymer^{3,12}. The radical

is generally denoted by $\text{RCH}_2\dot{\text{O}}$. Palit *et al.*³, suggest that the radical is formed by the abstraction of the hydrogen atom attached to the carbon. However, according to Mino *et al.*¹³, even if the radical is formed by the removal of the hydrogen atom attached to oxygen, the radical

rearranges to

In the cases of grafting onto cellulose derivatives, the grafting takes place via the oxygen atom of the -OH group¹⁴⁻¹⁶. Also not all the oxidants appear to attack secondary alcohols through C-H bond fission¹⁷⁻²⁰. Cobalt (III) and chromium (VI) seem to remove preferentially at the hydrogen atom attached to oxygen^{21,22} whereas vanadium (V) removes the hydrogen atom attached to carbon²³. In the case of cerium (IV) and iron (III) it is evident

from this work that they attack the hydrogen atom of the —OH group and the grafting proceeds via the oxygen atom of the —OH group. Thus the low absorbance of the grafted PVA gives indirect evidence for the location of the grafted site.

Application of gas chromatography to the analysis of thermal decomposition products of some sulphur containing polyurethanes

T. Lesiak, J. Hetper*, J. Pielichowski†, A. Prewysz-Kwinto and K. Marzec

Institute of Chemistry, N. Copernicus University, Toruń, Poland
(Received 1 June 1976)

INTRODUCTION

In continuing earlier studies¹⁻³ on the synthesis of new types of polyurethane resins Lesiak, Pielichowski and Prewysz-Kwinto recently pointed out the possibility of applying 4,4'-dihydroxydibutyl thioether for that purpose⁴. Polyurethanes prepared using this compound show exceptionally high mechanical strength, a good thermal resistance and excellent adhesion to metals, wood and other materials. Their practical applications are of great promise and therefore it seemed appropriate to develop a simple method for their analysis. Among several possibilities, the method described by Hetper and Zagórski⁵ was chosen. They showed, that several polyurethane resins could be identified by pyrolytic gas chromatography. Basically, the method depends on a certain selection of gas chromatographic separation conditions for the polyurethane pyrolysis product, to obtain on a pyrogram, peaks of the key components derived exclusively from the destruction of the 'polyol' part of the resin mentioned. This method has

been found to give much better results than other methods of that type^{6,7} including the 'Attenuated Total Reflection' method (ATR method)⁸.

A procedure, which complements this method was used by Takeuchi and coworkers⁹ who characterized in a similar way, diisocyanates used for the synthesis of polyurethanes. The present study was undertaken in order to determine the key thermal degradation products of 4,4'-dihydroxydibutyl thioether bonded in the polyurethane resins and to elucidate the mechanism of their formation.

For comparison, similar analyses of the decomposition products of the polyol constituent of polyurethane prepared using 4,4'-dihydroxydibutyl ether were performed. In all the cases studied, pyrolysis of resins investigated was carried out at 770°C.

The products were separated using gas chromatography and identified by mass spectrometry. The method was found to be suitable for the identification of pyrolysis products of thioetherdiol constituents of polyurethanes, since the decomposition products of isocyanic acid derivatives were held in the chromatographic column. It was found that tetrahydrothiophene was the main pyrolysis product of resins ob-

INTRODUCTION

In continuing earlier studies¹⁻³ on the synthesis of new types of polyurethane resins Lesiak, Pielichowski and Prewysz-Kwinto recently pointed out the possibility of applying 4,4'-dihydroxydibutyl thioether for that purpose⁴. Polyurethanes prepared using this compound show exceptionally high mechanical strength, a good thermal resistance and excellent adhesion to metals, wood and other materials. Their practical applications are of great promise and therefore it seemed appropriate to develop a simple method for their analysis. Among several possibilities, the method described by Hetper and Zagórski⁵ was chosen. They showed, that several polyurethane resins could be identified by pyrolytic gas chromatography. Basically, the method depends on a certain selection of gas chromatographic separation conditions for the polyurethane pyrolysis product, to obtain on a pyrogram, peaks of the key components derived exclusively from the destruction of the 'polyol' part of the resin mentioned. This method has

been found to give much better results than other methods of that type^{6,7} including the 'Attenuated Total Reflection' method (ATR method)⁸.

A procedure, which complements this method was used by Takeuchi and coworkers⁹ who characterized in a similar way, diisocyanates used for the synthesis of polyurethanes. The present study was undertaken in order to determine the key thermal degradation products of 4,4'-dihydroxydibutyl thioether bonded in the polyurethane resins and to elucidate the mechanism of their formation.

For comparison, similar analyses of the decomposition products of the polyol constituent of polyurethane prepared using 4,4'-dihydroxydibutyl ether were performed. In all the cases studied, pyrolysis of resins investigated was carried out at 770°C.

The products were separated using gas chromatography and identified by mass spectrometry. The method was found to be suitable for the identification of pyrolysis products of thioether-diol constituents of polyurethanes, since the decomposition products of isocyanic acid derivatives were held in the chromatographic column. It was found that tetrahydrothiophene was the main pyrolysis product of resins ob-

tained from 4,4'-dihydroxydibutyl thioether. In addition, tetrahydrofuran and small amounts of n-butanol as well as 3-buten-1-ol were also formed. Polyurethanes obtained from 4,4'-dihydroxydibutyl ether, decomposed under these conditions to give tetrahydrofuran and the above mentioned alcohols. A mechanism of formation of these compounds is proposed below.

EXPERIMENTAL

Polyurethanes used in this study were obtained from equimolar amounts of 4,4'-dihydroxydibutyl thioether and various organic diisocyanates using the method described in ref 4. One sample was prepared in the same way using 4,4'-dihydroxydibutyl ether. Symbols for these polymers and a list of components used for their syntheses are shown in Table 1.

Instrumentation and measurement techniques

A gas chromatograph, Pye 104 provided with a pyrolysis accessory working on the principle of the Curie point was used with a mass spectrometer, LKB type GC/MS 2091 connected.

Polymers were pyrolysed in a micro-

reactor connected to the gas chromatograph. The pyrolysis was carried out in a stream of carrier gas at 770°C with a heating time of 5 sec. The pyrolysis products were separated on a glass chromatographic column packed with poly(ethylene glycol) 1000 (15%) on Chromosorb P 60/80 mesh; column length, 3 m; temperature, 100°C; carrier gas, helium; flow rate, 30 ml/min. Under these conditions the high boiling components were adsorbed, practically irreversibly, in the first section of the chromatographic column. Mass spectra of the main components were measured at the top of their chromatographic peaks with ionization energy, 70 eV and temperature of the ion source, 200°C.

Results and discussion

The pyrogram of polyurethane TT-24 is shown in Figure 1. Identical pyrograms, which are not shown here, were obtained for all polyurethanes synthesised from 4,4'-dihydroxydibutyl thioether and other aromatic diisocyanates (TT-26, TT-24-26 and TBP-44). Figure 1 indicates, that under the conditions of chromatographic separation used in this study, pyrograms show only those products which are formed from the diol part of the polymer (decomposition products of thioether bonded in polyurethane). According to the literature data⁹ systems formed from aromatic diisocyanates decompose mainly to amines, nitriles and mono-isocyanates. These compounds are held in the chromatographic column under the conditions used.

In the case of polyurethane obtained from an aliphatic diisocyanate (TP-5) the basic character of the pyrogram is not changed except that peaks corresponding to C₁-C₄ hydrocarbons are increased (Figure 2). On the other hand, the alicyclic system present in TBC 44 polyurethane gives as a result of pyrolysis a series of aliphatic hydrocarbons with higher molecular weights. Peaks of these hydrocarbons overlap with peak number 2, but even in this case the characteristic pattern of 3,4 and 5 peaks, remains unchanged (Figure 3). The main components present in all pyrolysis products investigated, were identified on the basis of their mass spectra. The results are presented in Table 2.

The results of this study show, that tetrahydrothiophene is the main pyrolysis product of the thioether component of polyurethane. However in addi-

Figure 3 Pyrogram of polyurethane obtained from 4,4'-dihydroxydibutyl thioether and diisocyanato-4,4'-bicyclohexylmethane (TBC-44)

3	Tetrahydrothiophene
4	n-Butanol
5	3-Buten-1-ol

tion to this compound, tetrahydrofuran and small amounts of n-butanol and 3-buten-1-ol are formed too. Pyrolysis of polymer ET-24 (not containing sulphur) gives the same products except for tetrahydrothiophene. The main product in this case is tetrahydrofuran (Figure 4).

Mechanism of formation of the above mentioned compounds, can be explained on the basis of the characteristic property of higher esters which easily undergo the pyrolytic decomposition to carbon dioxide and the highly reactive free radicals. Thus in this case, the radical I, (scheme 1), adopting a suitable conformation, can cyclize to five membered systems. Elimination of a molecule of heterocycle II gives again a radical which can lead to tetrahydrofuran III. Scheme (1) illustrates these reactions. R,R' represent fragments of the polymer molecule and Y a hetero-

Letters

atom (sulphur in the case of thioether and oxygen in the case of ethers used).

If the bond $\geq\text{C}-\text{O}-$ in polyurethane undergoes cleavage with subse-

quent hydrogen migration, instead of decarboxylation, a chain with OH groups at the ends can be formed. This prevents the cyclization reactions and

can lead to formation of alcohols with four carbon atoms (IV or V, scheme 2). This procedure can be accompanied by the Y-C bond cleavage with or without hydrogen atom migration as shown in scheme (2). The method presented here has been found useful for the identification of the diol constituent degradation products of polyurethanes of the type described. This makes possible a partial qualitative characterization of polyurethane composition.

Chain atoms between entanglements and cross-sectional area per chain

We recently demonstrated a linear log-log correlation of slope -3 between the ratio C_2/C_1 of the Mooney-Rivlin constants (at $2C_1 = 0.2 \text{ N/mm}^2$) and cross-sectional area per polymer chain^{1,2}. It was suggested² that either strain induced local order or chain entanglements might be involved in what appeared to be an intermolecular effect.

Kraus and Mocvgemba³ had proposed that the molecular origin of the C_2 term was a result, at least in part, of chain entanglements. Preliminary examination of an extensive tabulation by Porter and Johnson⁴ of entanglement distances indicated a positive correlation with cross-sectional area per polymer chain. However, the scatter in data points was so great as to discourage any firm conclusions. The entanglement data in the literature

have now been examined in detail and a preliminary strong correlation has been made.

A specific tabulation by Fox and Allen⁵ was used as a source of N_c , the number of chain atoms between entanglement points determined from concentrated or bulk viscosity measurements as a function of molecular weight. Cross-sectional areas per polymer chain were calculated by a method described previously², which differs only in minor details from that used by Vincent⁶ for a different purpose.

Figure 1 shows a log-log correlation between N_c and chain areas in nm^2 . The line as drawn has a slope of approximately 0.5. The marked deviation of atactic PMMA from the trend line is considered to arise because of molecular association between iso- and syndio-tactic species present in a

PMMA⁷. Porter and Johnson note that any form of association tends to promote low values of N_c .

A detailed study of this subject will be presented elsewhere⁸. As one in-

atom (sulphur in the case of thioether and oxygen in the case of ethers used).

If the bond $\geq\text{C}-\text{O}-$ in polyurethane undergoes cleavage with subse-

quent hydrogen migration, instead of decarboxylation, a chain with OH groups at the ends can be formed. This prevents the cyclization reactions and

can lead to formation of alcohols with four carbon atoms (IV or V, scheme 2). This procedure can be accompanied by the Y-C bond cleavage with or without hydrogen atom migration as shown in scheme (2). The method presented here has been found useful for the identification of the diol constituent degradation products of polyurethanes of the type described. This makes possible a partial qualitative characterization of polyurethane composition.

Chain atoms between entanglements and cross-sectional area per chain

We recently demonstrated a linear log-log correlation of slope -3 between the ratio C_2/C_1 of the Mooney-Rivlin constants (at $2C_1 = 0.2 \text{ N/mm}^2$) and cross-sectional area per polymer chain^{1,2}. It was suggested² that either strain induced local order or chain entanglements might be involved in what appeared to be an intermolecular effect.

Kraus and Moczygemba³ had proposed that the molecular origin of the C_2 term was a result, at least in part, of chain entanglements. Preliminary examination of an extensive tabulation by Porter and Johnson⁴ of entanglement distances indicated a positive correlation with cross-sectional area per polymer chain. However, the scatter in data points was so great as to discourage any firm conclusions. The entanglement data in the literature

have now been examined in detail and a preliminary strong correlation has been made.

A specific tabulation by Fox and Allen⁵ was used as a source of N_c , the number of chain atoms between entanglement points determined from concentrated or bulk viscosity measurements as a function of molecular weight. Cross-sectional areas per polymer chain were calculated by a method described previously², which differs only in minor details from that used by Vincent⁶ for a different purpose.

Figure 1 shows a log-log correlation between N_c and chain areas in nm^2 . The line as drawn has a slope of approximately 0.5. The marked deviation of atactic PMMA from the trend line is considered to arise because of molecular association between iso- and syndio-tactic species present in a

PMMA⁷. Porter and Johnson note that any form of association tends to promote low values of N_c .

A detailed study of this subject will be presented elsewhere⁸. As one in-

Figure 1 Number of chain atoms, N_c , between entanglements from data of Fox and Allen⁵ vs. chain cross-section in nm^2 . A, PE; B, poly(decamethylene adipate); C, poly(decamethylene sebacate); D, poly(ε-caproamide); E, poly(propylene oxide); F, PIB; G, PDMS; H, PVAc; I, atactic PMMA; J, atactic PS.

cludes more bodies of data, and especially other measures of chain entanglement to be found in ref 4, the scatter increases significantly. However, the trend shown in *Figure 1* is not lost.

Since both C_2/C_1 and N_c correlate with a common variable, area in nm^2 , it follows that one should expect a linear correlation between C_2/C_1 and N_c . This indeed is the case with five data points for PE, *cis-trans* PBD, NR, PIB, and PDMS⁸. This correlation does not necessarily mean that chain entanglements are solely responsible for the

C_2 term.

The correlation line of *Figure 1* on a homogeneous set of data provides a criterion for judging and/or selecting from discordant literature values for these and other polymers.

The involvement of singlet oxygen in the sensitized photodegradation of cellulose

The dye sensitized photo-oxidative degradation of cellulose has long been an area of practical and theoretical interest, but the mechanism of this process is still a controversial subject¹. Of the two principal mechanisms that have been proposed, namely the singlet oxygen theory² and the hydrogen (or electron) abstraction theory³, the former has received relatively little credence. This is probably because it is relatively easy to demonstrate that a dye will photochemically abstract hydrogen or an electron from cellulose, whereas it is much more difficult to show unambiguously that singlet oxygen will react with this substrate. Almost all efficient sensitizers of singlet oxygen are good hydrogen abstractors (e.g. the quinonoid vat dyes, heterocyclic cationic dyes, and porphins), thus photodegradation studies with these compounds are ambiguous. The few known sensitizers that do not photoreduce (e.g. the acenes) are of little value because of their reactivity towards singlet oxygen. Non-photochemical sources of singlet oxygen are also suspect, as these systems are contaminated with other oxidizing species that could play an uncertain role in cellulose degradation.

We have looked for new stable singlet oxygen sensitizers that have a minimal tendency to undergo photochemical reduction. A particularly suitable compound is (I), which is obtained by the reductive methylation of Vat Yellow 2 (*CI* 67 300), using zinc and methyl-*p*-toluenesulphonate in alkaline solution. This compound, which was characterized by elemental analysis, is soluble in benzene (λ_{max} 408, 422 nm; $\log \epsilon$ 4.36, 4.29), and gives weakly fluorescent solutions. It

is particularly resistant to photo-oxidation, and no decomposition was observed after irradiating an oxygen saturated solution for 48 h (600 W tungsten lamp). The compound was an efficient sensitizer of singlet oxygen, as shown by the rapid photo-oxidation of tetraphenylcyclopentadienone when solutions of the two were exposed to visible light⁴. The reaction could be suppressed by the known singlet oxygen quencher, diazabicyclo[2,2,2]-octane⁵.

As (I) is an aromatic system that is, in effect, a prerduced form of a known photodegrading dye, it is unlikely to take part in further photoreduction processes with any degree of efficiency. To verify this, comparison experiments were carried out with (I) and 1-methoxyanthraquinone (II), an efficient hydrogen abstractor. The latter compound undergoes photoreduction in degassed isopropanol with a quantum yield of 0.53⁶. In isopropanol-benzene mixtures (3:2 by vol) under nitrogen the dimethoxy compound (I) underwent only a slow irreversible fading, in contrast to the rapid reversible photoreduction of (II). Under conditions of equal light absorption, photoreduction of (II) was at least 200 times more rapid than the fading of (I). Thus (I) can be regarded as a useful sensitizer of singlet oxygen that is free from the usual complications of competing hydrogen abstraction.

Photodegradation of regenerated cellulose film was most conveniently followed by measurement of the intrinsic viscosity $[\eta]$ of solutions in Cadoxen. Measurements were carried out at 30°C with an Ubbelohde suspended-level dilution viscometer, and the viscosity of solutions measured

over a range of concentrations. The intrinsic viscosity of the undergraded samples had an average value of 1.30 dl/g.

Cellulose films freed from plasticizer were immersed in benzene solutions of (I) (4×10^{-4} M) and were irradiated with a fluorescent lamp (8W) for 530 h. Control samples containing no sensitizer were irradiated at the same time. The unsensitized samples showed a 13% decrease in intrinsic viscosity, whereas the sensitized samples showed a corresponding decrease of 30%. Thus it can be concluded that singlet oxygen causes degradation of cellulose.

It was of interest to examine the relative efficiencies of the singlet oxygen and hydrogen abstraction mechanisms, and thus a comparison experiment was carried out with (I) and (II).

These two compounds absorb over roughly the same region of the spectrum above 350 nm, and so rate differences due to different light absorption characteristics could be minimized by using appropriate concentrations of the two compounds. Cellulose films were immersed in benzene solutions of (I)

cludes more bodies of data, and especially other measures of chain entanglement to be found in ref 4, the scatter increases significantly. However, the trend shown in *Figure 1* is not lost.

The involvement of singlet oxygen in the sensitized photodegradation of cellulose

The dye sensitized photo-oxidative degradation of cellulose has long been an area of practical and theoretical interest, but the mechanism of this process is still a controversial subject¹. Of the two principal mechanisms that have been proposed, namely the singlet oxygen theory² and the hydrogen (or electron) abstraction theory³, the former has received relatively little credence. This is probably because it is relatively easy to demonstrate that a dye will photochemically abstract hydrogen or an electron from cellulose, whereas it is much more difficult to show unambiguously that singlet oxygen will react with this substrate. Almost all efficient sensitizers of singlet oxygen are good hydrogen abstractors (e.g. the quinonoid vat dyes, heterocyclic cationic dyes, and porphins), thus photodegradation studies with these compounds are ambiguous. The few known sensitizers that do not photoreduce (e.g. the acenes) are of little value because of their reactivity towards singlet oxygen. Non-photochemical sources of singlet oxygen are also suspect, as these systems are contaminated with other oxidizing species that could play an uncertain role in cellulose degradation.

We have looked for new stable singlet oxygen sensitizers that have a minimal tendency to undergo photochemical reduction. A particularly suitable compound is (I), which is obtained by the reductive methylation of Vat Yellow 2 (*CI* 67 300), using zinc and methyl-*p*-toluenesulphonate in alkaline solution. This compound, which was characterized by elemental analysis, is soluble in benzene (λ_{max} 408, 422 nm; $\log \epsilon$ 4.36, 4.29), and gives weakly fluorescent solutions. It

is particularly resistant to photo-oxidation, and no decomposition was observed after irradiating an oxygen saturated solution for 48 h (600 W tungsten lamp). The compound was an efficient sensitizer of singlet oxygen, as shown by the rapid photo-oxidation of tetraphenylcyclopentadienone when solutions of the two were exposed to visible light⁴. The reaction could be suppressed by the known singlet oxygen quencher, diazabicyclo[2,2,2]-octane⁵.

As (I) is an aromatic system that is, in effect, a prerduced form of a known photodegrading dye, it is unlikely to take part in further photoreduction processes with any degree of efficiency. To verify this, comparison experiments were carried out with (I) and 1-methoxyanthraquinone (II), an efficient hydrogen abstractor. The latter compound undergoes photoreduction in degassed isopropanol with a quantum yield of 0.53⁶. In isopropanol-benzene mixtures (3:2 by vol) under nitrogen the dimethoxy compound (I) underwent only a slow irreversible fading, in contrast to the rapid reversible photoreduction of (II). Under conditions of equal light absorption, photoreduction of (II) was at least 200 times more rapid than the fading of (I). Thus (I) can be regarded as a useful sensitizer of singlet oxygen that is free from the usual complications of competing hydrogen abstraction.

Photodegradation of regenerated cellulose film was most conveniently followed by measurement of the intrinsic viscosity $[\eta]$ of solutions in Cadoxen. Measurements were carried out at 30°C with an Ubbelohde suspended-level dilution viscometer, and the viscosity of solutions measured

over a range of concentrations. The intrinsic viscosity of the undergraded samples had an average value of 1.30 dl/g.

Cellulose films freed from plasticizer were immersed in benzene solutions of (I) (4×10^{-4} M) and were irradiated with a fluorescent lamp (8W) for 530 h. Control samples containing no sensitizer were irradiated at the same time. The unsensitized samples showed a 13% decrease in intrinsic viscosity, whereas the sensitized samples showed a corresponding decrease of 30%. Thus it can be concluded that singlet oxygen causes degradation of cellulose.

It was of interest to examine the relative efficiencies of the singlet oxygen and hydrogen abstraction mechanisms, and thus a comparison experiment was carried out with (I) and (II).

These two compounds absorb over roughly the same region of the spectrum above 350 nm, and so rate differences due to different light absorption characteristics could be minimized by using appropriate concentrations of the two compounds. Cellulose films were immersed in benzene solutions of (I)

Letters

(4×10^{-4} M) and (II) (2×10^{-3} M), and were irradiated under oxygen as described previously. It was found that (I) caused an 18% decrease in the intrinsic viscosity of the cellulose, whereas (II) caused a 23% decrease. The small difference indicates that the two mechanisms are of comparable efficiency.

Because of the low affinity of (I) and (II) for cellulose, it was necessary to use two-phase systems for these experiments. It might be argued that this does not give a true reflection of the conditions operating in dyed cellulose, and might favour the singlet oxygen mechanism. However, cellulose films dyed with Vat Yellow 2 (2% based on weight of film), which is a very effective photodegrading dye for cellulose, underwent degradation at comparable rates to the two-phase systems under conditions of similar light intensity. Thus whether the dye is in intimate contact with the cellulose or is dissolved in a solvent appears to have little influence on the rate of degradation.

As singlet oxygen is an intermediate in cellulose photodegradation, we have examined the protecting effect of a singlet oxygen quencher. Cellulose films dyed with Vat Yellow 2 (2% of the film weight) were impregnated with diazabicyclo[2,2,2]octane (0.5%), and these were found to undergo photo-oxidative degradation more slowly than films containing no quencher. Thus after 300 h exposure to a 200 W tungsten lamp, the protected films showed 5–11% decrease in intrinsic viscosity, whereas the unprotected films showed a decrease of 22–23%. A nickel ketoxime chelate has also been found to afford protection in some cases⁷, and

this may be due to the quenching of singlet oxygen⁸ or the triplet state of the sensitizer.

The reaction of singlet oxygen with cellulose possibly involves hydrogen abstraction from one of the CH groups, with rapid recombination of the radical fragments to form a hydroperoxide. Thus the process would closely parallel the degradation pathway involving direct hydrogen abstraction by the photoexcited sensitizer. The introduction of a hydroperoxide function at positions 1 or 4 of a glucose unit could then be followed by a homolytic process, causing chain scission at the carbon–oxygen bridging bond, and the formation of a carbonyl group. However, the secondary processes involved in the photodegradation of cellulose are still a subject of speculation. Although singlet oxygen is a reactive dienophile, and normally attacks alkenes, there is good evidence that it can in certain instances, take part in hydrogen abstraction reactions⁹. Whether such processes could involve the higher excited state of singlet oxygen ($^1\Sigma_g$) is still uncertain¹⁰. It should be noted that the quantum yield of dye sensitized chain scission of cellulose is very low ($\sim 10^{-5}$)¹¹, and thus the mode of attack by singlet oxygen on cellulose need not involve processes regarded as more characteristic of that species.

In conclusion, it is evident that singlet oxygen can cause degradation of cellulose at a rate at least comparable to the hydrogen abstraction mechanism. As it has been demonstrated that various dyes active towards the photodegradation of cellulose are also efficient sensitizers of singlet oxygen⁴, it must be assumed that singlet oxygen plays a

significant role in the degradation of vat-dyed cotton fabrics, although not necessarily in every case⁷. It is important in interpreting experimental results that one mechanism should not be considered to the exclusion of the other, as has often been done in the past.

Book Reviews

The Permeability of Plastic Films and Coatings to Gases, Vapours and Liquids

Edited by H. P. Hopfenberg

Plenum Press, New York, 1975, \$35.10

This book records the proceedings of a symposium arranged to mark the presentation of the Borden Award of the American Chemical Society's Division of Organic Coatings and Plastics Chemistry to Vivian Stannett in 1974. It consists of thirty two separate papers in the general area described by the title. The authors include many of the currently most active US workers in this field and there are five papers in the 'Fundamental' section from European laboratories.

The papers are grouped into three sections: Fundamental (17), Industrial (10) and Biomedical (5). Thus more than half the volume is devoted to fundamental considerations. Here the standard of work is high and most of the authors are highly distinguished and recognized authorities. Seven of the papers are primarily reviews and cover a considerable area of diffusion in polymers and, together, they form a useful collection. Ten contain a substantial content of new work, four theoretical and six experimental. In several cases these have enough general interest to justify inclusion but one or two are highly specific and more appropriate to a research journal.

In the industrial section the style and content is far more variable. Several papers describe well constructed and carried out research on technological problems. They make interesting reading. There are two reviews predicting rather different future trends in reverse osmosis membrane development. The remaining papers are either less relevant or describe technological studies containing little exact science.

Three of the biomedical papers are reviews: on the controlled release of drugs from capsules, on the preparation of grafted hydrogel membranes for biomedical devices and on ultrafiltration through

asymmetric hollow fibres. Two papers contain new work concerning dialysis and blood compatibility of membranes of potential use in haemodialysis.

The symposium must have been a great occasion for those who attended it. That this was so is made apparent by the editor's preface about Professor Stannett. The justification for publishing this volume is more arguable. It is a fitting form of recognition of the contribution that Professor Stannett has made over some twenty five years but the papers could, in some cases with advantage, have been as well published through the normal research journal channels. Some of them probably will be. However, the decision has been taken and the volume has been published. Its quality should certainly earn for it a place in libraries of polymer science and plastics technology. Although reproduced from the authors' typescripts the output of the many anonymous typists is of very high standard and the variety of type faces used did not disconcert this reader.

R. H. Peters

Elsevier, Amsterdam, 1975, 902 pp. \$112.50

It is now a quarter of a century since Vickerstaff's 'The Physical Chemistry of Dyeing' was first published and although major books on this topic have appeared since then, the comprehensive treatise on the subject that Professor Peters has produced is still welcome.

Nominally this volume forms the third, and last, of a series on Textile Chemistry, hence the title 'The Physical Chemistry of Dyeing' appears only as a subtitle to the main work. This is in some ways to be regretted as the author is acknowledged to be an expert in the subject matter of the present volume, whereas in the first two volumes which dealt with a series of rather disjointed topics he sometimes betrayed the fact that he was not always familiar with the particular topic under discussion.

The present work extends outside the strict range of the title. Thus four introductory chapters cover such topics as dyeing machinery, including 13 detailed diagrams, tests devised by the Society of Dyers and Colourists for assessing dyeing properties, and the estimation of dyes and their purification, including a brief introduction to the laws of light absorption.

The next 15 chapters, which comprise the heart of the book, describe the properties of various dye classes (dispersed, acid, direct, vat, reactive, etc.). An analysis of the equilibrium sorption behaviour is given for each dye/fibre system which is complemented by a description of the kinetics of sorption which are analysed in terms of diffusion processes.

The final eight chapters deal with a series of specialized topics such as solvent dyeing, dye aggregation and the dyeing of specialized fibres such as polypropylene.

The author is to be congratulated on producing such a detailed and well presented work. Throughout the book theoretical aspects of a particular process are supplemented copiously by experimental data in the form of tables and graphs. The book is excellently produced but the writer does not quite do himself justice by failing to provide an Author Index. Such an addition would have increased the value of the book as a source of references since it is particularly well provided for in this respect.

The major adverse criticism of this book is its price. Volume I of the series (published 1963) was £3.75, volume II (published 1967) cost £5.00 whereas the present volume is £50. Even allowing for the fact that it is a much larger book than its predecessors and the publisher is not responsible for the poor performance of the pound against foreign currencies, this price is still very high. This book will be beyond the reach of virtually all students and most private buyers. It will probably be purchased by libraries if only to complete the series, but since many of these are operating on nearly static budgets, the future of such high priced books must be very doubtful.

C. Earland

Conference Announcement
**6th Europhysics Conference on
Macromolecular Physics
Phase Transition in Bulk Polymers
Varna, Bulgaria, 26–29 September 1977**

The Macromolecular Physics section of the European Physical Society together with the Bulgarian Academy of Science are organizing the 6th EPS Conference on Macromolecular Physics—Phase Transitions in Bulk Polymers, to be held at Varna, Bulgaria, 26–29 September 1977. The topics to be discussed include: (1) crystallization and melting of polymers, thermodynamics, kinetics and mechanisms; (2) phase transitions in polymer liquid crystals, including oligomers; (3) conformational changes in bulk polymers: folding and unfolding of molecular nascent polymers obtained by polymerization reactions. A limited number of contributed papers can be accepted and those interested are invited to submit abstracts on subjects related to the topics above by 1 January 1977. Prospective contributors and those interested in attending the conference should write for further details to: Professor M. Mihailov, Bulgarian Academy of Sciences, Central Laboratory for Polymers, EPS Conference, 1113 Sofia, Bulgaria.

Classified Contents

- Anionic polymerization, block polymers of poly(*para*-xylelene) and polystyrene or poly(vinyl pyridine) prepared by, 817
- Anisotropic materials, effect of sample geometry on the measurement of mechanical properties, 495
- Anisotropic scattering of light in an electric field, effect of macromolecular length, 1039
- Anisotropy, optical and orientation of structural units, 167
- Anisotropy, optical, of polyisobutene, 511
- Annealing effects of polymers and their underlying molecular mechanisms, 309
- Anomalous diffusion of water in glassy polymers, 690
- Block polymers and multiphase polymer systems, structure and properties of: an overview of present status and future potential, 938
- Block polymers of poly(*para*-xylelene) and polystyrene or poly(vinyl pyridine) prepared by anionic polymerization, 817
- Bound rubber and swelling in silicone rubber/silica mixes and in silicone rubber vulcanizates, comparison, 147
- Brillouin scattering study of gelatin gel using a double passed Fabry-Perot spectrometer, 573
- Carboxylic acids and the peptide group, interaction between, 563
- Catalysis, Ziegler-Natta: 7. The settling period, 130
- Cellulose, the involvement of singlet oxygen in the sensitized photodegradation, 1113
- Cellulose acetate, small-angle X-ray scattering from ultrathin films, 93
- Cellulose tricarbaniolate, non-Newtonian viscosity and non-linear flow birefringence of, 155
- Cellulose tricarbaniolate, persistence length of, by small-angle neutron scattering, 363
- Cellulose trinitrate, configuration of, in solution, 1027
- Chain atoms between entanglements and cross-sectional area per chain, 1112
- Chain conformation of poly(tetramethylene terephthalate) and its change with strain, 807
- Chain structure, effect of, on the melting of low molecular weight poly(ethylene oxide), 109
- Chemorheology of irradiation-cured natural rubbers: 2. Stress relaxation mechanisms of sulphur-containing cured systems in air, 325
- Configurational and dynamic flexibility of polymer chains, 395
- Conformation and thermodynamics of adsorbed macromolecules at the liquid/solid interface, 864
- Cooling of a polymer sheet, 1103
- Copolymers, block, ethylene-propylene oxide type P(EP)_n, melting of, 105
- Copolymers, butene/propylene, monomer sequence distribution by ¹³C nuclear magnetic resonance, 548
- Copolymers of α -methylstyrene and maleic anhydride, relationship of temperature to composition, 21
- Copolymerization, radical, of styrene and methyl methacrylate, radiochemical study, 217
- Crack growth in plastic panels under biaxial stress, 627
- Craze growth and crack growth in poly(vinyl chloride) under monotonic and fatigue loading, 335
- Craze kinetics for PMMA in liquids, 439
- Creep behaviour of annealed UPVC and PMMA, 77
- Crotamine, optical rotatory dispersion: effect of denaturants, 638
- Crown ether catalyzed modification of partly chloromethylated polystyrene, 1107
- Crystallization of dilute polyethylene solutions: influence of molecular weight, 99
- Crystallization and isothermal thickening, study of in polyethylene using SAXD, low frequency Raman spectroscopy and electron microscopy, 471
- Crystallization kinetics, polymer, use of differential scanning calorimetry to study, 1015
- Crystallization rates, comparative study by d.s.c. and depolarization microscopy, 12
- Deformation mechanism of hard elastic polyethylene films, 1063
- Dielectrics, anisotropic, reaction field in, 7
- Dielectric and viscoelastic properties of two poly(propylene glycol) liquids, comparison, 665
- Differential refractometry and light scattering on nylon-6 and poly(methyl acrylate) in mixed solvents, 587
- D.s.c. and depolarization microscopy, comparative study of crystallization rates by, 12
- D.s.c. studies on phase transition of glucose and cellulose oligosaccharides, 559
- D.s.c., use of to study polymer crystallization kinetics, 1015
- Diffusion of large molecules in polymers: a measuring technique based on microdensitometry in the infrared, 481
- Diffusion rates, directional, in keratin, 748
- Diimide reduction of *cis*-1,4-polyisoprene with *p*-toluenesulphonylhydrazide, 117
- 1,1-Diphenylethyl methacrylate, stereospecific anionic polymerization and copolymerization, 618
- Drag reduction effectiveness of macromolecules, 81
- Dynamics of solutions of entangled polymers, 1035
- Elastic modulus in the crystalline region of poly(*p*-phenylene terephthalamide), 517
- Elasticity, stored, in flowing solutions of polyisobutylene as measured by recoil, 246
- Elastin, bovine, solubilization of, by a formic acid + salt method, 173
- Electric birefringence of aqueous solutions of methyl cellulose, 508
- Electro-optic Kerr birefringence of polystyrenes in dilute solutions, 651
- Equilibrium ring concentrations and the statistical conformations of polymer chains: 14. Calculation of the concentrations of medium sized cyclics in poly(dimethyl siloxane) equilibrates, 601
- Cis*- and *trans*- Ethyl propylene ethers, salt effect on cationic copolymerization between, 828
- Extruders, single screw, melting in, 905
- Fabry-Perot spectroscopy, multi-pass, of polymers, 501
- Failure criterion for the fracture of structural adhesive joints, 727
- Failure, time-dependent of poly(methyl methacrylate), 717
- Fibrillation mechanism in the flow of molten polymer mixtures, 831
- Filler enhancement of rubber modulus, 734
- Flame retardancy, some aspects of, in high density polyethylene, 1095
- Fracture surface energy in notched tension, influence of the molecular weight of poly(methyl methacrylate), 161
- Free radicals, distribution and desorption of, in the emulsion polymerization of styrene, 740
- G.p.c., differential, determination of concentration dependence of the hydrodynamic dimensions by, 455

- Gelatin gel, Brillouin scattering study of, using a double passed Fabry—Perot spectrometer, 573
- Gelatinization, theory of, in a starch—water—solute system, 854
- Glass transition temperature determination of poly(ethylene sulphide), poly(isobutylene sulphide) and their random copolymers, 348
- Glass transition temperature of ideal polymeric networks, 859
- Glass transition temperature in nylons, 1049
- Glass transition temperature of poly(*N*-vinyl pyrrolidone) and the effect of water, 739
- Glasses, theory of, 933
- Glow discharge polymerization of hexamethylcyclotrisilazane, mechanism of polysilazane thin film formation, 673
- Glucose and cellulose oligosaccharides, differential scanning calorimetric studies on phase transition, 559
- Grafting onto poly(vinyl alcohol): a new spectral method to estimate the extent of grafting, 1108
- Grignard compounds, polymeric, preparation and reactions, 1020
- Hafnium polythioethers, synthesis and thermal characterization, 231
- Heterocycles, coordinate polymerization: 1. Oligomerization of epichlorohydrin by TiCl_4 , 519. 2. Oligomerization of tetrahydrofuran by TiCl_4 in the presence of acetyl chloride or epichlorohydrin, 528. 3. Oligomerization of tetrahydrofuran induced by TiCl_4 in the presence of acetyl chloride and epichlorohydrin, 535
- Hydrodynamic dimensions, determination of concentration dependence of by differential g.p.c., 455
- Impact yielding of high density polyethylene, 1099
- Infra-red studies, polarized far, of hot-drawn polytetrafluoroethylene, 153
- I.r. study of poly(1-pentene) and poly(4-methyl-1-pentene), 121
- Initiators, new thermal, of free-radical polymerization and block copolymerization, 94
- Interesterification of starch with methyl palmitate, 555
- Intra-chain double bonds, effect of on the melt crystallization of aliphatic polyesters, 802
- Intra-chain *trans* double bonds, influence of, on the melt crystallization of polyamides, 185
- Intra-chain double bonds, influence of, on the properties of solution grown single crystals of polyethylene, 541
- Ion-clustering and viscoelastic properties in poly(butadiene—styrene—4-vinylpyridine) crosslinked by nickel chloride, 382
- Keratin, directional diffusion rates in, 748
- Laser flash photolysis investigations on primary processes of the sensitized polymerization of vinyl monomers: 1. Experiments with benzophenone, 419
- Laser—Raman spectroscopic studies of mechanically-loaded polymers, 838
- Liquid/solid interface, conformation and thermodynamics of adsorbed macromolecules, 864
- Lithium polystyryl and iodinated polystyrene, reaction between, 351
- Mechanical motions in amorphous and semi-crystalline polymers, 996
- Melt crystallization of polyamides, influence of intra-chain *trans* double bonds, 185
- Melt rheology of some aliphatic polyamides, 377
- Melting of polymers in narrow annular shear devices, 443
- Melting in single screw extruders, 905
- Methyl cellulose, electric birefringence of aqueous solutions, 508
- Molecular complexes in polymer synthesis—from Lewis acid adducts to exiplexes, 957
- Molecular design of polymers, 965
- Molecular motion of poly(methyl methacrylate), polystyrene and poly(propylene oxide) in solution studied by ^{13}C n.m.r. spin—lattice relaxation measurements: effects due to distributions of correlation times, 399
- Molecular motions and segmental size of vulcanized natural and acrylonitrile-butadiene rubbers by the spin-probe method, 448
- Molecular orientation, a study of, in drawn and shrunk poly(ethylene terephthalate) by means of birefringence, polarized fluorescence and X-ray diffraction measurements, 25
- Molecular weight, effect of, on the thermal properties of polycarbonates, 51
- Morphological aspects of AB cross-linked polymers, 367
- Morphological study of chain-extended growth in polyethylene: 1. Crystallization, 275.2. Annealed bulk polymer, 284. 3. Annealing of solution-grown lamellae, 291
- Mosaic concept in polymer crystals, a re-examination of the necessity, 736
- Networks, ideal polymeric, glass transition temperature, 859
- Neutron scattering, low angle, trajectory of polyethylene chains in single crystals by, 37
- Neutron scattering studies, small-angle, of molten and crystalline polyethylene, 751
- Non-Newtonian viscosity and non-linear flow birefringence of cellulose tricarbaniolate, 155
- N.m.r., broad line resonance, interpretation of in poly(ethylene terephthalate), 125
- N.m.r., ^{13}C , determination of monomer sequence distribution in butene/propylene copolymers, 548
- N.m.r., ^{13}C and i.r. spectroscopy, determination of chain branching in low density polyethylene by, 345
- N.m.r., ^{13}C spectra of some poly(*N*-acyliminoalkenes), 656
- N.m.r., ^{13}C , spin—lattice relaxation measurements, molecular motion of poly(methyl methacrylate), polystyrene and poly(propylene oxide) in solution studied by: effects due to distributions of correlation times, 399
- N.m.r., ^{13}C , study of optically active polymers: poly(4-methyl-1-hexene), 901
- N.m.r., pulsed, of a SBS 'macroscopic single crystal', 41
- N.m.r. relaxation times of some aromatic polymers, effect of molecular oxygen, 758
- N.m.r. studies, pulsed, of molecular motion in wet nylon-6,6 fibres, 761
- Nylon-1 polymers and copolymers, properties, 926
- Nylon-6 and poly(methyl acrylate), differential refractometry and light scattering in mixed solvents, 587
- Nylon-6,6 fibres, wet, pulsed n.m.r. studies of molecular motion, 761
- Nylons, glass transition temperature in, 1049
- Oligourethanes, structure: 6. Fine structure of melt crystallized oligourethanes, 3
- Optical rotatory dispersion of crota-mine: effect of denaturants, 638
- Optically active polymers, ^{13}C n.m.r. study of: poly(4-methyl-1-hexene), 901
- Optimum filler content in semi-crystalline polymers, a method for the calculation, 836
- Osmotic pressures of moderately concentrated poly(γ -benzyl-L-glutamate) solutions in *N,N*-dimethylformamide, 919
- Oxygen, molecular, effect of on the n.m.r. relaxation times of some aromatic polymers, 758
- Palladium/ π -catalysts, effect of phosphine ligand on the activity, 58
- Palladium/ π -complexes as catalysts for olefin polymerization, 710
- Permeation chromatography calibration, a new approach, 90

Classified Contents

- Persistence length of cellulose tricarbani-
late by small-angle neutron scatter-
ing, 363
- Phase transition and morphology of
bulk poly(*trans*-1,4-butadiene),
effect of pressure on, 249
- Phosphine ligand, effect of, on the
activity of palladium/ π -catalysts, 58
- Phosphonitrilic chloride: 33. Cyclomat-
rixphosphazene polymers formed
from hexachlorocyclotriphospha-
zene and metal acetates, 319. Elec-
trical conductivity of polybisamino-
phosphazenes, 1013
- Phosphonitrilic chloride: polymeriza-
tion behaviour of some hexaalkoxy-
cyclotriphosphazenes, 898
- Photoconduction, field dependent, in
poly(*N*-vinylcarbazole), 646
- Photodegradation of cellulose, sensi-
tized, the involvement of singlet
oxygen, 1113
- Photoelastic non-equilibrium behaviour
of natural rubber networks, 732
- Photoinitiating systems and photoactive
polymers, new, and their applica-
tions, 321
- Polarization studies, persistent internal,
in poly(*N*-vinylcarbazole)/trinitro-
fluorenone charge complex, 192
- Poly(acryloyl morpholine) xerogel net-
works, synthesis and characteriza-
tion, suitable for the gel permeation
chromatography of small molecules,
843
- Poly(*N*-acyliminoalkenes), ^{13}C n.m.r.
spectra, 656
- α -Poly(L-alanine), potential energy cal-
culations about the chain folding,
257
- Poly(γ -*N*-alkyl-L- α,γ -diaminobutyric
acids) and their carbobenzoxy deri-
vatives, syntheses and conforma-
tional studies, 429
- Poly(*N*-alkyl maleimides), thermal
stabilities, 199
- Polyamidation process, new solid state,
409
- Polyamides, amorphous, structure—
property relationships in, 875
- Polyamides, melt crystallization of,
influence of intra-chain *trans* double
bonds, 185
- Polybenzazoles, cobalticinium-bridged:
1. Low temperature solution poly-
merization, 423
- Poly(γ -benzyl-L-glutamate), osmotic
pressures of moderately concentra-
ted solutions in *N,N*-dimethylfor-
mamide, 919
- Poly(*trans*-1,4-butadiene), bulk, effect
of pressure on phase transition and
morphology, 249
- Poly(butylene terephthalate), thermal
degradation, 1044
- Poly(ϵ -carbobenzoxyl-L-lysyl- γ -benzyl-
L-glutamate), synthesis and charac-
terization, 847
- Poly(*O*-carbobenzoxy-L-tyrosine), con-
formational study of, in solution, 1105

- Structure of a compatible mixture of two polymers as revealed by low-angle neutron scattering, 640
- Styrene-butadiene block copolymers, cruciform, correlation between physical-mechanical properties and morphological features, 72
- Styrene, distribution and desorption of free radicals in the emulsion polymerization, 740
- Superstructure of high density polyethylene film crystallized from stressed polymer melts as observed by small-angle light scattering, 1075
- Swelling of bonded-rubber cylinders, 142
- Swelling of linear polymers in mixed swelling agents: predictability by means of solubility parameters, 835
- Tetrafluoroethylene, polymerization of, in acetic acid photoinitiated by metal carbonyls, 225
- Thermal analysis of heat set poly(ethylene terephthalate) fibres, 241
- Thermal degradation of poly(butylene terephthalate), 1044
- Thermal oxidation of poly(1-pentene): 1. Identification of products and mechanisms, 61
- Thermal stabilities of poly(N -alkyl maleimides), 199

Classified Contents

- Thermally stimulated discharge, analysis of relaxation processes in methacrylate polymers by, 212
- Thermally stimulated discharge, study of polymer crosslinking by, 921
- Thermochemical behaviour of natural rubber, time effects on, 87
- Thermodynamics of α , ω -methoxy-poly(ethylene oxide)/*n*-alkane systems by gas-liquid chromatography, 374
- Transition metal impurities in crystalline conjugated polymer, 623
- Universality approach to the expansion factor of a polymer chain, 179
- Upper and lower critical solution temperatures in poly(ethylene glycol) solutions, 685
- 2-Vinylanthraquinone, novel synthesis, 643
- N*-Vinylcarbazole, polymerization of in systems containing maleic anhydride and benzoyl peroxide, 742
- Vinyl chloride polymers, heat treated, structural order in, 44
- Vinyl monomers, some aspects of stereoregulation in the stereospecific polymerization, 977
- Vinyl polymers, optically active, containing fluorescent groups: 1. Synthesis and properties of copolymers of *N*-vinylcarbazole with optically active monomers, 641
- Viscosity-molecular weight concentration relationships beyond the critical region in polymer solutions and melts, 570
- Wool, dyed, modification of the fastness properties of through grafting, 705
- X-ray diffraction patterns, wide-angle, of aligned glassy polymers, analysis of with particular references to polystyrene, 488
- X-ray scattering, small-angle, from ultrathin films of cellulose acetate, 93
- X-ray studies of surface melting in single crystals of linear polyethylene, 1059

an international journal

bimonthly in English

POLYMER JOURNAL

of significant original papers on new research and studies
in the fields of polymer chemistry, physics and biopolymers
for quick beautiful publication with world-wide circulation;
appreciated in 50 countries

● **Editor in Chief** Teiji Tsuruta (University of Tokyo)

● **Subscription Rate** US \$ 85.00 per volume (calendar year)

The Society of Polymer Science, Japan

HONSHU BUILDING 5-12-8 GINZA CHUO-KU TOKYO 104 JAPAN

An exclusive sales agent **U.S. - Asiatic Co., Ltd.**

13-12 Shimbashi 1-Chome Minato-ku Tokyo 105 Japan

POLYMER

*the science and technology of
polymers and biopolymers*

- 3 Structure of oligourethanes: 6. Fine structure of melt crystallized oligourethanes
Masanobu Nagura, H. Ishikawa, Hiroyuki Tagawa and Eiichi Wada
- 7 Reaction field in anisotropic dielectrics
K. H. Lau and K. Young
- 12 Comparative study of crystallization rates by d.s.c. and depolarization microscopy
C. F. Pratt and S. Y. Hobbs
- 17 A rapid technique for the qualitative analysis of polymers and additives using stop-and-go g.p.c. and i.r.
Francis M. Mirabella Jr, Edward M. Barrall II and Julian F. Johnson
- 21 Relationship of temperature to composition of copolymers of α -methylstyrene and maleic anhydride
Raymond B. Seymour and David P. Garner
- 25 A study of molecular orientation in drawn and shrunk poly(ethylene terephthalate) by means of birefringence, polarized fluorescence and X-ray diffraction measurements
J. H. Nobbs, D. I. Bower and I. M. Ward
- 37 Trajectory of polyethylene chains in single crystals by low angle neutron scattering
D. M. Sadler and A. Keller
- 41 Pulsed n.m.r. of a SBS 'macroscopic single crystal'
G. E. Wardell, D. C. Douglass and V. J. McBrierty
- 44 Structural order in heat treated vinyl chloride polymers
A. Gray and M. Gilbert
- 51 Effect of molecular weight on the thermal properties of polycarbonates
G. A. Adam, J. N. Hay, I. W. Parsons and R. N. Haward
- 58 Effect of phosphine ligand on the activity of palladium/II-catalysts
Fereidun Hojabri
- 61 Thermal oxidation of poly(1-pentene): 1. Identification of products and mechanisms
S. M. Gabbay and S. S. Stivala
- 65 Model polyurethane networks
G. Allen, P. L. Egerton and D. J. Walsh
- 72 Correlation between physical-mechanical properties and morphological features of cruciform styrene-butadiene block copolymers
Enrico Pedemonte, Giovanni Dondero, Francesco de Candia and Gennaro Romano
- 77 Creep behaviour of annealed UPVC and PMMA
D. C. Wright
