# THE ASYMMETRIC NON-CARBON ATOM

V.I. Sokolov and O.A. Reutov

CONTENTS

1. General outline of the history of the problem 1
2. Group V 2
3. Group VI 5
4. Group IV 7
5. Spirans with a non-carbon spiro-atom 8
6. Influence of the asymmetric atom on the optical rotation 8

The stereochemistry of compounds with asymmetric carbon was long ago consolidated into a unified system which rests on numerous correlations of the configurations of important classes of compounds and received its principal consummation after the establishment of the absolute configurations. Later, in the fifties, the stereochemistry of compounds exhibiting molecular dissymmetry (without an asymmetric atom) was formulated: substituted biphenyls, allenes, etc. This process is still not completely finished, although there has been great progress in the last decade. It must also be noted that in this period great interest was aroused in the theory of optical activity in general and the method of optical rotatory dispersion was vigorously developed as a tool for the investigation of organic and inorganic compounds.

Until recent years much less attention was paid to molecules containing an asymmetric atom other than carbon. Meanwhile the great diversity of types of such compounds is of great interest for stereochemistry. This region of investigation, which has been exploited particularly intensively during the last 5–6 years, has not been surveyed in the review literature known to us.

## 1. GENERAL OUTLINE OF THE HISTORY OF THE PROBLEM

In the history of this problem it is possible to distinguish several periods, the start of each being indicated by the origination of a certain idea (naturally, it is impossible to draw sharp boundaries between these periods). The start of the stereochemistry of the non-carbon asymmetric atom can be ascribed to the time when one of the founders of stereochemistry, LeBel[1], obtained an optically active salt (the chloride) of the ethylisobutylisopropylmethylammonium cation by a microbiological method (1891). In the first period the main interest of chemists was in the demonstration of the possibility of the existence of tetra- and tri-substituted non-carbon atoms in an optically active form. This was evidence of the generality of the tetrahedral model and of its applicability also to elements other than carbon. The most important works in the years 1900–1910 were completed by the English stereochemical school (Pope and Peachey): ammonium[2] and sulphonium[3] salts, etc., were separated into antipodes. At the end of the twenties optically active esters of sulphinic acids[4], sulphoxides, and related compounds were obtained. Exhaustion of the possibilities in this direction appeared to be the reason for the considerable reduction in the number of publications (up to the fifties). However, the description work retains significance, for example, a quadruply-substituted sulphur derivative[6] was obtained in the optically active state in 1960, and an amine oxide[7] only in 1963.

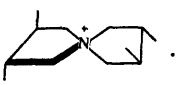
The start of the second period can be considered to be the work of Meisenheimer[8,9] (1911–1926). At this time a persistent interest commenced in the nature of optical

activity, which first arose, of course, in the stereochemistry of carbon (beginning with Chugaev). Meisenheimer took up an idea of Werner [10] about the role of the central atom in complexes and introduced it into organic chemistry. He was not only the first who posed the problem of the influence of the nature of the asymmetric central atom on the magnitude of the rotation, but he also carried out experimental work that was a model in its execution. His work retained a demonstrative character (for the semipolar bond in amine oxides and phosphines), but the general statement of the question was elegant. After Meisenheimer, interest in this aspect of the problem was lost for a long time, being maintained only in the laboratory of Mann [11] (Cambridge), where unusual refraction was obtained.

The third period starts at the end of the fifties: compounds with an asymmetric non-carbon atom are used as models for studying reaction mechanisms, in which it is already necessary to take into account differences between carbon and other elements. In recent years the stereochemistry of Si, P, Ge, and As has been practically established and information obtained on the mechanisms of substitution at phosphorus and silicon. The greatest success is the establishment in certain instances of the absolute configuration of non-carbon asymmetric centres, which is one of the main tasks of static stereochemistry. A second task presents much greater difficulty: the determination of the magnitude of the optical rotation as a function of structure. This is still far from solution.

Specific interest in the limits of the problem under review is the problem of the dependence of rotation on the nature of the asymmetric atom. In compiling this review this has received the greatest attention. On the other hand we have not aimed at an exhaustive treatment of the problem of dynamic stereochemistry. Of the older works (which can be found in the well-known handbooks on stereochemistry) we consider in detail only those which are of significant importance in the aspect referred to; the others are simply mentioned. The most recent literature used in the review appeared in Autumn 1963. [The authors have added some more recent references at the end of the bibliography (Ed. of Translation).]

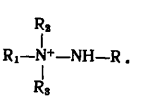
At present, optical activity due to asymmetric atoms of the following elements (other than carbon) has been established: Si, Ge, N, P, As, Sb, S, Se, Te. The material will be considered according to the Groups of the Periodic System, beginning in greater detail with Groups V and VI, whose stereochemistry has a greater history, and then reverting to the more recent work on Group IV. A special Section deals with spirans with a hetero-spiro-atom. The last part of the review contains an attempt to analyse the published material using the semiempirical method of calculating optical rotation developed by Brewster [12-14] for compounds with asymmetric carbon.



## 2. GROUP V

Salts of quadruply-substituted ammonium were long ago separated into antipodes [2]; in most instances their optical stability is small on account of the ease of the reverse reaction:

$$R_1R_2R_3R_4\overset{+}{N}\overset{-}{X} \rightleftarrows R_1R_2R_3N + R_4X.$$



Greater optical stability is exhibited by the spiran systems with a bicyclic nitrogen, first resolved by Mills [15]. Their racemisation is hindered by the necessity for breaking two carbon–nitrogen bonds. [This does not follow (Ed. of Translation).]

There are two interesting points in connection with these systems. Firstly, there are the very rare instances of self-produced resolution observed by Havinga [16,17]: on long standing in a sealed ampoule benzylethylmethylphenylammonium iodide deposited crystals of an (-) enantiomer containing chloroform. Secondly, to this class belongs the only known example of a molecule which is optically inactive, since it is superimposable with its mirror image, although it does not possess a planar centre of symmetry [18]:

Here a rare symmetry element is realised — a fourfold axis of rotation-inversion, the absence of optical activity for such molecules had been suggested earlier [19].

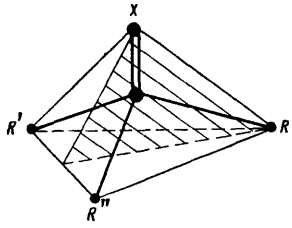
A unique isologue of ammonium has been described in an optically active form — the hydrazonium salt (I) [20]:

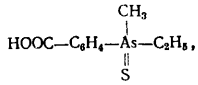
(I)

In contrast to ammonium salts, phosphonium and arsonium salts could not be resolved into antipodes for long on account of rapid racemisation. Earlier works [21-23] were unsuccessful but sometimes slight and rapidly disappearing rotation was observed. Enantiomers of phosphonium salts were obtained only in the last decade by a few groups of investigators, especially Vanderwerf and McEwen [24-26]. Certain arsonium salts have also been obtained in an optically active form [27,28]. Of particular interest is the successful use by Kamai and Klabunovskii [29] for the separation of benzylethyl-n-pentylphenylarsonium bromide by selective adsorption of one of the antipodes on dissymmetrical crystals of quartz, for the effectiveness of this rather simple operation was greater than laborious multistage crystallisations.

The optical activity of stibonium salts has still not been observed experimentally, but there can be little doubt about its possibility.

The increase in the valency of the central atom on passing from carbon to the elements of Group V brings about the appearance of new types of asymmetric molecules. Here a new geometrical model is encountered — a distorted tetrahedron with a double bond directed to one of the vertices (Fig. 1). When the three remaining substituents are different, the molecule does not possess a plane of symmetry. This structural type in a pure form is represented in the sulphides of phosphines and arsines, $R_1R_2R_3P{=}S$ and $R_1R_2R_3As{=}S$. Evidently in these molecules a genuine double bond is present. Significantly there is a difference in the properties of the oxides and sulphides: phosphine sulphides, unlike phosphine oxides and amine oxides, do not add on hydrogen halides, which probably indicates the absence of an appreciable negative charge on the sulphur. The essential reason is that sulphides of tertiary amines do not exist [30]; evidently sulphur cannot be the negative end of the dipole of a semipolar bond (in the sense of $E^+-S^-$), and a double bond is impossible in the case of nitrogen.





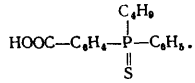


Fig.1.

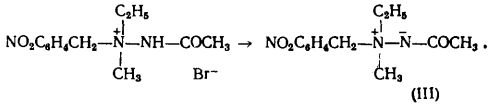
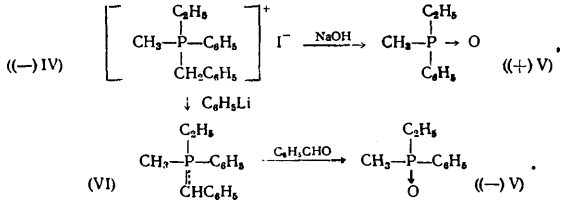
Sulphides of a tertiary arsine (II*a*) was resolved into antipodes by Mills and Raper[31] in 1925, and its phosphorus analogue (II*b*) by Davies and Mann[32] in 1944. They then posed the question of comparison of the optical rotation of corresponding oxides, sulphides, and selenides, which has still not been investigated experimentally.



(IIa)

(IIb)

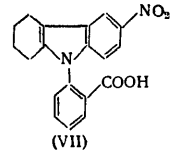


Oxides of ternary phosphines and amines were studied in the classical works of Meisenheimer and coworkers[8,9,33]. As a result of prodigious labour they succeeded in obtaining in an optically active form more than 20 compounds, of which they studied in detail the compounds containing the radicals methyl, phenyl, and ethyl (or benzyl). In many instances the work was restricted to the separation of diastereomers, since the exchange of the optically active anion led to racemisation. The results relating to the influence of the structure and solvent on the molecular rotation will be discussed in the final Section of this review.

Wawzonek[7] obtained a nitrogenous analogue of an amine oxide (III) from the corresponding hydrazonium salt:

(III)

Papers on optically active phosphine oxides appeared again only after 30 years had elapsed. In a series of papers[24,34-37] Vanderwerf and McEwen and their coworkers described various transformations of compounds with asymmetric phosphorus, which enabled them to establish a connection between the relative configurations (IV) and (V):



The ready detachment of the benzyl group in an alkaline medium leads to the phosphine oxide with opposite rotation. The transition state has the configuration of a trigonal bipyramid and the stereochemical result is the reversal of the configuration[38]. The action of phenyllithium on the benzylphosphonium salt (IV) gives an optically active Wittig reagent (VI), naturally of the same configuration. With (VI), benzaldehyde gives ((-)IV) as this stage, in accordance with the four-membered cyclic mechanism of the Wittig reaction[39], must involve retention of configuration. This enables the same configuration to be ascribed to the phosphorus atoms in ((-)IV) and ((-)V).

For a long time great interest was aroused in the problem of the possibility of the existence of stable enantiomers of triply-substituted nitrogen, phosphorus, arsenic, and antimony. Meisenheimer[40] did not succeed in resolving phenyltolyl-*o*-carboxyphenylamine into antipodes. At the end of the thirties the frequency of inversion of the pyramids of the hydrides of the Group V elements was evaluated from spectroscopical data[41] (Table 1).

The frequency decreases appreciably as the mass of the substituent is increased, which gave the possibility of stability of the configuration on passing to organic radicals. Mann assumed that the existence of optical antipodes is possible for all elements of the principal subgroup, excluding nitrogen. In 1954 Weston[42] evaluated by quantum chemical methods the configurational stability of the pyramid for $(CH_3)_3E$, by calculating the "racemisation temperature" — the temperature at which the half-period for inversion of the pyramid equals 2 h (Table 2).

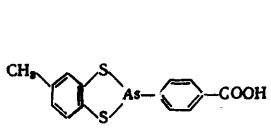
According to Weston, the configurations of arsenic and antimony are sufficiently stable at room temperature, but phosphorus at somewhat lower temperature. However, it is not at all clear how $T_{rac}$ changes with change of radicals. For the trialkylsulphonium cation an incorrect result was obtained, since the sulphonium salts are completely stable optically. Evidently care must be taken in using this prediction.

The optical activity of certain aromatic systems with tervalent nitrogen, for example (VII)[43],

(VII)

is probably due to the hindrance of rotation. A stable structure with tervalent nitrogen atoms also occurs in

TABLE 1.



| | $NH_3$ | $PH_3$ | $AsH_3$ | $PD_3$ | $AsD_3$ |
|---|---|---|---|---|---|
| Frequency of inversion, $s^{-1}$ | $2\cdot10^{10}$ | $5\cdot10^{6}$ | $16\cdot10^{4}$ | $6\cdot10^{3}$ | 30 |

TABLE 2.

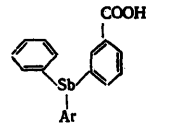
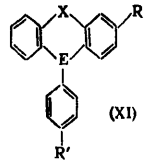
Troger's base, which was separated into antipodes by Prelog and Wieland[44], who for this made the first use of an asymmetric adsorbent, *d*-lactose.



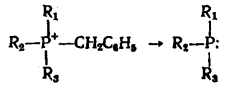
In the fifties Campbell and coworkers[45-49] published a series of papers in which they described optically active derivatives of arsenic, phosphorus, and antimony. The hetero-atom was included in a cyclic system condensed with benzene rings (VIII)–(X).

(VIII)

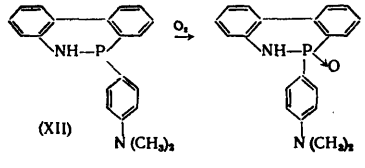


(IX); E = As, Sb

(X); Ar = α-$C_{10}H_7$ or (2-$C_6H_5$)$C_6H_4$



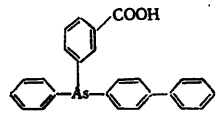
Earlier, structures of similar types were separated into antipodes by Lesslie and Turner[50-52], their distinguishing feature being the presence of two hetero-atoms, uniting aromatic rings (XI).



(XI)

Thanks to the specificity of these structures, doubt arose as to whether their optical stability was the result of steric hindrance due to the congestion of the rigidly bound aryl groups or the stability of the folded conformation (along the E–X axis); Mann[53] defended such a point of view. The problem of the asymmetry of the hetero-atom in a ring remained open.

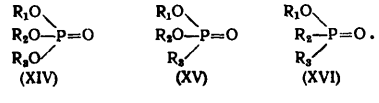
This old problem of stereochemistry was recently solved in Horner's laboratory. Success was achieved in obtaining stable enantiomers of tertiary phosphines[54] and arsines[55] of completely normal structure: with one aryl and two alkyl radicals. An original method was used for this — the detachment of a benzyl† group in the reduction at the mercury cathode of the enantiomorphs of the corresponding phosphonium



or arsonium salts. These compounds are extremely stable optically, some of them withstanding boiling in solution for many hours without the slightest racemisation! The German investigators found that electrolytic reduction of the onium salts of phosphorus and arsenic and also alkylation, oxidation, and addition of sulphur to $R_1R_2R_3E$ takes place with complete retention of the configuration[56-58]. Campbell[49] also observed retention of the configuration in the oxidation of tervalent phosphorus in the complex (XII)[49]:

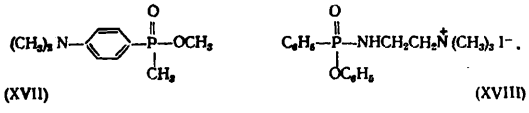
(XII)

† It was found subsequently that the allyl group can also be split off electrolytically[57].



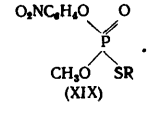
In 1963 Mislow[59] showed that the optical activity of the Lesslie–Turner compounds (XI) is due to the configurational stability of the arsenic atom, whereas these molecules are quite labile conformationally (the energy barrier for the "folding" of the molecule about the E–X axis totals ~ 6 kcal × × mole$^{-1}$). In this work the triarylarsine (XIII) was also separated into antipodes:

(XIII).



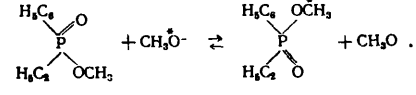
It is free from steric hindrance; optical rotatory dispersion curves without the Cotton effect (up to 310 mμm) are obtained. Hence the question of the possibility of the existence of three-covalent derivatives of the elements of the main subgroup of Group V in an optically active state is confirmed for phosphorus, arsenic, and antimony. The stability of the nitrogen pyramids is evidently too low: for example, the NMR spectra[60] show that for an *N*-alkylethyleneimine the inversion of the nitrogen configuration takes place with a frequency of 60 s$^{-1}$ at room temperature.

In addition to the classes of compounds considered, the elements of Group V form other molecules with a tetrahedral structure: derivatives of acids, for example, (XIV)–(XVI) for phosphorus, and various analogues with sulphur, halogen, or nitrogen instead of oxygen.



(XIV) (XV) (XVI)

It seems that the first compounds with an asymmetric acidic phosphorus (XVII) and (XVIII) were resolved into antipodes by McEwen and Vanderwerf[61,62], and also by Aaron *et al.*[63]:

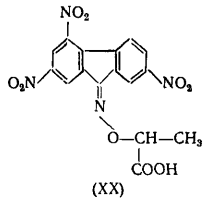


(XVII) (XVIII)

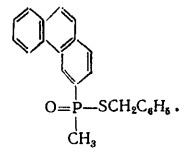
Then Hilgetag and Lehmann[64,65] obtained in an optically active state the ether (XIX), which does not contain a phosphorus–carbon bond.

(XIX)

In addition to the investigators mentioned, Green and Hudson in Switzerland and Michalski in Poland are now working on this problem. Most of the work has been carried out on derivatives of thiophosphoric acid; the main aim is to study the mechanisms of the reactions involving phosphorus[38]. For example, by studying the isotopic exchange:



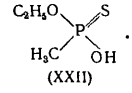
Green and Hudson[66] found that the rate of racemisation is exactly twice the rate of exchange. This is the application to phosphorus of the classical proof of the strict reversal



of the configuration for nucleophilic substitution of the $S_N2$ type, given for carbon (halogen exchange) by Hughes[67].

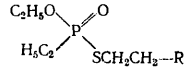
In Aaron and Miller's laboratory antipodes of esters of phosphonic acids have been used for studying the mechanism of action of cholinesterase[68]; the inhibition constants differ by a factor of ten. This can be of interest to enzymology.

The elegant use[69] of Newman's reagent (XX) for the optical separation of compound (XXI) and the 2-naphthylmethyl ester of methylphosphonic acid is worthy of note:



(XX)

(XXI)



The geometric requirements are evidently very strict, for ester of 2-naphthylphosphonic acid does not give a molecular complex with (XX).

The configurations of the compounds with asymmetric acidic phosphorus are completely unknown; by the example of compound (XXII) it has been established[70] that changing the alkyl radical in the ester part of the molecule does not change the sign of rotation:

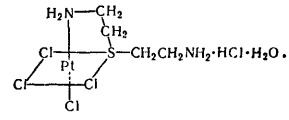
(XXII)

One of Michalski's papers[71] shows that the stereochemical course of reactions can depend on fine details of the structure: (XXIII*a*) and (XXIII*b*) with the same configuration

(XXIII) *a*: R = H; *b*: R = Cl,

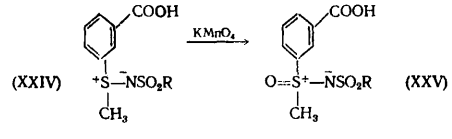
give with $SO_2Cl_2$ chlorides with rotations of different sign. It is not possible to discuss in detail all the papers devoted to these systems, and we will merely mention a few[72-76].

The correlation of the configuration of the phosphorus atom in acids with other types of phosphorus compounds is an important and fascinating task. The most convenient method is the replacement of a chlorine atom or alkoxy--group on a hydrocarbon radical by the action of a Grignard reagent, with conversion into the oxide of a tertiary phosphine.



The optical isomerism of analogous derivatives of arsonic acids has not yet been investigated experimentally.

## 3. GROUP VI

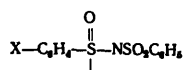


Many types of structure containing an asymmetric sulphur atom are known; the optical activity has usually been observed experimentally. On the other hand, with selenium and tellurium the only type of molecule obtained in an optically active form are onium compounds[77,78]. The case of oxygen is of interest. Meerwein's oxonium compounds[79] hardly merit attention on account of their low stability. There remain Nesmeyanov and Tolstaya's triaryloxonium salts[80,81], for which it is not known precisely whether they have pyramidal or planar structure. According to Syrkin[82] they are compounds of "oxanic" type, as with the salt $[O(HgCl)_3]^+Cl^-$, and therefore should be planar. X-Ray structural analysis of triphenyloxonium salts has still not been completed[83]. Meanwhile a repeat investigation[84] of the salt $[O(HgCl)_3]^+Cl^-$ has recently been made, which showed that the cation has the structure of a pyramid with height $\sim 0.5$ Å. The problem still remains unsolved; in the case of a pyramidal structure for the triaryloxonium salts, obviously separation of $Ar_1Ar_2Ar_3O^+$ into antipodes could be expected.

Optical activity is observed in compounds where the sulphur is bonded to three or four different groups. First of all, Pope and Peachey[3] in 1900 resolved the methoxycarbonylethylmethylsulphonium cation. Then Philipps and coworkers obtained esters of sulphinic acids[4], sulphoxides[5], and sulphimines[85] in the optically active state. At that time this played a large part in establishing the fact of the existence of the semipolar bond. The optical activity of sulphoxides, distinct from detones, was considered to be the conclusive proof of the tetrahedral configuration of sulphur. Strictly speaking, the tetrahedral structure is still not a proof of the semipolar nature of the sulphur–oxygen bond[86], since a decisive role could be played by the free pair of electrons (absent from the carbonyl carbon of the ketone molecule); geometrically the molecule could resemble an arsine sulphide.

Mann[87] synthesised an interesting structure in 1930: an asymmetric sulphide sulphur atom is produced as a result of coordination with a platinum central atom in a complex. This complex shows quite a large angle of rotation but is rapidly racemised:

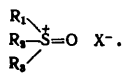
Oxidation of coordinationally unsaturated sulphur of sulphoxides leads to symmetrical sulphones, but that of sulphimines to the slightly studied sulphoximines which have four different substituents at sulphur. Only in 1960 did Barash[6], by separating the diastereomers, show that sulphoximines can exist in an optically active form. In 1962 a detailed investigation[88] of the stereochemistry of oxidation of the sulphimine (XXIV) to a sulphoximine was completed:



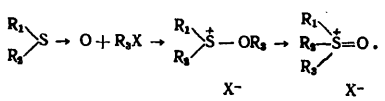
(XXIV) $[\alpha]_D^{20} + 254°$ (XXV). $[\alpha]_D^{20} + 143.5°$

Each compound was resolved into antipodes and during the oxidation complete preservation of the optical activity and configuration was observed which is confirmed by the proximity of the optical rotatory dispersion curves for enantiomers (XXIV) and (XXV) of the same sign. We note that in sulphones and sulphoximines only one bond is

(formally) semipolar, and sulphur has a decet of electrons and a single positive charge (in accordance with the principle of electrical neutrality [89]).



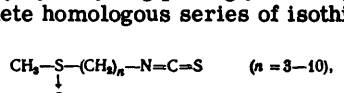
A second example of an optical isomerism of derivatives of quadruply-substituted sulphur was described at the end of 1963, by Levchenko and Kozlov [90]:



*a*: X = H, $[\alpha]_D^{24} \pm 16.6°$,
*b*: X = $NO_2$, $[\alpha]_D^{24} \pm 5.5°$.

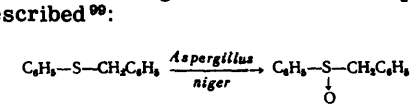
The enantiomers were obtained, probably, in an optically pure state through salts with (-)-1-phenylethylamine.

Optical activity should also be shown by an original class of compound discovered by Kuhn and Trischmann [91] and also by Smith and Winstein [92], namely sulphoxonium salts:



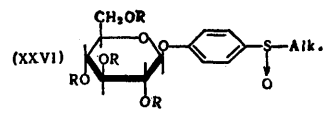
It is remarkable that they contain a true double bond S=O, as is shown by the infrared spectra and also the impossibility of obtaining them by direct oxidation of sulphur in sulphonium salts, although the existence of a positive charge on the sulphur does not hinder the "analogous" formation of sulphones and sulphoximines. The formation of a true double bond in this instance is the only means of fulfilling the principle of electroneutrality. The synthesis of sulphoxonium salts proceeds as follows:

The second stage obviously has a similarity to the regrouping of sulphinic esters and sulphones [93]. Starting with the optically active sulphoxide would probably give an enantiomer of the sulphoxonium salt; this has not yet been described. It is especially interesting that the geometry of the cation is evidently the same as in the sulphides of the Group V elements.



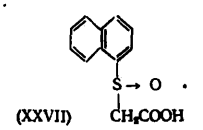
Optically active sulphoxides are encountered in nature, for example, biotin sulphoxide [94], alliin [96], and sulphorafan [95].

Kjaer [97,98], by hydrolysing plant glycosides, isolated almost a complete homologous series of isothiocyanates



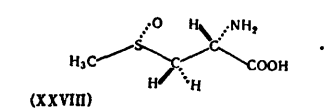
exhibiting strong laevo-rotation, as do most natural sulphoxides.

Several interesting specific methods have been used for preparing optically active sulphoxides. Thus a case of stereospecific microbiological oxidation of simple sulphides has been described [99]:

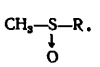


The authors consider that the substance is not optically pure.

Wagner and Böhme [100] obtained glycosidic derivatives of 4-hydroxyphenylsulphoxides (XXVI), and the diastereomers were then subjected to the action of an enzyme, which cleaved only the $\beta$-glycosidic bond:

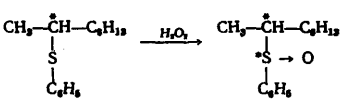


In Poland, Janczewski is working with the oxides of arylcarboxymethyl sulphides [101,102], which are interesting for the large angle of rotation in the visible region, for example, (XXVII) has $[\alpha]_D^{20} = \pm 480°$.



In particular, he described the first case of a pseudoasymmetric non-carbon atom [103].

An asymmetric sulphur atom was the first of the non-carbon atoms whose absolute configuration was established by X-ray analysis [104,105]. The sulphoxide of *S*-methylcysteine contains a carbon atom of known configuration, therefore the configuration of the sulphur was easily determined relative to carbon: ((+)-XXVIII) has sulphur in absolute configuration S:



However, this method is not applicable to determining the configuration of sulphur in other compounds. In recent years rather a large number of investigations on asymmetric sulphoxides have been carried out [106-109]. A partial asymmetric synthesis took place by the action of optically active per-acids on sulphides. Using the rule of asymmetric induction this enables the absolute configuration to be described: the S configuration for the (-)-enantiomer:

Let us consider in detail an example from the work of Cram and Pine [110]. In the oxidation of optically active 2-octyl phenyl sulphide with hydrogen peroxide, two diastereomeric sulphoxides were isolated:

I $[\alpha]_D^{25} - 155°$
II $[\alpha]_D^{27} + 140°$

The ratio of the quantities of the diastereomers formed was I : II = 1.6 : 1. Since the absolute configuration of the carbon centre is known, the sulphide can be represented in the Newman projection (Fig. 2).

According to Cram's rule [111], oxygen will be attached preferentially to the least screened electron pair, adjacent to the hydrogen atom in the projection. If conformations

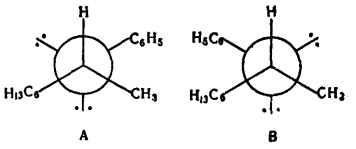


Fig. 2.

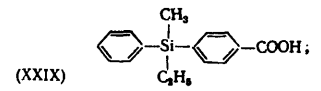
A and B were equally probable, then as a result both diastereomers would be formed in equal amounts. However, the effective volume of the n-hexyl group is greater than that of the methyl group, therefore the position adjoining it is less favourable for phenyl. This signifies that conformation A is the more stable, from which one can draw conclusions about the electron pair which can be preferentialy attacked and about the configuration of the asymmetric centre which is produced.

The following reaction enables sulphoxides to be obtained from the esters of sulphinic acids [112]:



$$R{-}\underset{\underset{O}{\downarrow}}{S}{-}OR' + R''MgX \rightarrow R{-}\underset{\underset{O}{\downarrow}}{S}{-}R'' + Mg(OR')X.$$

It is a convenient method for the synthesis of optically active sulphoxides [113], starting from diastereomeric sulphinic esters, for example, the *l*-methyl ester. It is quite probable that in this reaction there is an inversion of configuration at the sulphur atom; in support of this there are the recently obtained optical rotatory dispersion curves of these classes of compounds [114]. The reversal of the configuration during substitution at the sulphur atom in sulphonic acids has also been established recently [115].

## 4. GROUP IV

A few compounds of silicon were resolved into antipodes by Kipping [116] at the start of the century. About this time Pope and Peachey [117] resolved ethylhalogenomethylpropyltin. In the thirties their result was confirmed by Manulkin [118], who also described an optically compound of germanium [119], In all three instances a very small angle of rotation was observed, so that the experiments cannot be considered completely reliable.

The first trustworthy example is the resolution of the organosilicon compound (XXIX) recently described by Eaborn and Pitt [120]:

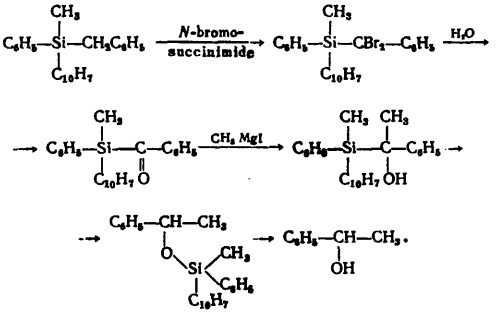
(XXIX)

but the stereochemistry of silicon began in earnest with the work of Sommer's laboratory [121-123], where success was achieved in separating the diastereomers $R_1R_2R_3SiOR^*$, and then isolating optically pure $R_1R_2R_3SiX$, where $R_1$ = 1-naphthyl, $R_2$ = phenyl, $R_3$ = methyl, and X = various substituents, including H, F, Cl, Br, OH, $OCH_3$, $C_2H_5$, etc. The American investigators used these enantiomers for a broad study of the stereochemistry and mechanism of substitution at the silicon atom [124-126].

Without dwelling in detail on this work, we will note the cases when the results differ from the corresponding ones for the carbon atom. For example, homolytic replacement of hydrogen by molecular chlorine takes place with retention of the configuration:

$$R_1R_2R_3SiH \xrightarrow{Cl_2} R_1R_2R_3SiCl.$$

Significantly, the configuration is also retained in some, but not all, reactions of nucleophilic substitution reactions of type $S_N2$:



$$R_1R_2R_3SiOCH_3 \xrightarrow{LiAlH_4} R_1R_2R_3SiH,$$
$$R_1R_2R_3SiOCH_3 \xrightarrow{Bu^tMgCl} R_1R_2R_3SiH.$$

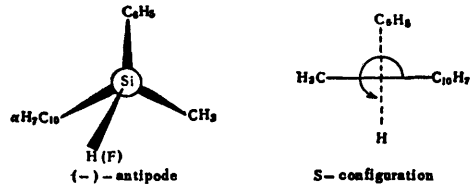
This agrees with earlier results about the readiness of the $S_N2$ reaction at the silicon atom at the head of the bridge [127] which certainly proceeds with retention of the configuration. In comparison with carbon, the anomalous, behaviour of silicon in nucleophilic substitution reactions is explained by the presence in silicon of a vacant *d* orbital, which also serves as an acceptor of the electron pair of the substituting agent at the rate-determining stage of the process.

There is special interest in the asymmetric silicon atom, for this is the first isolated non-carbon atom whose configuration has been determined. Two groups of research workers established simultaneously by different methods the absolute configuration of $R_1R_2R_3SiX$: Pepinsky [128] by means of X-ray analysis of isomorphic crystals of silane and fluorosilane, and Brook and Limburg [129] by chemical means (Fig. 3).

The relative configurations were established earlier by the method of quasiracemates and optical rotatory dispersion [124]: (-)-$R_1R_2R_3SiH$, (-)-$R_1R_2R_3SiF$, and (+)-$R_1R_2R_3SiCl$ have the same configuration.

The following scheme shows the succession of reactions which Brook and Limburg used [129] to establish the configuration:

The regrouping of an $\alpha$-hydroxysilane into a silicon ether of the corresponding alcohol used here was discovered earlier [130]. Cram's rule, which determines which of the



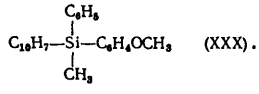


Fig. 3.

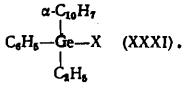
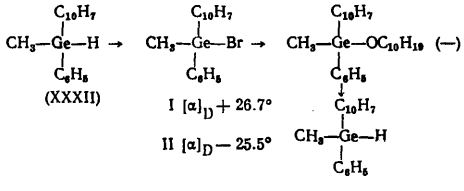


diastereomers is formed in excess, depending on the configuration of the neighbouring asymmetric silicon atom, applies at the stage of addition of the Grignard reagent at the carbonyl group. Finally, from the sign (and configuration) of the 1-phenylethanol the configuration of the silicon atom can be determined unambiguously if it is assumed that regrouping of the $\alpha$-hydroxysilane (under alkaline conditions) occurs with retention of the configuration.

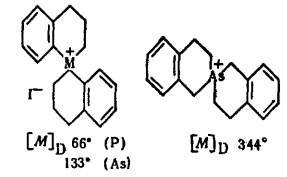
Eaborn [131] used the optically active compound (XXX) for studying the replacement of an aryl radical by a halogen, with retention of the configuration:



(XXX).

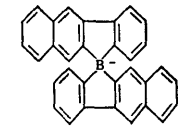
There has been an extremely rapid development of the stereochemistry of the elements of Group IV in the last few years. Following Sommer's method, Bott *et al.* [132] first made a reliable resolution of compound (XXXI) with an asymmetric germanium atom:

(XXXI).



Immediately after this Brook and Peddle [133] published a detailed investigation of the reactions of optically active methyl-1-napthylphenylgermane and its derivatives. The scheme of separation into antipodes, which is similar for silicon and germanium, is:

The second reaction, carried out by Sommer and coworkers for silicon, was found by Brook and Peddle [133] to be completely analogous in steric course for germanium, except for the replacement of hydrogen by bromine, which occurred with racemisation (in the case of silicon there was retention of the configuration). They also established the absolute configuration of the germanium atom, using the structural identity of compound (XXXII) and the analogous silane and employing the method of quasiracemates. As expected, the enantiomers of silane and germane of the same configuration have the same sign of rotation.



## 5. SPIRANS WITH A NON-CARBON SPIRO-ATOM

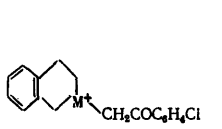
There is a limited group of spiro-compounds containing a hetero-spiro-atom which exhibits optical activity because of the asymmetry of the molecule as a whole. Formally, they are not within the scope of this review, but they are closely connected with the problem of the influence of the nature of the non-carbon atom on the magnitude of the optical rotation. The synthesis and resolution of these compounds was carried out in Mann's laboratory in Cambridge [134-136].

These compounds form a "eutropic series" (unfortunately, of only two members), in which there is an increase in the molecular rotation with the atomic weight (from phosphorus to arsenic).

Torsell [137] described the opposite case (when the spiran system forms an anion, not a cation), the spiro-position being occupied by a boron atom:

(XXXIII).

The molecular rotation of this anion, calculated from the rotation of its salt with an optically active ammonium cation, is -338°. It was first shown that the rotation of the cation (benzylmethylphenylpropylammonium) is independent of the anion and amounts to -258°.

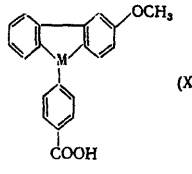


## 6. INFLUENCE OF THE ASYMMETRIC ATOM ON THE OPTICAL ROTATION

The problem of the optical activity of compounds with an asymmetric non-carbon atom must find a complete solution within the framework of the general problem of the optical activity of both organic and inorganic molecules. However, a general theory has not yet been established. The contemporary theoretical concepts relate mainly to compounds with asymmetric carbon and *a priori* it is not obvious what will be the effect of a change in the nature of the asymmetric centre. The absence of a general theory makes it desirable to seek partial rules applicable to restricted groups of compounds.

An essential obstruction in the path of a quantitative study of the problem is that the limiting value of the angle of rotation is often unknown. The absence of a definite criterion of optical purity was for long a general deficiency in stereochemistry. The main argument was the production of antipodes with rotations identical in magnitude but opposite in sign, but this was not always reliable. It was only in 1959 that Berson and Ben-Efraim [138] proposed an absolute method for the determination of optical purity and maximal rotation, apparently without limitations in principle. However, as yet it has hardly been used, even for carbon compounds (probably on account of the necessity for working with isotopes).

After Meisenheimer, whose work will be further considered below, the dependence of optical rotation on the asymmetric atom became of interest to Mann, who constructed the only example of a "eutropic series" [77] in which



there has been observed a significant increase in molecular rotation in the series: sulphur < selenium < tellurium.

| | $[M]_D$ picrate |
|---|---|
| S | 250° |
| Se | 530° |
| Te | > 750°. |

A second example is provided by the spiro-derivatives of phosphorus and arsenic referred to above [136].

The insignificant increase in $[M]_D$ found by Campbell [45-49] for compounds (XXXIV) on replacing As by Sb cannot be considered conclusive, because the rotations of pyridine solutions of the acids were compared.

(XXXIV)

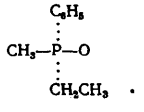
There is no guarantee that the extent of salt formation was the same; it is also completely unknown how the angle is affected by the increase of electron density on the arsenic or antimony atom due to the influence of the substituent through the benzene ring.

Subsequently we will attempt to analyse the published information relating to molecules of comparatively simple structure, on the basis of the system proposed in 1959 by Brewster [12-14]. It was found that this semi-empirical method successfully predicts the sign and magnitude of the rotation of wide circle of compounds with asymmetric carbon atoms (assigned configuration), when steric hindrance and strain do not play a large part [139]; in particular, the method is also applicable with a metal atom as the asymmetric centre [140]. Interesting work on the calculation of the rotation of polymeric hydrocarbons has been published [141].

According to the rule of conformational asymmetry, the contribution to the molecular rotation of the dissymmetrical structural unit represented in Fig. 4 is given by the expression:

$$\Delta [M]_{XY} = + k\,(X{-}H)\,(Y{-}H) = + 160\,(R_X^{1/2} - R_H^{1/2})\,(R_Y^{1/2} - R_H^{1/2}).$$

This is based on the idea of the rotational capacity being proportional to the square root of the atomic refraction, after which the additivity principle applies. The quantities $\Delta[M]_{XY}$ are determined from experimental results and in almost every case they agree well with calculation by the right-hand side of the equation. It can be assumed, as Brewster does in a footnote to one of his papers [14], that the constant $k$ is linked in some manner with the nature of the asymmetric centre and retains a constant numerical value (160–165) only in dealing with carbon. Brewster suggested the possibility of a change in $k$ when the central atom had a polarisability differing greatly from that of carbon. It is completely unknown whether the form of the function is then retained (that is, $k = \beta R_0^{1/2}$, where $R_0$ is the refraction of the central atom), or whether, within the framework of the stated approximate method, the nature of the asymmetric centre is allowed for in the numerical value of $k$ in another way. It should be noted that in the calculation of $\Delta[M]$ by the conformational asymmetry rule, constant $k$ should be a function of the parameters of two atoms $k = f(1, 2)$, and not $k = f(1)$, where 1 is an asymmetric atom and 2 a neighbour which participates in the formation of an axis of the Newman projection. Since atom 2 is known to be carbon it must be expected that the value of $k$ would only change slightly on changing the asymmetric atom, so that this change would not be experimentally observable at every $R_0$.



It is significant that when Brook and Limburg established the absolute configuration of silicon in methyl-1-naphthylphenylsilane, in 1963, they noted the agreement of the sign of the rotation for three substances with that predicted by Brewster's method. That showed for the first time the applicability of the atomic asymmetry rule to a non-carbon centre (qualitative aspect).

We calculated [142] the rotation of ethylmethylphenylphosphine by the conformational asymmetry rule using the value of $\Delta[M]_{XY}$ which is used for carbon compounds. Two antipodes are obtained experimentally [9,24], with $[\alpha]_D = \pm 22.8$, $[M]_D = 37.8 \pm 1.7°$. Fig. 5 shows two permissible conformations of this compound. Assuming them to be equally probable [12], we obtain:

$$[M]_D = \frac{-k(C{-}H)(C_{Ar}{-}H) - k(C{-}H)(O{-}H) + k(C{-}H)(O{-}H) + k(C{-}H)^3}{2} = -\frac{140-60}{2} = -40°.$$

For this calculation, it is necessary to know the rotational constant for oxidic oxygen (although it can also be calculated from refractometric data). The only assumption which is made is that the effective volume of oxygen is small in comparison with that of the methyl group.

Bearing in mind the precedent of the absolute configuration of silicon [129], the good agreement suggests that the (+) antipode of the oxide can be ascribed to the R configuration with a high degree of probability:

Since there has been a correlation of the configuration of this compound with a tertiary phosphine and a phosphonium salt [38], their absolute configuration is also determined [142].

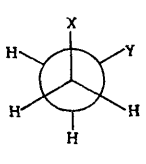


Fig. 4.

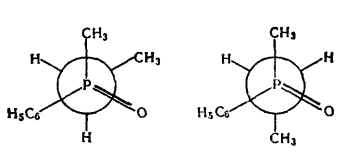

Fig. 5.

A comparison of the rotations of corresponding amine and phosphine oxides in various solvents, from Meisenheimer's data[9], is especially interesting (Table 3). Comparison of the values in Table 3 suggests that the essential role is played not by the nature of the central atom but by the character of its bond with oxygen (possibly, the degree of charge separation). The difference in $[M]_D$, very great in a non-polar solvent, disappears completely on passing to the hydrochloride, when the M–O bonds becomes of the same type as the others. It is significant that this takes place on account of a change in the rotation of the amine oxide, which increases regularly as the polarity of the N–O bond decreases, whereas the rotation of the phosphine oxide (bond not purely semipolar) is almost independent of the solvent. The calculation given above also describes the rotation of the amine oxide hydrochloride. The anomalously low rotation of the amine oxide in benzene may be explained by the formation of associates in the absence of reaction with the medium.

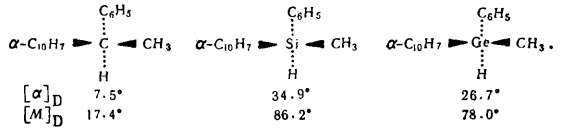
Meisenheimer's results with analogous compounds were not very definite, and are not always understood. Thus benzylmethylphenylphosphine has $[M]_D = +162°$ in HCl and $-17°$ in chloroform! Such a marked difference seems inexplicable. It is true that the experiment in this case, as in some others, is not completely reliable because the value of $[M]_D$ is often estimated from the difference in rotation of the diastereomers.

It is interesting that the molecule of ethylmethylphenyl--phosphine or -arsine is structurally similar to 2-phenylbutane. Calculation by Brewster's method for the two compounds gives a single value: $[M]_D = 40°$, which agrees well with that found experimentally for the hydrocarbon [143]. The results for phosphines and arsines[54-56] do not agree very well with one another but the simplest molecules have $[M]_D = 27.8°$. Here again there is the impression that the replacement of phosphorus by arsenic has no effect. The following discussion shows that this can be explained by distortion of the tetrahedron of the hetero-atom in the absence of a fourth substituent (compare Fig. 6).

The presence of a free electron pair instead of a fourth substituent necessitates the approach of the phosphorus atom to the plane of formation. If the Newman projection is constructed along the $R_2$–P bond, then the change in the angles of the pyramid also leads to a change in the angles between the substituents in the projections, the direction of which is easily understood. Evidently, in the limit the atom of phosphorus tends to take up a position in the plane $R_1R_2R_3$, and in the projection $R_1$ and $R_3$ would be situated on a single straight line. Actually at this moment the molecule acquires planar symmetry and loses its optical activity but as a matter of fact this state is not reached.

Further, $\Delta[M]_D$ is evidently, as Brewster once proposed, a sinusoidal[12] function of the angle formed by the bonds in the Newman projection; the tabulated values of $\Delta[M]_D$ are specially standardised by the direct multiplier $1/\sin 60° = 2/\sqrt{3}$ for the normal angle of 60°. Therefore if we wish to calculate the influence of a variable angle the multiplier should be $(2/\sqrt{3})\sin\varphi$. For the limiting point $\varphi = 30°$,

$$[M]'_D = \frac{2}{\sqrt{3}} \sin 30° [M]_D = \frac{1}{\sqrt{3}} \times 40° \simeq 23°.$$



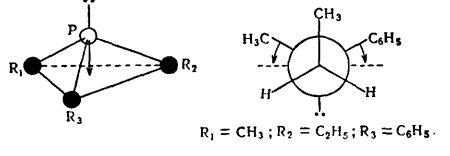
Consequently, in this way the lower limit for the angle of rotation can be roughly evaluated; as a result:

$$23° < [M]_D < 40°.$$

It is evident that the experimental value does not contradict this inequality.

Unfortunately there is no information on the rotation of phosphine salts; it seems that $[M]_D$ of the cation must be close to 40°.

The most valuable material for comparison relates to Group IV, for which Brook[144] constructed the first "isoconfigurational series" of enantiomers $R_1R_2R_3R_4M$ with identical structure and configuration, which differ only in the nature of the asymmetric atom M:



First of all it appeared that all (+) enantiomers have the absolute configuration R: the nature of the central atom does not affect the sign of the rotation. The optical rotatory dispersion curves are essentially similar and have a positive Cotton effect (Fig. 7).

The carbon analogue exhibits a much smaller angle of rotation: Brook finds that the rotation is a linear function of the electronegativity of the central atom.

It appears possible that the increase in $[M]_D$ on passing from carbon to silicon and germanium is due to the appearance of free *d* orbitals. It is known that there is an electronic displacement in the direction from aryl to silicon or

TABLE 3. $[M]_D$ of a phosphine oxide and amine oxide in various solvents.

| | $(CH_3)(C_6H_5)(C_2H_5)P \rightarrow O$ | $(CH_3)(C_6H_5)(C_2H_5)N \rightarrow O$ |
|---|---|---|

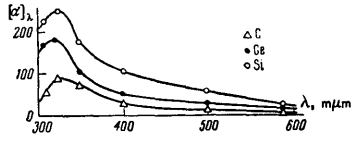
| Water | +38° | +24° |
| HCl | +40° | +40° |

$R_1 = CH_3$; $R_2 = C_2H_5$; $R_3 = C_6H_5$.

Fig. 6.



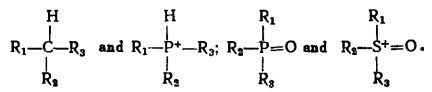


Fig. 7.

germanium [145]. There are several consequences, one of which may also affect the optical rotation: (1) increased electron density on the asymmetric atom; (2) shortening of the metalloid–aryl bonds on account of partial doubling of the bonds; (3) hindrance to free rotation about these bonds for the same reason.

Whereas in a carbon compound the rotation about C–aryl bonds, generally speaking, is free, then on account of the partial double bond character, some orientation of the ring can be preferred. In this sense it is interesting that passing from silicon to germanium has little effect on $[M]_D$. If the reason actually consists in the presence of the *d* orbital then a subsequent change, to an asymmetric tin atom, should slightly affect the rotation.

The relation of concentration of electron density at the asymmetric atom to the optical rotation is also of interest. This can most conveniently be traced by introducing various substituents in the aromatic ring adjacent to the asymmetric atom. In one instance [90] the replacement of hydrogen by a nitro-group significantly reduced the angle. Unfortunately investigations of this type have not been carried out in carbon stereochemistry, with a few exceptions [146-148]. Valuable information can be obtained by comparison of structurally analogous molecules containing asymmetric atoms which belong to different groups of the Periodic System (influence of charge), for example:

Such data are still absent. Naturally the study of each of these problems requires considerable experimental work.

# ABILITY OF ELEMENTS TO FORM POLYMERS WITH INORGANIC CHAIN MOLECULES

K.A.Andrianov, I.Khaiduk [I.Haiduc]†, and L.M.Khananashvili

The chemistry of organoelemental compounds is being intensively developed as an independent branch of chemistry in the direction of studying the general regularities of the formation and transformation reactions of the organoelemental compounds, the investigation of the reactivitv of various compounds, and also in the field of the synthesis and study of the properties of high-molecular-weight compounds.

The development of the chemistry of high-molecular--weight organoelemental compounds is linked not only with the study of the transformation reactions of the monomeric compounds into polymers, but also with the investigation of the possible uses of various elements and their compounds for the synthesis of polymers. The synthesis of organoelemental polymers is complicated by the variety, not only of monomeric compounds, but also of elements whose monomeric compounds can be used for this purpose. Therefore we consider some aspects of the theory which characterise the ability of various elements to form homo- and hetero--chain polymers. Polymers which do not contain carbon atoms in the chain are known as polymers with inorganic main-chain molecules, framed‡ by various organic, inorganic, and organoelemental groups.

At present the general principles which determine the formation of inorganic chains of molecules of various elements have been insufficiently worked out, and the known reactions for the synthesis of polymers, for example, polyorganosiloxanes, are always accompanied by the formation of cyclic compounds, which serve as "monomers" for the synthesis of high-molecular-weight compounds.

The use of inorganic cyclic compounds framed by organic groups for the production of polymers is also linked with the fact that unsaturated compounds of the general formulae $R_nE{=}O$ and $R_nE{=}ER_n$, capable of polymerising through the double bonds, as in the synthesis of organic homo- and hetero-chain polymers[1-3], have not yet been obtained.

An attempt will be made here to establish the most important factors which determine the ability of elements to form inorganic rings and chain molecules, framed by organic and organoelemental groups. It is evident that the routes to the formation of inorganic rings and chain molecules are extremely varied, not only on account of the large number of elements which can be used to construct these chains, but also on account of the diverse types of chemical bonds which may be used in the formation of cyclic and chain polymeric compounds.

Two types of chemical bonds play an important part in the formation of polymers with inorganic chain molecules: covalent and coordination. They can be the basis for the formation of large molecules of various structures. Aggregates, consisting of a large number of ionic particles bound to one another by ionic bonds, for example, ionic crystals, cannot be considered as proper molecules, and such structures are not true polymers, although they consist of a large number of structural units. It is true that covalent bonds between elements with different electronegativities have polar character, or, in other words, are partly ionic, preventing the strict demarcation of polymers with inorganic chain molecules from ionic aggregates (crystals). Usually ionic aggregates have a three-dimensional structure, whereas for polymers there is greater interest in chains of linear, branched, or network type of molecular structure. The present review considers mainly polymers with chain molecules of such structure, for otherwise we would have to consider a large number of inorganic compounds going beyond the bounds of polymer

‡ Not considered in the text of the review.

† Present address: Universitatea "Babes-Bolyai" Cluj, Facultatea de Chimie, Cluj, Roumania (Ed. of Translation).

‡ The term "framed" presumably means having side-groups of the type mentioned (Ed. of Translation).

chemistry (for example, borides, silicides, silicates, and phosphides), although in broad conception they can be classified as high-molecular-weight compounds. Coordination polymers will also not be considered here. Polymers with inorganic chain molecules can also be formed using multicentric bonds, characteristic, in particular, of the boron hydrides [4-6]. However, such compounds have low stability, oxidise and hydrolyse readily, and also will not be considered here. Hence this article considers the ability of elements to form polymers with inorganic chain molecules framed by organic and organoelemental groups of the covalent and ionic type of chain structure.

General consideration of the experimental material both on homocyclic compounds and on compounds with chain molecules shows that unlike organic chemistry homo-rings play a lesser part and homo-chain molecules with a high degree of polymerisation are not formed. This is the result of the essential difference between the properties of carbon and those of other elements (and even of the non-metals of Periodic Group IV), in terms of ability to form stable chains or cyclic compounds consisting of the same atoms.

On the one hand, the energy of the C–C bond is greater than the E–E bond of other elements (Table 1), and on the other hand the C–C bond is chemically more inert than the E–E bond of other elements.

Carbon forms various types of chain molecules based on the C–C bond: linear, branch, network, cyclic. For other elements – either non-metals or metals – the formation of homo-chain molecules with a significant degree of polymerisation is not characteristic. Only compounds containing short E–E chains are known. For example, silicon forms long chains in the molecule $Si_{25}Cl_{52}$ where 25 atoms of silicon are directly linked [10], but this compound is unique and in other homologous series the highest terms are $Si_{10}F_{22}$,[11] $Si_4Br_{10}$,[12] $Si_6H_{14}$.[13] The longest Si–Si chain with organic side-groups is the molecule $Si_9(C_6H_5)_{16}(CH_3)_4$, where nine silicon atoms are directly linked [14]. Recently a series of polymeric compounds with P–P bonds has been described [15], but a very large degree of polymerisation was not attained.

On the contrary, the possibility of forming organoelemental hetero-chain molecules is much wider than in carbon chemistry, but the realisation of such possibilities is not always clear, since they are linked with the properties of various elements to form stable cyclic and chain molecules with one another. The tendency of various elements to form cyclic compounds and chain molecules depends on the chemical properties of the elements and, in particular, their electronic structure. We consider that an important factor determining the ability of an element to form hetero-chain polymeric molecules is its electronegativity and the electronic hybridisation of its atoms [16].

TABLE 1. E–E bond energies.

| Bond | Bond energies | | | Bond | Bond energies | | |
|---|---|---|---|---|---|---|---|
| | Ref. 7 | Ref. 8 | Ref. 9 | | Ref. 7 | Ref. 8 | Ref 9 |
| C–C | 83.1 | 66.2 | 64 | As–As | 32.1 | 35 | 38 |

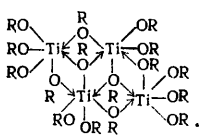
Consideration of the electronegativity of various elements (Table 2) shows that carbon occupies a central position between the most electronegative element, fluorine ($x_F = 4.0$) and the most electropositive element, caesium ($x_{Cs} = 0.8$).

Therefore carbon has the least tendency to donate or receive electrons, that is, to form positive or negative ions and less to submit to electrophilic or nucleophilic attack. This is one of the reasons for the stability of carbon chain molecules. Other elements possessing electronegativity close to carbon, for example, sulphur and selenium, are also characterised by an ability to form long chains of similar atoms, S–S or Se–Se. This explains also why other elements form less stable homo-chain structures.

If an element has an electronegativity greater than that of carbon, the homo-chain is of low stability on account of the tendency to produce electrons. Therefore long chains or rings consisting of N–N or O–O bonds are unstable. If the electronegativity of an element is less than that of carbon, the stability of the E–E bond is diminished, on account of the tendency to yield electrons. Hence B–B, Si–Si, P–P, As–As, and Ge–Ge bonds are readily oxidised and are less stable than the C–C bond.

The great stability of bonds between atoms of elements of different electronegativities (greater and less than for carbon) is probably linked with the compensations of opposite tendencies of the atoms which form the chain to give and receive electrons. Comparison of the mean electronegativities of the interconnected elements shows that for many pairs of elements the mean value is close to the electronegativity of carbon. Inorganic hetero-rings and polymers with organic side-groups, formed by alternation of two interconnected elements, have mean electronegativities differing from that of carbon by 0.35–0.40 units [17]. The following pairs of elements, for example, fall within this interval:



| | | | | | | |
|---|---|---|---|---|---|---|
| B–N | Al–N | Si–N | Ge–N | Ti–N | Sn–N | (Pb–N) |
| B–O | Al–O | Si–O | Ge–O | Ti–O | Sn–O | Pb–O |
| B–S | (Al–S) | Si–S | Ge–S | (Ti–S) | Sn–S | Pb–S |
| P–N | As–N | (Sb–N) | S–N | Se–N | — | — |
| P–O | As–O | Sb–O | — | Se–O | Mo–O | W–O |
| P–S | As–S | Sb–S | S–S | Se–S | — | — |

For all these pairs, except those in parentheses, inorganic rings [16,18] and some polymers [3,4,19] have been described. It should be noted that the concept of electronegativity relates to a simple bond of the interconnected elements and does not take into account that in molecules it

is possible for additional donor–acceptor bonds to be formed, unshared electron pairs to be delocalised, multicentric bonds to be formed, induction effects to operate, etc.[20]

An important factor, determining the ability of an element to form hetero-rings or hetero-chains, with organic side-groups, is the characteristic hybridisation of the electron cloud of the elements. It is determined by the number and direction of the chemical bonds, the presence or absence of unshared electron pairs and free orbitals, and also by the coordination number of the elements. Of course, the coordination number, that is, the number of atoms of one element with which the atoms of another element can be bound, is determined by steric factors (that is, the relation between the dimensions of the given atoms) as well as by electronic hybridisation.

Fundamentally, the coordination number (c.n.) of elements of the second period of the Periodic System is not greater than four. With elements of the third period the c.n. can reach 6, but the corresponding configuration is unstable. With elements of the fourth and fifth periods a higher c.n. is easily effected. The elements of these periods form octahedral structural units (at c.n. = 6), which readily unite to form monocyclic compounds and linear polymers and often form polymers with other types of structures, in particular, polycyclic coordination polymers. For example, the tetramer tetraethoxytitanium $[Ti(OC_2H_5)_4]_4$ is not a monocyclic coordination compound, as might be expected, and its molecule consists of four octahedra with Ti atoms at the centre, joined at the vertices[21], which can be represented by a structural formula containing four-membered Ti  Ti rings:

Inorganic rings and chain molecules are formed by alternation of two elements of different electronegativity, therefore it is important to consider, on the one hand, elements having an electronegativity greater than that of carbon (that is, oxygen and nitrogen) and, on the other, elements having an electronegativity less than that of carbon, in particular the non-transition elements: boron, aluminium, silicon, germanium, tin, lead, titanium, phosphorus, arsenic, and antimony. Sulphur and selenium, which have an electronegativity close to that of carbon, occupy an intermediate position.

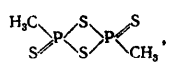
The electronegative elements, oxygen and nitrogen, have the following structure of the valency electron shells:

$$\text{oxygen} - 2s^2\ 2p_x^2p_y^1p_z^1,$$

$$\text{nitrogen} - 2s^2\ 2p_x^1p_y^1p_z^1,$$

and form chemical bonds by virtue of the $p$ orbital. Covalent bonds, using $p$ orbitals, are separated by an angle of 90°. Both oxygen and nitrogen retain unshared electron pairs. They can form additional coordinate bonds or be delocalised intramolecularly into free orbitals of the element bonded with the oxygen or nitrogen. This means, in other words, the participation of the unshared pair of electrons in electronic hybridisation with the $p$ orbitals which leads to a change in the valence angle of oxygen or nitrogen from 90° to greater values. Therefore the angle of the N< or O< bonds can indicate the delocalisation of the unshared electron pairs or their partial participation in hybridisation with the $p$ orbitals. In inorganic hetero-rings there is the same phenomenon: the angles of the R–N< and O< bonds vary widely, depending on the elements with which they are connected.

Thus the valence angle of oxygen in a ring varies from 112° ± 4° in trimethylboroxole[22] to 142.5° in octamethylcyclotetrasiloxane[23]. The valence angle of nitrogen in a ring varies from 91.7° ± 2° in *N*-bis(trimethylsilyl)tetramethylcyclodisilazane[24] to 131° in octachlorocyclotetraphosphazene[25] and octamethylcyclotetraphosphazene[26].



Since the valence angle can change over a wide range, oxygen, nitrogen, and sulphur have a great possibility of forming heterocyclic and hetero-chain polymeric compounds with many less electronegative elements.

Sulphur, as the electronegative element of a hetero-ring, is usually bivalent. The same can be said about selenium. The valence electrons of sulphur and selenium are disposed thus in the outer shell:

$$S^{II} \text{ and } Se^{II};\ s^2;\ p_x^1p_y^1p_z^1.$$

Evidently sulphur and selenium in the divalent state form $p^2$ bonds with a valence angle of 90°. This value is also observed in hydrogen sulphide, $SH_2$, but in the homo-ring $S_8$ it even acquires the value 107°.[27,28] The valence angles of sulphur in inorganic hetero-rings also vary over a wide range — from 75° in tetramethylcyclodisilthiane[29] to 138° in tribromoborosulphone[30].

However, sulphur has a tendency to form bonds of small angles: in the compound:

the valence angle of the sulphur in the ring is 84°,[31] but in hexamethylcyclotrisilthiane it is 110°.[29] In this connection the valence angle in tribromoborosulphone seems excessively large. Sulphur easily forms valence angles less than 90°, which facilitates the formation of four-membered rings with boron, silicon, and phosphorus, whereas not a single oxygen-containing four-membered ring is known (excepting coordination rings) and only one nitrogen-containing four-membered ring ($S_2N_2$). Hence the conclusion that the valence angles of nitrogen, sulphur, and oxygen are not the decisive influence on the formation of inorganic rings since they can be varied over a wide range of values and probably will not impede cyclisation with any less electronegative partner-element. However, they can determine the number of groups of interbonded elements in the hetero-ring and facilitate the formation of only one or two more sterically favourable hetero-rings from a whole series of possible ones. For example, 6-, 8-, 10-, and 12-membered hetero-rings, etc., with Si–O bonds are known, but $Si_2O_2$ hetero-rings are unknown. The hetero-rings $Si_2N_2$, $Si_3N_3$, $Si_4N_4$ are known, but the hetero-rings $Si_5N_5$ and $Si_6N_6$ are not known, although their oxygen analogues have been obtained[18].

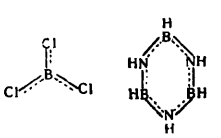
There are now experimental data which show that combination of an element with oxygen leads to the formation of long E–O–E–O– chains more easily than combination of the element with nitrogen or with sulphur. In the case of

E–N and E–S alternations the tendency to ring formation is more sharply expressed and this probably explains why long E–N–E–N or E–S–E–S chains have not yet been obtained and why attempts to prepare them result only in derivatives of the corresponding rings. An exception is provided by the phosphazenes, but in such derivatives the valence angle of the nitrogen is greater and reaches values characteristic for oxygen. Evidently a small valence angle for an electronegative element facilitates cyclisation and hinders the formation of long chains. Hence the conclusion not only about the significance of steric factors but also that oxygen-containing inorganic polymeric chains are capable of reaching a high degree of polymerisation.

The value of the bond angle of an electronegative element is also determined by the number of atoms in an inorganic hetero-ring. For example, comparing the known hetero--rings of silicon formed by alternation of silicon with oxygen, nitrogen, and sulphur:

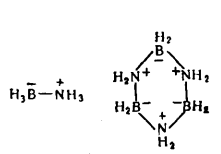
$$\underline{Si_2O_2}\ \underline{Si_4O_4}\ Si_6O_6\ Si_8O_8 \ldots Si_nO_n$$
$$Si_2N_2\ \underline{Si_3N_3}\ \underline{Si_4N_4}$$
$$\underline{Si_2S_2}\ \underline{Si_3S_3}\ Si_4S_4$$

(rings which are formed readily are underlined), we can conclude that on passing from oxygen-containing to nitrogen- and sulphur-containing cyclic compounds of silicon the tendency towards formation of lower-molecular-weight rings grows simultaneously with a decrease in the valence angle of the electronegative element.



Let us now consider the hybridisation of elements more electropositive than carbon.

The atoms of Group III of the Periodic System (main subgroup): boron, aluminium, gallium, indium, thallium, are characterised in their compounds by $sp^2$ and $sp^3$ hybridisation: the latter is observed in the formation of an additional coordinate bond.



For boron $sp^2$ hybridisation is particularly characteristic. It determines the planar distribution of the bonds at an angle of 120°. This explain the planar structure of such molecules as $B(CH_3)_3$, $BF_3$, $BCl_3$, and the comparative ease of formation of $B_3N_3$ and $B_3O_3$ planar hetero-rings.

The elements of Group III have a free $p$ orbital which can be used by an unshared pair of electrons. With boron this can take place in two ways:

1. Intramolecular delocalisation of unshared electron pairs of an element bonded to boron (the formation of additional $\pi$ bonds between boron and the element bonded to it):

2. The formation of coordinated monomeric and cyclic compounds of boron (with $sp^3$ hybridisation of $\sigma$ bonds between boron and the element bonded to it):

In this case the bonds to boron are tetrahedrally directed, as in the carbon atom.

The advantageous valence angle of boron (120°) and the possibility of using its vacant $p$ orbital can evidently explain the fact that in all the reactions the formation of only 6-membered $B_3N_3$ and $B_3O_3$ rings is observed.

The formation of an 8-membered $B_4N_4$ ring [32] or the linear chain B–N–B–N– (with a low degree of polymerisation) [33] is observed only when the formation of a six-membered ring is sterically hindered.

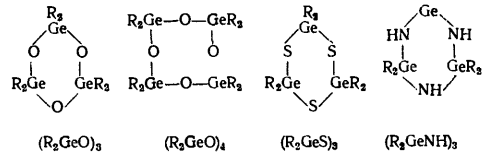
With aluminium, gallium, indium, and thallium the tendency to use free $p$ orbitals is still greater than with boron, which leads to the formation of compounds with coordination number 4 or even 6 (since these elements can use the $d$ orbital). This leads, in particular, to the formation of coordinated rings and polymeric chains of aluminium, gallium, etc.

The elements of Group IV of the Periodic System have four electrons in the valency shell and with carbon three types of hybridisation are possible:

$sp^3$ four $\sigma$ bonds (tetrahedral direction);
$sp^3$ three $\sigma$ bonds (triangular direction) + one $\pi$ bond;
$sp$ two $\sigma$ bonds (linear direction) + two $\pi$ bonds.

Carbon does not possess $d$ orbitals. Hence in any hybrid state a carbon atom uses all its valency electrons and orbitals, that is, carbon has neither unshared electron pairs nor vacant orbitals.

The remaining elements of the principal subgroup of Group IV — silicon, germanium, tin, and lead (in the quadrivalent state) — possess empty $d$ orbitals. Usually four valency electrons participate in $sp^3$ hybridisation while the $d$ orbital remains vacant. Hence the structure of most of the compounds of these elements comprises a few united tetrahedra. The tendency to form $p_\pi$ bonds is quite insignificant for these elements and therefore the elements Si, Ge, Sn, and Pb do not form stable monomeric compounds with double bonds of the type Si=E, Ge=E, Sn=E, and Pb=E. The hybrid states $sp$ and $sp^2$ are uncharacteristic for these elements and they always change into the $sp^3$ hybrid state. This is important in the chemistry of inorganic rings and polymers with inorganic chain molecules, for thanks to the instability of the $sp$ and $sp^2$ hybrid states, the derivatives of silicon, germanium, tin, and lead, which from their composition should possess multiple bonds, polymerise to form rings or polymeric chains of various structures. For example, all compounds with the general formulae $R_2SiO_2$, $R_2SiNR'$, and $R_2SiS$ are polymerised with the formation of cyclic or polymeric structures [1-3,18].

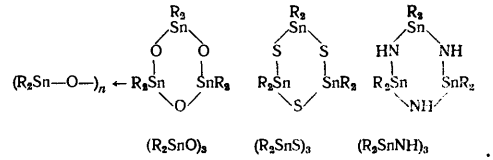


The existence of five vacant $d$ orbitals of silicon would in principle permit the formation of another five coordination bonds by filling them with unshared electron pairs of another element, but this is almost impossible sterically. The c.n. of silicon reaches six in the anion $[SiF_6]^{2-}$ and in certain complexes of $SiF_4$ with amines, which becomes possible owing to the small dimensions of the fluorine atom. With increase in the dimensions of the ligand the c.n. of silicon diminishes: the ion $[SiCl_6]^{2-}$ is unstable and the similar ion with bromine is generally not formed.

In relation to oxygen, silicon usually exhibits c.n. = 4, but some examples are known in which the silicon is linked with six oxygen atoms, for example, in an acetylacetonato--complex [34]. Silicon with c.n. = 5 is formed in an intermediate complex in several chemical reactions [35]. This is important in the chemistry of inorganic rings and polymers based on silicon, since such intermediate complexes appear

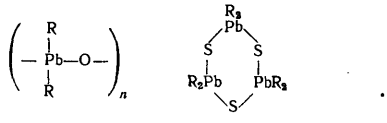
in the reactions of ring opening, telomerisation, and polymerisation by both electrophilic and nucleophilic reagents [3,18].

The presence of the empty *d* orbitals of the silicon atom brings about intramolecular delocalisation of the unshared electron pairs from atoms of oxygen, nitrogen, and chlorine bonded to the silicon. This leads to the appearance of double-bonding between such elements as Si–O, Si–N, and Si–Cl. In the chemistry of inorganic rings and polymeric chains this plays a determinative role and is probably one of the factors affecting the thermal stability of these compounds.



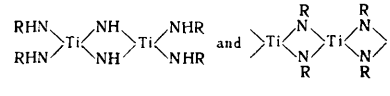
Similar conclusions can be drawn for germanium, tin, and lead. Germanium compounds of type $R_2GeO$, $R_2GeNR'$, and $R_2GeS$ are not monomeric. Cyclic and polymeric diorganogermoxanes [36] and trimeric organogermathianes $[R_2GeS]_3$ [37] have been described. It is interesting to note that the molecular weight of $R_2GeNH$ (R = $C_2H_5$) is close to that of a trimer [38] which indicates a cyclic structure:

$(R_2GeO)_3$ $(R_2GeO)_4$ $(R_2GeS)_3$ $(R_2GeNH)_3$



The molecular weight of the polymer $(R_2GeO)_n$ [36] is unknown.

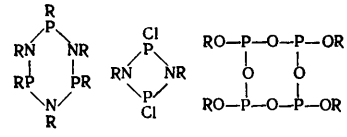
Tin derivatives of the type $R_2SnO$, $R_2SnS$, and $R_2SnNR'$ are also polymeric. Oxygen derivatives of tin compounds are described as linear polymers [39] and as cyclic trimers [40]. Sulphur-containing derivatives [41] and nitrogenous derivatives [42] are cyclic trimers:



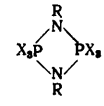
$(R_2SnO)_3$ $(R_2SnS)_3$ $(R_2SnNH)_3$

The lead derivatives of the types $R_2PbO$, $R_2PbS$, and $R_2PbNR'$ have been little studied. The oxygen derivatives are described as linear polymers [39] and the sulphur derivatives have a tripled molecular weight [43] indicating a cyclic structure:

Titanium, zirconium, and hafnium are transition elements of the fourth group and the *d* orbitals play an important part in their electronic structure. The value c.n. = 6 is characteristic for these elements and in the case of Zr and Hf even reaches c.n. = 8. Therefore the chemistry of polymeric compounds with inorganic chain molecules takes another form for these elements and the monocyclic compounds of these elements are not formed as a rule. Here, coordination polymers predominate. Titanium, for which c.n. = 4 and 6, exhibits great possibilities for the formation of rings and polymers. Compounds of the type:



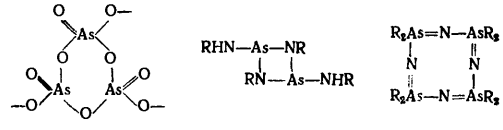
were recently described [44], reminiscent of silicon compounds with an analogous structure. When titanium has c.n. = 6, it forms polycyclic coordination compounds.



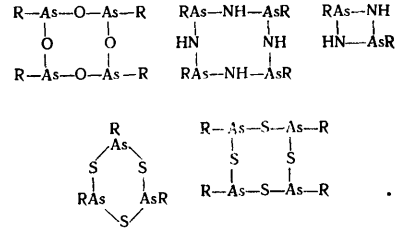
The elements of Group V have five valency electrons. Their valency is variable, and, depending on the distribution of the valency electrons in the orbitals, can be either three or five. In the case of phosphorus, arsenic, and antimony the following hybrid states are possible:

$$p^{III} - p^3;\ p^V - sp^3,\ sp^3d,\ \text{and}\ sp^3d^2.$$

The hybrid state $p^3$ plays a small part in the chemistry of inorganic rings and polymers. Only a few rings with tervalent phosphorus [43,45,46] are known:



The hybrid state $sp^3d$ is also rarely encountered in the chemistry of phosphorus and only a few cyclic compounds of this type [47,48]:

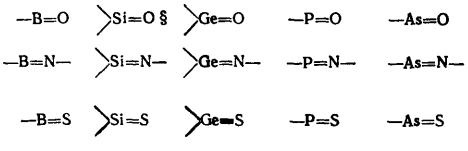


are known.

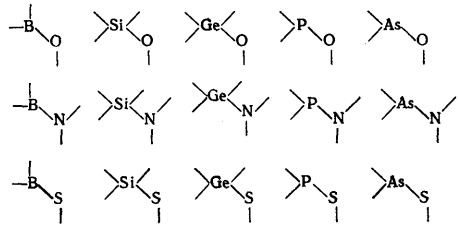
The most characteristic hybrid state of phosphorus is $sp^3$, which corresponds with the tetrahedral direction of the phosphorus bonds [49]. This hybrid state is encountered in all polymeric and cyclic compounds of phosphorus: in metaphosphates [49,50], phosphazene derivatives [51,52,53], and in phosphorus–sulphur compounds [54]. It is worth noting that phosphorus readily forms both cyclic and linear polymeric high-molecular chains.

In its compounds arsenic also usually displays the hybrid states $p^3$ (tervalent arsenic) and $sp^3$ (quinquevalent arsenic). A few cyclic arsenic compounds [55–57] and high-molecular-weight polyarsenates [4] have been described:

Compounds of the type RAsO, RAsNR', and RAsS are also known. Their molecular weights do not correspond to monomeric forms: RAsO [58] and RAsNH [59] are tetramers and RAsS trimers [58] and tetramers [60], which corresponds to the following cyclic compounds [61,62]:



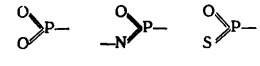
The elements of Group VI possess six valency electrons and exhibit the valencies 2, 4, and 6. Bivalent sulphur and selenium participate in inorganic rings and polymers as the electronegative element. As electronegative components sulphur and selenium enter inorganic rings and polymeric chains in the quadrivalent or sexivalent states respectively with $p^3$ (or $sp^2$) and $sp^3$ hybridisation. Cyclic compounds of sulphur with oxygen — for example $(SO_3)_x$ [63] — and nitrogen [64,65] are also now known. The non-transition elements under consideration can be divided into the following types: elements which after hybridisation have neither free orbitals nor unshared electron pairs (carbon); elements which after hybridisation have unshared pairs of electrons (nitrogen and oxygen); elements which after hybridisation have free orbitals [boron and aluminium ($p$ orbitals), silicon and germanium ($d$ orbitals)]; elements which after hybridisation have both unshared electron pairs and vacant orbitals (phosphorus, arsenic, antimony, sulphur, selenium, and tellurium).



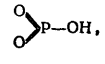
All transition elements have vacant orbitals, therefore they have a tendency to form mainly coordination rings and polymers.

As this classification indicates, carbon differs from all other elements (apart from hydrogen) in exhibiting neither free orbitals nor unshared electron pairs. In addition to its electronegativity, this property explains the especial stability of homo-chain structures with C–C bonds. Homo--rings and homo-chains of other elements, having an electronegativity close to that of carbon (for example, sulphur and selenium) enter into various reactions with electrophilic and nucleophilic reagents, on account of the existence of unshared electron pairs or vacant orbitals; therefore their reactivity is greater than for carbon chains.

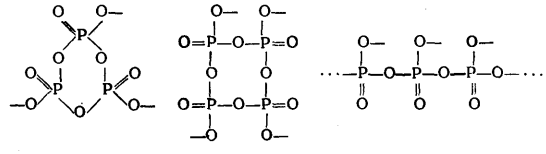
As the examples given show, each element enters into the composition of an inorganic ring or polymeric chain in the hybrid state most stable and most characteristic for it. This explains the instability of the multiple bonds of some elements with oxygen, nitrogen, and sulphur. Not a single compound containing one of the following multiple bonds:



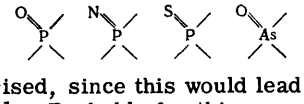
has yet been obtained. In such bonds boron, phosphorus(III), and arsenic(III) would have the hybrid state $sp$ or $p^2$, which are uncharacteristic for them. Silicon and germanium would also have the $sp^2$ hybrid state, which is uncharacteristic of them. Therefore such monomeric compounds with multiple bonds, if they are formed, would probably be labile and consequently difficult to isolate. In all the reactions in which the formation of monomers with such bonds could be expected, only cyclic or polymeric compounds with the following structural units are always obtained:



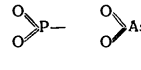
In such groups every element exhibits its stable hybridisation: boron $sp^2$, silicon $sp^3$, germanium $sp^3$, phosphorus(III) $p^3$, arsenic(III) $p^3$. Therefore, many compounds which in the initial period of development of organoelemental chemistry were considered monomers were shown by subsequent investigation to be cyclic or polymeric compounds. And now the literature contains descriptions of many compounds which are considered to be monomers with double bonds of the above type (in particular, in the chemistry of phosphorus, arsenic, and antimony), but the structure of these compounds was not studied and actually they are probably cyclic or polymeric compounds. The same can be expected of compounds of the types $R_nEO$, $R_nENR'$, and $R_nES$, where E = Al, Ga, In, Sn, or Pb.



Electronic hybridisation also provides an explanation for the instability of the groupings:

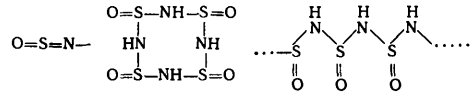


in which the phosphorus atoms have the $sp^2$ hybrid state, uncharacteristic of it. By polymerisation of such monomers phosphorus effects $sp^3$ hybridisation, which is more stable and characteristic of its quinquevalent state. Therefore, for example, metaphosphoric acid and its salts do not exist in the monomeric form:



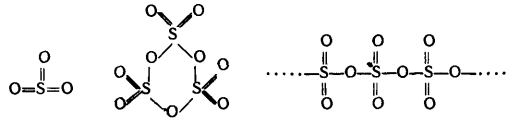
but only as cyclic or linear polymers:

On the basis of hybridisation it is possible to understand why other compounds which contain the same multiple bonds P=O, P=N, P=S (and also As=O, As=N–, and As=S–) are not polymerised. This occurs in those compounds in which the phosphorus(V) or arsenic(V) atom has a hybrid state most characteristic for it ($sp^3$). Compounds containing the grouping:



are not polymerised, since this would lead to the less stable hybrid state $sp^3d$. Probably for this reason compounds containing the groupings:

§ In mass-spectrographic investigations of polyorganosiloxane [66] the species $R_2Si{=}O$ were observed. They are formed in the depolymerisation of polyorganosiloxanes but cannot exist for any considerable time.

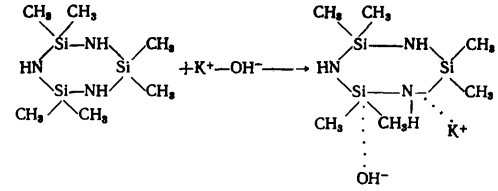


are polymerised only on account of one of the double bonds, which produces the hybrid state $sp^3$.

In the case of sulphur and selenium, the various hybridisations which are able to appear in a definite valency state, either monomeric compounds with multiple bonds or the corresponding cyclic and polymeric analogues can exist. For example, for quadrivalent sulphur the following compounds are known [65]:

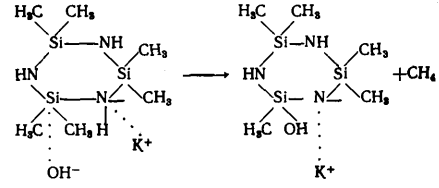
although the hybrid states of sulphur in the monomer and in the polymers are different.

In the case of sexivalent sulphur the $sp^3$ hybrid state is more stable than the $sp^2$ hybrid state, therefore sulphur trioxide polymerises with formation of a cyclic trimer and a linear polymer [63]:



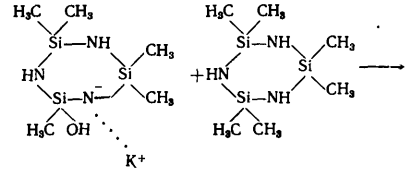
The stability of the $sp^3$ hybrid state of sexivalent sulphur explains why the sulphones $R_2SO_2$ do not polymerise, despite the presence of two double bonds in the molecule.

On the basis of the above review we can draw the following conclusions about the paths for obtaining inorganic rings and polymers with inorganic main-chain molecules with organic and organoelemental side-groups. In our opinion the most important direction of the synthesis of polymers with inorganic main-chain molecules is that which ensures the formation of chain molecules constructed from atoms of two or more elements alternating in the main chain. In choosing the elements for constructing the chains of large molecules it is necessary to take into account which type of hybridisation is most stable for these elements and also the electronegativity of the elements forming the chain. The alternation of elements in the chain of the molecule should be selected so that one element would be more electronegative and the other less electronegative than carbon. In this case the difference in the electronegativity of the elements leads to a polar type of bonds for the interlinked elements A–B (or to its partially ionic character), which increases the bond energy ($Dp_{AB}$) in comparison with the hypothetically pure covalent bond ($Dnp_A + Dnp_B$) in accordance with the formula:

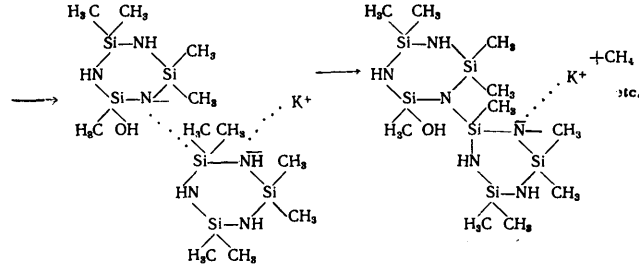


$$Dp_{AB} = Dnp_A + Dnp_B + 23.06\,(X_A - X_B)^2,$$

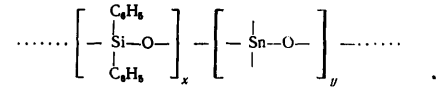
where $Dp_{AB}$ is the energy of the polar bond AB, $Dnp_A$ and $Dnp_B$ are the "non-polar contribution" of the corresponding elements A and B to the bond energy, and $X_A$, $X_B$ are the electronegativities of elements A and B on the Pauling scale.



As examples illustrating this thesis we can quote the synthesis of polymers with silicon–nitrogen bonds obtained recently by catalytic polymerisation of dimethylcyclosilazanes [67]. The polymerisation of these rings with the aid of catalytic quantities of alkalis takes place not with cleavage of the ring, as occurs in the case of the alkaline polymerisation of dimethylcyclosiloxanes, but by detachment of a methyl group from the silicon atom and hydrogen from nitrogen, with formation of methane:



In the transitional complex formed as a result of redistribution of the electronic density one of the Si–C bonds is weakened and methane is detached with formation of a negatively charged ion:



Subsequently the process proceeds through coordination of the ions of cyclosilazanes by the reaction:

Several polymers have been obtained with chain molecules, including both Si–O and Sn–O bonds. Such polymers are obtained from the disodium salt of diphenyldihydroxysilane and tin chloride [68]. These organostannosilicon polymers have the following structure:

Organostannosiloxane oligomers were obtained in an analogous way from difunctional organotin monomers and the sodium salts of dialkyl(aryl)dihydroxysilanes [69], and polyorganostannosiloxanes by the polycondensation of diethoxydimethylsilane with tin diacetate and with diacetoxydiisobutyltin [70].

The possibility of preparing polyorganostannosiloxanes of linear structure by the polycondensation of dialkoxy-derivatives of tin with organosilicon hydroxyl derivatives has been described [71].

In the formation of the main chains of large molecules steric hindrance can become an unsurmountable difficulty, for even when the hybrid state characteristic for the elements concerned is maintained and the electronegativity of the elements is correctly chosen the formation of the main chain of a large molecule is unsuccessful. This shows that in choosing the direction for the synthesis of polymers with inorganic chain molecules account should be taken of all the factors considered above.

In the present article an attempt has been made to evaluate the ability of various elements to form the chains of large molecules, and general consideration has been given to the trends for the preparation of polymers with inorganic chain molecules. The authors do not pretend to have given a complete exposition of these problems, but hope that the article will be of assistance to those who are working in the field of the synthesis and investigation of organoelemental compounds.

## I. INTRODUCTION

The considerable advances in the elucidation of the role of nucleic acids in the biosynthesis of protein[1] have led to increasing interest in synthetic polynucleotides which serve as models in the investigation of the chemical, biochemical, and biological properties of nucleic acids. There is particular interest in the methods of preparation of nucleotides with a known sequence of nucleotide residues in the polynucleotide chain. One of such methods is the stepwise synthesis of the specific internucleotide bond which consists of a phosphodiester unit joined to the $C_{3'}$ atom† of one nucleotide and the $C_{5'}$ atom of another[2]:

In developing methods of synthesis of the specific $C_{3'}$–$C_{5'}$ internucleotide bond it is necessary to solve two principal problems: (1) to find ways of protecting the functional groups present in nucleoside and nucleotide molecules (the hydroxy-group of the sugar and the amino-groups of purine and pyrimidine bases) and thus obtain derivatives of the nucleosides and nucleotides with only one reactive group; (2) to achieve the condensation of these residues in such a way that only the $C_{3'}$–$C_{5'}$ phosphodiester linkage is formed. In both cases it is necessary to bear in mind the low stability of the $C_{3'}$–$C_{5'}$ linkage which is hydrolysed by acids[4] and alkalis[5] and isomerises to the $C_{2'}$–$C_{5'}$ linkage in an acid medium[6,7]. All these factors restrict the choice of protective groups, since their subsequent complete or selective removal often requires fairly severe conditions.

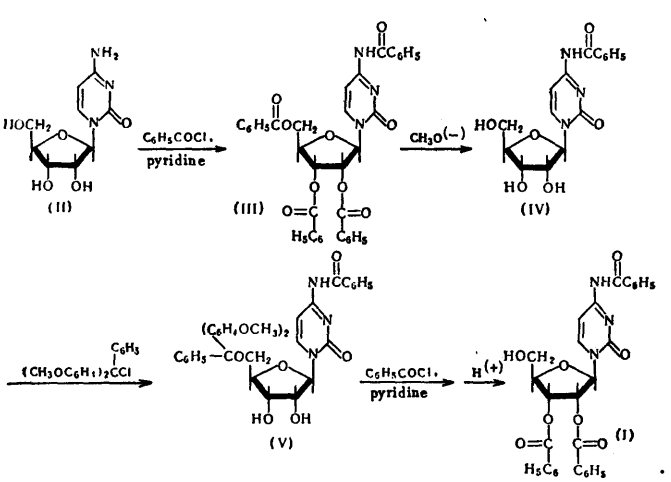
## II. METHODS OF SPECIFIC PROTECTION OF FUNCTIONAL GROUPS IN NUCLEOSIDES AND NUCLEOTIDES

The synthesis of the $C_{3'}$–$C_{5'}$ linkage may be achieved in two ways: (1) a nucleoside-3′ phosphate is condensed with a nucleoside having a free hydroxy-group in position $C_{5'}$ (5′-OH); (2) a nucleoside-5′ phosphate is condensed with a nucleoside having a free hydroxy-group in position $C_{3'}$ (3′-OH). Thus for the synthesis of the $C_{3'}$–$C_{5'}$ internucleotide bond it is necessary to have nucleosides with free 3′-OH and 5′-OH groups (nucleoside components) and nucleotides with a phosphate residue in position $C_{3'}$ or $C_{5'}$ with the remaining functional groups completely protected (nucleotide component).

### 1. Protection of Hydroxy-Groups in Deoxyribonucleosides and Deoxyribonucleotides

The preparation of protected deoxyribonucleosides and deoxyribonucleotides does not present great difficulties because there is no hydroxy-group in position $C_{2'}$ and the 3′-OH and 5′-OH groups are known to differ in their reactivity. The use of triphenylmethyl chloride (trityl chloride) for the protection of the 5′-OH group is based on this difference: trityl chloride reacts much more rapidly with the primary hydroxyl[8–12]. Although the trityl group is most often used for the protection of the 5′-OH group in deoxyribonucleosides[13] and deoxyribonucleotides[14], the acetyl group[15] and the di-(*p*-anisyl)phenylmethyl group (di-*p*-APM group) are employed for this purpose too[16,17]. The acetyl group has also been used for the protection of

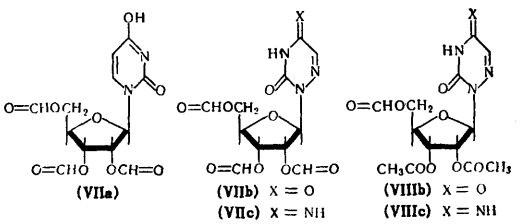
† The numbering of the atoms in the base and sugar residues of nucleic acids is based on that given by Kochetkov *et al.*[3].



the 3'-OH group in deoxyribonucleosides[14] and deoxyribonucleotides[18], the mixture of 3'-*O*-acetyl and 5'-*O*-acetyl derivatives obtained in the first case being separated by countercurrent distribution[19].

The preparation of protected ribonucleoside and ribonucleotide derivatives is much more difficult since the hydroxy-groups in positions $C_{2'}$ and $C_{3'}$ do not differ in their properties.

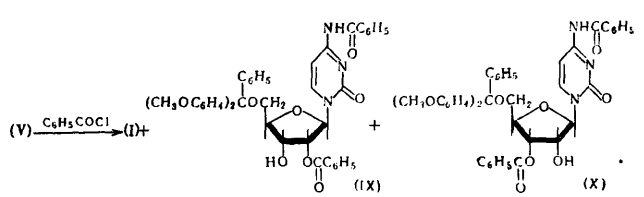
## 2. Synthesis of Ribonucleosides with a Free Hydroxy-Group in Position $C_{5'}$



Ribonucleosides with a 5'-OH group may be obtained via the acetals of the *cis*-glycol group in the ribose residue: 2',3'-*O*-isopropylidene-[20,21], 2',3'-*O*-anisylidene-[22], 2',3'-*O*-cyclopentylidene-[22], 2',3'-*O*-cyclohexylidene-[22], or 2',3'-*O*-benzylidene-ribonucleosides[22,23]. However, the application of these ribonucleoside derivatives for the synthesis of oligonucleotides is limited, because the subsequent removal of the acetal group requires fairly severe conditions. For the same reason even the more labile *p*-methoxybenzylidene group[7] did not prove to be very suitable either. Nor was it possible to use on a preparative scale the method proposed by Todd and coworkers[24] for the synthesis of 2',3'-di-*O*-acetyluridine: by partial deacetylation of 2',3',5'-tri-*O*-acetyluridine with subsequent separation of the mixture of mono-, di-, and tri-acetyluridines by countercurrent distribution.

Usually ribonucleosides with a free 5'-OH group are obtained via the 5'-*O*-trityl derivatives: 2',3'-di-*O*-benzoyluridine was prepared from 5'-*O*-trityluridine[25] or from 5'-*O*-di-*p*-APM-uridine[26]. $N^6O^{2'}O^{3'}$-Tribenzoylcytidine (I) can be obtained by the reaction of cytidine (II) with benzoyl chloride in pyridine, the product being the fully benzoylated cytidine (III),[27] careful treatment of which with sodium methoxide gives crystalline $N^6$-benzoylcytidine (IV) in good yield. The 5'-OH group in (IV) is then protected with the di-*p*-AMP group and the 2'-OH and 3'-OH groups in the resulting $N^6$-benzoyl-5'-*O*-di-*p*-APM-cytidine (V) are rebenzoylated. The removal of the di-*p*-APM group in an acidic medium yields (I):

The simpler synthesis via 5'-*O*-di-*p*-APM-cytidine (VI), which is benzoylated with subsequent splitting of the di-*p*-APM group, cannot be used, since in the synthesis of (VI) some mono-$N^6$-di-*p*-APM-cytidine is also formed[26].

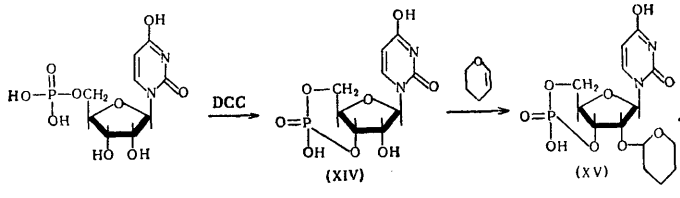


Šorm and coworkers[28] suggested the synthesis of specifically protected ribonucleosides via their *O*-formyl derivatives, which can be obtained by the usual formylation procedures[29-31]. *O*-Formyl groups are split off even on heating in methanol, i.e. under conditions in which other protecting groups, for example acetyl, are unaffected. Investigation of the methanolysis of 2',3',5'-tri-*O*-formyl derivatives of uridine (VIIa), 6-azauridine (VIIb), and 6-azacytidine (VIIc) showed that formyl groups in positions $C_{2'}$ and $C_{3'}$ are hydrolysed more rapidly than in position $C_{5'}$. The difference in the rate of methanolysis is almost independent of the structure of the heterocyclic base although the latter affects the rate of methanolysis of the formyl group in position $C_{5'}$: 5'-*O*-formyluridine hydrolyses to uridine in 1 h, while 5'-*O*-formylazauridine requires 16 h.

The 5'-*O*-formyl derivatives of (VIIIa) and (VIIIb) were prepared. The attempt at selective removal of the *O*-formyl group in the presence of an *O*-acetyl group was unsuccessful: on heating with methanol, 2',3'-*O*-diacetyl-5'-*O*-formylazauridine (VIIIb) and 2',3'-*O*-diacetyl-5'-*O*-formylazacytidine (VIIIc) were converted into (VIIb) and (VIIc).

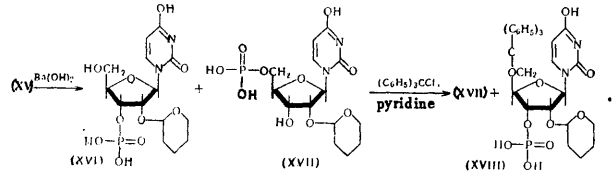
## 3. Synthesis of Ribonucleosides with a Free Hydroxy-Group in Position $C_{3'}$

Numerous attempts to prepare ribonucleosides with a free 3'-OH group have been unsuccessful[26]. Partial benzoylation of (V) with a slight excess of benzoyl chloride yields a mixture of (I) and two mono-*O*-benzoylated substances, probably $N^6O^{2'}$-dibenzoyl-$O^{5'}$-di-*p*-APM-cytidine (IX) and $N^6O^{3'}$-dibenzoyl-$O^{5'}$-di-*p*-APM-cytidine (X), which could not be separated. Partial debenzoylation of (III) gives a mixture of $N^6O^{5'}$-dibenzoylcytidine (XI) and $N^6O^{3'}O^{5'}$-tribenzoylcytidine (XII) which can be separated on a silicic acid column. Treatment of (XI) with benzoyl chloride (somewhat more than one equivalent) gives both expected isomers: (XII) and $N^6O^{2'}O^{5'}$-tribenzoylcytidine (XIII).



Phosphorylation of (XII) and (XIII) showed that some of the acyl groups migrate from 2'-OH to 3'-OH, in agreement with earlier data[32-34]. It is suggested that this migration may be acid-[35] or base-catalysed and that in an alkaline medium there is probably also rapid migration from 2'-OH to 3'-OH.[5] Taking all this into account, it may be assumed that direct use of ribonucleoside derivatives with a 3'-OH group and an acyl group in position $C_2$ is almost impossible.

4. Protection of Hydroxy-Groups in Ribonucleotides

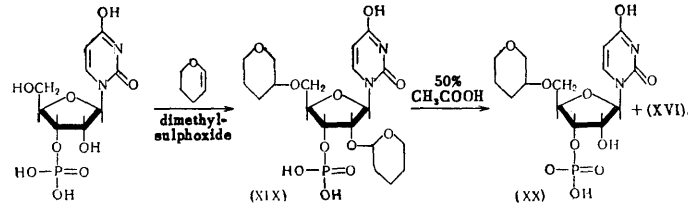


As already mentioned, the synthesis of oligonucleotides with the specific $C_{3'}-C_{5'}$ linkage requires that the nucleotides be fully converted into protected derivatives, so that the phosphate residue is the only reactive group, and that the groups protecting 5'-OH and 2'-OH or 3'-OH and 2'-OH should be removable independently of one another.

As in the case of deoxyribonucleotides, the use of trityl chloride was suggested for the protection of the 5'-OH group[36]. In order to protect the 2'-OH groups in mononucleotides, attempts were made to prepare the 2'-*O*-benzyl esters of nucleoside-3',5' cyclic phosphates using benzyl chloride and potassium t-butoxide[36,37]. However, the benzyl group migrates to the pyrimidine ring in the monobenzylated derivatives. According to the authors of these investigations, the discrepancy between their results and those of Todd and coworkers[38], who synthesised the *O*-benzyl ethers of nucleosides, is due to different reaction conditions being used.

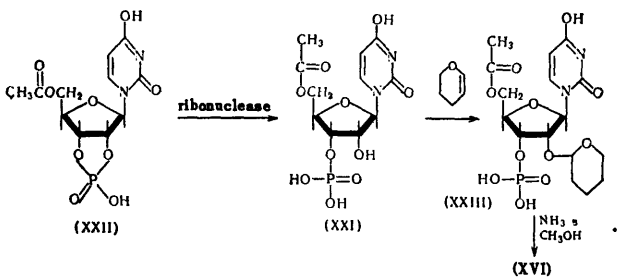
The following method of protecting the 2'-OH group proved to be more successful[7,36]: uridine-5' phosphate in very dilute solution is converted in the presence of dicyclohexylcarbodiimide (DCC) into uridine-3',5' cyclic phosphate (XIV) which on treatment with dihydropyran in aqueous dioxan at about 20° is quantitatively converted into the 2'-*O*-tetrahydropyranyl (2'-*O*-THP) derivative (XV):

Hydrolysis of (XV) with barium hydroxide gives a mixture of 2'-*O*-THP-uridine-3' phosphate (XVI) and 2'-*O*-THP-uridine-5' phosphate (XVII) in 5 : 1 ratio, which could not be separated. Treatment of the mixture with trityl chloride in pyridine results in a quantitative yield of 2'-*O*-THP-5'-*O*-trityluridine-3' phosphate (XVIII), which can be readily separated from (XVII) (not participating in the reaction) by partition or ion-exchange chromatography:



This pathway proved unsuitable for cytidine-5' phosphate, since opening of the phosphate ring with alkali is accompanied by rapid deamination of the cytosine moiety[39].

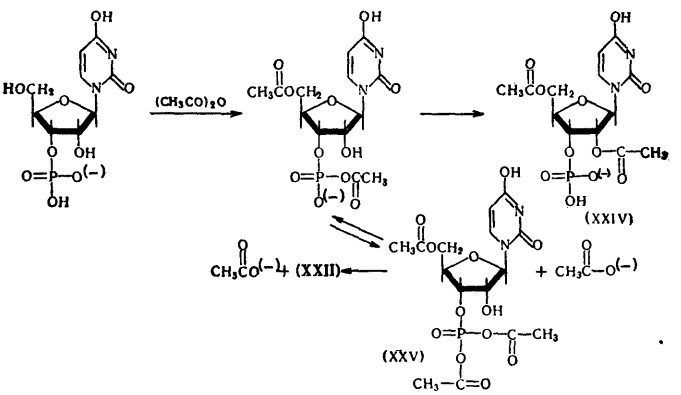
Both the trityl and the THP groups are removed on treatment of the derivative with aqueous acetic acid, the THP group being hydrolysed off at a higher rate than the trityl group[7]. Since stepwise synthesis of the $C_{3'}-C_{5'}$ linkage requires the selective removal of the 5'-*O*-trityl group, an attempt was made to use catalytic hydrogenation for this purpose, but the results were in many cases unsatisfactory[40,41]. In particular it was found that the cytosine ring may also be hydrogenated[42].



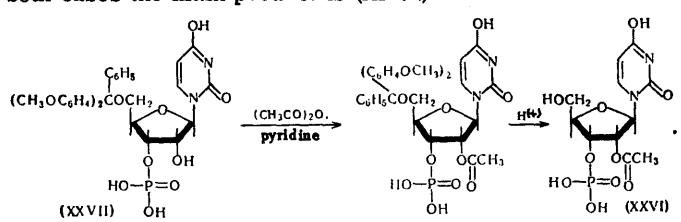
Bearing in mind that the ease of ionisation of *p*-methoxy-substituted triphenylmethanols increases greatly on introduction of each *p*-methoxy-group[43], Khorana and coworkers[7] suggested the use of a modified trityl group for the protection of the 5'-OH group. Investigation of the hydrolytic stability of 5'-*O*-*p*-anisyldiphenylmethyluridine, 5'-*O*-di-*p*-APM-uridine, and 5'-*O*-tri-*p*-anisylmethyluridine showed that the introduction of each *p*-methoxy-group increases the rate of hydrolysis in 80% acetic acid at 20° by a factor of about ten. Introduction of *p*-methoxy-groups into trityl chloride also increases the rate of its reaction with hydroxy-groups, including secondary hydroxy-groups, which may be a disadvantage in the preparation of nucleotide derivatives. It proved convenient to use di-*p*-APM chloride for the protection of the 5'-OH group, since the difference in the rate of removal of 2'-*O*-THP and 5'-*O*-*p*-anisyldiphenylmethyl groups is still insufficient for the selective elimination of the latter, while treatment of 2'-*O*-THP-5'-*O*-di-*p*-APM-uridine-3' phosphate with 80% acetic acid at 0° for 6 h gives a good yield of (XVI).

Todd[44] was the first to attempt the blocking of the 2'-OH group by treating uridine-3' phosphate with methyl iodide in the presence of silver oxide. He obtained a mixture of 2'- and 3'-phosphate derivatives. It is possible to obtain the protected ribonucleoside-3' phosphate by reacting the latter directly with dihydropyran in dimethylsulphoxide in the presence of trifluoroacetic acid[26]. In the case of uridine-3' phosphate the reaction is almost quantitative, the tetrahydropyranylation of the 2'-OH group being more rapid than the migration of the phosphate residue. Under the same conditions adenosine-3' phosphate gives 70% of 2',5'-di-*O*-THP-adenosine-3' phosphate and a small amount of *NO*$^{2'}$*O*$^{5'}$-tri-THP-adenosine-3' phosphate, which increases with the duration of tetrahydropyranylation. It was established that the rate of hydrolysis of the THP groups in positions $C_{2'}$ and $C_{5'}$ is different[45,46]: treatment of 2',5'-di-*O*-THP-uridine-3' phosphate (XIX) with 50% acetic acid at 0° for 3 h gives a mixture of (XVI) and 5'-*O*-THP-uridine-3' phosphate (XX), the latter predominating (75%). The mixture may be separated by treatment with di-*p*-APM chloride followed by chromatography on a DEAE-cellulose column:

Šorm and coworkers[47,48] suggested that the 2'-OH groups should be tetrahydropyranylated after preliminary acylation of the 5'-OH groups in ribonucleoside-3' phosphate, which makes possible subsequent selective removal of the protective groups, because the acetyl residue is more readily split off in an alkaline medium in which the THP group remains unaffected. The calcium salt of 5'-*O*-acetyluridine-3' phosphate (XXI) was obtained from 5'-*O*-acetyluridine-2',3' cyclic phosphate (XXII) by splitting the latter with pancreatic ribonuclease. Tetrahydropyranylation may be effected using the calcium salt and adding one equivalent of hydrochloric acid to form a homogeneous solution. It is also necessary to add a small excess of hydrochloric acid in order to catalyse the reaction, which



is quantitative under these conditions after 40–50 h at room temperature. There is no migration of the phosphate residue. The reacting resulting in the formation of 5′-*O*-acetyl-2′-*O*-THP-uridine-3′ phosphate (XXIII) is much more rapid (8 h) if it is carried out by adding two moles of hydrochloric acid per mole of phosphate to the ammonium or pyridinium salt of 5′-*O*-acetylnucleoside-3′ phosphate in a mixture of dimethylsulphoxide and dimethylformamide [49]. The acetyl group is split off by a mixture of methanol and ammonia at 50° (at 20° the yield of the deacetylated products is lower):

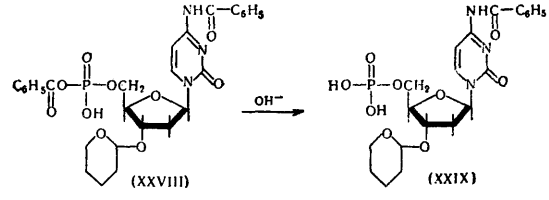


Apart from aqueous acetic acid, strongly acid ion-exchange resins, for example Dowex 50 in the pyridinium or ammonium form, can be used to remove the THP group. The rate of removal depends on the degree of cross-linking of the resin and the concentration of pyridine in solution: the THP group is readily removed if the degree of cross-linking is low, the rate of removal falling as the concentration of pyridine is increased. The most favourable conditions for the removal obtain when Dowex 50 × 8 in 30% pyridine is used.

The use of THP and di-*p*-APM nucleotide derivatives for the synthesis of dinucleoside phosphate showed that a disadvantage of these protective groups is their incomplete removal on brief treatment with acid [7] (longer treatment results in partial isomerisation of the $C_{3'}$–$C_{5'}$ linkage). Thus treatment of 2′-*O*-THP-5′-*O*-di-*p*-APM-uridylyl-(3′→5′)-uridine with 80% acetic acid for 4 h yields 50% of uridylyl-(3′→5′)-uridine. After treatment for 10 h, the yield rises to 69%, but the product contains about 1% of uridylyl-(2′→5′)-uridine. Similar results were obtained in the synthesis of uridylyl-(3′→5′)-adenosine: after a 4 h treatment with 80% acetic acid, 2′-*O*-THP-5′-*O*-di-*p*-APM-uridylyl-(3′→5′)-adenosine gave 54.5% of pure uridylyl-(3′→5′)-adenosine, while after 11 h the yield increased to 70%, but the product contained about 1.5% of uridylyl-(2′→5′)-adenosine. The low yield (28–40%) in the synthesis of uridylyl-(3′→5′)-uridine, uridylyl-(3′→5′)-cytidine, and uridylyl-(3′→5′)-adenosine from (XIX) and the corresponding derivatives of uridine, cytidine, and adenosine [26] is also due to the incomplete removal of the protecting groups, particularly the 5′-*O*-THP group.

Khorana and coworkers [45] suggested that these groups be replaced by acetyl groups. In contrast to the data of Šorm and coworkers [48] who state that acetylation of nucleoside-3′ phosphate always results in the formation of 2′,3′ cyclic phosphates, it was found that, depending on the conditions, the reaction of acetic anhydride with ribonucleoside-3′ phosphate can take place in different ways: in an acid medium uridine-3′ phosphate yields predominantly 2′,3′ cyclic phosphate, while in an alkaline medium (pyridine) an excess of acetic anhydride gives a mixture of (XXII) and 2′,5′-*O*-diacetyluridine-3′ phosphate (XXIV), which constitutes 35% of the mixture. If acetic anhydride is replaced by acetyl bromide, a 51% yield of (XXIV) is obtained. Acetylation of other ribonucleoside-3′ phosphates takes place similarly. Bearing in mind that the presence of water in the pyridine–acetic anhydride mixture reduces the yield of cyclic phosphate and assuming that the role of water reduces to the formation of acetate ions, Khorana and coworkers [45,46,50] suggested that the acetylation be carried out in an anhydrous medium using tetraethylammonium acetate as a source of acetate ions. (XXIV) was obtained in 92% yield from the pyridinium salt of uridine-3′ phosphate in dry pyridine with an excess (30-fold) of acetic anhydride at about 20° in 1 h. It is believed that (XXII) is formed via an intermediate diacylphosphate (XXV) and that acetate ions probably inhibit its formation:

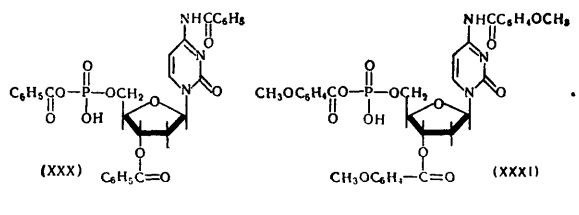
The acetyl group has also been used to protect the 2′-OH group after preliminary blocking of the 5′-OH group in the ribonucleoside-3′ phosphate with a group which is stable in an alkaline medium and is removed in an acid medium [46]. Thus 2′-*O*-acetyluridine-3′ phosphate (XXVI) was obtained from (XX) and 5′-*O*-di-*p*-APM-uridine-3′ phosphate (XXVII) by treating them with an excess of acetic anhydride in pyridine with subsequent removal of the protecting group in the $C_{5'}$ position: the THP group is removed at pH 2.8 in the presence of Dowex 50 resin after 7.5 h at room temperature and the di-*p*-APM group after 7 min at pH 2.5. In both cases the main product is (XXVI).



## 5. Protection of the Amino-Groups of the Purine and Pyrimidine Bases in Nucleosides and Nucleotides

The amino-groups in the purine and pyrimidine bases in nucleosides and nucleotides are extremely reactive [42,51–53]. Thus when 3′-*O*-acetylthymidine-5′ phosphate is condensed with 5′-*O*-trityldeoxycytidine in the presence of dicyclohexylcarbodiimide (DCC), the main reaction is phosphorylation of the amino-group of deoxycytidine by the activated nucleotide component [52]. Therefore in the synthesis of oligonucleotides with the $C_{3'}$–$C_{5'}$ linkage it is necessary to

protect the amino-groups as well as the hydroxy-groups of the nucleoside and nucleotide components. Acetyl[15,42,54], benzoyl[17,52,55], and anisyl[52,55] groups are usually employed for this purpose.



*N*-Acetyl derivatives of nucleosides and nucleotides are obtained from the *NO*-acetyl derivatives using the different rates of hydrolysis of the *O*-acetyl and *N*-acetyl groups[41,42]; in an alkaline medium the *O*-acetyl groups are removed much more rapidly than the *N*-acetyl groups. Nevertheless it was not possible to remove selectively the 3'-*O*-acetyl group from $N^6O^{3'}$-diacetyldeoxycytidine-5' phosphate[42]. The method of selective acetylation of the amino-group in cytidine-2',3' cyclic phosphate with a limited amount of the acetylating agent[54] proved to be unsuitable for the preparation of $N^6$-acetyldeoxycytidine-5' phosphate, since the acetic (or other) anhydride reacts with the mononucleotide, forming predominantly a mixed acylphosphate anhydride[56]. A disadvantage of *N*-acetyl protection is its instability in an acid medium[7,52,57]: partial removal of the *N*-acetyl group was noted after brief treatment with dilute acetic acid of $N^6$-acetyl-$O^{3'}$-THP-deoxycytidine-5' phosphate[52], $NO^{2'}O^{3'}$-triacetyl-$O^{5'}$-trityladenosine[57], and *N*-acetyl-$O^{5'}$--tri-*p*-anisylmethyladenosine[7]. Furthermore, *N*-acetyl derivatives of nucleosides and nucleotides are insufficiently soluble in pyridine.

*N*-Benzoyl derivatives[26,52,55] are more stable to acids and are more soluble. On prolonged treatment of 3'-*O*-THP--deoxycytidine-5' phosphate with benzoic anhydride in pyridine, compound (XXVIII) is probably formed, the anhydride bond in which is very stable to aqueous pyridine[58]. $N^6$-benzoyl-3'-*O*-THP-deoxycytidine-5' phosphate (XXIX) is obtained in high yield after brief treatment of (XXVIII) with alkali, followed by purification on DEAE-cellulose:

(XXVIII) (XXIX)

$N^6$-Benzoyldeoxycytidine-5' phosphate was obtained by the benzoylation of deoxycytidine-5' phosphate with an excess of benzoic anhydride or benzoyl chloride in pyridine with subsequent treatment of the product (XXX) with a mixture of pyridine and aqueous sodium hydroxide under rigorously controlled conditions[52]. *N*-Benzoyldeoxyadenosine-5' phosphate was obtained similarly[55]. The *N*-benzoyl group in the latter is more stable than in the corresponding derivative of deoxycytidine-5' phosphate. $N^6$-Benzoylcytidine is obtained by partial debenzoylation of $N^6O^{2'}O^{3'}O^{5'}$-tetrabenzoylcytidine with sodium methoxide[26]. Benzoylation of adenosine under mild conditions with an excess of benzoyl chloride gives a crystalline pentabenzoyl derivative[7]. At a high temperature two benzoyl groups can be added to the adenine ring[59,60]. It is suggested[7] that one of them is attached to $N^6$ and the other possibly to $N^2$.

(XXX) (XXXI)

*N*-Anisyl derivatives of nucleosides and nucleotides are very stable to alkali: treatment with alkali of a fully substituted derivative of deoxycytidine-5' phosphate (XXXI) gives a 90% yield of $N^6$-anisyldeoxycytidine-5' phosphate, no deoxycytidine-5' phosphate being detected in the product[52]. Study of the rate of hydrolysis of various *N*-acyldeoxycytidine-5' phosphates in 9 *N* ammonium and sodium hydroxides at room temperature showed that ammonium hydroxide is more effective in the hydrolysis and that the *N*-acyl residues can be arranged in the following sequence as regards their stability: *N*-anisyl > *N*-benzoyl > *N*-acetyl. After prolonged interaction of *N*-anisyl- and *N*-benzoyl--deoxycytidine-5' phosphate with alkali and with aqueous acetic acid, some deamination is observed[52]; it is even more extensive in the case of $N^6$-acylcytosines[27]. Ammonia does not cause deamination. When acetic acid is used, the degree of deamination varies, depending on the nature of the *N*-acyl group: the *N*-acetyl group is more readily deaminated than the *N*-benzoyl group.

## III. METHODS OF SYNTHESIS OF THE $C_{3'}$–$C_{5'}$ INTERNUCLEOTIDE BOND

### 1. Synthesis of Dinucleoside Phosphates with a Non--Specific Internucleotide Bond

The first attempts at the synthesis of dinucleotides led to the formation of dinucleoside phosphates in which the phosphate residue was linked to analogous carbon atoms of the respective sugar residues[61]. Thus uridylyl-(5'→5')--uridine was obtained from 2',3'-*O*-benzylideneuridine and phenyl phosphorodichloridate after the removal of the protecting groups[62]. When *p*-nitrophenyl phosphorodichloridate was used, thymidylyl-(5'→5')-thymidine was obtained from 3'-*O*-acetylthymidine[63,64]. Adenylyl-(5'→5')-uridine was prepared from the protected silver salt of adenosine-5' phosphate and 2',3'-isopropylideneuridine[65], and also by the method of mixed anhydrides[18,66]. Using the monoacyl chlorides of the activated nucleotide derivatives[19], adenylyl--(2'→5')-uridine, and also the first dinucleoside phosphate with the $C_{3'}$–$C_{5'}$ linkage, thymidylyl-(3'→5')-thymidine[19] were synthesised. Nevertheless this method did not find wide application, because the yield of the dinucleoside phosphate is small and the preparation and purification of the intermediate are difficult. Mixtures of substances with the $C_{2'}$–$C_{5'}$ and $C_{3'}$–$C_{5'}$ linkages were obtained in numerous experiments on the synthesis of dinucleoside phosphates and trinucleoside diphosphates from various derivatives of adenosine, guanosine, and cytidine using diphenyl phosphorochloridate[54]. The above methods of synthesis of dinucleoside phosphates leads to compounds with a non-specific internucleotide bond or requires starting materials which are not readily available.

### 2. The Carbodiimide Method of Synthesis of the $C_{3'}$–$C_{5'}$ Bond

The method providing for direct condensation of the nucleoside and nucleotide components in the presence of activating agents proved to be much more effective. The most widely used activating agent is DCC, the excess of which does not lead to side-reactions, and the dicyclohexylurea formed from it can be readily removed from the reaction mixture. Using in the reaction various nucleoside and nucleotide components (Table 1), Khorana and co-

TABLE 1. Preparation of dinucleotide phosphates by condensation in the presence of DCC.

| Nucleoside component | Nucleotide component | Yield of dinucleoside phosphate, % |

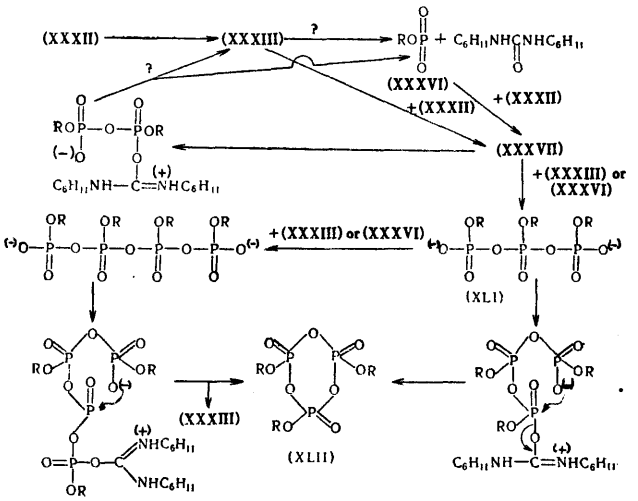
workers[16] showed that, when equimolar amounts of both components and a fivefold excess of DCC are employed, the reaction rates are approximately the same, the yields varying from 60 to 76%. However, it should be noted that both the rate and the yield of the reaction greatly depend on the size of the protecting group in the nucleotide component[67,68] (Table 2)‡.

A 100% excess of one component raises the yield to 96–100% with respect to the second component[14]. Addition of a second mole of the nucleotide component at the end of the reaction does not increase the yield whilst addition of a second mole of the nucleoside component at the end of the reaction makes the yield almost quantitative. It is believed that the nucleoside component disappears as a result of a side-reaction[14,68]. In the reaction of deoxyribonucleotides the condensation proceeds in the same way regardless of the carbon atom in the carbohydrate residue to which the reacting groups are attached[14], but it is usual to condense nucleoside-5′ phosphates with nucleosides having a free 3′-OH group, since deoxyribonucleoside-5′ phosphates are more readily available than the 3′-phosphates and the derivatives of deoxyribonucleosides with a free 5′-OH group are in many cases unstable. On the other hand, for the specific synthesis of diribonucleoside phosphates, it is more convenient to use a procedure involving the condensation of protected ribonucleoside-3′ phosphate with a ribonucleotide having a free 5′-OH group, since ribonucleosides with a free 3′-OH group are virtually unavailable[26].

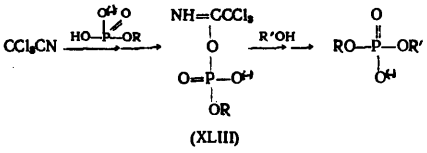
A study has been made of the mechanism of the formation of the phosphodiester linkage in the condensation of nucleotide and nucleoside derivatives in the presence of DCC.[15,42,67–71] It is believed that the first stage of the reaction is activation of the nucleotide component (XXXII) with formation of a protonated adduct (XXXIII), the alcoholysis of which with an excess of the nucleoside component (XXXIV) yields the dinucleoside phosphate (XXXV). (XXXIII), or its metaphosphate (XXXVI), forms the pyrophosphate (XXXVII) preferentially when stoichiometric amounts of (XXXII) and (XXXIV) are used. Actually in a study of the reaction of 5′-*O*-acetylthymidine (XXXVIII) with 3′-*O*-acetylthymidine-5′ phosphate (XXXIX) Khorana and coworkers[15] showed that in the first few minutes $P^1P^2$-di-(3′-*O*-acetylthymidine-5′) pyrophosphate (XL) is formed. Since pyrophosphates are not effective as phosphorylating agents, the next stage in the synthesis must be further activation of (XXXVII). This activation is inhibited by water or strong bases (such as tri-n-butylamine), addition of which results in pyrophosphates being the final reaction products[70], a fact which has been widely used for the synthesis of coenzymes and related compounds[72]:



Study of substances obtained on treatment of (XXXIX) and (XL) with DCC in dry pyridine for 10–30 min established[68] that the main reaction product is $P^1P^2P^3$-tri-(3′-*O*-acetylthymidine-5′) triphosphate [(XLI), R = 3′-*O*-acetylthymidine-5′] in both cases. It is believed that the actual active phosphorylated intermediate is not (XLI) but the trimetaphosphate (XLII), which is readily converted into (XLI) in the presence of water[67,68]. Since trimetaphosphates are very labile[72,73], it was impossible to demonstrate directly the presence of (XLII) (R = 3′-*O*-acetylthymidine-5′) in the reaction mixture. However, model experiments with the more readily accessible ethyl phosphate confirmed the formation of (XLII) ($R = C_2H_5$), which is identical with the compound obtained in a preliminary experiment from silver trimetaphosphate and ethyl iodide[73]. The monomeric metaphosphate (XXXVI), which Todd regarded as an intermediate phosphorylating agent[74,75], can probably form as a short-lived intermediate, but according to Khorana[68] it is more likely to be attacked by the second phosphate anion (XXXII) than by the neutral hydroxy-group of (XXXIV). The possible reaction pathways of (XXXII) and (XLII) have been represented schematically by Weimann and Khorana[68] (see p. 27).

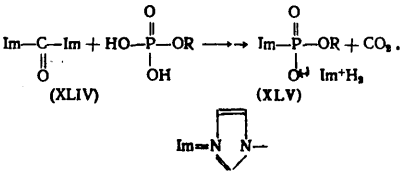
‡ More detailed information about the kinetics of the synthesis of the $C_3'-C_5'$ linkage in the presence of DCC is given in the paper of Khorana and coworkers[69] published after this review had been written.

### 3. The Use of Other Reagents for the Synthesis of the Specific $C_{3'}-C_{5'}$ Internucleotide Bond



Apart from DCC, *p*-toluenesulphonyl chloride[13], mesitylenesulphonyl chloride[76], trichloroacetonitrile[77], carbonyldiimidazole[78,79], ethoxyacetylene[80-83], and *N*-alkyl-(methyl- or ethyl)-5-phenylisoxazolium salts have been proposed as activating agents for the synthesis of the $C_{3'}-C_{5'}$ linkage§[84,86].

Schematic representation of the formation of the trimetaphosphate (XLII) from the monoalkyl phosphate (XXXII).

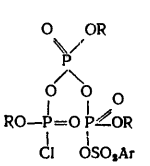


Condensation of the nucleoside and nucleotide components in the presence of *p*-toluenesulphonyl chloride also gives satisfactory yields of dinucleoside phosphates[15], but an excess of the reagent gives rise to the formation of side-products, in particular mixtures of polymers. The mechanism of the formation of the phosphodiester linkage in the presence of *p*-toluenesulphonyl chloride has not been studied in detail, but it has been suggested that the nature of the initial phosphorylating agent is the same as for the condensation in the presence of DCC¶.[68]

When a phosphomonoester is dissolved in a mixture of trichloroacetonitrile and pyridine, reactive intermediates — imidoylphosphates (XLIII)[92-95] — are formed and react with alcohols to give asymmetric phosphodiesters:

These observations were of interest for the development of methods of synthesis of the $C_{3'}-C_{5'}$ phosphodiester linkage. However, the first attempt to prepare thymidilyl-(3′→5′)-thymidine by the condensation of 5′-*O*-tritylthymidine-3′ phosphate with 3′-*O*-acetylthymidine in the presence of trichloroacetonitrile at room temperature over a period of 64 h was unsuccessful, the main product being $P^1P^2$-dithymidine-3′ pyrophosphate[14].

Carbonyldiimidazole (XLIV)[78,79] reacts with phosphomonoesters which are quantitatively converted into the imidazolides (XLV); these can be readily isolated as salts and possess phosphorylating properties[96]:

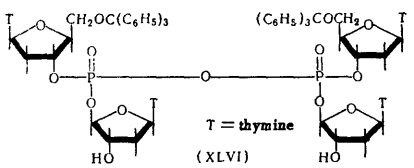


(XLV) forms phosphodiesters with alcohols but its application to the synthesis of the $C_{3'}-C_{5'}$ linkage is so far unknown†.

To compare the different activating agents, a study was made of the formation of thymidylyl-(3′→5′)-thymidine from (a) 5′-*O*-acetylthymidine-3′ phosphate and 3′-*O*-acetylthymidine or (b) from (XXXIX) and 5′-*O*-tritylthymidine, taken in stoichiometric amounts, at room temperature in pyridine in the presence of a 100% excess of *p*-toluenesulphonyl chloride or mesitylenesulphonyl chloride or a fourfold excess of DCC, ethoxyacetylene, or *N*-ethyl-5′-phenylisoxazolium fluoroborate[87,97]. It was found that the use of ethoxyacetylene in method (a) yields the symmetrical pyrophosphate after 96 h. The isoxazolium salt and DCC give approximately the same yield of the dinucleoside phosphate (68%). The sulphonyl chlorides proved to be the most effective in method (b): the yield of thymidylyl-(3′→5′)-thymidine in the presence of *p*-toluenesulphonyl chloride was 78% after 6 h, while in the presence of mesitylenesulphonyl chloride it was 71% after 1 h and 90% after 20 h. The use of activating agents such as mesitylenesulphonyl chloride permits the synthesis of the more soluble trialkylammonium salts of mononucleotides, which is impossible in the case of DCC and isoxazolium salts, since, as already mentioned, trialkylamines then lead to the formation of pyrophosphates[70].

§ The results of the use for this purpose of ethyl metaphosphate[88,89] and the product of the addition of phosgene to dimethylformamide[90,91] have also been published[87]. It was found that the first compound does not have any practical value for the synthesis of $C_{3'}-C_{5'}$ linkages, while the second gives a 30–40% yield of the dinucleoside phosphate, but side-reactions are possible.

¶ According to the latest data[87], the phosphorylating agent is in this case much more reactive than in the condensation in the presence of DCC and probably consists of the product of the addition of sulphonyl chloride to the trimetaphosphate:



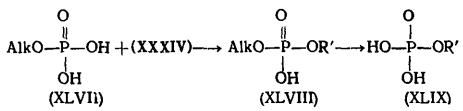
† The first attempt to obtain a dinucleoside phosphate was unsuccessful[87].

4. Synthesis of Oligonucleotides with the $C_{3'}-C_{5'}$ Bond

The methods of synthesis of oligonucleotides with a specific internucleotide bond must provide for the formation of such a bond when either the nucleoside or the nucleotide component or both simultaneously contain phosphodiester groups.

Khorana and coworkers[14,42] established that high-molecular-weight mixed oligonucleotides can be obtained by the usual methods of synthesis of dinucleoside phosphates. Three versions of the general procedure were examined. In the first version[42] the phosphodiester group was included in the nucleoside component: 5'-*O*-tritylthymidine-(3'→5')-thymidine was treated in pyridine with an excess of DCC for 1 h, to avoid the formation of an anhydride (XLVI), and then with two equivalents of 3'-*O*-acetylthymidine-5' phosphate for two days at room temperature. After treatment with alkali to remove the acetyl group, 5'-*O*-tritylthymidylyl-(3'→5')-thymidylyl-(3'→5')-thymidine was obtained in 68% yield, which after hydrogenation gave thymidylyl-(3'→5')-thymidylyl-(3'→5')-thymidine (83%). Thymidylyl-(3'→5')-deoxyadenylyl-(3'→5')-deoxycytidine[42] and thymidylyl-(3'→5')-deoxycytidylyl-(3'→5')-deoxycytidine[98] were obtained similarly.

(XLVI)



In the second version the phosphodiester group was included in the nucleotide component: 5'-*O*-tritylthymidylyl-(3'→5')-thymidylyl-(3'→5')-thymidine was obtained by the carbodiimide method in 49% yield from 5'-*O*-tritylthymidylyl-(3'→5')-thymidine-3' phosphate and 3'-*O*-acetylthymidine. Finally, the condensation was carried out with the phosphodiester group in both components: 5'-*O*-tritylthymidylyl-(3'→5')-thymidylyl-(3'→5')-thymidylyl-(3'→5')-thymidine was obtained from 5'-*O*-tritylthymidylyl-(3'→5')-thymidine-3' phosphate and thymidylyl-(3'→5')-3'-*O*-acetylthymidine in 23% yield[14]‡. The structure of the oligonucleotide was in all cases confirmed by enzymic hydrolysis. Thus it is possible to increase the chain length by stepwise synthesis of polynucleotides using components already containing internucleotide bonds. The optimum conditions for the stepwise synthesis of oligonucleotides with a specific internucleotide bond cannot be regarded as finally established. In particular, it should be borne in mind that the solubility of intermediate compounds diminishes with increase in chain length and this must complicate the requirements which have to be met by protecting groups.

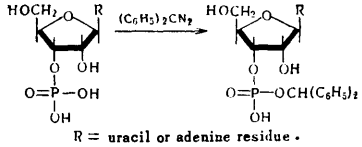
‡ Recent communications have described the preparation of two triribonucleotides[99,100]: uridylyl-(3'→5')-uridylyl-(3'→5')-uridine (yield 80%) and adenylyl-(3'→5')-uridylyl-(3'→5')-uridine (yield 75%), two tetranucleotides: thymidylyl-(3'→5')-deoxycytidylyl-(3'→5')-deoxycytidylyl-(3'→5')-deoxycytidine[101] (yield 59%) and uridylyl-(3'→5')-adenylyl-(3'→5')-uridylyl-(3'→5')-uridine[100] (yield 75%), and two pentanucleotides: thymidylyl-(3'→5')-deoxyadenylyl-(3'→5')-thymidylyl-(3'→5')-thymidylyl-(3'→5')-thymidine[102] (yield 12%) and deoxycytidylyl-(3'→5')-deoxyguanylyl-(3'→5')-deoxycytidylyl-(3'→5')-deoxycytidylyl-(3'→5')-deoxycytidine[101] (yield 15–17%).

## IV. METHODS OF SYNTHESIS OF OLIGONUCLEOTIDES WITH A FREE PHOSPHOMONOESTER GROUP

True oligonucleotides, i.e. oligonucleotides with a free phosphate residue at the end of the polynucleotide chain, are obtained in two ways: either by introducing the phosphate residue into the oligonucleotide itself or by synthesising the phosphodiester linkage from the nucleoside component in which the phosphate group is protected.

The phosphate residue is nowadays introduced into the oligonucleotide by a method based on the condensation of the alcohol (XXXIV) and the monoalkyl phosphate (XLVII) in the presence of DCC:

(XLVII) (XLVIII) (XLIX)



(XLVII) is chosen in such a way that the alkyl group is selectively removed after the formation of the phosphodiester (XLVIII), the final result of the reaction being the conversion of (XXXIV) into its phosphate (XLIX).[103] The phosphorylating agents investigated were monobenzyl phosphate[68,70], β-cyanoethyl phosphate[104], and tetra-*p*-nitrophenyl pyrophosphate[105]. β-Cyanoethyl phosphate, which in contrast to other phosphorylating agents is stable and becomes active only in the presence of DCC, proved to be the most convenient for the phosphorylation of oligonucleotides[106]. Since DCC is always used in a large excess, the reaction does not require absolutely anhydrous conditions. Usually a 1.5–2-fold excess of β-cyanoethyl phosphate is employed for phosphorylation. The excess of the reagent is completely decomposed after 5 min in 1 *N* sodium hydroxide at 100° and after 30 min in 0.1 *N* sodium hydroxide at 100°. The β-cyanoethyl group is removed from the nucleotide after 2 min at 100° in 1 *N* sodium hydroxide while at 50° in 0.1 *N* sodium hydroxide the rate of removal is much lower than in the reagent itself. 2 *N* sodium hydroxide removes the β-cyanoethyl group from the dinucleotide derivative in about 1 min at 0°,[14] i.e. the group can probably be selectively eliminated in the presence of certain other protecting groups, such as *N*-benzyl groups, in purine and pyrimidine bases. Free amino-groups are phosphorylated by β-cyanoethyl phosphate but the resulting phosphoramidate bonds can be readily broken: in the case of guanosine and adenosine in a weakly acid or even neutral medium and in the case of cytidine in a weakly alkaline or neutral medium on heating to 100°. Glycoside bonds are not broken under these conditions. This method was used to phosphorylate 5'-*O*-tritylthymidylyl-(3'→5')-thymidine[14], which was treated with an excess of a mixture of β-cyanoethyl phosphate and DCC, the mixture containing three times more DCC than β-cyanoethyl phosphate. When the above reagents are present in an equimolar ratio, the yield of the phosphorylated product does not exceed 23% even if the mixture were taken in a fivefold excess with respect to the dinucleoside phosphate. After treatment of the phosphorylation product with alkali, the pure dinucleotide was isolated in 68% yield. 5'-*O*-Phosphorylthymidylyl-(3'→5')-thymidine-3' phosphate and the tetranucleotide thymidylyl-(3'→5')-thymidylyl-(3'→5')-thymidylyl-(3'→5')-thymidine-3' phosphate[14] were obtained similarly from thymidylyl-(3'→5')-thymidine[52]. Thymidylyl-(3'→5')-thymidine-3' phosphate was also obtained using tetra-*p*-nitrophenyl pyrophosphate[15].

Another phosphorylating agent which has been used is dibenzyl phosphorochloridate[15]: thymidylyl-(5′→3′)-thymidine-5′ phosphate was obtained as the sodium salt in 50% yield. Phosphorylation of 5′-*O*-tritylthymidylyl-(3′→5′)--thymidine gives thymidylyl-(3′→5′)-thymidine-3′ phosphate in low yield, probably because of the relatively low activity of the secondary 3′-OH group.

The second method of preparing oligonucleotides with a terminal phosphomonoester group, based on a nucleoside with a protected phosphate group as one of the starting materials, has been used in several versions, differing in the nature of the protecting groups in the phosphate residue being "introduced" and in the condensation conditions. Thymidylyl-(5′→3′)-thymidine-5′ phosphate was obtained from 3′-*O*-acetylthymidine-5′ phosphate and thymidine-5′ dibenzyl phosphate using DCC.[15,18] The benzyl groups were removed by hydrogenation in 10% acetic acid in the presence of palladium oxide on barium sulphate[107] and the acetyl group by mild alkaline treatment. The crystalline trisodium salt of the dinucleotide was isolated in a yield not exceeding 40%. The relatively low yield is probably due to complications which arise as a result of the monodebenzylation of the dibenzyl phosphate group. Lowering of the temperature to 0° hardly increases the yield: condensation of *NO*$^{3'}$-diacetyldeoxyadenosine-5′ phosphate with thymidine-5′ dibenzyl phosphate followed by removal of the protecting groups gave 40% of deoxyadenylyl-(5′→3′)--thymidine-5′ phosphate[15].

The use of β-cyanoethyl derivatives of nucleoside phosphates as the nucleoside components was more successful[14]: 5′-*O*-tritylthymidine-3′ phosphate and thymidine-3′ β-cyanoethyl phosphate were condensed in the presence of DCC, using 1 : 1, 2 : 1, and 1 : 2 ratios of the initial components. The yield of the dinucleotide was approximately the same in all the experiments (55–60%). It is interesting that with the 1 : 1 ratio the condensation proceeds better if the nucleoside component contains the phosphate group: when 3′-*O*-acetylthymidine was used instead of thymidine-3′ β-cyanoethyl phosphate, the yield of the dinucleoside phosphate was 45% instead of 55–60% in the case of the dinucleotide. Condensation of 5′-*O*-tritylthymidylyl-(3′→5′)-thymidine-3′ phosphate with 1.5 moles of thymidine-3′ β-cyanoethyl phosphate gave thymidylyl-(3′→5′)-thymidylyl-(3′→5′)--thymidine-3′ phosphate in 44% yield.

It has also been suggested that the hydroxy-group in the phosphate residue could be protected with a t-butyl group[86] which is introduced by the trichloroacetonitrile method[108] and is removed with 20% acetic acid. In addition, the reaction with diphenyldiazomethane may be used for this purpose[86]:

R = uracil or adenine residue.

Because of the large size of the diphenylmethyl residue, the 2′-OH group becomes "inaccessible" and does not participate in condensation. This method has been used to prepare the first synthetic diribonucleotide, uridylyl--(3′→5′)-uridine-3′ phosphate[108]: the pyridinium salt of 5′-*O*-acetyl-2′-*O*-THP-uridine-3′ phosphate[48] was reacted with the ammonium salt of uridine-3′ diphenylmethyl phosphate in the presence of a sevenfold excess of DCC in pyridine. After four days the protecting groups were removed and uridylyl-(3′→5′)-uridine-3′ phosphate was isolated in 30% yield. Uridylyl-(3′→5′)-adenosine-3′ phosphate (yield 39%) was synthesised similarly.

In one of the latest papers on stepwise synthesis of oligonucleotides with the $C_{3'}$–$C_{5'}$ linkage[98] it is suggested that the introduction of the phosphomonoester group be carried out by transphosphorylation, using phenyl phosphate and the appropriate enzyme[109].

All the oligonucleotides synthesised, starting with dinucleoside phosphates, are listed in Table 3.

TABLE 3. Synthetic oligonucleotides with the $C_{3'}$–$C_{5'}$ linkage.

7. Interaction between intermetallic compounds 44

## 1. HISTORICAL

Metals and alloys have played an important role in the development of human civilisation since the earliest times. However, they have only been the object of scientific investigation since the 17th–18th centuries. The development of the chemical approach to the formation of alloys is discussed in a number of papers [1-6].

Mendeleev's Periodic Law[7] of the chemical elements was by far the most important single contribution to the understanding of the regularities of chemical interactions between metals. The application of this law to the study of interactions between metals is due to Kurnakov[8]. It was he who proposed the term "metallic compounds or metallides", now widely used in the chemistry and physics of metals and in metal science, for the compounds formed by the combination of metals. The term will be used in the present article [but is hereafter translated "intermetallic compounds" (Ed. of Translation)].

The thermodynamic works of Gibbs[9] were of the utmost relevance to the development of equilibrium studies in chemical systems, including metallic systems. His papers on heterogeneous equilibria, as interpreted by Kurnakov, led to the creation of an international language based on the geometrical representation of the equilibrium diagrams of systems. Since the beginning of the 20th century, the work of Tammann[10], Roberts-Austen[11], Le Châtelier[12], and Howe[13] has contributed to progress in this direction. Systematic studies of metal interactions and of equilibrium and phase transformation diagrams received further impetus from the general advances in physicochemical analysis[14,15], metallography[16-19], and physical metallurgy[20-23].

## 2. DEFINITION OF THE SCIENCE OF METAL CHEMISTRY

The chemical approach to the science of alloys, which began with Kurnakov's application of the Periodic Law and with his equilibrium studies, has been called the chemistry of alloys[24,25], but is now unified under the general heading of metal chemistry[26-28]. This science straddles the boundary between inorganic and physical chemistry, and is also related to crystal chemistry, solid state physics, and metallography.

The general problems with which metal chemistry is concerned, identified during its development, were formulated as follows in a paper[28] presented to the Plenary Session of the Division of Chemical Sciences of the Academy of Sciences of the USSR in 1956: "the study of chemical interactions involving the metallic elements of the Periodic Table, with each other or with metalloids, with formation of solutions and compounds showing metallic and covalent bond character, and the establishment of the general principles underlying the formation, structure, and properties of this broad range of solutions and compounds of metals as a function of their composition".

Metal chemistry is a subdivision of inorganic chemistry, dealing with the formation (as a result of the interaction between atoms of metals and metalloids) of solid solutions or of intermetallic compounds of variable or fixed composition. These compounds do not, as a rule, obey the theory of valency thus: the chemistry of metallic solutions and intermetallic compounds is richer and more comprehensive than the chemistry of compounds of non-metals.

There is no class of inorganic (or, indeed, of organic) compounds, in which the tendency towards isomorphic substitution or introduction of foreign atoms into the crystal lattice is developed as strongly as in the formation of various metallic solid solutions. In this respect, only the very large number of naturally occurring inorganic materials is at all comparable with metallic solid solutions and intermetallic compounds: these are the minerals, which can show a strong tendency towards isomorphic substitution of compounds within a series (for example, oxides, sulphides, silicates, etc.), and iron meteorites, which consist mainly of solid solutions of iron, nickel, and cobalt.

Metal chemistry encompasses the chemical reactivity problems of more than 80 metals of the Periodic Table. Many products of the reaction of metals with non-metals (boron, carbon, silicon, and to a lesser extent oxygen, nitrogen, etc.) also show metallic or covalent bond character. Solutions and compounds of metals with these non-metals are also studied in metal chemistry, and in many respects these compounds can be visualised as cross-links between purely metallic compounds and compounds having a covalent or ionic bond character.

It is the purpose of metal chemistry to study: (1) the principal factors which determine the interaction between metals; (2) the formation of solid solutions between metals; (3) the formation of intermetallic compounds; (4) the crystal chemistry of reactions in metallic systems; (5) interactions between intermetallic compounds.

These problems continue to be the object of extensive investigations by chemists, physicists, and metallurgists. Very many papers in this field have been published in the past 50 years. A number of contemporary problems in metal chemistry were discussed at a special symposium on the physical chemistry of metallic solutions held in London[29].

## 3. PRINCIPAL FACTORS WHICH DETERMINE THE INTERACTION BETWEEN METALS

The conditions leading to the formation of complex substances with metallic bond character have not yet been definitely established. Problems concerning the electron distribution and the chemical bond character in complex metallic solutions and intermetallic compounds are particularly difficult. However, there are a few generally accepted physicochemical factors[18-29] which appear to determine, largely if not completely, the conditions of formation of metallic solid solutions and intermetallic compounds.

The most important condition for characterising the reactions between metals is their relative position in the Periodic Table, which determines similarities and differences in the electronic structure of the atoms and in the physicochemical properties of the elements.

Generalising the opinions expressed by various authors, we can accept the view that the nature of the interaction of metals with each other and with metalloids is very largely determined by the following factors: (1) the atomic radii; (2) the position in the electronegativity series of the elements; (3) the valency and ionisation potential.

None of these factors, taken in isolation, can explain the nature of the reactivity of metals. Correct conclusions can only be reached by considering them as interrelated factors.

### Atomic Radii

Many reactions between metals differ from normal chemical reactions (such as ionic, molecular, etc.) by having an atomic mechanism and by forming solutions and compounds in which the bond between the atoms is typically metallic. From this point of view, interatomic distances (which are determined by the atomic radii of the elements) acquire a special significance.

Atomic radii, like many other properties of the elements, exhibit a strong periodicity when plotted against atomic number. Atomic radii are shown in Fig. 1. In contrast to earlier methods of presentation by periods, the atomic radii are arranged by groups of the Periodic Table. In this scheme, the elements beryllium, boron, and aluminium are assigned to the B subgroups of second and third Groups II and III, because this provides greater continuity of the atomic radii than the alternative assignment to the A subgroups.

Nekrasov's "Course of General Chemistry"[30] mentions further examples of the similarity in chemical properties between beryllium and the metals of the zinc subgroup and aluminium. Also in the electronegativity series of the elements, beryllium is adjacent to the metals of subgroup IIB (see below).

As regards atomic radii, all the elements can be classified into three families: one includes the elements of moderately high atomic radius, the other two families include the elements at either extreme of the range of atomic radii.

Inspection of Fig. 1 shows the following characteristic features: the largest atomic radii are found with the metals of low atomic number of subgroups IA and IIA, that is, the most typically metallic elements; the smallest radii apply to the typical metalloids — B, C, N, O, H — found in the B subgroups of Groups III–VII. Within this series of elements the atomic radius decreases continuously from B to H. Heavy metals (of high atomic number) in those groups, such as In, Tl, Sn, Pb, Sb, Bi, Te, and Po, also show an increase in atomic radius with increasing atomic number. Metals belonging to transition groups (from III to VIII) and having unfilled *d*-electron shells, and also metals of Groups I and II (subgroup B) have intermediate values of the atomic radius, and most of them belong to the first family.

Within any one group, the atomic radius of the elements changes in the sense of continuous decrease with decrease in atomic number. Very closely similar elements, such as Ti, Zr, Hf; V, Nb, Ta; Mo, W; Fe, Co, Ni; Ag, Cu; and others, have very similar atomic radii.

The similarity (or the difference) in atomic radii of the elements, in conjunction with other properties of the reacting atoms, exerts a decisive influence on the interaction between metals, particularly as regards the formation of solid solutions.

### Position in the Electronegativity Series of the Elements

The second factor which determines whether a reaction of metallic character is possible is the position of the metals in the electronegativity series of the elements. In spite of the great importance of this factor in chemical reactions[31-37], its application to metal chemistry has attracted little attention. The concept of electronegativity[31,34,36]

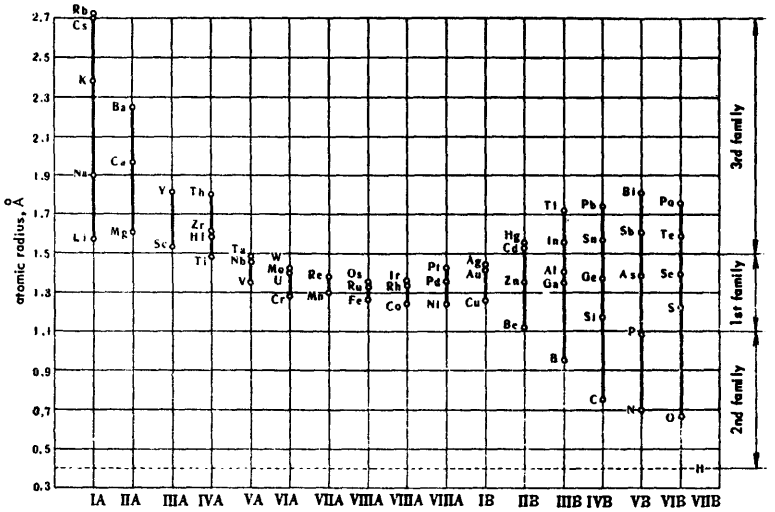

Fig.1. Variation of the atomic radii of the elements with their position in the groups of the Periodic Table.

embraces all the properties of an element stemming from the behaviour of the outer electrons of the atom. As a rule an element is electropositive if it shows a predominant tendency to give up electrons, and it is electronegative if its electron affinity is greater. The electronegativity difference between atoms A and B during formation of a chemical bond can be identified with the extent of electron transfer from atom A to atom B. The theory of this process is discussed in a number of monographs and reviews[31-35]: the conclusion is that metals are the most electropositive elements, and non-metals the most electronegative.

The electronegativity of the elements is arranged in an arbitrary series such that each element is electropositive with respect to the following element and electronegative with respect to the preceding element. In accordance with the project on the nomenclature of inorganic compounds set up by the Commission on the Nomenclature of Chemical Compounds, of the Division of Chemical Sciences of the Academy of Sciences of the USSR[36], the arbitrary electronegativity series for metals and non-metals is reproduced in Table 1.

It can be seen from Table 1 that the most electropositive metals are those of the alkali and alkaline earth series (with the exception of beryllium), whilst the metals of the B subgroups and beryllium are the most electronegative. These groups of metals are separated by braces in the table. Thus, as we have already pointed out, beryllium is situated close to aluminium from the standpoint of this important chemical property, and its behaviour towards other metals resembles that of aluminium rather than that of magnesium.

The transition group metals are situated between these two extreme poles corresponding to the electropositive and the electronegative metals. This series begins with actinium and ends with nickel, the most electronegative element of this group. In Table 1, the transition group is also separated from the other groups by a brace.

With very few exceptions, the electronegativity of metals within a group increases from bottom to top (see Table 1) with decreasing atomic number: for example U–W–Mo–Cr, etc. The exceptions are lithium, magnesium, beryllium, and tin, which occupy more electronegative positions than their analogues. The non-metals, bracketed together at the bottom of the table, show large deviations from electronegativity sequence within a group.

TABLE 1. Electronegativity series of the elements.

The position of an element in the electronegativity series plays two important roles: it establishes the cause of the formation of solid solutions and intermetallic compounds and it explains the gradual transition from metallic compounds through covalent compounds to ionic compounds. The arbitrary electronegativity series of the elements helps to systematise the designation of intermetallic compounds.

In naming inorganic compounds, the most electropositive metal should be taken to be the electropositive part of the compound, and all the other elements present should be taken to be the electronegative part according to their position in the electronegativity series. As proposed by the above-mentioned Commission[36], the electropositive metal is written first in the formula of the compound. This basis of classification can also be used for naming intermetallic compounds†.

† The order in Table 1 is not that given in the 1957 IUPAC rules (Ed. of Translation).

The order in which the elements of ternary and more complex intermetallic compounds are written is the following: the most electropositive metal is written first in the formula, followed by the other elements in order of decreasing electropositivity. By analogy with Kurnakov's terms "metallic compounds" or "metallides", we may use the terms aluminides, beryllides, borides, carbides, nitrides, etc. All such generic names for intermetallic compounds are derived from the name of the electronegative elements present in the compounds.

## Valency and Ionisation Potential

The main factor which controls chemical reactions between elements is, of course, their valency.

The number of valency or outer electrons frequently ensures that the atoms in the resulting chemical compounds are present in stoichiometric ratios.

The number of valency electrons in interacting metals, and their quantum state, play an important part in determining the limiting concentrations of solid solutions and the composition of intermetallic compounds. The valency of the elements, like the properties discussed above, depends on their position in the Periodic Table. The most electropositive metals (Group I) have one outer electron; the number of these electrons increases as the number of the group increases, to six for metals and to seven for non-metals.

The increase in the number of outer electrons and in the interatomic binding force is reflected by a decrease in interatomic distance and in other properties of the metals, which show a gradual increase in density, in melting point, in hardness, in yield point, in elastic modulus, and a decrease in compressibility coefficient.

The binding force of electrons within the atom is determined by the ionisation potential, which is measured by the energy required to remove the outer (valency) electrons from the atom[31-34].

The first ionisation potentials of the elements of the Periodic Table are reproduced in Fig. 2 (after Vedeneev *et al.*[34]). Again, they are arranged in groups rather than by atomic number. From these data we can say that the most electropositive metals (Group I) have the lowest ionisation potentials, and that the ionisation potential increases with increasing group number: this is evident from Fig. 2. Another characteristic feature is that the transition group metals show very small differences in electronegativity irrespective of the number of outer electrons. This is a very significant factor in the formation of a wide class of solid solutions based on these metals.

With certain exceptions, the ionisation potential decreases within a group as the atomic number of the element increases. Metallic elements differ from non-metals in having lower ionisation potentials: this is particularly striking with elements of one and the same group. Thus, the ionisation potential of Group IVB elements, with the same number of outer electrons, drops sharply on going from C to Si, and more gradually on going from Si towards the more metallic elements Ge, Sn, and Pb (see Fig. 2). The ionisation potentials of the Group VB elements cover a wider range, that of nitrogen being highest, those of phosphorus and arsenic also quite high, and similar, and those of antimony and bismuth not far from the values

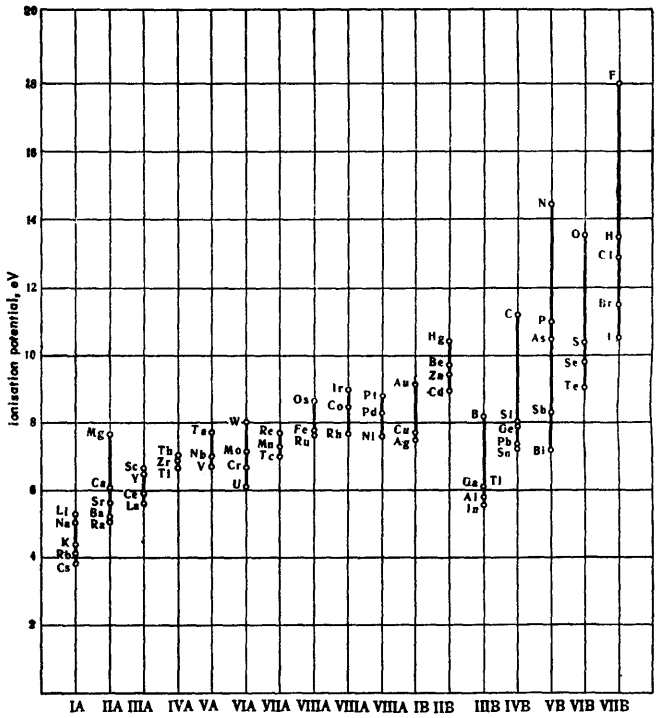

Fig. 2. Ionisation potential (first) of the elements arranged in groups of the Periodic Table.

typical of metals. Hence we can say that metals of low ionisation potential tend to give up their outer electrons during ordinary chemical reactions, whereas non-metals (large ionisation potential) readily accept electrons. Accordingly, reactions between metals and non-metals will produce compounds of ionic bond type.

Metal chemical reactions, in contrast to ordinary chemical reactions, show a characteristic tendency to form crystalline phases in which the electrons reside in the interionic regions, and can move with relative ease. This peculiarity of the collective distribution of valency electrons in the crystal lattice of complex metallic substances, without directional bonds, is highly typical of many metallic solutions and compounds. As a consequence, many products of metal chemical reactions have the metallic type of chemical bond.

By studying the physicochemical nature of metallic solid solutions, and the transition from solid solutions to compounds, it is easy to demonstrate a gradual change in chemical bond type and to relate it to the respective positions of the constituent elements in the Periodic Table. The wide spectrum of bond types observed in the products of reactions between metals, varying from purely metallic to ionic, demonstrates the fundamental status of the Periodic Law in the theory of metallic alloys.

## 4. FORMATION OF SOLID SOLUTIONS OF METALS

The term solid solutions (literally, "solidified solutions") first appeared in the literature in a report by Matthiessen[6], who studied the electrical conductivity of alloys as a function of composition, and was able to distinguish chemical

compounds, "solidified solutions", and mechanical mixtures of two metals from the shape of the "composition–property" curves. Following the development of the theory of phase equilibria, the concept of solid solutions achieved a wider significance, and was extended to include all solid phases of variable composition: isomorphous mixtures of metals, silicates, and other inorganic and organic systems. Thus, its influence has spread to all the fundamental types of equilibrium diagram for chemical systems[9,14,15,38,39].

The discovery of X-rays and their application to the study of the crystal structure of matter has made possible further developments in the theory of the formation of metal solid solutions. The conditions leading to the formation of solid solutions could be explained on the basis of ideas regarding the crystal lattice, the way in which atoms are located at crystal lattice sites, and data on interatomic distances in crystals. Metallic solid solutions (phases of variable composition) are formed either by replacing solvent atoms by solute atoms in the crystal lattice or by introducing solute atoms into the interstices of the solvent lattice. Thus, we now refer to two types of solid solution: 1) substitutional solid solutions, 2) interstitial solid solutions.

The fullest review of the historical developments in the science of solid solutions, of the theory of their formation, and of problems of chemical binding in metallic solid solutions is contained in the papers presented to the All-Union Conference on Solid Solutions, organised by the Division of Chemical Sciences and by the Institute of General and Inorganic Chemistry of the Academy of Sciences of the USSR [39,40] in 1944.

Many theoretical approaches to the nature and properties of metallic solid solutions were considered at that conference. Substitutional solutions are treated as solutions or as the chemical replacement of metal atoms in the solvent metal lattice by foreign atoms (S. T. Konobeevskii), and it is shown that the formation of all metallic solid solutions is accompanied by a positive thermal effect, arising from the formation of chemical bonds between solvent and solute atoms. Dorfman concludes[40], from a study of various nickel solid solutions, that a rudimentary form of valence bond between atoms of the solvent and of the alloying element is present.

Thus, solid solutions are described as phases of variable composition with a single type of chemical bond. Under certain conditions, chemical reactions can occur in a uniform medium of these solutions: they take the form of ordered distributions of atoms and of singularities and extrema in the physicochemical properties on the composition–property diagrams.

Many theoretical problems in the chemistry of metallic solutions and of reactions occurring in such media (for example, heterogeneities in solid solutions and the formation of various compounds with a special type of bond between the electrons of the different atoms) have great scientific interest. These problems are discussed in a special monograph by Grum-Grzhimailo[41].

From the chemical point of view, problems such as the electronic structure of solid solutions, the theoretical model of the structure of solid solutions (Friedel *et al.*), atomic radii and distortions of the crystal lattice, lattice structure and lattice defects in solid solutions, are equally important. These problems are of immediate relevance to the departures of real solid solution systems from the ideal conditions of homogeneity and stability. Departures of this type are symptomatic of chemical reactions between the dissolved atoms.

Modern researches on the physicochemical nature of solid solutions confirm that the theory of metallic solid solutions is based on the electronic theory of metals[43]. The basic postulate of this theory is that the atoms of solid solutions are randomly distributed in the lattice, and that the electrons are distributed (as in the case of pure metals) in the interstices between lattice ions, without any directional bonds. This model of the atoms and electrons of the solvent and solute metals presupposes the existence in the lattice of solid solutions of ionised atoms, with a collective distribution of quasi-free electrons. However, the possibility of interactions between the electrons of different atoms cannot be excluded, since atoms of different kinds are present in such a lattice[41,42].

The presence of chemical binding of this type in solid solutions manifests itself in changes in the thermochemical, physical, and other properties of systems consisting of solid solutions. These changes cannot be easily explained by simple geometrical considerations of substitutional or interstitial foreign atoms in the lattice of the solvent metal, without allowance for the chemical interaction between the electrons of the different atoms in solid solution lattices.

The number of valency electrons involved, and the extent to which they interact, control the conditions of formation of solid solutions, the degree of distortion of the crystal lattice, and the degree of disorder in the distribution of the atoms over the solid solution lattice. As we shall show below, these same factors determine the change from solid solutions to intermetallic compounds.

We shall now discuss the basic factors which control the conditions of formation of metallic solid solutions.

The most general and most important factor, as Ageev correctly points out[43], is the position of the elements in the Periodic Table, since this determines the electronic structure of the interacting atoms. From this fundamental factor stem derived criteria, which determine the conditions most favourable to the formation of a continuous series of solid solutions. These are: (1) not too large a difference in atomic radii and in electronegativity and ionisation potential — as was pointed out in the previous Sections, this criterion is met mainly by metals which are analogues or which occupy neighbouring positions in the Periodic Table; (2) if all these parameters have reasonably similar values, a continuous series of solid solutions is formed provided that the atomic radii do not differ by more than 8–10%. The conditions most conducive to the formation of a continuous series of solid solutions are that the metals should belong to the same group and have the same number of valency electrons, and that they should be capable of crystallising in isomorphous lattices.

If the difference between the atomic radii of the metals is increased from 10 to 16%, if their position in the electronegativity series is changed, or if the number of valency electrons is varied, the tendency to form solid solutions decreases. When the difference between the atomic radii exceeds 16%, and the difference in electronegativity and ionisation potential is large, there is a sharp drop in the tendency to form solid solutions, and when the difference exceeds 20% not only are solid solutions not formed, but the metals are immiscible even in the molten state.

This relation between atomic radii and the ability to form solid solutions can be explained by assuming that the

crystal lattice of the solvent metal can accommodate a certain amount of distortion when solvent atoms are replaced by solute atoms. Evidently, there is a maximum degree of lattice distortion beyond which the lattice has no stable existence. The writer has discussed these problems in the particular case of iron solid solutions[44]. Fig. 3 shows the distribution of atoms in the $\alpha$-Fe body-centred cubic lattice, both without lattice distortion (Fig. 3*a*) and with lattice distortion due to a 15% difference in atomic radius between a solute atom and iron (Fig. 3*b*). It is easy to see, by comparing Figs. 3*a* and 3*b*, that the solvent lattice becomes deformed when this difference ($dr$) increases: as long as the atomic radius difference is no more than 8–10%, atoms can be replaced indefinitely without destroying the stability of the lattice, but for larger radius differences (15% and over), and larger degrees of lattice distortion, solvent atoms can be replaced only up to a definite concentration at which the solubility limit is reached and a new phase of different crystal lattice type is formed. Analogous effects have also been reported by other workers[20,41] in the formation of solid solutions with various interatomic radii.

This treatment of the conditions under which solid solutions will form, being primarily based on the size-factor, is not comprehensive and should be coupled with the behaviour of the valency electrons and their interactions in the lattice of solid solutions.

The criteria for the formation of a continuous series of solid solutions listed above are most nearly satisfied by transition group metals with an unfilled *d*-electron shell, showing the greatest similarity in atomic radii and chemical properties (see Figs. 1 and 2). Many metals of these groups will give continuous solid solutions both within their group of the Periodic Table (same number of outer electrons) and with metals of adjacent groups (small difference in the number of valency electrons). Examples of this are the interactions between metals of the following groups: Group IV Ti, Zr, Hf; Group V V, Nb, Ta; Group VI Cr, Mo, W; Group VIII Fe, Co, Ni (iron subgroup) and Pd, Pt, Ir (platinum subgroup), and others. Metals crystallising in different lattice types are the only exceptions.

All the analogue-metals of the above triads form continuous series of solid solutions with one another. Continuous solid solubility for many of these systems was predicted by the writer[44] and confirmed by later work[45]. The formation of continuous series of solid solutions by metals of the transition groups also shows some regularity along horizontal rows, as evidenced by the systems Ti–V, Ti–Cr, Zr–Nb, Nb–Mo, Nb–W, etc.

The maximal number of systems of this type was calculated, according to the crystal lattice type, for three

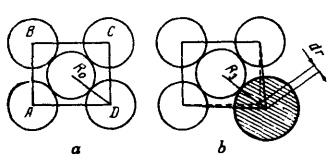

Fig. 3. Arrangement of atoms in the $\alpha$-Fe lattice (body-centred cubic) and in derived solid solutions:
*a*) in the $\alpha$-Fe lattice;
*b*) after substitution of an atom with 15% difference in radius.

classes of continuous solid solutions: (1) face-centred cubic lattice ($\gamma$-Fe); (2) body-centred cubic lattice ($\alpha$-Fe); (3) hexagonal lattice ($\alpha$-Ti).

Systems with continuous solid solutions between transition group metals of these three classes are listed in Table 2, which shows that metals which are nearest analogues can give continuous solid solutions even when the difference in atomic radii is as high as 10–11% (Ni–Rh, Ni–Ir, and some others). This is an example of the position of the elements in the Periodic Table and the similarity in chemical properties having a decisive effect on the nature of the interaction.

These metallic systems had not been investigated prior to the writer's publication[44], and the continuity of the solid solutions was then only tentatively predicted. Many of the systems have now been experimentally investigated, and it has been shown that the solid solutions are indeed continuous[45].

The systems with continuous solid solubility listed in Table 2 include the most refractory metals. Some typical fusion diagrams for these systems are shown in Fig. 4. As an example, we have reproduced the diagrams for systems with the $\gamma$-Fe lattice (Fe–Ni, Pt–Ir), the $\alpha$-Fe lattice (Fe–Cr, Cr–Mo, Cr–W, etc.), and the $\alpha$-Ti lattice (Ti–Zr, Zr–Hr, Ru–Os).

The tendency to form continuous solid solutions within a group of elements is also shown by groups other than the transition metals within which the difference in atomic radii is small and the electronic structure of the atoms is similar. This rule applies equally to highly electropositive and highly electronegative metals, including also some metalloids.

For example, among the electropositive metals, pairs such as K and Rb, Rb and Cs, Ca and Sr, Ca and Ba, and Ba and Sr, and among the electronegative elements Ge and Si, Bi and Sb, and Sb and As, have closely similar atomic radii and other properties (see Figs. 1 and 2), and

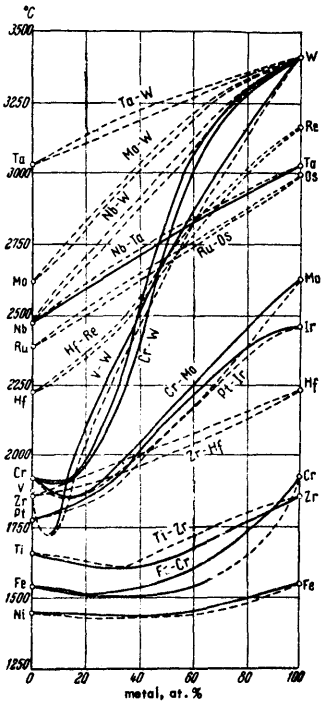

Fig.4. Fusion diagrams of systems of transition group metals forming continuous solid solutions.

form continuous solid solutions[45]. The mutual replacement of germanium and silicon, or antimony and arsenic atoms in the crystal lattice of these substances depends on the closeness of the atomic radii, on the equality of the number of valency electrons, and on the identity of crystal types. It is characteristic of these systems that germanium and silicon, being nearest analogues, can form continuous solid solutions in spite of the fact that one of them is a metal and the other a typical non-metal.

However, if the difference in atomic radii and in ionisation potential and electronegativity is large for elements of a given group (for example, C and Si, Bi and As), solid solutions cannot be formed, even though the number of valency electrons is the same[45].

The tendency towards restricted solid solubility in systems increases as we go from metal analogues to metals belonging to different groups, with different metal chemical properties (atomic radii, electronegativities, and number of valency electrons).

Thus, the tendency of a given metal (from Group VIII, say) to form solid solutions with metals of the Fourth Period decreases from right to left, whilst the opposite is true for a Group IV metal, the tendency decreasing from left to right. This can be illustrated by taking Ni (Group VIII) and Ti (Group IV) as examples.

The solubility of metals in nickel decreases in the following sequence:

| | Ni → Co → Fe → Mn → Cr → V → Ti → Sc → Ca → K | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Solubility, at. % | 100 | 100 | 100 | 50 | 43 | 15 | unknown—insoluble. | |

Nickel forms continuous solid solutions with the series from Co to Mn; from Cr to Sc only restricted solid solutions are formed, the solubility decreasing from Cr toward Ti and Sc, and with Ca and K there is practically no interaction. This is exactly what would be expected from the similarities and the differences in metal chemical properties between these metals and nickel. With titanium — a Group IV metal — the situation is reversed. The solubility of elements in β-titanium decreases in the sequence

| | V → Cr → Mn → Fe → Co → Ni | | | | | |
|---|---|---|---|---|---|---|
| Solubility, in Ti, at. % | 100 | 100 | 28 | 20 | 13 | 10 |

The β modification of titanium forms continuous solid solutions with V and Cr, but it forms only restricted solid solutions with Mn, Fe, Co, and Ni. It is clear from the solubility series that the maximum concentration of metals having a restricted solubility in β-titanium also decreases progressively from manganese towards nickel, that is, as the difference in metal chemical properties between these metals and titanium increases.

The systems formed by the β modification of titanium with the series of elements from Cr to Ni are illustrated in Fig. 5. Whereas Cr has an unrestricted solubility in β-titanium, the solubility of the other metals at their eutectic temperature decreases continuously in the sequence Mn → Fe → Co → Ni. The crystallisation temperature of the eutectic also decreases accordingly in these systems. The strictly sequential decrease in solubility in β-titanium of the series Mn → Fe → Co → Ni corresponds to the increasing separation of these elements of the Fourth Period from the position occupied by titanium, to a gradual increase in the number of electrons in the unfilled *d* shell, and to an increasing difference in atomic radii between titanium and these elements. These regular changes in limiting solubility can be demonstrated with many other metals.

Thus, starting from the fundamental physicochemical factors which determine the type of interaction between metals, the formation of solid solutions can be similarly classified for a number of metals of the Periodic Table. This has been done for silver and copper[20], magnesium and aluminium[46,47], iron and nickel[46,48], and chromium and

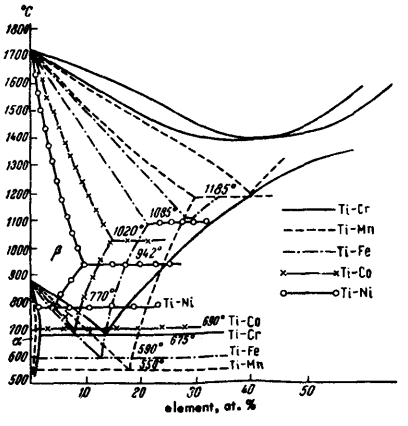

Fig.5. Fusion and solubility diagrams for the systems formed by β-Ti with Cr, Mn, Fe, Co, and Ni.

titanium[49,50]. The solubility of various elements in manganese[51] has been discussed recently, as well as more general aspects of the metal chemistry of niobium and vanadium, including the problem of the solubility of elements in these metals[52,53].

A knowledge of the mutual solubility of metals in binary systems is valuable in studies of the equilibria in multicomponent metallic systems with solid solutions. The limiting concentrations of alloys in multicomponent systems can be calculated from data on the behaviour of metals in binary systems, and complex solid solution compositions can be made. Calculations of this type were made by the writer for the production of 4-, 6-, 15-, and 16-component solid solutions based on nickel[54] and of 5-, 9-, and 10-component solid solutions based on $\alpha$-titanium.[55] These complicated solid solutions have many properties which are superior to those of pure metals and binary solid solutions. The preparation of these multicomponent solid solutions and the study of their properties are therefore of great theoretical and practical interest.

## 5. FORMATION OF INTERMETALLIC COMPOUNDS

The formation of various types of compound by metals with other metals or with non-metals is one of the characteristic reactions of metal chemistry. The products of such reactions have been termed intermetallic compounds or metallides[8]. This term applies to all the compounds formed between metals, whether their bond type is metallic or covalent. In addition to the reviews already mentioned[24-29], many investigations have been concerned with the formation, classification, and structure of intermetallic compounds, and have surveyed work in progress[56-61].

On the basis of the general principles for the classification of chemical compounds put forward by Kurnakov[8,14,15], intermetallic compounds can be subdivided into two main types: (1) compounds of variable composition (or berthollides), and (2) compounds of fixed composition (or daltonides).

These two types of intermetallic compounds are now generally accepted, and the terms are widely used in inorganic chemistry, metallography, and metal physics. They include not only the intermetallic compounds formed by crystallisation from molten alloys but also the compounds formed by transformations from solid solutions (see below). Among the berthollides and daltonides are included the many compounds formed by metals with non-metals of small atomic radius, such as carbon, nitrogen, oxygen, and hydrogen, and also the compounds with covalent bond type and semiconductor properties. Many compounds called carbides, nitrides, and sometimes suboxides and hydrides are in fact interstitial phases and have typically metallic properties.

The classification of high-melting compounds has been critically discussed[62] for a wide variety of compounds (mostly intermetallic compounds of the transition metals). The compounds were assigned to the following three classes: (1) compounds of two metals (true intermetallic compounds); (2) metal-like compounds (carbides, nitrides, phosphides, etc.); (3) compounds of two non-metals (non-metallic compounds between boron and carbon, carbon and silicon, etc.).

There is also a classification based on the regular changes in chemical bond character associated with the position of the elements in the Periodic Table. The first class includes the compounds formed by metals with other metals, that is, the true intermetallic compounds, such as beryllides, aluminides, stannides, antimonides, and many others. In the second class we find once again compounds with metallic bond type. The compounds of the first and the second class usually have a relatively simple crystal structure and belong to the cubic, the hexagonal, or the tetragonal system (close-packed atoms). All these compounds are studied in metal chemistry. Some of the compounds in the second class, composed predominantly of non-metal atoms, and the compounds formed by two non-metals, are non-metallic. Their chemical bond type is covalent or even ionic. Many have a complex crystalline structure and show semiconductor properties (high electrical resistance).

These compounds behave as independent components in equilibrium systems, and show distinctive singular points on composition–property diagrams (with the exception of the berthollides).

The singularity of properties is a characteristic criterion of compounds of fixed composition, whether formed by crystallisation from the melt or by transformations from solid solutions.

We will consider the metallic compounds formed as a result of decomposition of solid solutions. These compounds were first discovered (in 1914) by Kurnakov, during slow cooling of continuous solid solutions[56] in the Au–Cu system. The two compounds $AuCu_3$ and AuCu were identified in this way. Subsequently, compounds of this type were reported in many solid solutions, and called Kurnakov compounds in honour of their discoverer[26]. In contrast to solid solutions, all these compounds are characterised by an ordered distribution of atoms in their lattice.

At the present time, the systems giving continuous series of solid solutions without compound formation can be considered exceptional. Textbooks of physicochemical analysis[14,15], and many of the papers mentioned above[29], assign separate phases — corresponding to compounds on the equilibrium diagrams (see Fig. 6*a*) — to these metallic formations. These possess regions of homogeneity and the compositions of the compounds are distinguished by singular points. Compounds of this type are formed not only from continuous solid solutions, but also in systems with restricted solid solubility regions. Typical of these compounds are $VNi_3$, $VCo_3$, $MnAu_3$, $MgAg_3$, $Au_3Zn$, $Cu_3Zn$, $Fe_3Al$, and many others.

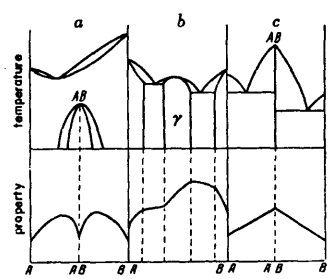

Fig. 6. Schematic equilibrium diagrams for metallic systems with three types of compound:
*a*) Kurnakov compound;
*b*) compound of the berthollide type;
*c*) compound of the daltonide type.

Among the recently discovered compounds are $Ti_6Al$ and $Ti_3Al$, formed from the restricted $\alpha$ solid solutions of aluminium in titanium[62]. Fig. 7, prepared from results obtained in the writer's laboratory, gives the equilibrium diagram of the system (above) and the variation of the Hall effect with alloy composition after long annealing (below). The compound $Ti_6Al$ is characterised by a break in the curve, whereas $Ti_3Al$ corresponds to the maximum at the intersection of two curves. The formation of this type of compound in the Ti–Al system causes marked changes in alloy properties; this has helped to clarify several anomalies in the mechanical and other properties of these alloys.

We have further developed Kurnakov's ideas regarding the importance of solid solutions in the formation of various types of compound, and have suggested that lower oxides of titanium can exist in the wide $\alpha$ solid solution region of the titanium–oxygen system. A detailed study of the alloys of the Ti–O system (up to 35 at.% oxygen) has recently provided experimental proof of the formation of the two previously unknown compounds $Ti_6O$ and $Ti_3O$ from titanium $\alpha$ solid solutions[63]. Both these compounds have metallic properties and crystallise with a hexagonal lattice, but $Ti_3O$ gives an X-ray pattern with superlattice lines which are characteristic of an ordered structure. The compounds $Ti_2O_3$ and $TiO_2$, which were previously known, belong to the valency type. The recently discovered compounds $Ti_6O$ and $Ti_3O$ can be classified as interstitial phases: they are still the only known examples of oxygen-containing compounds formed from restricted solid solutions. Because of these results, instead of the existing equilibrium diagram (Fig. 8) of the Ti–O system, showing a wide region of titanium $\alpha$ solid solutions, a new diagram was proposed[63], including the new compounds $Ti_6O$ and $Ti_3O$ (see Fig. 9). Analogous compounds of the suboxide type can be expected in other systems of chemically reactive metals with restricted oxygen solubility, for example, Zr–O, Hf–O, V–O, Nb–O, etc. A study of these systems would therefore be of interest.

The discovery of these compounds is very relevant to the understanding of the structure and physicochemical

properties of the alloys of titanium, zirconium, etc. which contain a high proportion of oxygen, and should help to throw light on the influence of oxygen on the mechanical and other properties of these metals.

The formation of intermetallic compounds and their relative stability depends on the difference in chemical properties (electronegativity, ionisation potential) of the interacting elements. The stability of intermetallic compounds

and the strength of their chemical bonds can be judged, as with any other chemical compound, by their heats of formation[64-66].

The available data show that the compounds between metal analogues, in which the difference in chemical properties between the two kinds of atom taking part in compound formation is smallest, are the least stable. In this sense, the least stable compounds are the Kurnakov compounds with an ordered structure, formed from solid solutions of analogue-metals. For example, the compound AuCu, mentioned above, has a heat of formation of 0.37 kcal × × mole$^{-1}$, whilst the compound FeCr, also formed from solid solutions, in the Fe–Cr system, has a heat of formation of 0.78 kcal mole$^{-1}$.

The author has made a study of the regularities displayed by the heats of formation of the intermetallic compounds of nickel of composition $MNi_3$, showing a gradual increase in the electronegativity difference between nickel and the metal M.

Fig. 10, prepared from the results of this work[67], shows the heats and temperatures of formation of the compounds of nickel with the following metals: Fe, Mn, Cr, V, and Ti, belonging to Groups VIII, VII, VI, V, and IV within the same period of the Periodic Table. As the difference in properties between nickel (electronegative) and the metals Fe, Mn, Cr, V, and Ti (electropositive) increases (see Table 1), the stability of the nickel compounds of composition $MNi_3$, involving these metals, increases in the sequence $FeNi_3 \rightarrow MnNi_3 \rightarrow CrNi_3 \rightarrow VNi_3 \rightarrow TiNi_3$.

The partly anomalous behaviour of the compound $CrNi_3$ in the above series calls for further examination. The first four compounds are formed from solid solutions and are therefore typical Kurnakov compounds, whereas $TiNi_3$, the most stable of the five, has the highest heat and temperature of formation and crystallises from the liquid phase. It should be noted that the difference in formation conditions (from the solid or the liquid phase respectively) has no effect on the gradual change in properties. This is proof of the generality of our proposition that the stability and the gradual changes in chemical bond strength of intermetallic compounds are a function of the position of the reacting elements in the Periodic Table.

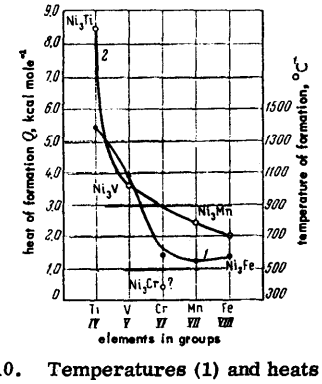

**Fig. 10.** Temperatures (1) and heats (2) of formation of compounds of nickel with iron, manganese, chromium, vanadium, and titanium of composition $MNi_3$.

We will now discuss some features of the formation of compounds of variable composition (the berthollides). They are characterised by the presence of a homogeneity region, and by the absence from the composition–property diagrams of well-defined singularities at the ordinates drawn through the composition of these compounds (see Fig. 6*b*). In the general classification of intermetallic compounds, berthollides are intermediate in stability between Kurnakov compounds and the compounds of the daltonide type. There are known examples of the formation of Kurnakov compounds from berthollide compounds stable at high temperatures when the temperature is lowered. A striking example of this is the transformation on cooling, in the Cu–Zn system, of the high-temperature $\beta$ phase of CuZn (berthollide) into the $\beta'$ phase (Kurnakov compound). The composition and crystal structure of these compounds is often determined by the ratio of the number of outer electrons to the number of atoms in the lattice of the compound. These compounds have been termed electron compounds; their quantum-mechanical theory is discussed in a number of papers[19,20,68]. Phases of this type are most readily formed by interaction between those metals of the B subgroups which are near neighbours in the Periodic Table and have a small electronegativity difference.

Isolated examples of the formation of such phases can be recognised in systems based on metals of Group I (Cu, Ag, Au) and metals of Groups II (Zn, Cd, Hg), III (Tl, In, Ga), V (Bi, Sb), and others. In some cases, the compounds under discussion are formed when these metals react with metals of the transition groups[46]. In the homogeneity region of these compounds, the properties change smoothly with composition, as shown in Fig. 6*b*.

With increasing difference in chemical properties between the reacting elements, associated with an increase in electronegativity difference, in the difference in ionisation potential, and in the difference in the number of valency electrons between the metals, the tendency to form intermetallic compounds of the second type (daltonides) increases. As shown in Fig. 6*c*, these are characterised by singularities in the composition–property diagrams.

This is particularly true of the interaction between the most electropositive metals of Groups I and II and the most electronegative metals of the B subgroups of Groups II–VI. This confirms Kurnakov's prediction[8] that the alkali and alkaline earth metals, being the main carriers of basic or metallic properties, should most readily form a variety of compounds with the heavy (and most electronegative) metals such as Hg, Zn, Cd, Pb, Sn, and Bi.

The gradual transition from metallic solutions through systems with berthollide compounds to intermetallic systems in which daltonides are formed can be demonstrated by selecting binary systems composed of analogue-metals and of metals differing in their chemical properties. Fig. 11, taken from Hansen and Anderko[45], shows three types of binary system: systems with continuous solid solutions of two nearest-analogue electropositive metals of Group I (K and Rb), restricted solid solutions based on metals and the berthollide $\omega$ phase in a system of two electronegative metals (Hg and Cd), and lastly a system in which no solid solutions are formed, but giving rise to six compounds of fixed composition (K, the most electropositive metal, and Hg, the most electronegative metal). All these compounds ($KHg_{11}$, $KHg_8$, $KHg_4$, $KHg_3$, $KHg_2$, and KHg) have higher melting points than their constituent metals: they are characterised by bonds of the metallic type and are typical intermetallic compounds.

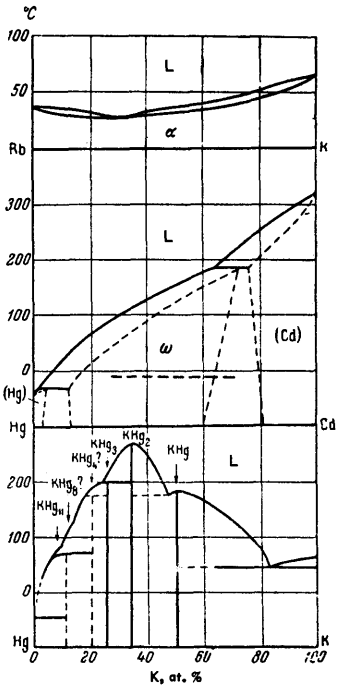

Fig. 11. Equilibrium diagrams of systems of two analogue-metals (K–Rb and Hg–Cd) and of metals from different subgroups (K–Hg).

On the other hand, compounds with different types of chemical bond are formed[31,65,66] in some metal–non-metal systems according to the concentration of the electronegative element. For example, in the series of compounds $Ti_6O$, $Ti_3O$, TiO, $Ti_2O_3$, and $TiO_2$ of the Ti–O system, the first two have metallic bonds, TiO has covalent bonds, and $Ti_2O_3$ and $TiO_2$ have predominantly ionic bonds.

Many compounds, for example, those formed by the electropositive metal magnesium with electronegative elements, show a characteristic transition from metallic to covalent and ionic bond character as the difference in chemical properties between the second component and magnesium is increased. This can be observed in the series of compounds formed by magnesium with the elements of Group IV (Pb, Sn, Ge, and Si). It should first be noted that all the compounds of magnesium with these elements correspond to the normal valency relationships: their composition is described in every case by the formula $Mg_2X$. As the electronegativity of the elements increases from Pb towards Si, transition from a purely metallic bond ($Mg_2Pb$) to a covalent bond takes place ($Mg_2Sn$, $Mg_2Ge$, $Mg_2Si$).

This same transition and gradual change in bond type is observed also in the series of compounds formed by magnesium with the elements of the Third Period: $Mg_3Al_2$, $Mg_2Si$, $Mg_3P_2$, MgS, and $MgCl_2$. These compounds also obey the valency rules, as their composition shows. The elements Al, Si, P, S, and Cl, present as a constituent, show increasing electronegativity and ionisation potential (see Table 1 and Fig. 2). Of these, only Al is a true metal, the remainder being non-metals. Although Al is situated in the Third Period close to Mg, it is quite unlike the electropositive element magnesium in its electronegativity (see Table 1). Hence, aluminium and magnesium form a series of compounds, including $Mg_3Al_2$, all of which are typically metallic. The next three compounds, $Mg_2Si$, $Mg_3P_2$, and MgS have covalent bonds and are semiconductors, possibly with partial ionic bond character. The last compound of this series, $MgCl_2$, is a typical compound with ionic bond character.

As the difference in chemical properties between magnesium and the above elements increases, whether along a group or along a period, the strength of the chemical bond of the magnesium compounds increases. This is reflected in an increase in the heat of formation and melting point of compounds of a given stoichiometric composition, as shown in Table 3.

The table lists the change in heat of formation ($Q$, kcal × × mole$^{-1}$) of compounds of magnesium with elements showing gradually increasing electronegativity difference with respect to magnesium.

A general survey of the heats of formation of compounds is sufficient to show that intermetallic compounds have much lower heats of formation than compounds of a covalent or ionic bond type. In all three columns of Table 3 the heat of formation increases from top to bottom, in the same sense as the electronegativity of the reacting elements: from Pb to Si for Group IV (B subgroup), from Te to O for Group VI (B subgroup), and from Si to Cl for the Third Period.

The stability of intermetallic compounds is also related to their melting point. The highest chemical bond strength corresponds, as a rule, to the highest melting point. This is illustrated by the linear plots of Fig. 12, which join the melting points of the compounds of Mg with Pb, Sn, Ge, and Si.

The melting points of the compounds $Mg_2Pb$, $Mg_2Sn$, $Mg_2Ge$, and $Mg_2Si$ show a gradual increase, corresponding to the tabulated heats of formation. For comparison, Fig. 12 also shows published values[45] of the melting point of compounds of lithium with lead and tin. These also show an increase in melting point on going from $Li_4Pb$ to $Li_4Sn$.

Linear extrapolation to the hypothetical compounds $Li_4Ge$ and $Li_4Si$, for which there are no published data, affords an estimate of their melting points (~870° for $Li_4Ge$ and ~980° for $Li_4Si$).

These regularities in the heats of formation and the melting points of intermetallic compounds, depending on the relative positions of the reactants in the Periodic Table, are expected to apply to many intermetallic and metal-like compounds. This can be demonstrated by inspection of a series of compounds between metals and metals or between metals and non-metals. Regularities of this type have been found in the gradual change in chemical bond type and heat of formation of borides[69], carbides[70], silicides[71],

TABLE 3. Heats of formation of compounds of magnesium with various elements.

| Compounds with Group IVB elements | $Q$, kcal mole$^{-1}$ | Compounds with Group VIB elements | $Q$, kcal mole$^{-1}$ | Compounds with elements of the Third Period | $Q$, kcal mole$^{-1}$ |
|---|---|---|---|---|---|
| $Mg_2Pb$ | 4.2 | MgTe | 25.0 | $Mg_2Si$ | 6.3 |
| $Mg_2Sn$ | 6.1 | MgSe | 30.0 | $Mg_3P_2$ | 25.6 |
| $Mg_2Ge$ | 6.1 | MgS | 42.2 | MgS | 42.2 |
| $Mg_2Si$ | 6.3 | MgO | 73.0 | $MgCl_2$ | 51.1 |

phosphides[72], and other compounds between metals and non-metals.

Tentative heats of formation[69-71] ($Q$, kcal mole$^{-1}$) of some borides and carbides of transition metals of Groups IV and V, of identical stoichiometry, are reproduced in Table 4. Although the data available for the borides of these metals are incomplete, we may conclude that the heats of formation increase in the same order as the electropositivity of the metal. The compounds formed between phosphorus and various metals are perhaps the most interesting from this point of view.

Starting from the fundamental properties of the phosphorus atom — larger atomic radius and lower electronegativity than its analogue, nitrogen — Samsonov and Vereikina point out[72] that the compounds of phosphorus with the transition metals cannot be regarded as interstitial phases except for the lanthanide phosphides. From electronegativity considerations, metal phosphidès should have a much lower ionic bond character than nitrides, and their properties should be less metallic than those of arsenides, antimonides, and bismuthides. Phosphorus also gives intermetallic compounds more readily than does sulphur.

As the number of phosphorus atoms in transition metal phosphides decreases, the role of the M–P and P–P bonds becomes less important and the M–M bond becomes predominant. The properties of the phosphides, like those of the carbides and nitrides, become more metallic under these conditions.

TABLE 4. Heats of formation of some metal borides and carbides.

| Group | Borides | | Carbides | | Group | Borides | | Carbides | |
|---|---|---|---|---|---|---|---|---|---|
| | composition | $Q$, kcal × mole$^{-1}$ | composition | $Q$, kcal × mole$^{-1}$ | | composition | $Q$, kcal × mole$^{-1}$ | composition | $Q$, kcal × mole$^{-1}$ |
| IV | $TiB_2$ | 70.2 | TiC | 43.8 | V | $VB_2$ | — | VC | 30.2 |

TABLE 5. Heats of formation of phosphides of the iron group.

| Compound | $Q$, kcal mole$^{-1}$ | Compound | $Q$, kcal mole$^{-1}$ | Compound | $Q$, kcal mole$^{-1}$ |
|---|---|---|---|---|---|
| $Fe_3P$ | 13.1 | $Co_2P$ | 28.45 | $Ni_5P_2$ | 17.4 |
| $Fe_2P$ | 19.25 | CoP | 34.0 | $Ni_2P$ | 19.2 |
| FeP | 29.0 | $CoP_3$ | 64.0 | $NiP_2$ | 38.0 |
| $FeP_2$ | 42.0 | | | $NiP_3$ | 45.2 |

In keeping with their greater percentage of metallic bond character, phosphides should have a lower heat of formation than nitrides. This is because the ionisation potential and electronegativity of the phosphorus atom are lower than those of the nitrogen atom. The transition from phosphides containing relatively few phosphorus atoms to phosphides containing more phosphorus atoms is accompanied by an increase in heat of formation ($Q$, kcal mole$^{-1}$), as shown[72] by the phosphides of iron, cobalt, and nickel listed in Table 5.

These data indicate that, as the number of phosphorus atoms in the compounds increases, so does the number of P–P and P–M bonds; as a result, covalent and ionic bonds begin to predominate. These raise the bond strength and bring about an increase in the heat of formation of the compounds.

Samsonov and Rodzinskaya[73] have demonstrated some measure of regularity in the chemical bond character of sulphides, related to the electronic structure of rare-earth elements and sulphur. They point out that "metallisation" of the bond occurs to a greater extent in sulphides than in the nitrides of the same metals, and ascribe this to the ionisation potential of sulphur, which, like that of phosphorus, arsenic, and carbon, is lower than the ionisation potential of nitrogen (see Fig. 2). Consequently, the sulphides of these metals (of given stoichiometric composition) can be expected to show greater collectivisation of the electrons from the metal and from the sulphur, and greater metallisation of the bond, than the corresponding nitrides. However, even the sulphides retain some covalent and ionic bond character: as in the phosphides, this increases with the number of sulphur atoms in the compound. For example thorium monosulphide ThS is a typical intermetallic compound[74], whereas $Th_2S_3$, $Th_4S_7$, and $ThS_2$ are classified among the compounds with a covalent and partially ionic bond.

This discussion of the influence of the physicochemical nature of the constituent atoms upon the nature of the chemical bond in intermetallic compounds demonstrates the importance of the metal chemical properties of the elements from the point of view of the formation of various types of compound. Many of the physical, mechanical, and other properties of these compounds are determined by the strength of the chemical bond.

## 6. CRYSTAL CHEMICAL REACTIONS IN METALLIC SYSTEMS

The study of crystal chemical reactions in metallic systems[28,74] is one of the main aspects of current work in the field of metal chemistry. The term includes a wide variety of reactions involved in phase transformations in

metallic systems and in surface reactions in the solid (crystalline) state. In contrast to the familiar chemical reactions in liquid and gaseous media, which usually occur by a homogeneous mechanism, these reactions are essentially heterogeneous and occur in a crystalline medium. We shall therefore call them crystal chemical reactions. Many of the problems involved are part of the general development of solid state chemistry.

Crystal chemical reactions include: (1) reactions leading to the formation of Kurnakov compounds from solid solutions; (2) reactions leading to the formation of compounds or other phases from supersaturated solid solutions; (3) eutectoid and peritectoid reactions; (4) surface reactions (oxidation, reduction, and other reactions in the solid state); (5) solid-phase reactions between powders of metals and non-metals.

Crystal chemical reactions are atomic rather than molecular in character[75]. They relate to the rearrangement and mutual replacement of atoms in a crystalline medium, and their rates are controlled by diffusion processes. The range of reaction times presented by these reactions is unusually wide: they vary from instantaneous reaction (in the case of martensitic transformations) to hundreds, thousands, or millions of hours, up to geological times (low-temperature decomposition of supersaturated solid solutions, etc.).

The rates of reactions in the solid state depend on a number of equilibrium considerations. Firstly, they depend on the chemical composition and crystal structure of the reaction medium, on the temperature, and on the pressure. These factors can accelerate or suppress the reaction rate. For example, it has been shown that individual chemical species involved in these processes correspond to singularities in the "composition–reaction time" diagrams. Hence, the author[76] has proposed a method of physicochemical analysis based on the effect of composition on the reaction time or the reaction rate in metallic systems. Studies of the reactivity of alloys (solid solutions, intermetallic compounds, heterogeneous alloys) are concerned with metal chemical reaction problems. Solid solutions and compounds can exhibit chemical passivation (the loss of reactivity at normal or elevated temperatures). Many corrosion-resistant and heat-resisting metallic materials have been developed on the basis of these properties. These are frequently homogeneous metallic solid solutions or intermetallic compounds. The chemical stability of these materials is hundreds of times greater than that of the starting components.

Crystal chemical reactions have one special feature in common: since they take place in the solid state, the intermediate states of reactions in progress may be "frozen" under various conditions, giving rise to a metastable structure of the resulting compounds or phases. Phases of this kind, being still in their formation stage, are dispersed in varying degrees: their atoms are not in their equilibrium crystal lattice sites. Due to their non-equilibrium state, these atoms are more reactive than the atoms of solid solutions and compounds in a state of equilibrium. This is strikingly confirmed by the high catalytic activity of many metastable states of metallic solid solutions and compounds[77].

A detailed characterisation of crystal chemical reactions and a substantially complete survey of the literature would go beyond the scope of the present review: there will be only a brief discussion of some types of crystal chemical reaction.

As was stated above, many solid solutions (both continuous and restricted) can undergo reactions with formation of Kurnakov compounds having, as a rule, a different type of crystal structure as compared with the solid solutions from which they are formed. The atoms have an ordered distribution in the lattice of these compounds, in contrast to the disordered structure of solid solutions. The compositions of these compounds can be recognised by singularities in the composition–property diagrams, and they extend over definite regions. The classical example of this type of equilibrium diagram arose from the experimental study[45,46] of the copper–gold system (see Fig. 13), showing the compounds $Cu_3Au$ and CuAu. Both these compounds, formed from solid solutions, are characterised by singular points on the plots of electrical resistivity and hardness against composition (Fig. 13).

Examples of the formation of Kurnakov compounds are very numerous[45]. At the moment, systems of solid solutions in which compounds of this type cannot be detected under suitable conditions are definitely exceptional.

Many restricted solid solutions in metallic systems show varying solubility in the solid state. As a rule, the solubility is highest at temperatures of transition from the solid to the liquid state (that is, at the solidus point), and decreases with decrease in temperature, as shown schematically by curves $SQ$ of Fig. 14*a*.

Because of this change in solubility, heat treatment — quenching the alloys from temperatures close to the solidus point — can be used to fix the solid solutions in a state of supersaturation for concentrations extending almost to the limiting solubility of the component at point $S$. The linear variation of lattice parameter with composition can be used to confirm that the solution is in a supersaturated condition, as shown in Fig. 14*b*. Under favourable conditions, decomposition of the supersaturated solid solution and precipitation of the phase in excess can occur in these metastable systems. This follows from thermodynamic considerations of the free energies of the phases in the

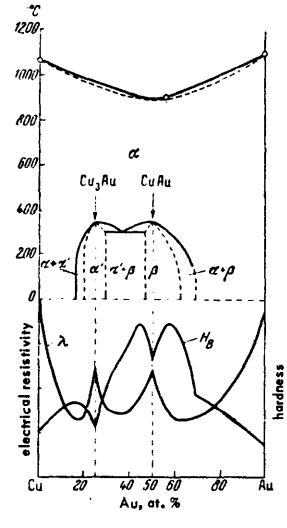

Fig. 13. Equilibrium diagram of the Au–Cu system, and change in electrical resistivity and hardness with alloy composition.

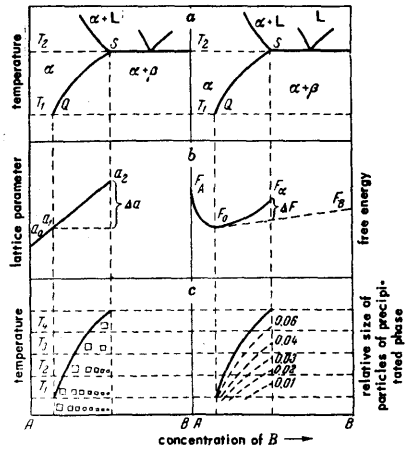

Fig. 14. Diagram showing changes in solubility (*a*), lattice parameter and free energy (*b*), and particle size of the precipitated phase formed by decomposition of supersaturated solid solutions (*c*).

equilibrium and the metastable states. The right-hand side of Fig. 14*b* shows the change in the free energy $F_A$ of the phase in equilibrium at temperature $T_1$. The minimum of the curve ($F_0$) corresponds to the equilibrium solubility limit, and its maximum ($F_\alpha$) to the non-equilibrium state of the $\alpha$ supersaturated solid solution. It follows that the supersaturated $\alpha$ solid solution must necessarily undergo transformation with formation of a precipitated phase in supersaturated (quenched) alloys lying to the right of the equilibrium solubility curve *SQ*. These decomposition reactions involve atomic rearrangements, the formation of intermediate, highly disperse phases, and the approach to and achievement of equilibrium phase structures. The grain size of the precipitated phases formed in these crystal chemical reactions depends on the composition, temperature, and time of the reaction.

The particles of the precipitated phase obtained in a fixed time at temperatures $T_1$, $T_2$, $T_3$, and $T_4$ are shown schematically in Fig. 14*c* as small squares (on the left) and as plots of their relative size (on the right). The size of the particles depends on the temperature and on the composition of the supersaturated solid solutions; it is determined by the conditions of formation of crystal nuclei and by the rate of growth of these nuclei.

This type of decomposition reaction in supersaturated solid solutions of metallic systems has been studied in a large number of alloys based on aluminium, iron, nickel, titanium, and other metals. They are of the utmost importance in raising the strength, heat-resistance, and changing other physicochemical properties as a function of conditions, and of the structure of the solid solutions undergoing decomposition and of the phases which are precipitated from them.

We can also suggest general mechanisms for the crystal chemical reactions occurring during eutectoid and peritectoid transformations in metallic systems.

Since a detailed discussion of these reactions is out of the question, we will merely state that eutectoid reactions proceed according to the scheme

$$\text{solid solution } \gamma \rightleftarrows \alpha + \text{AB (or } \beta \text{ phase)},$$

whereas peritectoid reactions involve the scheme

$$\gamma + \alpha \rightarrow \text{AB (or } \beta \text{ phase)}.$$

These reactions have their own individual peculiarities, depending also on composition and temperature, and the resulting phases can pass through a succession of intermediate states and exhibit different crystal structures. These reactions are particularly significant when the metals can exist in polymorphic modifications (Fe, Ti, Zr, etc.). These problems are dealt with in general textbooks on solid state chemistry[75] and metallography[18-23].

Surface reactions in alloys, occurring when these materials are heated in air or in special media[75,78-80], are a separate class of crystal chemical reactions. The branch of crystal chemistry concerned with reactions between metals and non-metal powders and with the formation of solid solutions, compounds, and heterogeneous alloy structures[75,81,82] has also attracted a great deal of work.

## 7. INTERACTION BETWEEN INTERMETALLIC COMPOUNDS

The reactions between intermetallic compounds, like reactions between metals, are determined by a number of physicochemical factors, which the writer has previously formulated[83]. The different types of interactions between intermetallic compounds in binary systems of these compounds can be described by means of the three main types of equilibrium diagram (see Fig. 15):

1. System AB–AC (continuous series of solid solutions),
2. System AB–AX (restricted series of solid solutions),
3. System AB–AY (eutectic mixtures without solid solutions).

The following factors are conducive[84] to the formation of continuous solid solutions (Fig. 15*a*) in intermetallic systems: (1) isomorphous crystal lattices of the two compounds; (2) identical chemical bond type; (3) compounds including elements with similar metal chemical properties; (4) compounds of identical stoichiometric composition.

Unless these conditions are met, the intermetallic compounds form only restricted solid solutions (Fig. 15*b*), and in the limit, for very large differences in chemical properties between the components, only mechanical mixtures are

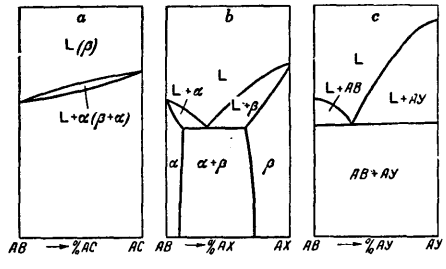

Fig. 15. Types of equilibrium diagram for intermetallic systems:
*a*) continuous solid solutions;
*b*) restricted solid solutions;
*c*) eutectic mixtures without solid solutions.

formed (Fig. 15*c*). All these problems of interactions between intermetallic compounds of different types have attracted a great deal of attention in recent times, and would justify a separate review article.

---o0o---

Thus, our review of the development and present status of the science of metal chemistry leads us to conclude that metal chemistry, as a scientific discipline, can unify the study of the interactions of over 80 metals of the Periodic Table, both with each other and with non-metals. By suitable application of Mendeleev's Periodic Law, metal chemistry establishes the principles which control the formation of the different classes of metallic solutions and compounds.

Metallic solid solutions, as phases of variable composition, have on the whole a single type of chemical bond: the metallic bond. On the other hand, there is a large number of intermetallic compounds showing very different bond types, from metallic to ionic. The study of solid solutions and metal compounds is highly relevant to an understanding of the mode of interaction of many metals, and it makes possible the prediction of equilibrium diagrams for as yet unknown simple and multicomponent metallic systems.

## I. INTRODUCTION

Pyrolytic graphite is the product of the pyrolysis of hydrocarbons on surfaces heated to 1000–2500°C. In recent years this material has attracted very considerable attention from research scientists, technologists, and engineers working in various fields of science and technology. This is because of the many quite unique properties of pyrolytic graphite. Its strength at temperatures

above 2500° exceeds that of any other known material. It has the highest ratio of strength to density (Fig. 1); its thermal and electrical properties show a very characteristic and highly developed anisotropy, the thermal conductivity being very low in the direction normal to the plane of deposition.

The particular method of preparation used ensures that pyrolytic graphite is practically a non-porous material.

Pyrolytic graphite (or pyrographite) also has great practical interest as one of the starting elements used in the production of other pyrolytic materials (pyrometals, pyrocarbides, pyrocarbonitrocompounds, etc.). The results of investigations on the production, structure, and properties of pyrographite can evidently be used to a great extent in the characterisation of these other pyrolytic materials. This is particularly true of the various pyrocarbides and pyrocarbonitrides, which can be expected to play an increasing part in the immediate future.

The study of the effect of formation conditions upon the structure and properties of pyrographite is very interesting also from a purely scientific point of view. Single crystals of graphite large enough to permit measurements of its physical and chemical properties have not yet been prepared. The properties of graphite are commonly studied using polycrystalline two-component or multicomponent materials, prepared by a kind of ceramic technique from graphitised carbon particles and a binding medium. The properties of specimens of these materials depend on many extraneous factors, such as the degree of dispersion of the particles, complex contact phenomena, uncontrolled porosity, etc.

The properties of pyrographite, which is prepared without the use of a binder, depend only on purely structural arrangements. Therefore, pyrographite is very attractive as a subject for investigation, especially in studies of the electrophysical properties of graphitised carbons.

## II. SHORT DESCRIPTION OF THE METHODS FOR THE PREPARATION OF PYROGRAPHITE

Pyrolytic carbon can be prepared by two paths:

1. Carbonisation, i.e. pyrolytic decomposition of carbon-containing materials in a condensed phase.

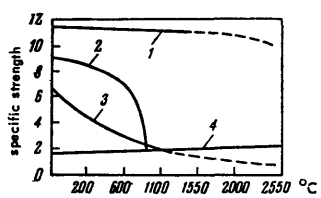

Fig. 1. Effect of temperature on the specific strength (ratio of strength to specific gravity) of pyrographite and of some other materials:
1) pyrographite, along the *a* axis;
2) stainless steel;
3) tungsten;
4) graphite.
[The units of specific strength are not given; it is often given as strength/density (Ed. of Translation).]

2. Deposition of carbon, i.e. homogeneous or heterogeneous decomposition of hydrocarbon gases and vapours.

In addition, pyrographites can be classified according to their preparation temperature into low-temperature (produced at 800–1100°) and high-temperature materials (produced at temperatures above 2000°). Low-temperature pyrographite can be prepared by deposition and by carbonisation methods, whereas the high-temperature form is usually prepared exclusively by deposition.

In the deposition method[1,2], hydrocarbons are made to impinge on a heated surface either in a stream of carrier gas at atmospheric pressure or by diffusion of gaseous hydrocarbons or the vapours of liquid hydrocarbons in an evacuated reactor. The carrier is usually an inert gas (nitrogen, argon, or helium).

There are many reports[3-14] of the use of various amounts of hydrogen in the reaction mixture, added to decrease the rate of pyrolysis.

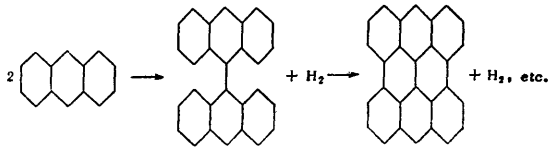
The solid deposition substrate, usually made of graphitised carbon, is heated either by induction or by a direct or an indirect resistance heater. Maintaining a constant temperature during the deposition seems to be very important. Many vacuum processes for making pyrographite have been described[6-8,15]. They differ mainly in the degree of vacuum used (from $10^{-1}$ mmHg[6-8] to $10^{-7}$ mmHg[15]).

## III. PHYSICOCHEMICAL PROCESSES OCCURRING DURING THE PREPARATION OF PYROGRAPHITE

The extreme thermal decomposition of hydrocarbons has been investigated by many workers[1,2,7,8,11-61]. One of the earliest papers on the mechanism of the thermal decomposition of hydrocarbons was published by Berthelot[41] as long ago as in 1866.

There are a number of opinions regarding the mechanism of the high-temperature pyrolysis of hydrocarbons.

According to Tesner and his coworkers[20,22-35], and also some non-Soviet authors[12-14,21], the decomposition of hydrocarbons on surfaces heated to high temperatures involves the direct dissociation of hydrocarbon molecules into carbon and hydrogen. However, Wheeler considers[13] that the decomposition proceeds through the adsorption of a hydrocarbon molecule on the surface, followed by dehydrogenation of the adsorbed molecule.



At low concentrations, the formation of pyrolytic graphite can only occur heterogeneously, since gaseous reactions are precluded. According to Tesner and Rafal'kes[25,29], the rate of formation of a pyrolytic film at 800–1000° is directly proportional to the hydrocarbon concentration, i.e. the reaction is of the first order with respect to the hydrocarbon. As the concentration is raised, the probability of gaseous reactions increases, and at a well-defined critical concentration (which Tesner calls[29] the "threshold" concentration) the reactions in the gas phase begin to produce carbon in a very fine state of subdivision (soot). However, the formation of carbon at the heated surface continues even when soot begins to precipitate in the reaction volume.

Tesner and his coworkers believe[20,22-26,29] that the inhibition by hydrogen of the pyrolysis reaction results from activated adsorption of hydrogen on the surface or from Stefan flow of hydrogen from the surface[31]. According to other workers[12-14,21], the effect of hydrogen can be

explained by a shift of the equilibrium towards the reactants.

An alternative mechanism suggested for the formation of pyrocarbon states that hydrocarbons are dehydrogenated during pyrolysis to give complex polymeric aromatic compounds, which are ultimately converted into solid particles. According to this hypothesis, pyrocarbon is an aggregate of extremely high-melting polymeric hydrocarbons[1,8,9,17,38,39,51]. This provides a fairly simple description of the pyrolysis of aromatic compounds. Kinney *et al.*[1,38,39] studied the pyrolysis of benzene and some of its derivatives and found that the yield of pyrocarbon increases with the molecular weight of the aromatic compound, and that under these conditions fission of the aromatic rings does not occur, since low-molecular-weight acetylene hydrocarbons are not detected in the effluent gases even when hydrogen is used as the carrier gas — hydrogen should favour the formation of these compounds. Gases which usually accompany acetylene (e.g. ethylene) are also absent[1].

These features of the pyrolysis of aromatic compounds were confirmed by the work of Rudenko[2], who demonstrated the absence of products from the decomposition of the benzene ring in the gases obtained from the pyrolysis of benzene. In a study of the pyrolysis of anthracene, Kinney *et al.*[39] obtained resinous products as well as solid carbon. Chromatographic analysis of the resin revealed the presence of the anthracene condensation products 9,10-diphenylanthracene and 1,2,5,6-dibenzanthracene. A fraction having an ultraviolet adsorption spectrum identical to that of 9,9′-bianthryl was isolated. Multiple dehydrocondensation, analogous to the process observed during coking of petroleum products[52], obviously occurs:

The presence of diphenylanthracene is due to the excess hydrogen, which causes partial rupture of the aromatic rings. The reaction occurs on the surface as a result of sorption and dehydrogenation of the hydrocarbons, with formation of highly condensed products unlikely to diffuse into the gas phase. On this model, hydrogen lowers the yield of carbon by causing hydrogenation.

The fact that hydrogen has a more pronounced effect in the pyrolysis of non-aromatic hydrocarbons[22] lends support to these views, since these compounds evolve more hydrogen.

Grisdale and coworkers[17,50] have suggested a similar mechanism, but they believe that condensation of aromatic rings occurs in the gas phase, with subsequent deposition of high polymers on the surface. The main evidence in favour of their mechanism is the frequent appearance of spherical drop-like formations on the pyrographite surface. However, the authors do not advance any really serious arguments in support of their views. The attempt by Conroy *et al.*[38] to detect highly condensed aromatic hydrocarbons in the gas phase was unsuccessful.

Other workers[15,40-49,51,53,58,60] point out that the pyrolysis of hydrocarbons involves a free-radical mechanism. Thus, the pyrolysis is characterised by the so-called "wall effect", i.e. the recombination of radicals at the walls of the reaction chamber or at other surfaces within the reaction zone.

In addition to wall recombinations (chain breaking), reactions between radicals occur also in the reaction volume: these lead to a whole spectrum of more complex hydrocarbons.

Hague and Wheeler[44] consider that the initial act in the decomposition of methane is the formation of hydrogen and a methyl radical.

Bone and Coward[11], and also Fischer[36,45], are of the opinion that the first stage in the decomposition of methane involves the formation of the radicals $CH_3$, $CH_2$, and CH.

Rice *et al.*[46] have shown that gaseous hydrocarbons, in particular butane and propane, when passed through a quartz tube heated to 800–1000° at a pressure of 10 mmHg, can destroy Pb, Zn, and Sn mirrors at a distance of 30–40 mm from the reaction zone. This is evidence for the presence of free radicals.

Rice and Dooley[47] showed that the main reaction occurring during the pyrolysis of ethane is dissociation into free radicals rather than splitting off of molecular hydrogen, as had been assumed by many other workers.

Poltorak and Voevodskii[58] used deuteration to prove that the pyrolysis of propane occurs by a radical mechanism; this relies on the ready exchange between deuterium and the hydrogen of free radicals. Propane was pyrolysed in the presence of deuterium, and deuterium was detected in the hydrocarbons produced by the reaction in amounts which were not a function of reaction time.

Shantarovich and Pavlov[60] studied the kinetics of the thermal cracking of methane on porcelain and carbon black surfaces. The shape of the kinetic curves given by the cracking reaction on carbon black is indicative of autocatalysis, the acceleration being due to the development of a chain process. The authors conclude that the decomposition of methane occurs by the following scheme:

$$CH_4 \rightarrow CH_3 + H,$$
$$H + CH_4 \rightarrow CH_3 + H_2,$$
$$CH_3 \rightarrow CH_2 + H,$$
$$CH_3 + CH_4 \rightarrow C_2H_6 \text{ or } CH_2 + CH_4 \rightarrow 2CH_3.$$

Retardation by hydrogen is probably associated with chain breaking by hydrogen, and with displacement of the equilibrium towards the reactants. A critical inspection of the suggested mechanisms prompts the following remarks.

The direct decomposition mechanism lacks adequate experimental proof. The authors quote only activation energy values, which are found to be of the same order as the energy of the C–H bond. The formation of carbon from aromatic hydrocarbons is inexplicable on the basis of this mechanism.

The multiple dehydrogenation mechanism is more realistic, and can claim sounder experimental confirmation. The retarding effect of hydrogen on the rate of formation of pyrolytic graphite is an additional indirect proof of the dehydrogenation scheme for the formation of carbon films. However, in view of the work of Stehling and others[40,42], a purely condensation type of mechanism is unacceptable. It is clear that this mechanism occurs in conjunction with radical polymerisation.

The radical mechanism for the formation of pyrolytic graphite appears to us to be the most probable, since it has quite unambiguous experimental confirmation. We may therefore describe the formation of pyrolytic graphite as follows.

When the hydrocarbon molecules enter the high-temperature region, they are split into free radicals. With aromatic hydrocarbons, fissure occurs at C–H bonds, whereas with aliphatic hydrocarbons the C–C bond is mainly affected[61]. The hydrogen atoms produced by the cleavage of the molecules react with the incandescent carbon surface to give lower hydrocarbons and their radicals: $CH_4$, $CH_3^{\cdot}$, $C_2H_5^{\cdot}$, $C_2H_6$, $C_2H_2$, $C_2H^{\cdot}$, and $^{\cdot}C\equiv C^{\cdot}$. These produce active centres on the carbon surface, able to react with newly formed radicals. Extensive dehydrogenation and consolidation of the radicals occurs before these can enter into the reaction from the gas phase.

Thus, a large number of local interactions occurs simultaneously at many sites. The resulting film of pyrolytic graphite is a true replica of the outline of the substrate surface, showing that the carbon atoms cannot move over the surface at high temperatures.

The hydrocarbon residues, being on a hot surface whose energy is higher than that of the surrounding gas phase, can split off hydrogen and react with neighbouring residues, thus forming a crystal lattice.

Since aromatic structures are thermodynamically the most stable at high temperatures, cyclisation takes place on the surface, with formation of a graphitic network. The distance between graphitic planes, and the development of three-dimensional order, depend on the deposition temperature. At low hydrocarbon concentrations (whether under atmospheric pressure or in a vacuum) and at temperatures of the order of 2000° the fundamental processes take place on the surface. At temperatures above 2800° in a vacuum the vapour pressure above the carbon surface is so high[62] that the radicals cannot reach the surface, and decomposition of the hydrocarbons occurs in the gas phase.

At relatively low temperatures (~ 1100°) the energy of the surface is much lower, and the radicals can penetrate inside the pores of the carbonaceous material and decompose there. This is the basis of the bulk densification of graphitised carbon articles, designed to impart greater strength and hardness and lower permeability to gases[19,20]. The process should be carried out at low concentrations, for otherwise the orifices of the pores may become rapidly covered over, and prevent the penetration of the hydrocarbon into the material.

Simultaneously with the surface decomposition, reactions leading to the formation of biphenyl, acetylene, hydrogen, etc. take place in the bulk[43]. The rate of these reactions is determined by the concentration of the vapours undergoing pyrolysis and also by the temperatures and duration of the process and by the physicochemical properties of the surface.

The influence of temperature and of partial pressure of the gas on the rate of growth of the carbon film was investigated by Murphy *et al.*[54], who used the logarithmic equation of Chen *et al.*[63] to describe the effect of these factors:

$$\log\left(\frac{m}{pT}\right)=\log\left[\frac{\pi D}{\rho L}\delta K\frac{k}{h}\left(\exp\frac{\Delta S^*}{R}\right)\right]-0.4343\,\frac{\Delta H^*}{RT},$$

where $m$ is the rate at which the electrical conductance increases, $p$ the partial pressure of the hydrocarbon, $D$ the diameter of the film of pyrographite, $\rho$ the electrical resistivity of the film, $L$ the length of the film of pyrographite, $\delta$ the thickness of a monatomic layer of carbon in the film of pyrographite, $K$ the rate constant for the growth of a monatomic layer, $k$ Boltzmann's constant, $h$ Planck's constant, $\Delta S^*$ the entropy of activation under standard conditions, $\Delta H^*$ the activation energy standard conditions, $R$ the gas constant, and $T$ the absolute temperature.

The rate constants measured experimentally for the pyrolysis of benzene, toluene, and methane are plotted against $1/T$ in Fig. 2. The linear plot shows that the reaction rate is quite low at temperatures below 860°, but becomes very large above 940°.

Similar kinetic curves were reported by Mar'yasin and Tesner[23,24], who studied the kinetics of the deposition of pyrographite films by the pyrolysis of methane in the temperature range 1400–1700°. This indicates that the temperature coefficient of the pyrolysis reaction rate is high. Between 1600° and 1800° this coefficient can apparently exceed the temperature coefficient which determines the lowering of the activation energy attending the ordering of the structure of the pyrographite film. This results in the phenomenon of structure disordering described below, and causes a decrease in the density of pyrographite in this temperature range.

The influence of the surface on the production of pyrolytic graphite needs special consideration.

Kobozev[56], in his study of the cracking of methane to acetylene, investigated the possible catalytic effect of the surface in the pyrolysis of methane to carbon. He found that the yield of carbon on the walls of the reactor was increased 50- to 100-fold when quartz or porcelain vessels were used. The reaction was typically catalytic, as shown also by the very specific action of various materials, depending on the type of surface, which was observed during a search for catalytic poisons to suppress the pyrolysis of methane to carbon.

Benevolenskaya and Kel'tsev[59] state that active alumina surfaces produce the most extensive decomposition of hydrocarbons undergoing cracking. At 1300° the hydrogen content of the effluent gases was as high as 96–97%.

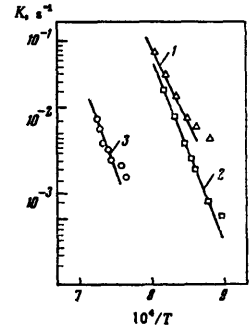


Fig. 2. Temperature variation (after Murphy *et al.*[54]) of the rate constant ($K$) for the pyrolysis of: *i*:
1) toluene;
2) benzene;
3) methane.

Kinney and Del Bel[1] studied the pyrolysis of aromatic hydrocarbons from benzene to chrysene on different surfaces. They found, in particular, that the rate of pyrolysis (e.g. of anthracene to carbon) increases with the amount of coke present in the reactor, which suggests a heterogeneous catalytic reaction. The rate of reaction is increased also by silicon, mullite, and quartz, the quartz being by far the least effective.

According to Holdeman and Botty[55], heavy metals are the most active catalysts for the formation of pyrolytic carbon. They believe that the cracking of methane to carbon at temperatures up to 1000–1200° is a purely surface catalytic process. The actual catalyst in this case is either adsorbed carbon or the substrate surface, modified by the reducing action of hydrocarbon radicals and hydrogen at these temperatures.

Fig.3. Electron diffraction pattern of pyrographite.

## IV. STRUCTURE OF PYROGRAPHITE

The remarkable properties of pyrographite are very much bound up with the structure of the material. This is particularly true of its highly developed anisotropy.

We know[64] that the various kinds of graphitic carbon material have in common a highly polymeric arrangement of the carbon atoms, which exist in hexagonal planes of different sizes and differently oriented in space.

In the most highly ordered state (graphite single crystals) the hexagonal planes of carbon atoms are stacked in the sequence ABAB. The interatomic distance in the six-membered rings is 1.42 Å, and between the symmetrically disposed planes it is 6.71 Å. In the hexagonal graphite lattice, three $\sigma$ electrons form strong covalent bonds with three neighbouring atoms in the plane, and the fourth electron forms a weak $\pi$ bond with a carbon atom from a neighbouring plane. The highly anisotropic properties in two mutually perpendicular directions is a direct consequence of this arrangement.

The opposite limiting case, a completely disordered state, corresponds to a statistically indeterminate distribution of the separate carbon planes over the volume of the material, the binding between the planes involving hetero-atoms, functional groups, or linearly polymerised carbon atoms.

However, this is an extreme case. In practice, even the most disordered carbonaceous materials consist of stacks of hexagonal planes which are mutually parallel, oriented with respect to the normal, and have dimensions of the order of 25 Å in thickness and 35 Å in diameter. These crystallites are bound together by the uncompensated valencies of the corner atoms, and also by the linearly polymerised carbon, hetero-atoms, etc. already mentioned.

Between these two extremes we find a whole range of intermediate structures[65]. Their distinguishing feature is the fact that the size of the crystallites in the direction of *a* axis varies from 50 to a few hundred Ångstrom units, and that only two-dimensional order persists. This means that orientation is complete only with respect to the normal to the crystallites.

Pyrographite is typical of the class of polycrystalline intermediate structures. However, it is distinguished by a high degree of preferential crystal orientation, observed in the aggregates of crystallites. The evidence for this is the electron diffraction pattern shown in Fig. 3 and the clearly developed hexagonal symmetry of the reflection patterns. X-Ray diffraction studies[66,67] have shown that the individual crystallites have a well-developed texture of (002) planes parallel to the deposition surface (Table 1).

This crystallographic picture is in good agreement with the results obtained by Fialkov *et al.*[68] in an X-ray structural investigation of natural graphites which had been made amorphous.

Other diffraction work has shown[8,67,69] that the degree of orientation of the hexagonal planes with respect to the deposition surface increases at higher deposition temperatures. The preferential orientation of pyrographite as a function of deposition temperature is assessed by X-ray diffraction[67] from the intensity of the (002) reflections obtained when the deposition surface is aligned at various angles to the incident beam. The degree of preferential orientation was evaluated[67] as the ratio of $n_{max}$ to $n_{min}$, the relative intensities obtained with the deposition surface perpendicular and parallel to the incident X-ray beam.

Bragg and Packer[70], from measurements of the integral intensity of the (002) line, constructed a plot of this parameter (expressed in arbitrary units) against the inclination of the specimen ($\alpha$) to the incident beam. They showed (Fig. 4) that the intensity of the (002) line varies linearly with $\alpha$ [Fig. 4 shows that the logarithm of the intensity varies linearly with $\alpha^2$ (Ed. of Translation)] for specimens deposited at 1950° (*1*) and 2100° (*2*). Heating at 3000° for various times (curves *3* and *4*) introduced some departures

TABLE 1. X-Ray diffraction analysis of pyrographite.

| Specimen | Interplanar spacing, $d_{002}$, Å | Crystallite size along a axis, $L_a$, Å | Degree of graphitisation (Ref. 71) |
|---|---|---|---|
| Prepared[66] in induction-heated vacuum furnace at 2300° | 3.38 | 300 | 0.57 |
| Prepared[66] in induction-heated vacuum furnace at 2400° | 3.35 | 600 | 1.0 |
| Prepared[66] in a vacuum resistance furnace at 2100° | 3.42 | 235 | 0.07 |
| Prepared[66] in a vacuum resistance furnace at 2500° | 3.37 | — | 0.78 |

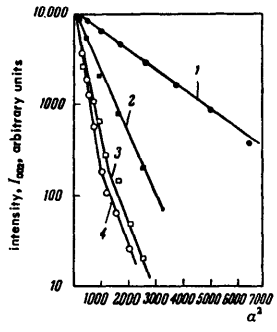

Fig. 4. Variation of the intensity $I_{002}$ with the angle of incidence of the X-ray beam (after Bragg and Packer [70]) for different specimens of pyrographite, deposited: 1) at 1950°; 2) at 2100°; 3) at 2100°, followed by heat treatment for 5 min at 3000°; 4) treated for 25 min at 3000°.

TABLE 2. Influence of temperature and method of heating of the deposition surface upon the degree of preferential orientation.

| Deposition temperature, °C | Method of heating | Subsequent heat treatment | Preferential orientation | | Literature references |
|---|---|---|---|---|---|
| | | | $n_{max}/n_{min}$ | $\chi_\perp/\chi_\parallel$ | |
| 1 | 2 | 3 | 4 | 5 | 6 |
| 2100 | in resistance furnace (at atmospheric pressure) | none | — | 8 | 10 |
| 2100 | in resistance furnace (at atmospheric pressure) | none | — | 11 | 10 |
| 2100 | in resistance furnace (at atmospheric pressure) | heated to 2900° | — | 16 | 10 |
| 2300 | in resistance furnace (at atmospheric pressure) | heated to 2900° | — | 17 | 10 |
| 2100 | in resistance furnace (at atmospheric pressure) | heated to 3400° | — | 24 | 10 |
| 2300 | in resistance furnace (at atmospheric pressure) | heated to 3400° | — | 40 | 10 |
| 1700 | induction (*in vacuo*) | none | 5 | — | 88 |
| 1700 | induction (*in vacuo*) | 3 h at 2500° | 5 | — | 88 |
| 2400 | induction (*in vacuo*) | none | 2000 | — | 88 |
| 2100 | in resistance furnace (*in vacuo*) | none | 2000 | — | 88 |
| 2500 | in resistance furnace (*in vacuo*) | none | 4000 | — | 88 |

from linearity. However, Fig. 4 justifies the general conclusion that the (002) planes of the crystallites in pyrographite show a gaussian distribution, which can be expressed in the form:

$$I(\alpha) = I_0 \exp(\alpha^2/2\sigma^2),$$

where $\sigma$ is the variance of the distribution.

At higher preparation temperatures, and after high-temperature treatment, $\sigma$ decreases. Measurements of the diamagnetic susceptibility of a pyrographite film in the above-mentioned directions are a good method for evaluating structural anisotropy [10].

Data on the degree of preferential orientation as a function of deposition temperature and method of heating are reproduced in Table 2. It can be seen that the value of $n_{max}/n_{min}$ varies from 5 at 1700° to approximately 4000 at 2500°.

The magnetic measurements reveal quite substantial changes in anisotropy after heat treatment (up to 3400°) of specimens prepared at 2100–2300°.

At temperatures of 2200–2300° and above, the pyrographite begins to develop three-dimensional order. This transition is preceded by a steady increase in crystallite size with temperature (both the height $L_c$ and the diameter $L_a$), and by a decrease in interplanar spacing (Table 1). The transition manifests itself by the appearance and development of a (112) X-ray structural reflection, detected by the increase in the ratio of line intensities $I_{112}/I_{110}$.

Another quantitative test of the incipient three-dimensional ordering is provided by the sharp increase in electrical and thermal anisotropy. Taking a value of approximately 3.42 Å for the interlayer distance in the disordered state, and 3.355 Å in the single crystal, Kasatochkin and Kaverov [71] proposed the parameter $\gamma$ for estimating the degree of graphitisation:

$$\gamma = \frac{3.425 - C_0/2}{3.425 - 3.355} = \frac{3.425 - C_0/2}{0.065},$$

where $C_0/2$ is the measured interlayer distance of the specimen.

Fig. 5 shows the variation of the three-dimensional ordering parameter of pyrographite with deposition temperature. By using induction heating (curve *1*), values varying between 0 and 1 can be obtained in the temperature range 1700–2400°.

These changes are characteristic of all types of graphitic carbon showing good graphitisation (homogeneous graphitisation, in Franklin's terminology [72]). When heating is by passage of an electric current through the specimen on which deposition is taking place (*cf.* curve *2* of Fig. 5), the graphitisation parameter is much lower. The difference between the two methods of heating is most probably due to an increasing thermal isolation of the pyrographite layer on the heater, causing a decrease in deposition temperature with increasing distance from the original surface of the heater.

Blackman and Ubbelohde [69] have published photometric curves obtained in an X-ray diffraction study of individual specimens of pyrographite of different thickness. Fig. 6 shows that the (*h*0*l*), (*hkl*), and (00*l*) lines decrease in intensity and increase in width as the thickness of the deposit increases, indicating a decrease in the degree of three-dimensional order with increasing separation from the original deposition surface.

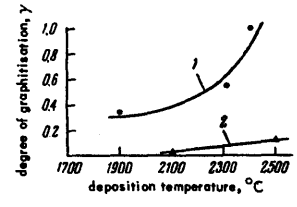

Fig. 5. Effect of deposition temperature and method of heating on the parameter for three-dimensional structural ordering in pyrographite:
1) heating in induction furnace;
2) heating in resistance furnace.

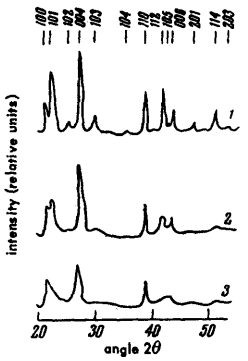

Fig. 6. Photometric traces from an X-ray diffraction study[69] of pyrographite, taken at various distances from the basal deposition plane:
1) 0.33 mm; 2) 0.49 mm; 3) 0.59 mm.

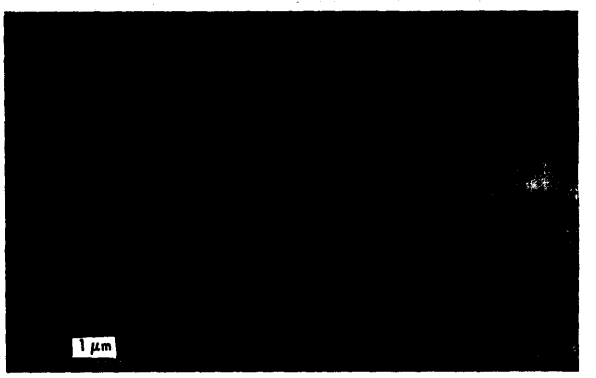

Fig. 8. Structure of pyrographite, observed in an electron microscope (× 8400).

Quite sharp differences in character between the resulting structures are revealed by the X-ray diffraction data for deposits of pyrographite obtained by Collingan and Galasso[37]. These authors showed that the structure of pyrographite is not a function of temperature only. Thus, they report that the (*hkl*) lines of specimens prepared at 1900° in an induction-heated furnace are sharper than those of specimens produced in a resistance furnace at 2200° and 2300°. It is right to point out, in this connection, that the deposition temperature is not a unique and sufficient criterion for the formation of the pyrographite structure. In addition to the temperature and to the method of heating, the composition and pressure of the gas phase, the gas flow rate, etc., can be expected to have a definite effect on the structure.

Fig. 7 shows a typical pyrographite microstructure, consisting of columnar formations of conical shape. As shown by X-ray diffraction, the hexagonal carbon planes are preferentially oriented normally to the conical formations, whose dimensions are typically a few microns. At higher deposition temperatures the columnar formations become dispersed[9,73,120].

High-temperature plastic deformation at 2750° tends to convert (10) lines into (100) and (101) lines. Thus, the degree of three-dimensional order — assessed by the increase in intensity of (101) lines — increases with the amount of plastic deformation[74]. Examination of pyrographite[75] in the electron microscope has revealed polygonal formations with a very fine internal structure.

The present authors have been able to detect[120] subgrains of less than 0.1 μm diameter in pyrographite preparations in the electron microscope (Fig. 8), thus confirming earlier reports[75,76].

## V. PROPERTIES OF PYROGRAPHITE

### 1. Density

The specific gravity of polycrystalline graphitised carbon materials is one of their most important characteristics. This criterion is also very informative with pyrolytic graphite.

The variation of density with deposition temperature has been described by Brown and his coworkers[7,8,73,77].

On the curve of density against deposition temperature (Fig. 9) we may distinguish the following sections: (1) 1000–1400°; (2) 1400–1700°; (3) 1700–2000°; (4) 2000–2500°.

It can be assumed that the density of a pyrolytic graphite deposit is controlled by two main factors: (1) the mobility of carbon atoms on the deposition surface (the rate of

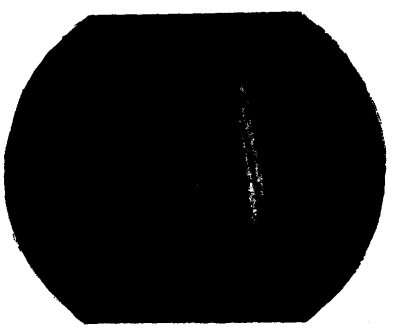

Fig. 7. Microstructure (× 50) of pyrographite, prepared by the authors[120] *in vacuo* at 2100° in a resistance furnace.

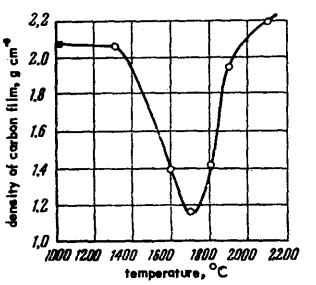

Fig. 9. Variation in density of pyrographite with temperature (after Brown and Watt[8]).

reorganisation of the crystallites); (2) the size of the hydrocarbon radical involved in the decomposition process at the surface.

In the temperature region 1000–1400° the mobility of carbon atoms is low and the hydrocarbon radicals are small, so that the resulting deposits are weakly oriented and have a high density (2.0–2.1 g $cm^{-3}$). Between 1400° and 1700° the activation energy of the dehydrogenation processes decreases, and the rate of formation of hexagonal carbon planes increases. At the same time, the hydrocarbon radicals become very much larger. The net result of these effects is to produce poorly oriented deposits of quite low density (as low as 1.29 g $cm^{-3}$ at 1700°).

At temperatures above 1700°, there is a sharp increase in the mobility of the hexagonal carbon planes, and fairly well oriented deposits of high density are formed in spite of the possibility of larger hydrocarbon radicals (the density exceeds 2.22 g $cm^{-3}$, and approaches the value of 2.26 g $cm^{-3}$ found in single crystals[9]).

The density and other properties of the deposits are not a function of the nature of the hydrocarbon[7,8,20,73,77].

Studies of gas permeability[19,73] have shown that open pores are absent. This suggests that the change in density of pyrographite is due exclusively to changes in the packing of the crystallites and of their constituent hexagonal layers.

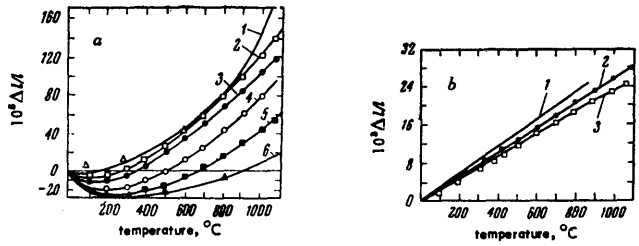

Fig.10. Temperature variation of linear thermal expansion for pyrographite and single crystals of natural graphite in two mutually perpendicular directions[80]:
*a*) along the *a* axis:
1) of specimens prepared at at atmospheric pressure;
2) of coarsely crystalline structures prepared *in vacuo* and heat treated for 3 h at 2700°;
3) of coarsely crystalline structures prepared *in vacuo*;
4) of microcrystalline structures prepared *in vacuo*;
5) of microcrystalline structures prepared *in vacuo* and heat treated for 3 h at 2700°;
6) of single crystals of natural graphite;
*b*) along the *c* axis:
1) of single crystals of natural graphite;
2) of pyrographite as prepared;
3) of pyrographite heat treated for 1 h at 3000°.

## 2. Hardness

The hardness of pyrographite is a function of the deposition temperature, and shows a maximum at 1000–1520° according to Tesner and Timofeeva[20]. This is because the material prepared at these temperatures has the maximal amount of structural disorder and the best developed system of cross-linking bonds.

The hardness of pyrographite has been found to be higher in the deposition direction than at right angle to it.

According to Lozier and Manofsky[9], pyrographite of density 2.2 g $cm^{-3}$ (deposited at 2000°) is nine or ten times harder in the deposition direction than ordinary polycrystalline graphite. Subsequent heat treatment at 3000° produces a four- or five-fold decrease in hardness, both in the deposition direction and perpendicular to it.

## 3. Linear Thermal Expansion

Pappis found[78-81] that the linear thermal expansion coefficient of pyrographite is directly related to the crystallographic anisotropy of the material. Fig. 10 shows the changes in linear thermal expansion of pyrographite specimens in two mutually perpendicular directions as a function of the temperature and method of preparation, and of heat treatment. An increase in the deposition temperature, and high-temperature heat treatment, cause the linear expansion coefficient in both directions to approach the corresponding values for single crystal specimens[9]. However, as Fig. 10 shows, the two values differ very considerably. This is because the linear expansion coefficient of pyrographite is sensitive not only to crystallographic factors but also to the microstructure, and to the internal stresses which develop in the material. Heat treatment at 3000°, by favouring the growth of structural anisotropy, also relieves internal stresses in the material. Specimens prepared at atmospheric pressure (unlike those prepared in a vacuum) do not show a negative temperature coefficient between 0° and 700° in the direction parallel to the deposition surface. This indicates a considerable decrease in the degree of preferential orientation of the hexagonal carbon layers.

The large difference (more than a factor of ten) between the linear thermal expansion coefficients in two mutually perpendicular directions causes the large internal thermal stresses which appear in pyrographite on cooling[69].

## 4. Mechanical Properties[4,74,78,80-84]

There are large discrepancies between results obtained by various authors, owing to the lack of a unique method of determining the mechanical properties of pyrographite. Hence, the statements made below should only be accepted as tentative. Like many of its other properties, the strength of pyrographite shows distinct anisotropy. It is highest in the direction parallel to the deposition surface.

(a) The tensile strength increases with temperature (as in the case of polycrystalline graphites). Pappis[80] explains this phenomenon in terms of the increase in plasticity of pyrographite on heating. However, it seems more likely that the increase in strength of pyrographite with temperature is associated with the relief of internal stresses, the closing up of microcracks, and the increase in area of contacting surfaces on heating.

The temperature coefficient of the tensile strength depends on the deposition temperature (Fig. 11), and to a lesser degree on the size of the conical fragments.

A decrease in grain size makes the appearance of internal stresses less likely, and thus raises the strength of these materials.

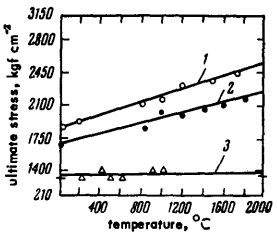

Fig.11. Temperature variation of the tensile and bend strengths of pyrographite:
1) bend strength[80] with load applied parallel to the *c* axis;
2) bend strength with load applied normal to the *c* axis;
3) ultimate tensile stress[85].

One of the main differences between pyrolytic graphite and the normal polycrystalline graphite carbons is the steady increase in strength of the former up to temperatures[83] in excess of 3000°.

(b) The bend strength increases with decreasing size of the conical formations, again because of the decreased probability of crack formation. This parameter also increases slightly with the temperature of the measurement (Fig. 11).

(c) The elongation increases from 0.1% at room temperature to 24% and 59.2% at 2500° and 2750° respectively[74]. At 1650° the elongation of pyrographite is higher than that of any other form of synthetic graphite.

## 5. Thermal Conductivity[8-9,69,71,73,74,80-82,84,86,87]

It is evident, from the data of Table 3, that the anisotropy coefficient at 300°K can vary from 50 to 100 according to the conditions under which the pyrographite is prepared[87]. In the direction parallel to the deposition surface the thermal conductivity can be as high as 320 kcal $m^{-1}$ $h^{-1}$ $deg^{-1}$, which is higher than the thermal conductivity of copper, whereas in the perpendicular direction it has a value of the order of 1–3 kcal $m^{-1}$ $h^{-1}$ $deg^{-1}$, which corresponds to the best high-temperature thermal insulants.

The temperature dependence of the thermal conductivity of various types of pyrographite is shown in Fig. 12. It is determined by phonon–phonon interactions and by the size of the crystallites. The curves go through a maximum at 50–100°K. Below these temperatures $K_\perp$ is proportional to $T^\alpha$, where $\alpha$ lies between 2.3 and 2.8. These data show that the anisotropy coefficient of the thermal conductivity of pyrographite is also a function of temperature.

TABLE 3. Thermal conductivity of pyrographite.

| Specimen | Density, g $cm^{-3}$ | Thermal conductivity, kcal $m^{-1}$ $h^{-1}$ $deg^{-1}$ | | | Thermal anisotropy $K_\parallel/K_\perp$ |
|---|---|---|---|---|---|
| | | measurement temperature, °K | $K_\perp$ | $K_\parallel$ | |
| Raytheon pyrographite (Ref. 87) | 2.10 | 300 | 2.25 | 215 | 95 |
| Raytheon pyrographite (Ref. 87) | 2.17 | 300 | 2.95 | 320 | 110 |
| General Electric pyrographite (Ref. 87) | 2.19 | 300 | 1.24 | 57 | 46 |

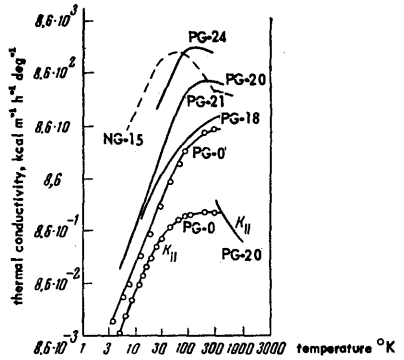

Fig.12. Temperature dependence of the thermal conductivity of various specimens of pyrographite (PG) and natural graphite (NG) at right angles to the *c* axis, after Slack[87]. Values of $K_\parallel$ (parallel to the *c* axis) are given only for two specimens. NG-15, Canadian natural graphite; PG-24, National Carbon pyrographite; PG-21, Royal Aircraft Establishment pyrographite; PG-20, Raytheon pyrographite; PG-18, National Carbon pyrographite; PG-0, General Electric pyrographite.

## 6. Electrophysical Properties

(a) Electrical resistivity. Fig. 13, based on Klein's results[88], shows the effect of deposition temperature on the electrical resistivity in a direction parallel to the deposition surface (see also Table 4).

The curve of Fig. 13 can be divided into sections corresponding to the following temperature ranges: 1100–1700°, in which the curve slopes gently; 1700–2000°, where the electrical resistance falls sharply (by about a factor of ten); above 2000°, where the curve slopes gently again.

This curve has a characteristic similarity to the behaviour of conventional well graphitised materials. However, the inflections occur at lower temperatures with the latter materials, and the resistance in the direction of the

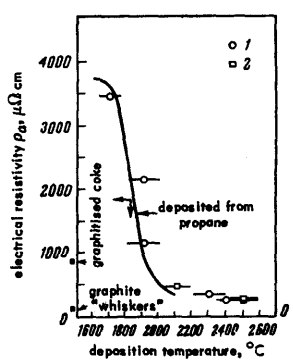

Fig.13. Effect of deposition temperature[88] on the electrical resistivity of pyrographite in the direction of the *a* axis:
1) pyrographite prepared in an induction furnace;
2) pyrographite prepared in a resistance furnace.

TABLE 4. Electrical resistivity at 20° of pyrographite and some graphites.

| Materials | Resistivity, Ω mm² m⁻¹ | | Anisotropy $\rho_a/\rho_c$ |
|---|---|---|---|
| | $\rho_a$ | $\rho_c$ | |
| Pyrographite[88] prepared at 2500° | 3 | 11000 | 3670 |
| Graphite single crystals[89,90] | 0.4 | 50 | 125 |
| Graphite "whiskers"[91] | 0.5 | — | — |
| Synthetic graphite | 10 | — | — |

deposition plane is much lower in the case of pyrographite. This is yet another manifestation of the sharp structural anisotropy of pyrographite. However, the electrical resistance in the direction of the *a* axis is about an order of magnitude higher than in a graphite single crystal.

For the reasons already discussed, the resistance at right angles to the deposition surface increases with deposition temperature. This gives rise to a large increase in the anisotropy of the electrical resistivity with increase in deposition temperature. As Klein points out[88], this effect is intimately related to the structural anisotropy of the material ($n_{max}/n_{min}$, measured by X-ray diffraction as described above).

(b) Magnetic susceptibility. The magnetic susceptibility of pyrographite, like that of other graphitic carbons, is of the diamagnetic type. This is explained by the aromatic structure of the carbon network.

Table 5 gives the diamagnetic susceptibility of pyrographite specimens (after Fishbach[10]), together with susceptibility data for single crystals.

The diamagnetic susceptibility of pyrographite was measured in two mutually perpendicular directions: $\chi_{\parallel}$ and $\chi_{\perp}$ (parallel and perpendicular to the deposition surface, respectively). The measurements were made by the Gouy balance method; the average susceptibility was calculated by the expression $\chi_{av} = \chi_{\perp} + 2\chi_{\parallel}$ CGS deg$^{-1}$.

It is clear from the data in Table 5 that the anisotropy of the diamagnetic susceptibility of pyrographite increases after heat treatment.

The effect of the heat-treatment temperature on the average magnetic susceptibility of pyrographite prepared at 2100–2300° is shown in Fig. 14. The susceptibility minimum found at 2900° is due to the removal of structural defects at these temperatures. Pyrographite prepared at 1900–2000° shows very small changes in susceptibility with the temperature of heat treatment.

TABLE 5. Diamagnetic susceptibility of pyrographite and of single crystals of natural graphite at 20°, $10^6$ CGS g$^{-1}$.

| Materials | $\chi_{av}$ | $\chi_{\perp}$ | $\chi_{\parallel}$ | $\chi_{\perp}/\chi_{\parallel}$ |
|---|---|---|---|---|
| Pyrographite prepared at 2100° (after Fishbach (Ref. 10) | 27.3 | 21.6 | 2.8 | 8 |
| Same specimen, heat treated at 2900° | 20.0 | 17.8 | 1.1 | 16 |
| Same specimen, heat treated at 3400° | 20.7 | 19.0 | 0.8 | 24 |
| Single crystals of natural graphite, data by Poquet *et al.* (Ref. 92) | 24.7 | 24.0 | 0.3 | 66 |
| data by Krishnan and Ganguli (Ref. 93) | 23.0 | 22.0 | 0.5 | 44 |

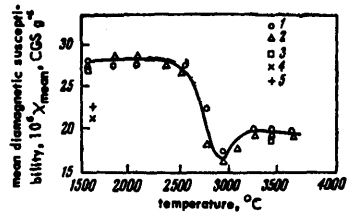

Fig. 14. Variation of the mean diamagnetic susceptibility of pyrographite with temperature of heat treatment (after Fishbach[10]):

2) pyrographite deposited at 2100°;
3) pyrographite deposited at 2200°;
4) from Ref. 92;
5) from Ref. 93.

(c) Hall coefficient. The following conclusion can be drawn from the variation of Hall coefficient and degree of graphitisation with deposition temperature[88], shown in Fig. 15.

(1) Pyrographite deposits offer a very wide range of electrophysical properties.

(2) The sign of the Hall coefficient changes twice over the range of deposition temperatures: from minus to plus when deposition occurs at 1500–1600° and from plus to minus at 2100–2200°.

(3) The highest value of the Hall coefficient in the *p*-region occurs at about 1800–1900°, as compared with 2000–2100° for conventional well-graphitised carbons. This same reduction by 200 deg in the critical temperature occurs also, as stated above, in the curve of electrical resistivity against deposition temperature: it is indicative of lower-temperature processes taking part in the formation of intermediate structures in the case of pyrographite.

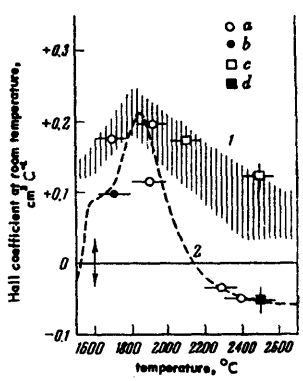

Fig. 15. Effect of deposition temperature on the Hall coefficient of pyrographite[88]:

2) curve for pyrographite;
*a*) prepared in an induction furnace;
*b*) the same, after heat treatment;
*c*) prepared in a resistance furnace;
*d*) the same, after heat treatment.

TABLE 6. Hall coefficients of some graphitic structures.

| Materials | $R_H$, cm³ C⁻¹ |
|---|---|
| Pyrolytic graphite[88] prepared in a resistance furnace at 2000° | +0.12 |
| Pyrolytic graphite, heat treated[88] at 2600° | −0.05 |
| Single-crystal natural graphite[94] | −0.05 |
| Industrial *p*-type graphite | +0.30 |
| Industrial *n*-type graphite | −0.01 |

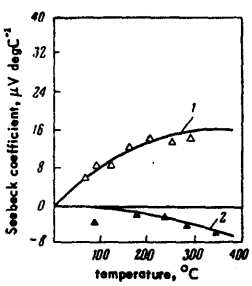

Fig.16. Temperature dependence of the Seebeck coefficient of pyrographite[89]:
1) as prepared;
2) heat treated at 3000°.

This can be explained in terms of the preferential orientation of the hexagonal layers in pyrographite, facilitating the subsequent structural transformations which ultimately determine the electronic properties.

(4) The *p*-region of the Hall curve corresponds to a degree of graphitisation $\gamma \leq 0.6$. In this region we observe the highest development of structural defects which act as "traps" for electrons and thus give rise to positive holes.

(5) Heat treatment which causes $\gamma$ to increase beyond $\gamma = 0.5$ can also convert pyrographite from the *p* to the *n* conduction type (see also Table 6).

(6) This latter circumstance offers the possibility of realising *p*–*n* junctions in thick layers of pyrographite heat treated at different temperatures. These can be used as high-temperature thermoelements.

Fig. 16 shows the change in Seebeck coefficient with temperature for a *p*–*n* junction in a flat wafer of pyrographite. The *p*-region of graphitised carbons is known[94-99] to conduct by both electrons and holes. The changes in Hall coefficient in this case are due to recombination effects arising from electron–hole interactions in the pyrographite. At the appropriate concentrations of the two types of carrier, and making allowance for the difference in mobility of electrons and holes, conditions for the minimal concentration of uncompensated positive charges (holes) can arise. These correspond to the maximum in the Hall curve.

## VI. USES OF PYROGRAPHITE

The high heat resistance, strength, and density of pyrographite, in conjunction with a highly anisotropic thermal conductivity, enable this material to be used in ultra-high-temperature technology as a highly heat-resisting constructional material and for thermal insulation[100-112]. It has been reported[3,6,83,86,101,108-110,113-115] that pyrographite can be used successfully as an erosion-resistant coating for the nozzles of rocket motors, combustion chambers, and nosecones. The properties of pyrographite are said to be superior to those of the best grades of graphite, previously used for these purposes.

Since pyrographite is a practically non-porous material, it has an interesting application as a moderator in nuclear technology. There has been a report[116] of particles of uranium or thorium dicarbide being covered with a 50–100 μm layer of pyrographite and mixed with graphite to produce the heat-evolving elements of a reactor.

The freedom from pores and high corrosion resistance of pyrolytic graphite enable it to be used in the chemical industry as a replacement for scarce metals. Furthermore, vacuum-tight and chemically stable high-temperature materials can be produced by filling the pores of conventional graphitised carbon ware with pyroltyic graphite[19-20].

Graphite tubes, coated with pyrolytic graphite, have proved highly satisfactory as heater elements for electrical resistance furnaces[117].

The unique electrical properties of pyrographite offer a wide scope for applications in electronics (various types of resistor, shunts, etc.)[16-18].

As stated above, the thermoelectric properties of pyrographite enable *p*–*n* junctions to be prepared in the material, and offer the possibility of using pyrographite in high-temperature thermocouples and thermoelements. The recent measurements by Rupprecht *et al.*[118] of the Seebeck coefficient of various pyrographites confirm this prediction.

Thin films of pyrographite show interesting optical properties[83], including that of optical anisotropy. The absorption coefficient for electromagnetic waves is a function of the direction of polarisation, as is the reflectivity. Thus, thin films of pyrographite can be used to polarise infrared radiation[119].

# THERMODYNAMICS OF MOLTEN SALTS WITH A COMMON ION

A.N.Kirgintsev and E.G.Avvakumov

CONTENTS

1. Introduction 58
2. Distinguishability of the common ion 58
3. Relation between the exchange energy and the properties of the constituents of the solution 63
4. Calculation of exchange energies 65

## 1. INTRODUCTION

According to Semenchenko's classification[1], ionic salt solutions belong to the group of homoeodynamic solutions. Hence, solutions of ionic salts can be expected to show the general properties of homoeodynamic solutions.

The theory of homoeodynamic solutions relies to a great extent on statistical methods. However, at least for the time being, any kind of statistical description can give no more than a relatively crude picture of real solutions. We believe, therefore, that simple and clearly defined physical models, whose conclusions can be put to simple experimental test, should prove very valuable in this field. The regular solution model is typical of such models.

According to the theory of regular solutions, the potential energy of formation of a solution, $\Delta E$, is given by the expression

$$\Delta E = \omega N_{AB}, \tag{1}$$

where $N_{AB}$ and $\omega$ are respectively, the number of bonds between atoms or molecules of different kinds in the case of atomic or molecular solutions and the average potential energy of one such bond (exchange energy). For solutions of ionic salts, these quantities refer to the number of bonds between ions of different kinds and the average potential energy of one bond. If the solution, composed of the salts $A_{n_1}C_{n_2}$ and $B_{n_3}C_{n_4}$, contains $n_1N_1$ ions of kind A and $n_3N_2$ ions of kind B, we have

$$N_{AB} = \frac{n_1N_1 \cdot n_3N_2}{n_1N_1 + n_3N_2}. \tag{2}$$

Since the chemical potential of the $i$th salt component is given by

$$\mu_i = \mu_{i0} + \frac{\partial \Delta E}{\partial N_i} - T\frac{\partial \Delta S}{\partial N_i}, \tag{2a}$$

it can also be expressed, using Eqns. (1) and (2), in the form

$$\mu_i = \mu_{i0} + \omega\beta_i(1 - x_i)^2 - T\frac{\partial \Delta S}{\partial N_i}, \tag{3}$$

where

$$\beta_1 = \frac{n_1}{\left(x_2 + \frac{n_1}{n_3}x_1\right)^2}, \quad \beta_2 = \frac{n_3}{\left(x_1 + \frac{n_3}{n_1}x_2\right)^2}, \quad x_i = \frac{N_i}{N_1 + N_2}; \tag{4}$$

and $\mu_{i0}$ denotes the chemical potential of the $i$th component in its standard state (taken to be the pure compound); $\Delta S$ is the entropy of mixing. In what follows, formulae relating to the first and to the second component of a solution or of a system will be written in that order.

The present article discusses the application of regular solution theory to solutions of ionic salts having a common ion, and considers the relation between the exchange energy $\omega$ and the properties of the individual constituents. Considerable use is made of published data as well as of values calculated by the writers.

## 2. DISTINGUISHABILITY OF THE COMMON ION

The earliest theories of ionic solutions[2,3,4], and some of the later ones[5,6], determine the potential energy of a solution in terms of the ionic radii and the composition. The entropy of mixing is usually assumed equal to the normal entropy of mixing of ideal solutions. This approximation can be too crude when ions of different valencies are involved, since the problem of the entropy of mixing is not considered in those papers.

From the thermodynamic point of view, the formation of an ideal solution presents three independent requirements:

1. The change in potential energy resulting from formation of the solution must be zero.

2. The volume change accompanying the formation of the solution must be zero.

3. The partial entropy of mixing of the $i$th component must equal $-k \ln x_i$ (where $k$ is Boltzmann's constant).

These conditions are usually assumed when dealing with molecular and atomic solutions belonging to the homoeodynamic class of solutions. The first two can also be adopted for solutions of ionic salts, but the third requires clarification.

The difference between ionic salt solutions on the one hand and atomic and molecular homoeodynamic solutions on the other is that in the former solutions the number of species (i. e. kinds of particles) is not the same as the number of solution components. For example, in a two-component KCl–RbCl solution we have three kinds of particles: potassium, rubidium, and chloride ions. The appearance of an additional species may give rise to an additional term in the entropy of mixing. Therefore, the third condition for the formation of ideal solutions of ionic salts should be formulated in the most general way, i. e. by stating that the particles (ions) in solution which determine the entropy of mixing must be distributed entirely randomly, according to the laws of chance.

The problem of ideal solutions of ionic salts appears to have been first discussed in a paper by Temkin[7], who used an ionic model of pure salts and their mixtures. The ions in pure salts and in solutions of salts are assumed to be distributed so that each cation is effectively surrounded by anions and vice versa. The electrostatic forces between ions are quite large, and therefore interchange of cations and anions must be excluded when computing the entropy of mixing. According to Temkin, the entropy of mixing is given by

$$\Delta S = \Delta S_+ + \Delta S_-;$$
$$\Delta S_+ = k \ln W_+; \quad \Delta S_- = k \ln W_-; \tag{5}$$

where $W_+$ and $W_-$ are the numbers of possible interchanges between cations only and between anions only.

Temkin applied Eqn. (5) only to solutions consisting of the salts AB and CD. For solutions of other salts, Temkin introduces the concept of activity coefficient by analogy with aqueous solutions. This is hardly justifiable, however[8]. It would be desirable, therefore, to apply Eqn. (5) to ionic salt solutions of any type. In fact, the entropy of mixing, determined by the interchange between distinguishable particles (i. e. those particles whose interchange produces a new microstate of the solution), is also the parameter which determines the formation of an ideal solution. This part of the entropy is given by Eqn. (5). We should also note that whereas Temkin's paper discusses liquid solutions (melts), the conclusions are equally applicable to solid solutions of ionic salts, since the state of aggregation is not taken into consideration.

Thus, the entropy of mixing of an ideal solution of ionic salts should be calculated from Eqn. (5). In accordance with this equation, the chemical potential of the $i$th salt component in an ideal solution is given by

$$\mu_i = \mu_{i0} - T\left(\frac{\partial \Delta S_+}{\partial N_i} + \frac{\partial \Delta S_-}{\partial N_i}\right). \tag{6}$$

We will discuss the application of Eqn. (6) to various binary solutions having a common ion. Although the formal discussion is confined to a common anion, all theoretical conclusions are equally applicable to solutions with a common cation. The general formulae of the salts which compose the solutions are $A_{n_1}C_{n_2}$ and $B_{n_3}C_{n_4}$: we shall refer to these as the first and the second component respectively. We shall use $N_1$ and $N_2$ for the number of "molecules" of $A_{n_1}C_{n_2}$ and $B_{n_3}C_{n_4}$ in the solution.

1. The cations A and B have the same valency. The chemical formulae of the salts forming the solution are $A_{n_1}C_{n_2}$ and $B_{n_1}C_{n_2}$. A solution composed of these salts has $n_1(N_1 + N_2)$ cation sites and $n_2(N_1 + N_2)$ anion sites. We shall assume that each cation can occupy only one cation site and each anion only one anion site. The anions corresponding to the cations A and B are indistinguishable, i. e. they form a "medium", within which cation interchange can take place. Then

$$W_- = 1, \ \Delta S_- = 0. \tag{7}$$

The cations in cation sites can be distributed in more than one way: two cases are possible.

(*a*) Cations of the two kinds are distributed randomly over the cation sites in such a way that "molecules" can be distinguished in the solution:

$$A_{n_1}C_{n_2}, \ A_{n_1-1}BC_{n_2}, \ A_{n_1-2}B_2C_{n_2}, \ \ldots, \ B_{n_1}C_{n_2}.$$

In this case the individual A and B ions can interchange places. Hence

$$W_+ = \frac{n_1N_1 + n_1N_2}{(n_1N_1)!\,(n_1N_2)!}. \tag{8}$$

Substituting Eqns. (7) and (8) into (5), and differentiating Eqn. (6), we find

$$\mu_1 = \mu_{10} + n_1kT \ln x_1;$$
$$\mu_2 = \mu_{20} + n_1kT \ln x_2. \tag{9}$$

(*b*) The different cations in solution are distributed in groups. Assume, for example, that the solution contains only "molecules" $A_{n_1}C_{n_2}$ and $B_{n_1}C_{n_2}$. In this case, A and B ions form a group of cation sites, and interchanges in cation sites are possible only in groups of $n_1$ A-cations and $n_1$ B-cations. If we assume that these groups are randomly distributed in the solution,

$$W_+ = \frac{(N_1 + N_2)!}{N_1!N_2!}. \tag{10}$$

Substitution of Eqns. (7) and (10) into (5), and differentiation of Eqn. (6), gives

$$\mu_1 = \mu_{10} + kT \ln x_1;$$
$$\mu_2 = \mu_{20} + kT \ln x_2. \tag{11}$$

Our general solution model cannot, of course, identify the solutions in which case *a* or case *b* is realised. We may conclude, however, on general grounds, that case *a* should obtain in solid solutions, since the formation of solid solutions requires that the cations A and B should have similar properties. In liquid solutions (melts), on the other hand, case *b* is also possible.

2. The cations A and B have different valencies. Here, the calculation of entropy of mixing for an ideal solution presents very real difficulties. With cations of the same valency we are able to treat the anions as a "medium" for the interchange of cations, but the situation has to be more accurately defined when cations of

different valency are envisaged. Consider, for example, the solution KCl–RbCl. According to our model, this solution consists of $N_1 + N_2$ cation sites and $N_1 + N_2$ anion sites. Let the cation and anion sites in the solution be distributed in a regular pattern, forming a lattice of cations and a lattice of anions. Interchange of cations within the cation lattice is possible, independently of any interchange of anions in the anion lattice. We can visualise a hypothetical spatial separation of the two lattices, which are then spatially reunited after carrying out cation and anion interchanges. Electrical neutrality of the final solution must, of course, be preserved. The criterion for indistinguishability of the anions is that cation interchanges shall be independent of anion interchanges.

Cation interchanges in solutions with cations of different valency cause either a change in the valency of one of the cations or the appearance of vacancies in the cation or the anion sublattice. These processes are needed to compensate the excess of charge arising from the exchange of cations of different valency in solution. Since excess charge compensation most frequently involves the formation of vacancies, we shall consider only this case. It must be clearly understood that these are not the familiar Schottky or Frenkel' vacancies, but simply vacancies resulting from the presence of cations of different valency in the solution. It may be thought that the appearance of vacancies must lead to an increase in the number of microstates, and that the entropy of mixing must be larger in the present of vacancies. It should be possible to calculate the increase in the entropy of mixing by taking into account the vacancy–ion interchanges. This procedure is followed in the papers by Flood, Förland, and others[9,10], but it meets serious difficulties because vacancies cannot be transferred to ionic sites without interchanging ions as well. Consequently, we are not in a position to calculate the number of interchanges by the normal procedure. An alternative approach seems more tractable[11]. Solutions of ionic salts can be subdivided into two classes:

1. Solutions in which cations of different kinds can be interchanged without interchanging anions.

2. Solutions in which cations of different kinds cannot be interchanged without interchanging anions.

Solutions of the first class include those in which the cations have the same valency, but solutions with cations of different valency may also belong to this class. Thus, if the formation of the solution can be described by the equation

$$A_{n_1}C_{n_2} + m\,B = A_rB_mC_{n_2} + (n_1 - r)\,A, \tag{12}$$

it is evident that interchange of unlike cations can occur without interchange of anions, and solutions of this type must therefore be assigned to the first class. However, cation migration can occur also by other mechanisms. We shall consider this in the concrete case of solutions with a univalent anion.

If, in the solutions formed by the salts $AC_{n_2}$ and $BC_{n_4}$, each cation occupies only one cation site, the additional anions will be located in additional anion sites. Interchange of unlike cations is impossible without anion interchange. Therefore, the anions must be treated as distinguishable species in systems of this type (with the obvious exception of $AC_{n_2}$–$BC_{n_2}$ solutions), and

$$W_+ = \frac{(N_1 + N_2)!}{N_1!\,N_2!};\quad W_- = \frac{(n_2N_1 + n_4N_2)!}{n_2N_1!\,n_4N_2!}. \tag{13}$$

Consequently

$$\mu_1 = \mu_{10} + kT\left(\ln x_1 + n_2 \ln \frac{n_2x_1}{n_2x_1 + n_4x_2}\right);$$
$$\mu_2 = \mu_{20} + kT\left(\ln x_2 + n_4 \ln \frac{n_4x_2}{n_2x_1 + n_4x_2}\right). \tag{14}$$

However, a solution with vacancies in the cation sublattice can be formed in the case of $AC$–$BC_2$, $AC$–$BC_3$, $AC$–$BC_4$, and $AC_2$–$BC_4$ solutions if $N_1 > N_2$, i.e. if the solution contains a higher proportion of the salt $AC_{n_2}$ than of $BC_{n_4}$ – we are confining the discussion to salts in which the valency of the cation does not exceed four. Formally, this means that the cation B must occupy two cation sites. For example, when B cations are added to AC, a B cation can take the place of an A cation. If the B cation is doubly charged, charge compensation requires that a neighbouring A cation site should be unoccupied. In such a solution, a B cation can be transferred to a pair of A cation sites without disturbing the anions. Hence, the anions can be treated as indistinguishable in this case, and for these solutions we have

$$W_+ = \frac{(N_1 + N_2)!}{N_1!N_2!};\quad W_- = 1. \tag{15}$$

Therefore,

$$\mu_1 = \mu_{10} + kT \ln x_1;$$
$$\mu_2 = \mu_{20} + kT \ln x_2. \tag{16}$$

Thus, depending on the mechanism of formation of the solution, the anions can be distinguishable or indistinguishable in solutions of the types $AC$–$BC_2$, $AC$–$BC_3$, $AC$–$BC_4$. and $AC_2$–$BC_4$.

We will now turn to a more complicated example. Consider solutions of the salts $A_4C_3$ and $B_4C$, in which the anion is quadrivalent. Assume that $N_1 > N_2$. The addition of B cations to $A_4C_3$ can be described as

$$A_4C_3 + 3B = A_3B_3C_3 + A, \tag{17}$$

a situation to which "reaction" (12) applies. We can think of the resulting solution as consisting of "molecules" of $A_4C_3$ and $A_3B_3C_3$. The excess of B cations in the $A_3B_3C_3$ "molecule" is located at additional cation sites. In this case the anions are, of course, indistinguishable.

The same procedure can be applied to other cases. Unfortunately, as was stated above, it is not always possible to decide unambiguously whether the anions are or are not distinguishable, but the essential features of the proposed method of evaluating the effect of the anions on the entropy of mixing are clearly illustrated by the examples given. In general, when dealing with solutions composed of the salts $A_{n_1}C_{n_2}$ and $B_{n_3}Cn_{n_4}$, we can write

$$\mu_1 = \mu_{10} + kT_{n_1} \ln \frac{n_1x_1}{n_1x_1 + n_3x_2};$$
$$\mu_2 = \mu_{20} + kT_{n_2} \ln \frac{n_3x_2}{n_1x_1 + n_3x_2}, \tag{18}$$

for indistinguishable anions, and

$$\mu_1 = \mu_{10} + kT\left(n_1 \ln \frac{n_1x_1}{n_1x_1 + n_3x_2} + n_2 \ln \frac{n_2x_1}{n_2x_1 + n_4x_2}\right);$$
$$\mu_2 = \mu_{20} + kT\left(n_3 \ln \frac{n_3x_2}{n_1x_1 + n_3x_2} + n_4 \ln \frac{n_4x_2}{n_2x_1 + n_4x_2}\right), \tag{19}$$

for distinguishable anions. The reader can easily verify that Eqn. (9) is a special case of Eqn. (18).

These expressions for the chemical potential in ideal solutions can be extended to real solutions in the usual way: by adding the term $kT \ln \gamma_i$ to the right-hand side of the equations, where $\gamma_i$ is the activity coefficient of the $i$th component. For dilute solutions (and, to a first approximation, for concentrated solutions as well), the parameter $\gamma_i$ can be taken to be constant. This allows the equations to be used with real solutions. Furthermore, the variation of $\gamma_i$ with solution composition can be calculated from regular solution theory.

This approach to the calculation of entropies of mixing for ideal solutions of ionic salts is based on Temkin's model. The extent to which it is justified by the behaviour of real systems will be demonstrated below. At this point we should mention that a model essentially different from Temkin's is proposed in the papers of Herasimenko[12] and Bradley[13]. In this model, the interchange of cations and anions is not excluded, i. e. anions and cations are treated as equivalent from the point of view of the entropy of mixing. The model fails to take account of the most important feature of ionic solutions (namely, that ionic solutions consist of ions, not of molecules!), and is therefore a cruder approximation to real solutions than is Temkin's model.

The form of the chemical potential in liquid solutions of ionic salts can be judged from the variation of melting point with composition when the system shows a simple eutectic. Thus, the equation of the liquidus curve can be written[14]

$$\alpha_{i0} \ln \frac{T_{i0}}{T} = \ln \frac{1}{a_i}, \qquad (20)$$

where $a_i$ is the activity of the $i$th component in the liquid phase, and $T_{i0}$ is the melting point of the pure $i$th component. The quantity $\alpha_{i0}$ is simply related to the entropy of fusion of the pure $i$th component, $\Delta S_f$:

$$\alpha_{i0} = \Delta S_f / kT_{i0}, \qquad (21)$$

since to a first approximation liquid salt solutions have the properties of regular solutions. Then, using Eqn. (3), we find

$$\ln a_i = \omega \beta_i (1 - x_i)^2 - T \frac{\partial \Delta S}{\partial N_i}. \qquad (22)$$

On the other hand, the entropy of mixing of a regular solution is equal to the entropy of mixing of an ideal solution. Therefore

$$(\mu_i - \mu_{i0})_{\text{ideal}} = -T \frac{\partial \Delta S}{\partial N_i}, \qquad (23)$$

where $(\mu_i - \mu_{i0})_{\text{ideal}}$ is determined by Eqns. (18) or (19).

Consider the fusion of the first component in the presence of the second component, with $x_1 > x_2$. Eqns. (18) and (19) for the chemical potential can be written, approximately, in the form

$$\mu_1 - \mu_{10} = kTn_3 \ln x_1, \qquad (24)$$

for Eqn. (18), and

$$\mu_1 - \mu_{10} = kT(n_3 + n_4) \ln x_1, \qquad (25)$$

for Eqn. (19). Substituting these expressions into Eqns. (22) and (20), we arrive at the general expression

$$Y = \alpha - KX, \qquad (26)$$

where

$$Y = \frac{\ln x_1}{\ln \frac{T}{T_{10}}}; \quad X = \frac{x_2^2}{T \ln \frac{T}{T_{10}}}. \qquad (27)$$

For indistinguishable anions

$$\alpha = \alpha_{10}/n_3, \qquad (28)$$

whereas for distinguishable anions

$$\alpha = \alpha_{10}/(n_3 + n_4). \qquad (29)$$

The quantity $K$ in Eqn. (26) is a constant, proportional to $\omega\beta_1$. For indistinguishable anions the proportionality coefficient is $1/kn_3$, whereas for distinguishable anions it is $1/k(n_3 + n_4)$. For more exact calculations, Eqn. (26) should be replaced by

$$Y = \alpha_{10} - \frac{\omega}{k} \beta_1 X, \qquad (30)$$

where the quantity $X$ is determined by the second Eqn. (27), and $Y$ by the equations given below:

$$Y = \frac{n_1 \ln \frac{n_1 x_1}{n_1 x_1 + n_2 x_2}}{\ln \frac{T}{T_{10}}} \qquad (31)$$

for indistinguishable anions, and

$$Y = \frac{n_1 \ln \frac{n_1 x_1}{n_1 x_1 + n_2 x_2} + n_2 \ln \frac{n_2 x_1}{n_2 x_1 + n_4 x_2}}{\ln \frac{T}{T_{10}}} \qquad (32)$$

for distinguishable anions.

Note that Eqns. (30) and (26) coincide for the case of indistinguishable anions and $n_1 = n_3$.

Table 1 gives the results of our calculations, by Eqn. (26), on 108 binary systems. The first component is taken as the major constituent. Values of $\alpha_{10}$ were calculated mainly from calorimetric data[15-18]. For lithium sulphate we used the calorimetric measurements of Voskresenskaya and Banashek[19]. For KSCN the values of $\alpha_{10}$ are taken from our calculations. Due to the large scatter in the heat of fusion values for $MgCl_2$, we were unable to choose a definite value of $\Delta S_f$ for this salt, and were again compelled to determine $\alpha_{10}$ from our calculations. Experimental liquidus data were taken mainly from a handbook[20]: column 9 of Table 1 gives the page references to this compilation. Other literature sources used in the calculations[21-26] are stated in column 10.

With the exception of systems 10–14 (as numbered in Table 1), we find $\beta_1$ = const for all other systems. For systems 10–14, $\beta_1 = 2/(2 + x_2)^2 \simeq 0.5 \simeq$ const. Therefore, experimental data from liquidus diagrams should give a straight line when plotted with the variables of Eqn. (26) as coordinates, and the values of $\alpha$ and $K$ should be obtainable from the parameters of the linear plots. In the vast majority of cases, the experimental data do give straight lines when plotted in the coordinates of Eqn. (26). Fig. 1 shows the agreement between Eqns. (26) and (30) and experimental results for a number of systems.

Table 1 also gives the values of the parameter $\omega$, calculated from the formula

$$\omega = \frac{n_3}{\beta_1} kK. \qquad (33)$$

For system 9, $n_3 = 2$; for all other systems, $n_3 = 1$. For system 9, $\beta_1 = 2$; for systems 10–14, $\beta_1 = 0.5$; for all other systems, $\beta_1 = 1$.

It is evident from the data of Table 1 that the systems can be divided into five groups: column 7 lists the group number of each system.

In the first group, $\alpha_{10}/\alpha = 1.02$ on the average, showing that the value of $\alpha$ obtained from liquidus data agrees with

TABLE 1. Results of calculations by Eqn. (26) for various binary salts systems.

the value derived from calorimetric experiments. This is observed in the majority of systems (66 out of 108). For all these systems $n_3 = 1$. We may conclude from the observed agreement that in these systems the common ions are indistinguishable.

In the second group of systems $\alpha_{10}/\alpha = 1.39$ on the average: this is fairly close to unity, and there would be grounds for assigning these systems to the first group. However, the departure from unity can hardly be ascribed to experimental error, since it is found in an appreciable number of systems (19 out of 108). Evidently, we are dealing with a rather "subtle" anomaly in the entropy of mixing.

The third group, which includes the systems $MgF_2$–RbF; $MgCl_2$–NaCl, $MgCl_2$–KCl, $MgCl_2$–RbCl, $MgCl_2$–CsCl; $BaF_2$–LiF, $BaF_2$–NaF, $BaF_2$–KF, $BaF_2$–RbF (in all of which $n_3 = 1$), gives $\alpha_{10}/\alpha = 2$. We conclude that these systems form solutions in which the anions are distinguishable, since Eqn. (29) requires just this value of $\alpha_{10}/\alpha$ for systems with distinguishable anions. The lower part of Fig. 1 shows the results of our calculations by Eqn. (26) for $BaF_2$ containing additions of LiF, NaF, KF, and RbF. The upper part of the diagram illustrates our calculations by Eqn. (30) for $BaF_2$ containing LiF, NaF, KF, and RbF, and our calculations by Eqn. (26) for $BaF_2$ containing $MgF_2$, $BaCl_2$, and $Ba_3(PO_4)_2$. It can be seen that the straight lines of all the solutes meet at a common point when corrected for the distinguishability of the anions.

In the fourth group we find $\alpha_{10}/\alpha = 0.76$ on the average. This group comprises nine systems. It can be shown that the formation of limited solid solutions can account for an $\alpha_{10}/\alpha$ ratio below unity, but only small departures from unity can be expected.

In the fifth group of systems the ratio $\alpha_{10}/\alpha$ is close to 0.5, a value which can be explained by the formation of dimers of the solute in the melt. This group includes only three systems.

The NaCl–$ZrCl_4$ system, for which the ratio $\alpha_{10}/\alpha$ is anomalously high, is quite unique.

Calculations by Eqn. (26) give a value of 2.28 for the ratio $\alpha_{10}/\alpha$ of the system $Li_2SO_4$–$K_2SO_4$. But $n_3 = 2$ for this system, and the theoretical value of $\alpha_{10}/\alpha$ is 2 if the chemical potential is described by Eqn. (9). This agrees with the experimental value. We should point out that our calculations support Grjotheim and Urnes' view[27] that Temkin's ionic model is applicable to the $Li_2SO_4$–$K_2SO_4$ system. Grjotheim and Urnes' calculations have been questioned by Kordes[28], who put forward an explanation of the cryoscopic results in terms of complex formation, but, as we have seen, the criticism is unjustified.

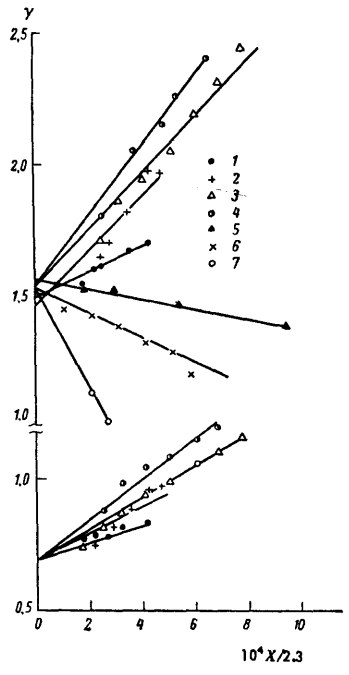

Fig. 1. Comparison of Eqns. (26) and (30) with experimental data for $BaF_2$ containing the following solutes:
1) LiF; 2) NaF; 3) KF; 4) RbF; 5) $MgF_2$; 6) $BaCl_2$; 7) $Ba_3(PO_4)_2$.

TABLE 2. Results of calculations by Eqn. (30) for a number of systems.

| No. | Solvent | Solute | $\alpha_{10}$ from Table 1 | $\alpha_{10}$ from Eqn. (30) | $\omega$, kcal |

| 5 | $MgCl_2$ | NaCl | 7.40 | 7.40 | —3.36 |
| 6 | » | KCl | 7.40 | 7.40 | —5.52 |
| 7 | » | RbCl | 7.40 | 7.40 | —9.43 |
| 8 | » | CsCl | 7.40 | 7.40 | —14.54 |
| 9 | $MgF_2$ | RbF | 4.53 | 4.90 | —6.67 |

Since the anion is distinguishable in systems 98–101 and 103–106, the value of $\omega$ should be calculated from the formula

$$\omega = \frac{n_3 + n_4}{\beta_1} kK, \qquad (34)$$

rather than from formula (33). However, this parameter was calculated even more precisely by using Eqn. (30). The results are set out in Table 2.

Returning to the data of Table 1, we see that the systems $AC_2$–BC exhibit anion distinguishability, as required by the theoretical considerations presented above. The $MgF_2$–KF system is exceptional in this respect, and does not have distinguishable anions. On the other hand, in the opposite type of system (AC–$BC_2$) anion distinguishability (and in some cases even cation distinguishability) is not observed. The possibility of loss of anion distinguishability in systems of this type has been discussed at the beginning of the present Section. Thus, the experimental information from liquidus diagrams which has been examined is in keeping, on the whole, with the theoretical considerations of anion distinguishability presented above. The proposition of anion distinguishability is supported also by data on crystallisation from aqueous solutions[29].

## 3. RELATION BETWEEN THE EXCHANGE ENERGY AND THE PROPERTIES OF THE CONSTITUENTS OF THE SOLUTION

The quantity $\omega$ reflects the change in interionic bond energy for the various components, and depends on the properties of the individual ions (charge, radius, structure of the electronic shell, etc.). The search for a relation between the value of $\omega$ and these properties is one of the major problems of the theory of ionic solutions.

Hildebrand and Salstrom[30] were the first to show that some binary mixtures of fused salts exhibit regular solution behaviour. These workers provided a theoretical basis for Eqn. (1) by a statistical procedure previously applied by Heitler[31] to non-electrolyte solutions. Among the systems examined by Hildebrand and his coworkers, those consisting of alkali metal bromides with silver bromide, and of lead halides with zinc halides, had the properties of regular solutions. The system were studied by an e. m. f. method, based on reactions between an electrode and the melt. Most of the experimental data now available for the activity of components in molten salts have been obtained by this method (see Table 3).

Data on heats of mixing are of the utmost importance in the thermodynamics of fused salts. Kleppa and coworkers[37,39,53] have undertaken a series of calorimetric measurements of the heats of mixing for the nitrates of metals in Groups I and II of the Periodic Table, and obtained some very interesting results, which show that these mixtures are regular solutions and have negative heats of mixing. Solid solutions of these salts have positive heats of mixing. The authors ascribe this difference to the fact that in solid solutions there is a loss of lattice energy due to the change in the distance between nearest neighbours, whereas in a melt the most important interactions are those between second nearest neighbours. They have shown[37] that the exchange energy for molten alkali metal nitrates is described by the empirical relation

$$\omega = -E\left(\frac{d_1 - d_2}{d_1 + d_2}\right)^2, \qquad (35)$$

where $E$ is the crystal lattice energy of the mixture, and $d_1$ and $d_2$ are the distances between the centres of the ions in the pure first and second component respectively.

We have already discussed calculations based on Eqn. (20). An alternative approach is to use the familiar form of Schröder's equation:

$$\ln a_i = \alpha_{i0}\left(\frac{T_{i0}}{T} - 1\right). \qquad (36)$$

Aukrust *et al.*[23] determined the activity of the components in the systems LiF–KF, LiCl–KCl, and LiBr–KBr from liquidus data by using Eqn. (36) in conjunction with the heat capacities of the components in the liquid and in the solid phase, and showed that solutions of these salts depart relatively little from regular solution behaviour.

Margulescu and Sternberg[54,55], using the equations

$$kT_1 \ln \gamma_1 = \omega x_2^2; \quad kT_2 \ln \gamma_1 = \omega x_2^2, \tag{37}$$

written explicitly for the two temperatures $T_1$ and $T_2$, arrived at the expression

$$\ln a_1(T_2) = \frac{T_1}{T_2} \ln a_1(T_1) + \frac{T_2 - T_1}{T_2} \ln x_1. \tag{38}$$

They used this equation to compare activity values obtained from liquidus diagrams with the values obtained at higher temperatures by the e.m.f. method. The results were satisfactory.

Sinistry proposed[36,38,56] the use of the equation

$$\frac{\Delta T}{1 - x_l} = fK_0 + b(1 - x_l). \tag{39}$$

for determining the value of $\omega$, where $\Delta T$ is the depression of the freezing point caused by addition of the solute, $K_0$ is the cryoscopic constant, $f$ is the number of particles into which the solute dissociates, and $b$ is a constant. Eqn. (39) was derived by Haaze[57]; unlike the van't Hoff equation[58]

$$\frac{\Delta T}{1 - x_l} = fK_0, \tag{40}$$

it can be applied to moderately concentrated solutions. According to Sinistry[38],

$$\omega = -\frac{b}{fK_0}. \tag{41}$$

The values of $\omega$ obtained by Sinistry from cryoscopic data and Eqn. (41) are sometimes in serious disagreement with Kleppa's calorimetric results. It should be noted that Eqn. (39) can be derived from Eqn. (20) for the case of dilute solutions with unlike ions of the same valency.

Flood *et al.*[40] measured the activity of $CaCO_3$ in $CaCO_3$–$M_2CO_3$ mixtures (where M is an alkali metal) by measuring the amount of carbon dioxide evolved in the decomposition of the mixture. These mixtures were found to behave like regular solutions.

Published experimental values of $\omega$ for various molten salts with a common ion are listed in Table 3. Data relating to the solid solutions NaCl–NaBr, KCl–KBr, CsCl–CsBr, and TlCl–TlBr are also tabulated. A comparison of the data of Tables 1 and 3 clearly shows that one of the two values of $\omega$ obtained from Eqn. (26) agrees satisfactorily with the corresponding value in Table 3 (systems LiF–KF, LiCl–KCl, KCl–AgCl, AgBr–LiBr, and KCl–$MgCl_2$). It is interesting to note, in this connection, that the value of $\omega$ determined in the crystallisation region of the first salt does not agree numerically with the $\omega$ value determined in the crystallisation region of the second salt for the same system (see Table 1). Yet, these two values should be identical if a regular solution treatment is strictly applicable. The discrepancy may be due to a difference in properties between the crystallisation regions of the first and the second salt. In particular, this behaviour has been reported[65] for the composition–property curves close to the eutectic temperature.

As already pointed out, the value of $\omega$ depends on the individual properties of the ions. Using available data we have tried to identify the functional relation between $\omega$ and the radii of the cations and anions present in the solution. The value of $\omega$ is plotted against the radius of the common ion in Fig. 2 for six families of salts with a common ion. It is obvious that the straight-line plots for salts with a common cation and those for salts with a common anion respectively converge to a point: this means that the salt solutions achieve ideality when the anion (for the case of salts with a common anion) or the cation (for the case of salts with a common cation) reaches a certain size. It is also found that the slope of the straight lines of Fig. 2 is proportional to the difference between the radii of the non-common ions present in the solution. The general equation for families of salts with a common ion is

$$\omega = 31 \left(\frac{r_1 - r_2}{r_1 + r_2}\right)\left(1 - \frac{r}{r_0}\right), \tag{42}$$

where $r_1$ and $r_2$ are the radii of the non-common ions of the first and second component, $r$ is the radius of the common ion, and $r_0 = r$ for $\omega = 0$. The value of $r_0$ is 3.06 for the particular family of salts with a common anion examined

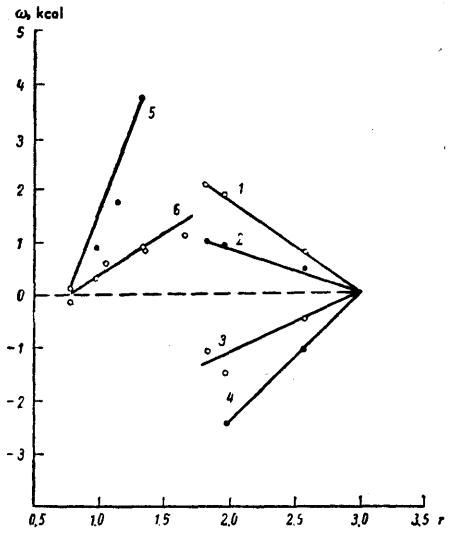

Fig. 2. Variation of the exchange energy in binary systems with radius of the common ion:
1) AgX–LiX; 2) AgX–NaX; 3) AgX–KX; 4) AgX–RbX (where X = Cl, Br, $NO_3$); 5) MCl–$M_2SO_4$; 6) MCl–MBr (where M = Li, Mg, Na, Tl, Ag, Pb, K, Cs).

6) $MgF_2$ (with additions of Rb, Ba, Ca fluorides).

in Fig. 2, and 0.78 for the family of salts with a common cation.

The value of $\omega$ in Eqn. (42) is expressed in kcal. Ionic radii, here and elsewhere in the present paper, are the Goldschmidt values for the crystalline state[69], expressed in Ångström units.

Table 4 gives the numerical values of the crystal lattice energy for the salts to which Eqn. (42) applies. $E_1$ and $E_2$ are the crystal lattice energies of the first and second salt component, taken from a handbook[69]. The quantity $\Delta E$ is the difference $E_1 - E_2$. The mean value of $\Delta E$ for all the salts listed in Table 4 is 23.1, i.e. of the same order of magnitude as the constant coefficient in Eqn. (42).

Semenchenko[59] proposed the use of generalised moments for characterising the properties of particles such as ions, atoms, and molecules. The physical significance of the generalised moment is quite simple: it corresponds to the force due to the charge on the particle. For ions, the generalised moment gives the potential at the surface of the ion, considered as a sphere of radius $r$.

Using the concept of generalised moments, Semenchenko developed a general approach[68] to solubility phenomena. According to his theory, the mutual solubility of substances is higher, the smaller the absolute difference between their generalised moments. Thus, plots of $\Delta\rho$ against solubility (where $\Delta\rho$ is the difference in generalised moments between solvent and solute) give a curve with a maximum at $\Delta\rho = 0$.

Our results for the variation of $\omega$ with $\Delta\rho$ give a curve similar to that of Semenchenko (Fig. 3). In these calculations, the salt present in solution at the lower concentration is treated as the solute. The generalised moment is found by dividing the charge on the ion by the ionic radius.

The relation between $\omega$ and the difference in generalised moments shown in Fig. 3 refers to salts with a common anion. An analogous relation for salts with a common cation does not appear to exist, at least judging from the data of Table 1. This is not surprising, since generalised moments are not a very accurate way of characterising the energetics of anions.

## 4. CALCULATION OF EXCHANGE ENERGIES

In theory, the exchange energy can be calculated if a procedure for calculating the crystal lattice energy of the solution is available. The energy of a crystal lattice is calculated most simply by means of Born's formula[60]

$$E = \frac{ANe^2z_1z_2}{d}\left(1 - \frac{1}{u}\right), \qquad (43)$$

where $A$ is Madelung's constant, $N$ is Avogadro's number, $e$ is the electronic charge, $z_1$ and $z_2$ are the numbers of electronic charges on the cation and the anion, and $u$ is a quantity which characterises the repulsive forces.

X-Ray diffraction experiments have shown that the average distance between oppositely charged ions in a

solution varies in the simplest case (Vegard's law) according to the expression

$$d = d_1x_1 + d_2x_2. \quad (44)$$

Various attempts have been made[2,3,4] to substitute an expression of this type into the Born formula. The result is that the energy of formation of the solution, which should be identified with the potential energy of formation of the solution, is always positive: this is, of course, contrary to experience. In subsequent papers the energy of the solution is calculated more exactly.

Lumsden[5] treats the excess energy $\Delta E$ of a solution as the sum of two terms:

$$\Delta E = \Delta E_1 + \Delta E_p, \quad (45)$$

where $\Delta E_1$ is the interaction energy of ions of a given kind in the immediate neighbourhood of an arbitrarily chosen ion, and $\Delta E_p$ the polarisation energy of the anions.

The quantity $\Delta E_1$ is calculated by the London formula

$$E_1 = -\frac{P}{d^6}, \quad (46)$$

where $P$ is a constant. In an ionic solution of the type AC–BC (the theory is concerned only with solutions of alkali metal halides) each cation is effectively surrounded only by anions, and each anion only by cations. Hence, in the immediate surroundings of any cation the energy of the C–C bond has to be considered, and in the immediate surroundings of any anion the energy of the A–A, B–B, and A–B bonds is relevant. The bond energy of cations is small in comparison with the bond energy of anions, and it is legitimate to consider only the energy of the C–C bonds. The C–C distance in the pure salts AC and BC is $2^{0.5}d_{AC}$ and $2^{0.5}d_{BC}$ respectively, where $d_{AC}$ and $d_{BC}$ are the distances A–C and B–C. In the solution, this distance has the value $(d_{AC}^2 + d_{BC}^2)^{0.5}$. Hence the energy of the solution due to London forces is

$$E_1 = -\left[\frac{P_{AA}}{(2d_{AC}^2)^3}N_{AA} + \frac{P_{BB}}{(2d_{BC}^2)^3}N_{BB} + \frac{P_{AB}}{(d_{AC}^2 + d_{BC}^2)^3}N_{AB}\right], \quad (47)$$

where $P_{AA}$, $P_{BB}$, and $P_{AB}$ are the constants of Eqn. (46) for the appropriate bonds; $N_{AA}$, $N_{BB}$, and $N_{AB}$ are the numbers of A–A, B–B, and A–B bonds in the solution. For a regular solution

$$N_{AA} = \frac{Z}{2}x_1^2(N_1 + N_2); \quad N_{BB} = \frac{Z}{2}x_2^2(N_1 + N_2);$$
$$N_{AB} = Zx_1x_2(N_1 + N_2), \quad (48)$$

where $Z$ is the coordination number. Substituting (48) into (47), and after some rearrangement, we obtain

$$\Delta E_1 = \omega_1 x_1 x_2 (N_1 + N_2), \quad (49)$$

where

$$\omega_1 = \frac{Z}{2}\left[\frac{P_{AA}}{(2d_{AC}^2)^3} + \frac{P_{BB}}{(2d_{BC}^2)^3} + \frac{2P_{AB}}{(d_{AC}^2 + d_{BC}^2)^3}\right]. \quad (50)$$

If the anion is surrounded by cations of different size it becomes polarised. The force $F_0$ of the field acting on an anion surrounded by oppositely distributed A and B cations is

$$F_0 = e\left(\frac{1}{d_{AC}^2} - \frac{1}{d_{BC}^2}\right). \quad (51)$$

The energy due to polarisation of the anions in solution is

$$\Delta E_p = \frac{mF_0^2}{2}N_{AB}, \quad (52)$$

where $m$ is the polarisability of the anion. Substituting (51) into (52), and using (48), we obtain

$$\Delta E_p = \omega_p x_1 x_2 (N_1 + N_2), \quad (53)$$

where

$$\omega_p = \frac{Z}{2}me^2\left(\frac{1}{d_{AC}^2} - \frac{1}{d_{BC}^2}\right)^2. \quad (54)$$

Lumsden[5] allowed also for the polarisation of the anion due to the second layer of cations, when Eqn. (54) becomes

$$\omega_p = \left(\frac{4}{5}\right)^2\frac{Z}{2}me^2\left(\frac{1}{d_{AC}^2} - \frac{1}{d_{BC}^2}\right). \quad (55)$$

However, the occupancy of the second layer of cations is rather indeterminate: this causes inaccuracies in the computed second-layer polarisation, which is therefore best ignored.

Adding (49) and (53) we obtain

$$\Delta E = (\omega_1 + \omega_p)x_1x_2(N_1 + N_2). \quad (56)$$

This equation can be used to calculate the properties of real solutions. The constants $P_{AA}$ and $P_{BB}$ for alkali halides have been calculated by Mayer[61]. For the constant $P_{AB}$, Lumsden assumes

$$P_{AB}^2 = P_{AA} \times P_{BB}. \quad (57)$$

Values of $m$ for the anions $F^-$, $Cl^-$, $Br^-$, and $I^-$ have been determined by Kordes[62]: they are 0.462, 1.63, 2.29, and 3.56 cm$^3$ respectively. The parameters $d_{AC}$ and $d_{BC}$ are equal to the anion–cation distances in the crystal. Values of $\omega$ obtained by Lumsden for a number of systems are reproduced in Table 5. A comparison between experimental liquidus curves and similar curves calculated from theoretical values of $\omega$ is given in Lumsden's paper[5]. On the whole, the calculated values agree with experiment. It should be noted, however, that whereas one branch of the liquidus curve coincides with the experimental data, the other branch usually shows some departure. This is further confirmation that the $\omega$ values for different components in a given binary system with simple eutectic are different.

The excess free energy can also be calculated with the help of the theory proposed by Vasastjerna[6] for solid

TABLE 5. Comparison of $\omega$ values obtained according to Lumsden and to Vasastjerna with the values derived from the liquidus diagram data by Eqns. (26) and (30).

solutions of ionic salts. According to this theory, the excess energy of mixing and the entropy of mixing are given by the expressions

$$\Delta E = \frac{Ae^2}{d}\left(\frac{\Delta d}{d}\right) x_1 \quad x_2(N_1+N_2)\left\{\frac{\theta_1}{8}[1+\sigma(1-4x_2)]+\right.$$
$$\left.+\frac{\theta_2}{8}[1+\sigma(1-4x_1)]+\frac{1}{2}(1+\sigma)\right\}; \quad (58)$$

$$\Delta S = -k(N_1 \ln x_1 + N_2 \ln x_2) - k(\varkappa \ln \varkappa + \lambda \ln \lambda + \mu \ln \mu + \nu \ln \nu). \quad (59)$$

In these expressions

$$\theta_i = \frac{3+4Tv}{\frac{\epsilon Ae^2}{6d_i^4 - Tv}}; \quad \varkappa = \frac{x_1}{x_1 - x_2\sigma};$$
$$\lambda = x_1x_2(1+\sigma); \quad \mu = \frac{x_1x_2}{x_2 - x_1\sigma}; \quad \nu = \frac{x_2}{x_2 - x_1\sigma}, \quad (60)$$

where the degree of short-range order, $\sigma$, is defined by

$$\sigma = \frac{1-2x_1 \quad x_2 l - \sqrt{1-4x_1x_2 l}}{2x_1 \quad x_2 l};$$
$$l = 1 - \exp\left\{\frac{Ae^2}{d}\left(\frac{\Delta d}{d}\right)^2 \frac{\theta_1(1-4x_2)+\theta_2(1-4x_1)+4}{8kT}\right\}, \quad (61)$$

$\Delta d = d_1 - d_2$, $v$ is the coefficient of thermal expansion, and $\epsilon$ the compressibility coefficient. The quantity $d$ in Eqn. (58) denotes the distance between cation and anion, which can be calculated by Vegard's law. The quantity $d_i$ refers to the distance between cation and anion in the corresponding pure salt.

In Hovi's papers[51,52,63] the theory of Vasastjerna is used to calculate the free energy of solid solutions, thus making it possible to predict critical separation temperatures. Unfortunately, these calculated results lack direct experimental confirmation. Heats of mixing calculated by Eqn. (58) for solid solutions are in tolerably good agreement with experiment[42,51,52,63].

Vasastjerna's theory can also be applied to molten salts. Margulescu and Sternberg[64] have applied it to the systems AgBr–LiBr, AgBr–NaBr, AgCl–NaCl, and AgBr–AgCl. The excess energies of mixing derived from experimental data are in general agreement with the calculated values.

The present writers have evaluated Eqn. (58) for a number of systems, using $d$ values taken from Levy *et al.*[66] and $\epsilon$ and $v$ values taken from Bockris and Richard[67]. The calculations were made for the composition $x_1 = x_2 = 0.5$. The value of $\omega$ was found from the relation

$$\omega = \frac{1}{x_1 \quad x_2} \quad \Delta E = 4\Delta E.$$

It should be noted that $\omega$ is required by Eqn. (57), to be a function of solution composition, but in a rough comparison with experiment it may be taken as constant.

The results of this calculation are entered in Table 5. For comparison, the table gives also the values of $\omega_1$, which relate to crystallisation of the first component, and of $\omega_2$, which relate to the region of crystallisation of the second component. These values are taken from Table 1, i.e. they were calculated by Eqns. (26) and (33). The arithmetic mean of $\omega_1$ and $\omega_2$ is tabulated as $\bar{\omega}$. Inspection of Table 5 shows that Lumsden's theory agrees, on the whole, with values taken from liquidus diagrams. In some cases, however, there is serious discrepancy. Thus, in the NaF–CsF system, $\omega_1 < 0$ and $\omega_2 > 0$, whereas Lumsden gives $\omega > 0$. For the NaCl–RbCl system $\omega_1$ and $\omega_2$ are positive, but according to Lumdsen $\omega < 0$. In the other systems the value of $\omega$ calculated by Lumsden's method is close to $\bar{\omega}$. On the other hand, the theory of Vasastjerna does not lead to satisfactory results.

---o0o---

The results presented in this review provide evidence that the theory of regular solutions is applicable to molten salts. A collection of exchange energy data more comprehensive than any hitherto available[41,54] is also presented. The data of Table 3 show that the absolute value of $\omega$ decreases or increases with increasing temperature according to whether $\omega$ is positive or negative, respectively. These changes are small, however, and the assumption made when using Eqns. (26) and (30) that $\omega$ is independent of temperature is, on the whole, justified. Hence, these equations can be used to interpret experimental data from liquidus diagrams. Furthermore, analysis of the liquidus curves in systems with a simple eutectic can provide information on the entropy of mixing of ionic salt solutions.

We have stated that Lumsden's theory is in agreement with experiment. However, its conclusions are still only applicable to solutions of uni-univalent salts. The variation of the exchange energy with difference of generalised moments can be used to give an approximate estimate of this quantity in solutions of salts with different cations and a common anion.

# ADVANCES IN THE CHEMISTRY OF CARBENES

G. G. Rozantsev, A. A. Fainzil'berg, and S. S. Novikov

CONTENTS

I. Introduction 69

II. The structure of carbenes 69

III. Preparation and characteristic properties of individual carbenes 70

1. Methylene 70
2. Dihalogenocarbenes 70
3. Monohalogenocarbenes 72
4. Keto- and thioketo-carbenes 72
5. Other carbenes 74

IV. Some aspects of the synthetic applications of carbenes 77

1. Substitution of carbenes in C–H, C–halogen, and other bonds 77
2. Addition of carbenes to carbon–carbon and other double bonds 79
3. Carbene synthesis of cyclopropene derivatives 81
4. Ring enlargement 83
5. Carbene syntheses of olefins 84

## I. INTRODUCTION

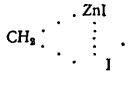
Some years ago the journal "Uspekhi Khimii" published a comprehensive review of carbenes by Knuyants *et al.*[1], covering the literature up to and including 1957. In view of the exceptionally rapid development of the chemistry of carbenes and the fundamental interest of this field for a wide variety of investigators, we thought it useful to review the work on carbenes which has been published in the subsequent five years — from 1958 to 1962 inclusive. Some papers published in 1963 have also been covered.

Although the literature dealt with in the present review covers a short period, the data accumulated on carbenes are extensive and often scattered in papers dealing with other problems. It is therefore not impossible that some data on the synthesis or a practical application of carbenes or a particular treatment of a reaction mechanism including the formation of a carbene have been omitted.

## II. THE STRUCTURE OF CARBENES

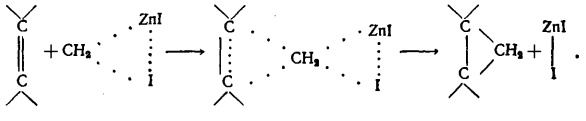
No definite new evidence for the geometrical and electronic structure of carbene has been obtained since the appearance of the review of Knunyants *et al.*[1] Of the work in this field, it is only necessary to mention that of Herzberg[2], who investigated methylene by ultraviolet spectroscopy and showed that it has a triplet ground state, the singlet state having a somewhat higher energy. This is to some extent confirmed by the reactions of free methylene, particularly by its addition to carbon–carbon double bonds. The point is that the carbene being in a triplet state adds to the double bond in several stages, the first involving the formation of a 1,3-biradical in which rotation about the carbon–carbon bond is possible, so that the formation of cyclopropanes is non-stereospecific. However, it is possible to obtain methylene in the singlet state, for example photolytically; such methylene adds to double bonds stereospecifically. If it then passes to its ground (triplet) state, having given up part of its excess energy in a collision, for

example non-stereospecific addition of methylene to carbon–carbon double bonds occurs again[3-6]. In the case of substituted methylenes a wide variety of situations arises, depending on the nature of the substituents linked with the key carbon atom. Thus it has been established that dihalogenocarbenes add to double bonds stereospecifically[7], while diphenylcarbene adds non-stereospecifically[8]; the latter result is also consistent with physical data: it has recently been shown by electron paramagnetic resonance[9] that phenylcarbene, diphenylcarbene, and fluorenylidene obtained by the photolysis of the corresponding diazo-compounds have triplet ground states.



It must be borne in mind that the key carbon atom in carbenes has a lone pair of electrons as well as an unfilled orbital so that, in addition to its electrophilic properties, which until recently have been the only ones to be investigated experimentally, it also has nucleophilic properties, which will be discussed below (pp. 75, 76, 77).

## III. PREPARATION AND CHARACTERISTIC PROPERTIES OF INDIVIDUAL CARBENES



### 1. Methylene

Although there is no direct proof that free methylene is produced in the reaction between methylene iodide and the zinc–copper couple, the fact that cyclopropanes are obtained in the presence of olefins in the reaction mixture can be explained by the intermediate formation of methylene[10,11]. The reaction of methylene iodide with the zinc–copper couple in dry ether is known to yield iodomethylzinc iodide[12], from which cyclopropanes can be obtained in two ways.

a. Iodomethylzinc iodide may be regarded as a complex of methylene and zinc iodide which breaks down spontaneously into zinc iodide and free methylene, the latter reacting with double bonds:

b. The $\pi$-bond of the olefin can replace zinc iodide in iodomethylzinc iodide with the formation of cyclopropane[11]:

Comparatively recently a study of ultraviolet, visible, and infrared spectra has established that the photolysis of diazomethane in nitrogen at 90°K yields a complex mixture of products including ethylene, cyclopropane, and a number of other stable and unstable substances. Possibly, free methylene is also present, but its formation in the reaction mixture has not been rigorously demonstrated. The presence of certain substances in this mixture can be accounted for by reactions of methylene with diazomethane[13].

Keten is formed in the photolysis of diazomethane in a mixture of nitrogen and carbon monoxide. However, even when the concentration of carbon monoxide is eighteen times greater than that of diazomethane, the yield of keten is only 50%. This is probably due to the simultaneous occurrence of two competing reactions: reaction of carbon monoxide with methylene and of diazomethane with methylene. Furthermore, it is known that keten itself breaks down into carbon monoxide and methylene when it is irradiated with ultraviolet light[14,15] and therefore a definite equilibrium exists between carbon monoxide and methylene on the one hand and keten on the other, which reduces the yield of the latter.

### 2. Dihalogenocarbenes

a. Difluorocarbene. In 1960 Simons and Yarwood[16] showed that the photolysis of *sym*-dichlorotetrafluoroacetone in the vapour phase results in the formation of difluorocarbene and proceeds as follows:

$$CF_2ClCOCF_2Cl + h\nu \rightarrow CF_2ClCOCF_2\cdot + Cl\cdot,$$
$$CF_2ClCOCF_2\cdot \longrightarrow CF_2Cl\cdot + CO + CF_2.$$

The authors draw attention to the low reactivity of difluorocarbene.

Haszeldine and coworkers[17] obtained difluorocarbene by decarboxylation of sodium chlorodifluoroacetate:

$$ClCF_2COO^- \rightarrow Cl^- + CF_2 + CO_2.$$

Difluorocarbene readily reacts with water, fluoride ions, and chlorine[18]:

$$CF_2 + H_2O \xrightarrow{H_2O} \begin{cases} \longrightarrow CO + 2HF \\ \longrightarrow HCOOH + 2HF, \end{cases}$$
$$CF_2 + F^- \xrightarrow{H_2O} CHF_3 + OH^-,$$
$$CF_2 + Cl^- \xrightarrow{H_2O} CHClF_2 + OH^-.$$

It can also be obtained by the reaction of potassium isopropoxide with chlorodifluoromethane in isopropanol[18]:

$$(CH_3)_2CHO^- + CHClF_2 \rightleftarrows (CH_3)_2CHOH + CClF_2^-,$$
$$CClF_2^- \rightarrow CF_2 + Cl^-.$$

Hine and Porter[19] obtained difluorocarbene by the action of sodium methoxide on difluoromethylphenylsulphone:

$$CF_2H-S(O)(O)-C_6H_5 \xrightarrow{NaOCH_3} CF_2.$$

Under suitable conditions difluorocarbene dimerises to tetrafluoroethylene with a yield reaching 95%[20]:

$$2CF_2 \rightarrow CF_2=CF_2.$$

b. Dichlorocarbene. The generally known method of preparing dichlorocarbene is by alkaline hydrolysis of chloroform[21]. A modification of this method is the reaction of chloroform with potassium t-butoxide in an inert solvent such as pentane[22]:

$$CHCl_3 + (CH_3)_3CO^- \rightleftarrows (CH_3)_3COH + CCl_3^-,$$
$$CCl_3^- \rightleftarrows CCl_2 + Cl^-.$$

The advantage of t-butoxides compared with other alkoxides is probably to a large extent associated with the weak reactivity of the anions of the sterically hindered tertiary alcohol[23].

The synthesis of dichlorocarbene from carbon tetrahalides and lithium alkyls in ethereal solution appears to be very promising[24]:

$$CCl_3X + RLi \rightarrow CCl_3Li + RX,$$
$$CCl_3Li \rightarrow CCl_2 + LiCl.$$

The effectiveness of this method of synthesising dichlorocarbene is evident from Table 1, which lists the yield of dichloronorcarane obtained by the addition of dichlorocarbene to cyclohexene. The reaction of lithium alkyls with chloroform finds a useful application when the dichlorocarbene formed is trapped by the nucleophilic triphenylphosphine. One then obtains alkylidenephosphorane which can be converted into substituted vinyl chlorides by the Wittig reaction[25]:

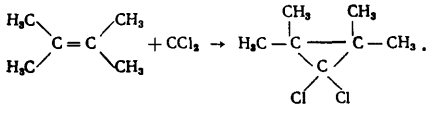
$$(C_6H_5)_3P + CCl_2 \rightarrow (C_6H_5)_3P=CCl_2,$$
$$(C_6H_5)_3P=CCl_2 + \rangle C=O \rightarrow \rangle C=CCl_2 + (C_6H_5)_3PO.$$

Recently a new method has been proposed for the preparation of dichlorocarbene, by the reaction of chloroacetate esters with alkoxides in an inert solvent:

$$CCl_3COR + RO^- \rightarrow CCl_3\overset{\overset{O^-}{|}}{C}-OR \rightarrow CCl_2 + Cl^- + RO-\overset{\overset{O}{\|}}{C}-OR.$$

The effectiveness of this method may be judged from the yield of cyclopropanes formed when olefins are introduced into the reaction system. When t-butyl dichloroacetate is allowed to react with potassium t-butoxide and isobutene, 1,1-dichloro-2,2-dimethylcyclopropane is obtained in only 10% yield[26]; Parham and coworkers[27] were able to increase the yield of cyclopropanes to 72–88% by carrying out the reaction with ethyl trichloroacetate and potassium t-butoxide, sodium ethoxide, or sodium methoxide. Thus the above reaction can give higher yields of cyclopropanes than the reaction in which chloroform is used as a source of dichlorocarbene. The use of readily available sodium methoxide is also an advantage of this method.

Table 2 lists the yields of cyclopropane derivatives obtained by the two methods described above. Wagner[30] proposed a modification of Parham's method[26,27] consisting in thermal decomposition of sodium trichloroacetate in an inert solvent:



$$CCl_3COONa \xrightarrow{t} CCl_2 + NaCl + CO_2.$$

It has recently been established by polarography that the electrochemical reduction of carbon tetrachloride in solution in acetonitrile proceeds via a stage in which dichlorocarbene is formed[31]:

$$CCl_4 + 2\bar{e} \rightarrow CCl_3^- + Cl^-,$$
$$CCl_3^- \rightleftarrows CCl_2 + Cl^-,$$
$$CCl_2 + 2\bar{e} \rightarrow CCl_2^{2-},$$
$$CCl_2^{2-} + 2CH_3CN \rightarrow CH_2Cl_2 + 2CH_2CN^-.$$

This is also confirmed by the synthesis of 1,1-dichloro-2,2,3,3-tetramethylcyclopropane when the electrolysis of carbon tetrachloride is carried out at -20° in the presence of tetramethylethylene[31]:

$$CCl_4 + 2\bar{e} \rightarrow CCl_3^- + Cl^-,$$
$$CCl_3^- \rightleftarrows CCl_2 + Cl^-,$$

In 1963 it was found[32] that dichlorocarbene can add to the double bond of tetrachloroethylene with the formation of hexachlorocyclopropane. Bearing in mind the fact that tetrachloroethylene is resistant to electrophilic attack, the authors suggest that dichlorocarbene behaves in this reaction either as a nucleophilic or a radical reagent.

Dichlorocarbene has been more thoroughly investigated than any other carbene, and we shall therefore return to its various reactions throughout this review.

c. Dibromocarbene. This compound can be formed as an intermediate either by the alkaline hydrolysis of bromoform[18,33,34] or by treatment of a mixture of the latter in anhydrous alcohol with alkali metal alkoxides[7,18,28]:

$$CHBr_3 + :B \rightleftarrows CBr_3^- + HB,$$
$$CBr_3^- \rightleftarrows CBr_2 + Br^-.$$

Strong bases such as methyllithium and n-butyllithium have also been tested in the synthesis of dibromocarbene. Closs and Closs[39] allowed these bases to react with dibromomethane and Miller and Kim[24] with carbon tetrabromide. It was found that, whereas n-butyllithium and carbon tetrabromide convert olefins into dibromocyclocyclopropanes albeit in very small yields, it was impossible to demonstrate the formation of dibromocarbene in the reaction of methyllithium with dibromomethane.

d. Diiodocarbene. Hine *et al.*[21] recently succeeded in synthesising diiodocarbene by the action of sodium ethoxide on iodoform:

$$CHI_3 + C_2H_5O^- \rightleftarrows CI_3^- + C_2H_5OH,$$
$$CI_3^- \rightleftarrows CI_2 + I^-.$$

The diiodocarbene so formed reacts with the excess of ethoxide ions, yielding acetaldehyde and methylene iodide:

$$CI_2 + C_2H_5O^- \longrightarrow CH_3CHO + CHI_2^-,$$
$$CHI_2^- + C_2H_5OH \longrightarrow CH_2I_2 + C_2H_5O^-.$$

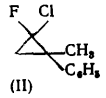
TABLE 1. Yields of dichloronorcarane obtained by the reaction of cyclohexene with carbon tetrahalides and different organolithium compounds.

| Carbon tetrahalide | Lithium alkyl | Yield of dichloro-norcarane, % |
|---|---|---|
| $CCl_4$ | $CH_3Li$ | 8 |
| $CCl_4$ | $n\text{-}CH_3(CH_2)_3Li$ | 50 |
| $CCl_3Br$ | $CH_3Li$ | 67 |
| $CCl_3Br$ | $n\text{-}CH_3(CH_2)_3Li$ | 91 |
| $CCl_3I$ | $CH_3Li$ | 71 |

TABLE 2. Comparison of the yields (%) of cyclopropane derivatives obtained from olefins by the "ethyl trichloroacetate" and "chloroform" methods.

| Reaction products | Initial chloride | | | |
|---|---|---|---|---|
| | $CCl_3COOC_2H_5$[27] | | $CHCl_3$ | |
| | 1,1-dichloro-2,2-dimethyl-cyclopropane | 7,7-dichloro-norcarane | 1,1-dichloro-2,2-dimethyl-cyclopropane | 7,7-dichloro-norcarane |
| In the presence of: | | | | |
| Potassium t-butoxide | 86 | 72 | 65[28] | 59[28] |
| Sodium ethoxide | 82 | — | — | — |
| Sodium methoxide | 76 | 88 | — | 38[29] |

e. Chlorofluorocarbene. This compound probably forms as an intermediate in the thermal decomposition (70–100°) of dichlorofluoroacetic acid in aqueous solution:



$$Cl_2CFCOO^- \longrightarrow Cl_2CF^- + CO_2,$$
$$Cl_2CF^- \longrightarrow CClF + Cl^-.$$

It later undergoes rapid hydrolysis as follows[36]:

$$CClF \xrightarrow{H_2O} HCl, HF, CO, \text{ and } HCOOH.$$

It has been shown recently that *sym*-tetrachlorodifluoroacetone can serve as a source of chlorofluorocarbene[37]. When the former was allowed to react with cyclohexene in the presence of potassium t-butoxide, 7-chloro-7-fluorobicyclo[4,1,0]heptane (I) was obtained and when 1,1-methylphenylethylene was used instead of cyclohexene, the product was 1-chloro-1-fluoro-2-methyl-2-phenylcyclopropane (II):

(I)

(II)

3. Monohalogenocarbenes

a. Alkoxyhalogenocarbenes. Hine and Tanabe[38] showed that fluoroisopropoxycarbene is formed in the decomposition of chlorodifluoromethane by potassium isopropoxide in isopropanol. Probably, initially difluorocarbene is formed[18] and then reacts with isopropanol, undergoing conversion into fluoroisopropoxycarbene:

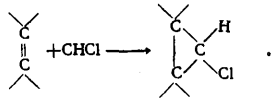
$$CHClF_2 + (CH_3)_2CHO^- \rightleftharpoons CClF_2^- + (CH_3)_2CHOH,$$
$$CClF_2^- \longrightarrow CF_2 + Cl^-,$$
$$(CH_3)_2CHOH + CF_2 \longrightarrow (CH_3)_2CH\overset{+}{O}-\overset{-}{C}F_2 \xrightarrow{-HF} \underset{H}{\overset{OCH(CH_3)_2}{C}}\!\!<_{F}.$$

Fluoroisopropoxycarbene is also formed in the reaction of dichlorofluoromethane with a dilute solution of potassium isopropoxide, but in this case the intermediate is chlorofluorocarbene and not difluorocarbene[21].

It seems strange why the above reaction has only a single final product, triisopropyl orthoformate in 71% yield. Under the same conditions chloroform and bromoform yield in addition carbon monoxide, propene, and isopropyl ether. Evidently the difference is due to the fact that the halogen in fluoroisopropoxycarbene is less strongly bound than in chloroisopropoxy- or bromo-carbene. The latter compound loses a halide anion forming the cation (A) which then undergoes the following chain of reactions:

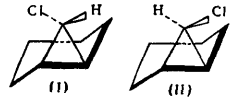
$$\underset{(A)}{(CH_3)_2CHOC^+} \xrightarrow{-CO} (CH_3)_2CH^+ \xrightarrow[-H^+]{(CH_3)_2CHO^-} CH_3CH{=}CH_2 + (CH_3)_2CH{-}O{-}CH(CH_3)_2.$$

b. Chlorocarbene. This compound forms when methyllithium[39], n-butyllithium[35,25], or phenyllithium[25] react with methylene chloride in dry ether:



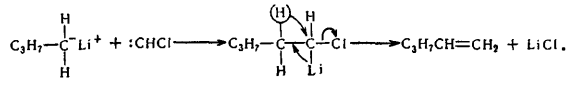
$$CH_2Cl_2 + RLi \longrightarrow LiCHCl_2,$$
$$LiCHCl_2 \longrightarrow CHCl + LiCl.$$

When methylene chloride reacts with n-butyllithium in the presence of triphenylphosphine, the corresponding alkylidenephosphorane forms in 65% yield, which falls to 40% when phenyllithium is used to form chlorocarbene[25]. This reaction is very important, since substituted vinylidene chloride can be obtained from the alkylidene phosphorane and aldehydes or ketones by the Wittig reaction[25]:



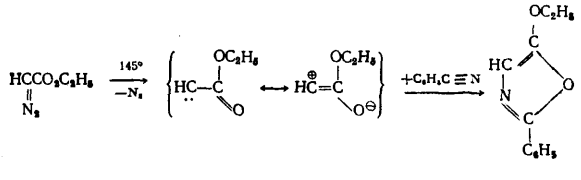
$$(C_6H_5)_3P + CHCl \longrightarrow (C_6H_5)_3P{=}CHCl,$$
$$>C{=}O + (C_6H_5)_3P{=}CHCl \longrightarrow >C{=}CHCl + (C_6H_5)_3PO.$$

Like the majority of carbenes, chlorocarbene is an electrophilic agent which reacts with olefinic double bonds, forming chlorocyclopropanes, whose yield depends on the nucleophilic properties of the olefins[35,40]:



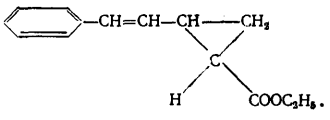
$$CH_2Cl_2 + n\text{-}C_4H_9Li \longrightarrow LiCHCl_2 \longrightarrow CHCl + LiCl,$$

Thus 2,3-dimethylbut-2-ene yields 1-chloro-2,2,3,3-tetramethylcyclopropane in 67% yield and *trans*-but-2-ene yields 1-chloro-2,3-*trans*-dimethylcyclopropane in 40% yield. Cyclohexene gives a 31% yield of a mixture of the two stereoisomeric 7-chlorobicyclo[4,1,0]heptanes (I) and (II) in 1 : 2 ratio, their reduction with sodium in liquid ammonia giving bicyclo[4,1,0]heptane[41]:



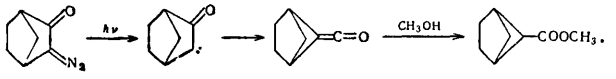
(I) (II)

In the absence of an olefin in the reaction medium, chlorocarbene reacts with n-butyllithium to give 1-chloro-n-pentyllithium which then undergoes $\alpha$-elimination of lithium chloride, forming pent-1-ene following the rearrangement of the hydride anion[35,41]:



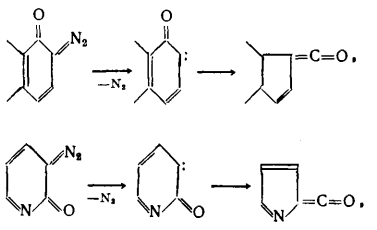
4. Keto- and Thioketo-Carbenes

Since by ketocarbenes we understand any carbenes containing the C=O group in their molecules, we think it appropriate to include in this Section some information about ethoxycarbonylcarbene. It can be obtained by the removal of nitrogen from diazoacetate ester, for example. Thus by the thermolysis of diazoacetate ester in benzonitrile, Huisgen *et al.*[42] obtained in 42% yield 5-ethoxy-2-phenyloxazole which is a product of the 1,3-dipolar cyclo-addition of ethoxycarbonylcarbene to benzonitrile:



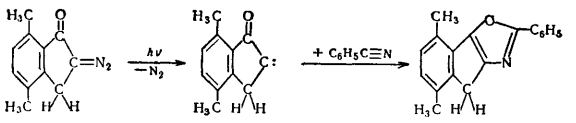
The high yield of the substituted oxazole is probably associated with the inability of ethoxycarbonylcarbene to undergo the Wolff rearrangement. Acetonitrile and phenylacetonitrile[42] also react with ethoxycarbonylcarbene, giving 2-substituted 5-ethoxyoxazole. When the decomposition of diazoacetate ester is catalysed by copper in the presence of tolane, the corresponding derivative of cyclopropene is formed[43]; the replacement of copper by copper sulphate sharply alters the mode of reaction, 2-ethoxy-4,5--diphenylfuran being formed[44,45]. Unfortunately this fact has not as yet been adequately explained (see pp. 81 and 82).

Comparatively recently the addition of ethoxycarbonylcarbene to phenylbutadiene has been described[46]. The reaction results in the formation of the following cyclopropane derivative:

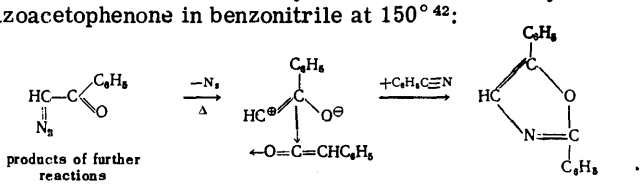


Other reactions of ethoxycarbonylcarbene are described on pages 81, 82, and 85.

Among the latest investigations of other ketocarbenes the work of Wiberg *et al.*[47], for example, is of interest; by irradiating diazonorcamphor in methanol, they obtained methylbicyclo[2,1,1]hexane-5-carboxylate:

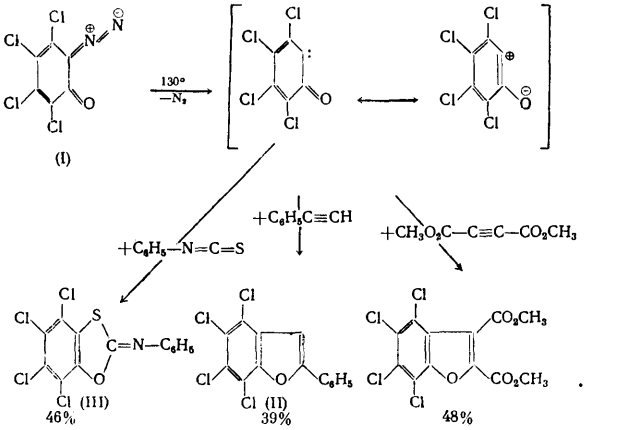


Similar ring contraction as a result of a Wolff rearrangement occurs in the photochemical[48,49] and thermal[50] decomposition of quinone diazides and naphthalene diazo-oxide, in the photochemical decomposition of diazopyridones[51],

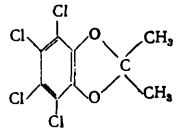


and in the photolysis of 4,7-dimethyl-4-diazoindan-1-one in aqueous tetrahydrofuran[52,53].

In the last case the Wolff rearrangement is somewhat retarded, probably as a result of the large amount of strain in the ring, so that when the reaction is carried out in benzonitrile it is possible to obtain the 1,3-adduct of the dipolar cyclo-addition of the intermediate ketocarbene to benzonitrile (the corresponding condensed oxazole)[54]:

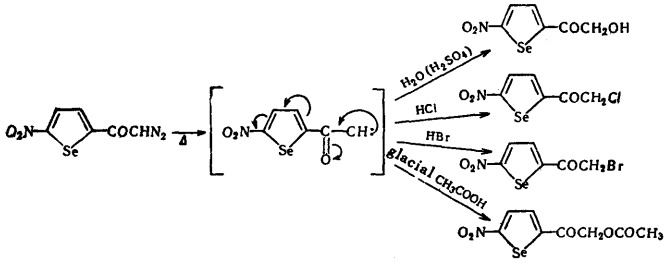


In other cases the formation of ketocarbenes was also confirmed by introducing into the reaction mixture various dipolarophiles which resulted in the formation of the corresponding 1,3-adducts. For example, 2,5-diphenyloxazole was isolated in 0.4% yield after the thermolysis of diazoacetophenone in benzonitrile at 150°[42]:

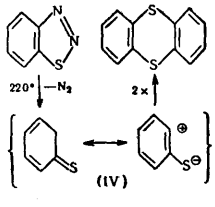


The very low yield of the 1,3-adduct in this case is due to the high rate of the Wolff rearrangement as a result of which a large part of the initially formed benzolycarbene is converted into the corresponding keten. When the carbene is stabilised with metallic copper or certain cuprous and cupric compounds, the product of 1,3-dipolar cyclo--addition can be obtained in higher yields. For example, when the above reaction is carried out in the presence of copper powder, cuprous cyanide, or cupric acetylacetonate, 2,5-diphenyloxazole is obtained in 16–17% yield[42]. By stabilising the ketocarbene with copper, Novak and coworkers[55] were able to obtain acylcyclopropanes in the decomposition of a diazoketone in the presence of olefins. It is interesting that, when the decomposition of diazoacetonephenone is catalysed with copper in the presence of tolane, 2,3,5-triphenylfuran is formed[54]. The formation of the corresponding adducts of acetonitrile and acetone with ethoxycarbonyltrifluoroacetylcarbene has recently been described[56].

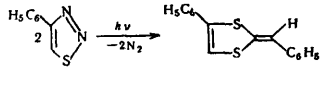
Aromatic ketocarbenes are distinguished by a long "life-time" in the absence of substances capable of reacting with them. This is because such carbenes would lose their aromatic character by undergoing a Wolff rearrangement. For example, the carbene formed in the photolysis of 3,4,5,6-tetrachlorobenzene-*o*-diazo-oxide (I) is so resistant to rearrangement than in methanol it gives the monoethyl ether of tetrachlorocatechol in 70% yield[54]. On the other hand, thermolysis of 2,3,4,5-tetrachlorobenzene-*o*--diazo-oxide in phenylacetylene at 130° gives the 1 : 1 adduct of the corresponding ketocarbene and the solvent; the adduct is 4,5,6,7-tetrachloro-2-phenylbenzo(b)furan (II).[42] If the decomposition of the diazo-oxide (I) is carried out in styrene, the 2,3-dihydro-derivative of the above adduct is obtained while in dimethyl fumarate the product is the diester of dihydrobenzo[b]furandicarboxylic acid. The intermediate ketocarbene also readily forms the corresponding adduct (III) with phenylisothiocyanate, whose C=S double bond is an active dipolarophile. The reactions undergone by the ketocarbene formed in the thermolysis or photolysis of 3,4,5,6-tetrachlorobenzene-*o*-diazo-oxide (I) can be represented schematically as follows:



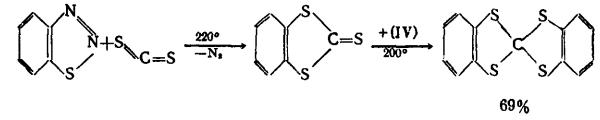
In the photolysis of the diazo-oxide (I) in acetone the carbene adds to the keto-group of acetone forming 1,3-benzodioxole in 30% yield:



The low dependence of the rate of decomposition of the diazo-oxide (I) on the nature of the dipolarophile used as solvent is a definite indication that the reaction between these components takes place after the removal of the nitrogen molecule from the diazo-oxide (I), i.e. the corresponding aromatic carbene really exists.



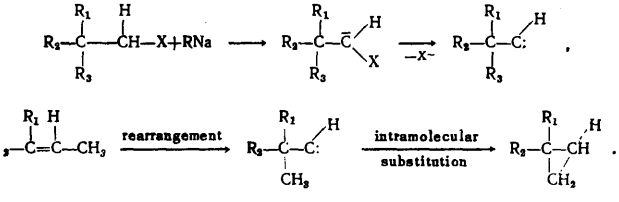
Ketocarbenes are longer-lived than alkylcarbenes, for example, which may be due to the conjugation of the lone pair of electrons of the key carbon atom and the carbonyl double bond[1]. However, the usual ketocarbenes nevertheless fairly readily undergo the Wolff rearrangement (particularly in the presence of colloidal silver), giving the corresponding ketens. The resistance of the ketocarbenes to rearrangement increases with increase in the extent of conjugation in the molecule. Thus it is reasonable that aromatic ketocarbenes are the most stable. Using aromatic ketocarbenes or ketocarbenes with a fairly long conjugation chain, it is possible to obtain high yields of the products of their direct reaction with alcohols, amines, water, hydrogen halides, etc., without resorting to additional stabilisation of the carbene with copper[57]. Thus it proves possible[58] to obtain ketones derived from selenophen, starting with 2-diazoacetyl-5-nitroselenophen:



Turning now to thioketocarbenes, we must mention that as early as 1893 Jacobson and Janssen[59] obtained thianthrene by the thermolysis of 1,2,3-benzothiadiazole, which probably involves the intermediate formation of the corresponding thioketocarbene (IV):

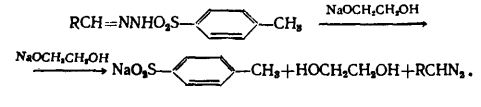
The formation of the derivative of dithiafulvene in the photolysis of 4-phenyl-1,2,3-thiadiazole[60] may be explained by the 1,3-addition of phenylthiocarbene to the product of its rearrangement — phenylthioketen:

In contrast to the ketocarbene obtained by the degradation of the diazo-oxide (I), the thiocarbene (IV) exhibits a striking tendency towards dimerisation. Only the most active dipolarophiles with a C=S double bond can give the corresponding adducts with this thioketocarbene. Such dipolarophiles are, in particular, carbon disulphide and phenyl isothiocyanate:



69%

There is as yet little information in the literature about the reactions of the thioketocarbene (IV) obtained in the photolysis of 1,2,3-thiadiazole[61].

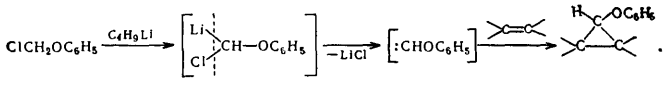


## 5. Other Carbenes

a. Alkylcarbenes. These compounds are obtained by the dehydrohalogenation of alkyl halides, the reaction being greatly affected by the strength of the base used for the dehydrohalogenation and by steric factors. For example, phenylsodium is more effective for the preparation of alkylcarbenes than sodium methoxide. When a secondary or a tertiary alkyl group is linked to the $\alpha$-carbon atom of the alkyl halide, the main products of the reaction are olefins and cyclopropanes formed from the carbene by rearrangement or intramolecular substitution (see below) respectively[62,63]:

It is also significant that alkyl iodides are dehydrohalogenated more sluggishly than the corresponding bromides and chlorides.

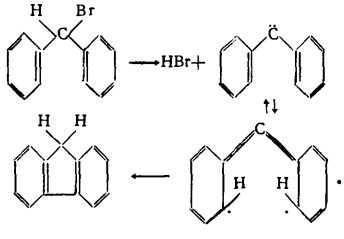
Bamford and Stevens[66] developed a method for the preparation of diazoalkanes which consists in the reaction of the corresponding tosylhydrazones with sodium in ethyleneglycol:



This reaction has been widely used for the preparation of alkylcarbenes. For example, it has been established that

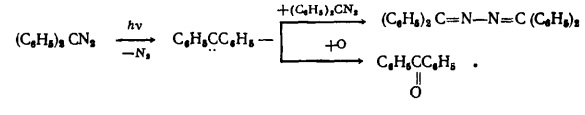
TABLE 3. Extent of dehydrohalogenation of alkyl halides (%) as a function of the base used.

| Base | Alkyl halide | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | n-butyl (Ref. 64) | | | isobutyl (Ref. 64) | | | neopentyl (Ref. 65) | | neohexyl (Ref. 65) |
| | Cl | Br | I | Cl | Br | I | Cl | Br | Cl |
| $C_6H_5Na$ | 94 | 94 | 65 | 89 | 62 | 13 | 70 | 25 | 67 |
| $NaNH_2$ | 30 | 15 | — | 7 | 1 | — | 60 | — | — |
| $NaOCH_3$ | 10 | — | — | 0 | — | — | — | — | — |



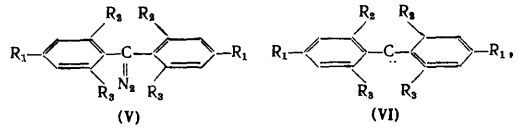
the tosylhydrazones of aromatic[63,67], aliphatic[63,68], and alicyclic[69] aldehydes and ketones react with bases in aprotic solvents, such as diethyl Carbitol, forming diazo-compounds which on thermal decomposition between 160° and 220° generate the corresponding carbenes. Alkylcarbenes obtained from aliphatic tosylhydrazones tend to undergo rearrangement with formation of olefins, and intramolecular substitution resulting in cyclopropanes. The rearrangement takes place to a greater extent in view of the higher yields of olefins.

b. Alkoxy- and phenoxy-carbenes. Schöllkopf and Paust[70] obtained in high yields a number of alkoxycyclopropanes by the reaction of dichloromethyl alkyl ethers with olefins in the presence of methyllithium. They believe that this reaction proceeds with the intermediate formation of the alkoxycarbene. Later these workers and Lerch[71] described a synthesis of phenoxycyclopropanes by the reaction of chloromethyl phenyl ether with olefins in the presence of butyllithium. They believe that the reaction proceeds as follows:



The addition of phenoxycarbene to the double bond takes place stereospecifically, like *cis*-addition.

c. Diphenylcarbenes. By pyrolysing diphenylmethyl bromide, Harrison and Lossing obtained fluorene and hydrogen bromide[72]. Probably diphenylcarbene forms as an intermediate and is then converted into fluorene as a result of migration of hydrogen atoms:



Photolysis of diphenyldiazomethane at low temperatures also result in the formation of diphenylcarbene, the latter rapidly reacting with diphenyldiazomethane and oxygen to give benzophenone azine [bis(diphenylmethylene)hydrazine] and benzophenone[73]:

Diphenylcarbene can also be obtained by the thermal decomposition of diphenyldiazomethane, the nature of the final reaction products depending on the solvent used. When the reaction is carried out with solvent or in benzene, benzophenone azine is formed exclusively. When petroleum ether is used, benzophenone azine, *sym*-tetraphenylethane, and a molecular complex of tetraphenylethane and benzophenone azine are formed. The authors believe that in this case diphenylcarbene reacts with petroleum ether forming diphenylmethyl radicals which on dimerisation give the substituted ethane.

Fairly stable substituted diphenylcarbenes (VI) were obtained by the pyrolytic and photolytic decomposition of the corresponding diazo-compounds (V):[74]

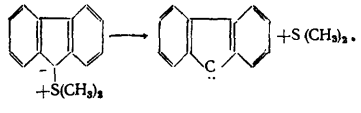
(V) (VI)

Va, VIa; $R_1$, $R_2$, $R_3$=$CH_3$;

Vb, VIb; $R_1$, $R_2$, $R_3$=Cl;

Vc, VIc; $R_1$=$CH_3$, $R_2$=$R_3$=$OCH_3$.

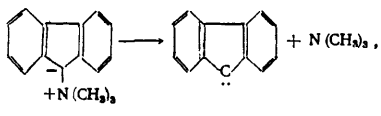
The low reactivity of carbenes of type (VI) is a consequence of steric hindrance. Paskovich's dissertation deals in particular with sterically hindered carbenes[75].



It is interesting that diphenylcarbene exhibits radical properties[76]; for example its addition to olefins is non-stereospecific[8]†.

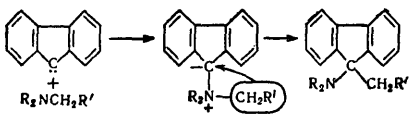
Recently Kirmse[78] observed nucleophilic behaviour in the case of diphenylcarbene: the latter was converted into the diphenylcarbenium cation after its synthesis by the photolysis of diphenyldiazomethane in alcohol. Thus the equilibrium

which previously was regarded as purely formal, found practical confirmation. The author notes that diphenylenecarbene obtained from diazofluorene shows much weaker nucleophilic activity.

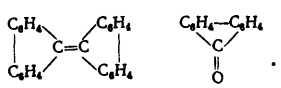


d. Fluorenylidene and cyclopentadienylidene. Johnson and La Count[79] showed that when dimethylsulphonium 9-fluorenylide is decomposed the corresponding carbene, fluorenylidene, is formed as an intermediate:

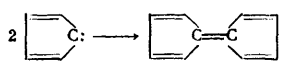
Swain and Thornton[80] found that other dimethylsulphonium compounds also break down with the formation of the corresponding carbenes. Thus decomposition of *p*-nitrobenzyldimethylsulphonium *p*-toluenesulphonate in the presence of sodium hydroxide at 60° yields *p*-nitrobenzylcarbene, which dimerises to *cis*- and *trans*-*pp'*-dinitrostilbenes:



Franzen[81] showed that trimethylammonium 9-fluorenylide also decomposes into fluorenylidene,



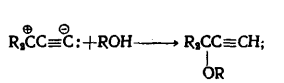
† Somewhat later Skell and Klebe[77] observed radical properties in the case of another carbene — propargylidene (HC≡C–C̈–H).



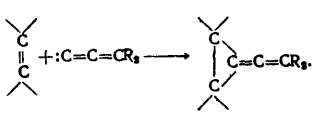
which then reacts, with amines for example[81,82] in the following way:

In the absence of suitable reagents fluorenylidene dimerises to difluorenylidene or reacts with oxygen to form fluorenone[13]:

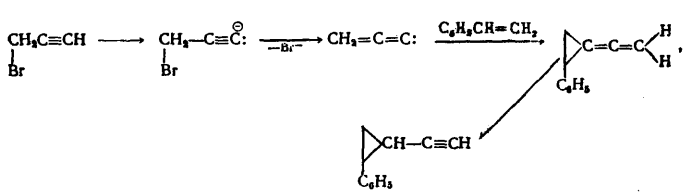
The photochemical decomposition of diazocyclopentadiene yields fulvalene; this is probably due to the formation of a carbene (cyclopentadienylidene) as an intermediate, which subsequently dimerises[13]:



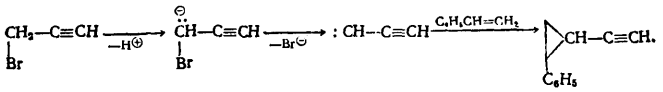
e. Vinylidenecarbenes. Hartzler[83] made a thorough study of the rearrangement of acetylene systems into allene systems in the presence of alkoxide and hydroxide ions and concluded that the formation of vinylidenecarbene is an intermediate stage in this reaction:



where R = $CH_3$, $C_6H_5$, H; and X = Cl, Br, OH, $OCOCH_3$.

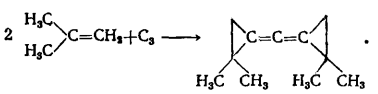


In the presence of alcohol the vinylidenecarbene reacts in the "propargyl form" with the formation of the corresponding propargyl ether[84],



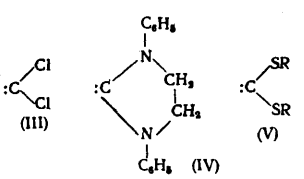
while in the presence of olefins it reacts in the "allenyl form" and is converted into cyclopropanes[83-85]:

The reaction of propargyl bromide with potassium t-butoxide in styrene yields 1-ethynyl-2-phenylcyclopropane. This compound can form in two ways: either via the vinylidene carbene[83]:

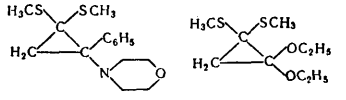


or by $\alpha$-elimination of hydrogen bromide with subsequent addition of the resulting propargylidene to styrene[83]:

According to Hartzler[83], the formation of tetraarylhexapentaenes in the reaction of diarylethynylmethanols with acetic anhydride and potassium hydroxide in dry ether[86] also proceeds via vinylidenecarbene:

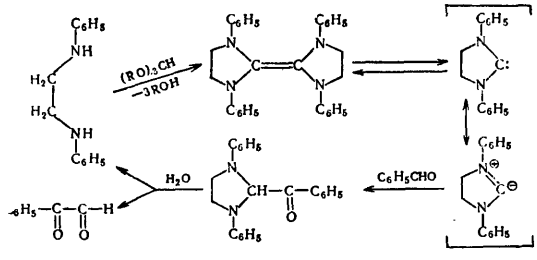


The dicarbene $C_3$ observed recently in the atmosphere of comets proved to be the main constituent of gaseous carbon[87]. This dicarbene is obtained by evaporating carbon into a vacuum corresponding to $10^{-3}$–$10^{-5}$ mmHg. It can enter into a variety of reactions on the walls of the reaction vessel cooled to -196°. For example, the reaction of the dicarbene $C_3$ with isobutene yielded a compound of a new class — the bisethanoallene series. The structure of the products, whose yield was 40%, was demonstrated by infrared and nuclear magnetic resonance spectroscopy[88,89]:

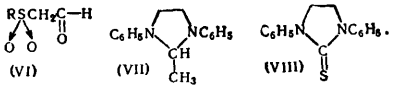


The reaction of the dicarbene with *cis*- and *trans*-but-2-enes is stereospecific to the extent of 90–95%, i.e. 90–95% of the dicarbene molecules are in the singlet state at the instant of the reaction and the remainder in the triplet state. Skell and Wescott[88] suggest that the structure of the $C_3$ molecule should be represented by a combination of the following two resonance formulae:  .

f. 1,3-Diphenylimidazolidin-2-ylidene. By reacting dianilinoethane with orthoformates, Wanzlick and coworkers[90-92] were able to synthesise an olefin which readily dissociated into two molecules of a carbene–1,3-diphenylimidazolidin-2-ylidene. This carbene, which we shall henceforth call stable carbene, is markedly nucleophilic probably because of the strong electron-donor properties of the nitrogen atoms, and does not react with the usual olefins. The authors isolated only the product of the reaction of stable carbene with tetracyanoethylene, in which the electron density at the double bond is known to be greatly reduced[91]. The structure of this product has not as yet been elucidated.

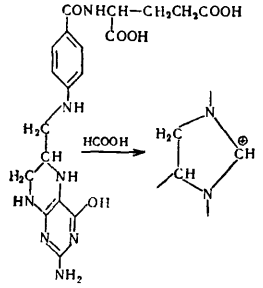


The electrophilic or nucleophilic properties of a carbene depend on the electron-acceptor (or correspondingly the electron-donor) properties of the atoms linked to the key carbon atom. In this connection it is interesting to compare dichlorocarbene (III), stable carbene (IV), and the carbene (V) in which two sulphur atoms are linked to the key carbon atom, since sulphur is intermediate between nitrogen and chlorine in its electron-donor properties.



Dichlorocarbene (III), being a typical electrophilic agent, readily reacts with the usual olefins and only to a very slight extent with olefins whose double bond is markedly deactivated, the reaction mechanism being evidently different in the latter case[32]. The stable carbene (IV) is a nucleophilic compound and does not react at all with the usual olefins. Schöllkopf and Wiskott[93] have established that the di(methylcapto)carbene (V) (R = $CH_3$, for example), does not react with a solution of cyclohexene in the dimethyl ether of ethylene glycol, because the sulphur atoms greatly reduce its electrophilic properties by virtue of their lone pairs of electrons. Nevertheless, in certain cases di(methylmercapto)carbene also shows electrophilic properties. Thus it is capable of adding to double bonds with enhanced electron density, yielding, for example, cyclopropane derivatives on reaction with 1-morpholino-1--phenylethylene or keten diethyl acetal:

Although the chemistry of the nucleophilic carbene has only just begun to be investigated, its possible synthetic applications are already apparent. Its preparation and certain reactions can be shown schematically as follows:



Apart from its use in the synthesis of keto-aldehydes, the stable carbene provides, for example, a possible pathway to the synthesis of the as yet unknown class of $\beta$-sulphone-aldehydes (VI).[94] Hydrolysis of the primary product of the reaction of the stable carbene with acetic anhydride yields 2-methyl-1,3-diphenylimidazolidine (VII) and monoacetylated dianilinoethane. The stable carbene reacts with sulphur even at room temperature, giving the corresponding derivative of thiourea (VIII):

While in their reaction with dichlorocarbene diazo--compounds eliminate a molecule of nitrogen[95], with the nucleophilic carbene they yield ketazines. On treatment with carboxylic acid chlorides, the stable carbene gives imidazolidinium salts acylated at the carbon atom in position 2, which are readily hydrolysed.

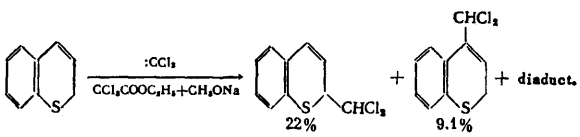
It is nowadays believed that tetrahydrofolic acid combines with formic acid or formaldehyde and participates in the metabolism of certain substances in living organisms, promoting transformylation, transhydroxymethylation, and certain other reactions[96]. It is interesting that tetrahydrofolic acid itself is structurally related to dianilinoethane, while the product of its reaction with formic acid, the so--called "anhydrocitrovorum factor", is none other than the protonated form of a carbene very similar in structure to the stable carbene[97]:

Hence it is not impossible that reactions involving the participation of carbenes occur also in nature. Quite recently Wanzlick and coworkers[98] have described the synthesis of new compounds of the type of bis(1,3-diphenylimidazolidin--2-ylidene).

## IV. SOME ASPECTS OF THE SYNTHETIC APPLICATIONS OF CARBENES

### 1. Substitution of Carbenes in C–H, C–Halogen, and Other Bonds

a. Intermolecular substitution of carbenes. Franzen and Fikentscher[99] allowed methylene labelled at the carbon atom to react with ethyl ether and showed that this results in the formation of ethyl n-propyl ether by direct substitution of methylene in the C–H bond of the ethyl group. Franzen and Kuntze[100] described similar reactions with other alkyl ethers, tetrahydrofuran, and *N*-methylpyrrolidine.

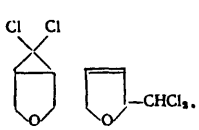


Doering and coworkers[101] showed that methylene obtained by the photochemical decomposition of diazomethane readily interacts with the C–H bonds of saturated hydrocarbons, for example n-pentane, 2,3-dimethylbutane, cyclopentane, etc., the products of the substitution of methylene in various C–H bonds being formed in amounts corresponding to the number of these bonds in the hydrocarbon molecule regardless of the nature of the bond. In view of the absence of selectivity in this reaction, Doering suggested that its activation energy is close to zero[101,102].

However, Frey[103] was able to show that methylene obtained by gas-phase photolysis of diazomethane reacts selectively with $\rangle$CH, $\rangle CH_2$, and $-CH_3$ bonds in hydrocarbons, in the ratios 1.5 : 1.2 : 1.0. Richardson *et al.*[4] carried out liquid-phase photolysis of diazomethane in solution in isomeric octanes and arrived at the same conclusions as Doering. They believe that the difference between the reactivity of methylene in the gas phase and in solution can be readily explained on the basis of Herzberg's spectroscopic data on its structure[3,104]. During photolysis in solution excited singlet methylene forms initially, almost each of its collisions with the solvent molecules resulting in reaction. Since the frequency of collisions is much greater than the frequency of the singlet–triplet transition, non-selective substitution of methylene in carbon–hydrogen bonds occurs. In the gas-phase reaction the frequency of the collisions of methylene with hydrocarbon molecules is approximately the same as that of the singlet–triplet transition and therefore methylene reacts selectively as a typical radical agent.

This interpretation is consistent with a number of experimental data[4,103,105,106]. Doering and Knox[102] showed that the replacement of hydrogen atoms in methylene by electronegative groups greatly increases the selectivity of the reaction of the carbene with C–H bonds. The ratios of the rates of substitution at tertiary, secondary, and primary carbon atoms of the alkane greatly increase in the following sequence of carbenes: $CH_2 < CHCOOC_2H_5 < C(COOC_2H_5)_2$. Doering and Knox suggest that the presence of the alkoxycarbonyl group increases the activation energy for the reaction and favours the reaction at the tertiary carbon atom relative to that at the primary atom.

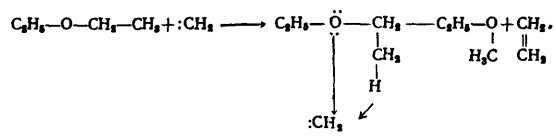
Recently it proved possible to substitute methylene in the C–H bond of pyridine, with 83% yield of α-picoline[107]. The specificity of the reaction was explained by the initial addition of methylene to the nitrogen atom with subsequent rearrangement.



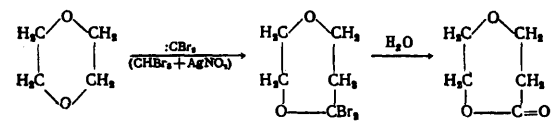
Until 1961 it was regarded as generally accepted[108] that dihalogenocarbenes cannot be substituted in C–H bonds. However, Parham and Koncos[109] showed that this reaction is possible:

They suggest that the benzothiopyranate anion forms initially under the action of sodium methoxide.

Since the formation of tetrachloroethylene from dichlorocarbene and chloroform is never observed in the liquid phase, its formation in the pyrolysis of chloroform probably involves the substitution of dichlorocarbene in the C–H bond of chloroform, the resulting pentachloroethane being converted into tetrachloroethylene after losing the elements of hydrogen chloride[97].

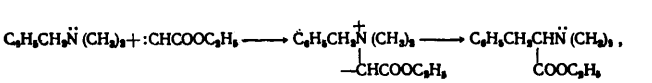


Anderson and Reese[110] showed that the addition of dihalogenocarbenes to carbon–carbon double bonds and their substitution in C–H bonds of olefins may compete with one another. Thus when 2,5-dihydrofuran is treated with a slight excess of dichlorocarbene obtained from ethyl ether, trichloroacetic acid, and sodium methoxide at 0°, a mixture of 6,6-dichloro-3-oxabicyclo[3,1,0]-hexane and 2-dichloromethyl-2,5-dihydrofuran is formed with an overall yield of 62%:



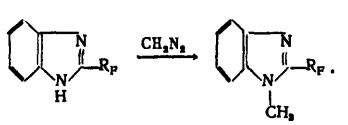
In the case of dibromocarbene a mixture of the corresponding bromo-compounds forms with an overall yield of 28%.

Of the latest work on the substitution of free methylene in C–halogen bonds, the investigation of Bradley and Ledwith[111] must be mentioned. They were able to substitute methylene in C–Cl bonds of primary, secondary, and tertiary alkyl chlorides. The substitution of methylene in C–halogen bonds is described in greater detail in D'yakonov's review[112].

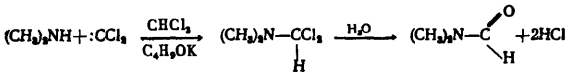


The C–O bond is fairly vulnerable with respect to carbenes. For example, methylene is not only substituted in the C–H bonds of alkyl ether but the latter are actually split with the formation of olefins and the corresponding methyl alkyl ethers. The reaction probably proceeds as follows[99]:

Phenylcarbene and ethoxycarbonylcarbene[99], obtained by the photolysis of the corresponding diazo-compounds, react similarly. The reaction of dibromocarbene with dioxan in aqueous solution is also an example of substitution in the C–O bond[113]:

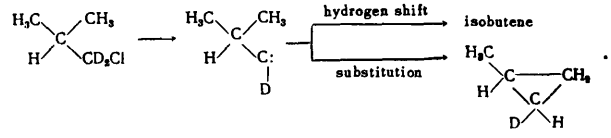


The substitution of carbenes in C–N bonds usually occurs only in those cases where the amino-nitrogen is linked to the benzyl radical, which is distinguished by exceptional cationoid activity[108,110,114]. The reaction probably takes place by a "ylid" mechanism:

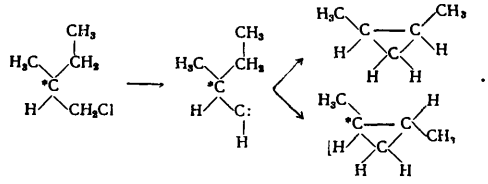


Braz *et al.*[115] showed that methylene is readily substituted in N–H bonds of benzimidazoles with a perfluoroalkyl substituent in the 2-position, which greatly increases the mobility of the hydrogen atom in the imino-group:

Other examples of substitution of carbenes in N–H bonds are known[116,117]:



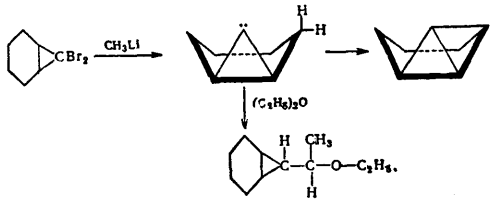
It has recently been shown that this reaction can be used also for the preparation of thioformamides[118].



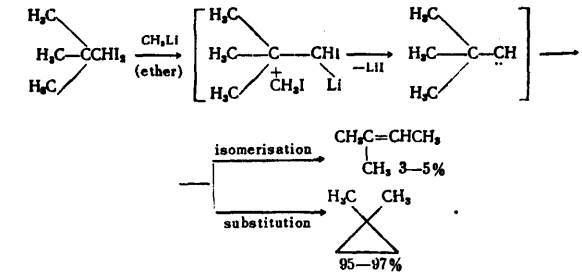
Reutov and Lovtsova[119] suggest that dichlorocarbene can be substituted in the Hg–Cl bond with the formation of trichloromethylorganomercury compounds.

b. Intramolecular substitution of carbenes. In the case of alkylcarbenes the substitution in C–H bonds often takes place intramolecularly. Kirmse and Doering[120] found that the formation of methylcyclopropane and isobutene under the conditions of the Wurtz reaction from isobutylene chloride labelled with deuterium

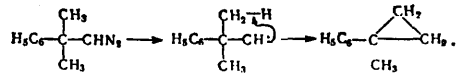
proceeds via α-elimination of deuterium chloride, i.e. in the intermediate dehydrohalogenation stage carbene is formed and then gives the final product by intramolecular substitution:



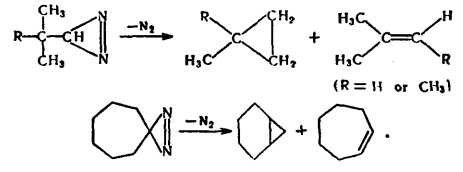
Doering and Kirmse[121] found an elegant application for the above reaction: they used it to establish the *cis*- and *trans*-configurations of the isomeric 1,2-dimethylcyclopropanes. This depends on the fact that the carbene formed from the optically active 2-methylbutyl chloride can react further in several ways: with formation of an olefin, ethylcyclopropane, and two dimethylcyclopropanes. Of the last two, only the *trans*-isomer can be optically active and therefore the presence of optical activity in the case of one of the dimethylcyclopropanes proves that it has the *trans*--configuration:



Skell and Krapcho[122] confirmed the mechanism of formation of the cyclopropanes, involving the α-elimination of the elements of hydrogen chloride, using the reaction of dideuteroneopentyl chloride with metallic sodium.



Another example of intramolecular substitution is the reaction of 7,7-dibromonorcarane with methyllithium yielding a carbene which reacts with the ether used as solvent: it is intramolecularly substituted in the C–H bond[123]:



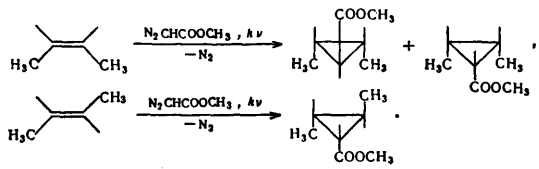
The reaction of the last type was investigated in greater detail by Kirmse and Wedel[124], who showed that, when lithium alkyls or metals (lithium, magnesium) are allowed to act upon *gem*-dihalogeno-compounds, both halogen atoms are eliminated with the formation of a mixture of the corresponding unsaturated compounds and cyclopropane derivatives. For example, the reaction between 1,1-dibromobutane and methyllithium or magnesium yields mainly but-1-ene, methylcyclopropane being formed only in small amounts. The tendency of the intermediate alkylcarbene towards intramolecular substitution in the C–H bond increases with the extent of branching of the alkyl group. Thus the reaction of 1,1-diiodo-2,2-dimethylpropane with methyllithium in ether gives a mixture of products consisting of 95–97% of 1,1-dimethylcyclopropane and 3–5% of 2-methylbut-2-ene.

The rearrangement which Philip and Keating[125] discovered and called "neophilic" rearrangement, is also an example of intramolecular substitution of a carbene in a C–H bond:

Schmitz *et al.*[126] showed that thermal degradation of diazirines yields carbenes which react further to give cyclopropane derivatives, products of intramolecular substitution, together with olefins formed as a result of rearrangement:

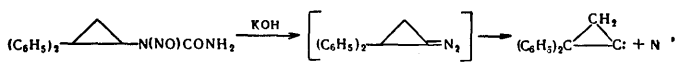
In contrast to the examples known until now, the solvent has no effect on the relative yields of the products in this case: whether the solvent contains hydroxy-groups or not, the yields of cyclopropanes and olefins are the same.

## 2. Addition of Carbenes to Carbon–Carbon and Other Double Bonds



All the carbenes, except the so-called nucleophilic carbene (see p. 76) add to the double bonds of olefins with the formation of cyclopropanes. Although this reaction is often used to prove the existence of carbenes, it is necessary to exercise a certain caution in this respect. Thus in the synthesis of cyclopropanes in the reaction of Simmons and Smith[11,127,128] an organometallic compound and not a carbene is probably formed in the intermediate stage[11,127,128]. However, in most cases there is no doubt about the formation of carbenes as intermediates in the synthesis of cyclopropanes from olefins.

We shall mention first of all the series of carbenes (produced by the reactions shown below) through which an enormous number of substituted cyclopropanes have become readily available[129–133]:

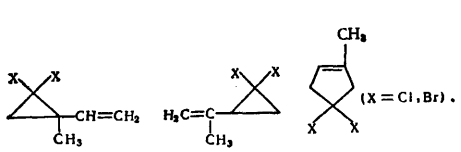


$$CF_2Br_2+RLi \rightarrow RBr+LiBr+ : CF_2,$$
$$ClH_2COR+RLi \rightarrow RH+LiCl+ : CHOR,$$
$$ClH_2CSR+RLi \rightarrow RH+LiCl+ : CHSR.$$

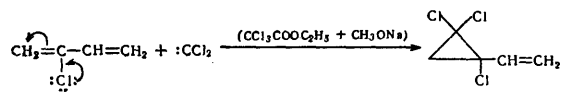
Having at their disposal the method at present available for the preparation of dihalogenocarbenes under neutral. conditions, which consists in the thermal decomposition of the salts of trihalogenoacetic acids, researchers are able to synthesise cyclopropanes from olefins which are sensitive to bases, for example allyl chloride[30,134].

While speaking of the characteristic features of the addition of carbenes to carbon–carbon double bonds, it must be mentioned that, as shown by Doering and Mole[135] and also D'yakonov and coworkers[136,137], alkoxycarbonylcarbenes, for example, add stereospecifically to the double bond in the *cis*-position:

2,2-Diphenylcyclopropylidene described by Jones[138],



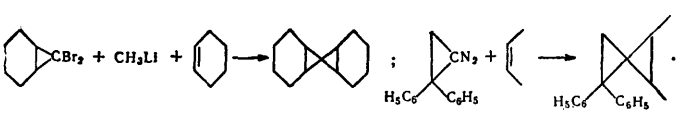
also probably adds stereospecifically to the isomeric but-2-enes[112].



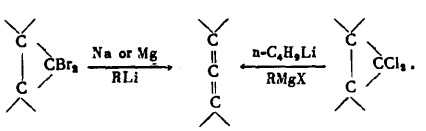
Skell and Etter[139] found that ethoxycarbonylcarbene, formed in the photolysis of diazoacetic ester, is much less stereoselective in the reaction with olefins than the same carbene prepared in a different way — by the decomposition of the diazoacetic ester in the presence of copper. Possibly under the conditions of copper catalysis the complex of the carbene with copper (or copper ions) reacts, and not the free carbene. Complex formation may increase the dimensions of the carbene reacting with the double bond and at the same time reduce its electrophilic activity[139].

Skell and Etter[140] established that the reactivity of ethoxycarbonylcarbene with respect to olefins of different structure varies in the same sense as that of the electrophilic bromonium cation. The rate of reaction in both cases diminishes as the nucleophilic properties of the olefin are weakened. This constitutes further evidence that the additions of carbenes to olefins are electrophilic reactions. In this connection we may mention that the rate of addition of the nucleophilic trichloromethyl anion to the same olefins varies in the opposite sense in the same sequence.

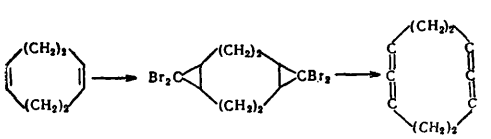
The reaction of dihalogenocarbenes with isoprene has been studied[141,143] and it has been found that the addition takes place mainly in the 1,2-position. Orchin and Herrick[141], who obtained a small amount of the product of 3,4-addition as well as that of the 1,2-addition, suggested that a very small amount of the product of the 1,4-addition is also formed:



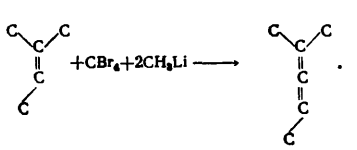
Later D'yakonov and coworkers[144] showed that dichlorocarbene also adds to chloroprene, mainly in the 1,2-position:



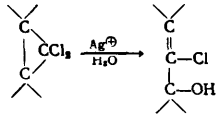
D'yakonov[112] explains this result by suggesting that during the reaction the important feature is not the negative inductive effect of the chlorine atom in the chloroprene molecule but its positive conjugation effect, which makes the 1,2-bond more nucleophilic than the 3,4-bond. It should be noted that the mode of addition to chloroprene of an electrophilic agent such as hydrogen chloride or bromide is consistent with the above explanation; in both cases the proton of the hydrogen halide is directed to the first carbon atom of chloroprene[145]. When dihalogenocarbenes are allowed to react with hexa-1,3,5-triene, mono- and di-adducts are formed. Clearly the more nucleophilic double bonds of the terminal vinyl groups of hexa-1,3,5-triene are involved in the reaction. Vinylcyclopropanes may be of interest as monomers. Thus polymerisation of vinylcyclopropane in the presence of $Al(C_2H_5)_3.TiCl_3$ gave a crystalline polymer[146,147].



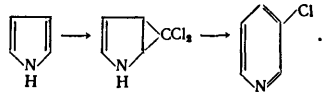
Using the addition of cyclic carbenes (cyclopropylidenes) to olefins[138,148], it is possible to obtain spiran derivatives:



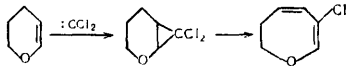
It is interesting that, when the adducts of olefins and dichloro- or dibromo-carbenes are acted upon by various alkaline agents, they lose two halogen atoms and are converted into allenes[10,148-150]:



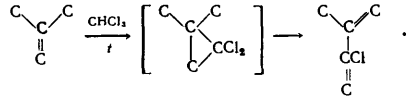
Skatteböl[149] used this reaction to convert cycloocta-1,5-diene into cyclodeca-1,2,6,7-tetraene:



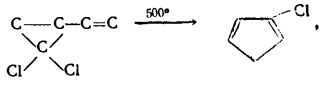
Since lithiumalkyls are among the reagents which convert dihalogenocyclopropanes into allenes and since, on the other hand, the reaction of lithiumalkyls with carbon tetrahalides can give dihalogenocarbenes, there is a possibility of converting olefins into allenes in one step, which Skatteböl[149] in fact achieved:



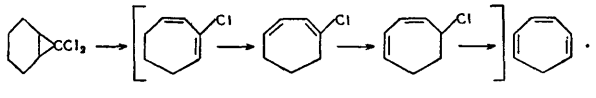
Dihalogenodicyclopropanes can be converted into allyl compounds as well, for example by treatment with an aqueous solution of silver nitrate[151]:



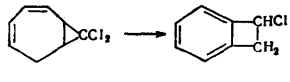
The rearrangement into allyl compounds takes place also with adducts of cyclopentene[152] and bicyclo[2,2,1]-heptadiene[153], the latter forming bicyclo[3,2,1]octadiene. The removal of a molecule of hydrogen halide together with the opening of the cyclopropane ring takes place particularly readily if an aromatic compound or a compound with conjugated multiple bonds is the product of the reaction[154]:



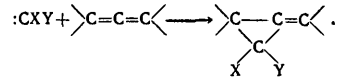
Chlorobenzene and β-chloronaphthalene are obtained in the same way from cyclopentadiene[159] and indene[156]. Monochlorocarbene, formed from methylene chloride and a lithium alkyl, gives pyridine on reaction with pyrrole[157]. Other dichlorocyclopropanes require more severe conditions for reactions of this kind. For example, the adduct of dichlorocarbene and dihydropyran is converted into chlorodihydrooxepin in boiling quinoline[158]:



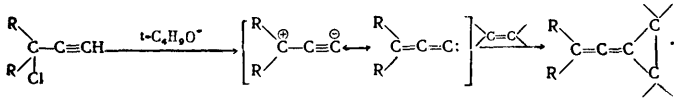
Pyrolysis of suitable adducts also gives dienes. Since chloroform, for example, is pyrolysed to dichlorocarbene[159], it is possible to obtain chlorobutadiene by the pyrolysis of chloroform in the presence of isobutene[160]:



In a number of cases the pyrolysis of the adduct of an olefin and dichlorocarbene does not give the expected chlorodiene; for example, the adduct of butadiene is converted into chlorocyclopentadiene on pyrolysis[161]:

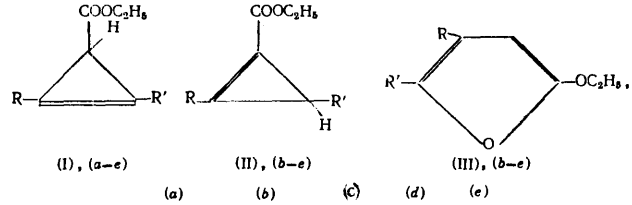


while 7,7-dichloronorcarane yields cycloheptatriene[29,162]:



The pyrolysis of the adduct of cycloheptatriene results in the formation of chlorobenzocyclobutene[155] and not chlorocyclooctatetraene:

Comparatively recently alkylidenecyclopropanes were obtained by the addition of carbenes to allenes[163-165]:

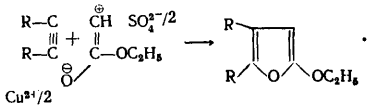


Hartzler established that αγ-elimination of the elements of hydrogen halide from a 3-halogenoalk-1-yne results in an intermediate compound of the carbene type which adds to olefins with the formation of alkenylidenecyclopropanes[83,85,166]:

As regards the addition of carbenes to double bonds other than carbon-carbon, for example the carbonyl group, we may mention the hypothesis of Knunyants *et al.*[1] concerning the possibility of the participation of carbenes in the Darzen reaction. The formation of epoxy-derivatives of alkenes from keto-derivatives of diazomethane probably occurs without the intermediate formation of the carbene[167]. The 1,3-dipolar cyclo-addition of suitable carbenes to the carbonyl groups of ketones has already been mentioned on page 73. Fields and Sandri[168] observed the addition of dichlorocarbene to the C=N double bond of *N*-benzylideneaniline.

### 3. Carbene Synthesis of Cyclopropene Derivatives

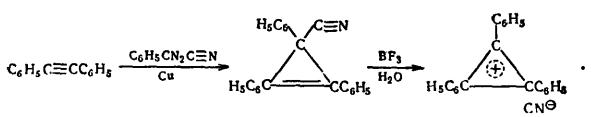
By allowing ethoxycarbonylcarbene to react with various acetylenic hydrocarbons, D'yakonov and coworkers[44,169,170] showed that, depending on the experimental conditions, the reaction can yield either two isomeric compounds or only one of them. Initially it was assumed that both isomers are esters of cyclopropenecarboxylic acids, (I) and (II), differing in the position of endocyclic double bonds. (I) forms in the high-temperature reaction without catalyst or in the presence of very small amounts of copper sulphate [in the latter case there is an admixture of (I)], and (II) forms in the low-temperature reaction in the presence of large amounts of copper sulphate[44,169,170]:



(I), (*a–e*) (II), (*b–e*) (III), (*b–e*)

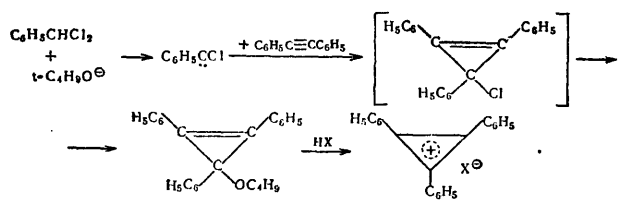
| | (*a*) | (*b*) | (*c*) | (*d*) | (*e*) |
|---|---|---|---|---|---|
| R | $C_6H_5$ | $CH_3C_6H_4$ | $C_6H_5$ | $C_3H_7$ | $C_4H_9$ |
| R′ | $CH_3$ | $CH_3$ | $C_6H_5$ | $C_3H_7$ | $C_4H_9$. |

Later it was found that (I) also forms in the presence of copper as a catalyst.

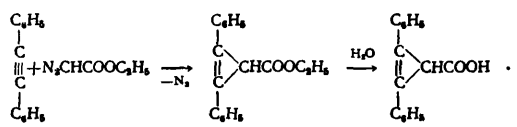


Breslow and Chipman[45] suggested that the properties of the compound hitherto assumed to be (II*c*) are more consistent with 5-ethoxy-2,3-diphenylfuran (III*c*). Similarly they suggested that the formulae (II*d*) and (II*e*) should be changed to (III*d*) and (III*e*) respectively. D'yakonov and coworkers made an additional investigation of the above compounds whose results[169] proved to be in complete agreement with the remarks of Breslow and Chipman.

The American workers explained the formation of 5-ethoxyfurans by 1,3-addition of ethoxycarbonylcarbenes to the triple bond, possibly as a complex with copper sulphate. There is also a possibility that the presence in the reaction medium of cupric and sulphate ions bearing opposite charges stabilises the 1,3-dipolar form of ethoxycarbonylcarbene, since in the absence of copper sulphate or the presence of metallic compounds which Breslow used[43], 1,1-adducts are formed:

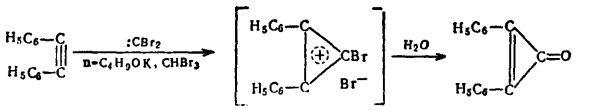


D'yakonov and coworkers succeeded in obtaining derivatives of dicyclobutane from the corresponding cyclopropene derivatives (Id) and (Ie) and the diazoacetate ester in the presence of copper[171].



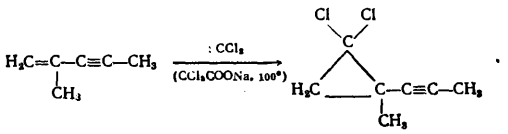
The cyclopropene derivative prepared by Breslow[172,173] from phenylcyanocarbene and tolane was used to form a new aromatic system — the *sym*-triphenylcyclopropenyl cation:

Breslow and coworkers[174,175] also obtained the same cation by the reaction of benzylidene chloride with potassium t-butoxide in the presence of diphenylacetylene, with subsequent acid treatment of the resulting cyclopropenyl ether:



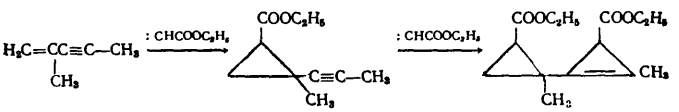
Breslow also carried out reactions between tolane and the diazomalonic ester and between tolane and the diazoacetic ester[176], with formation in the latter case of 1,2-diphenylcycloprop-1(2)-ene-3-carboxylic acid, identical with that synthesised by D'yakonov from the ester (Ic) (see p. 81):

Doering and Mole[135] carried out a photochemical reaction between diazomethane and but-2-yne which resulted in the formation of 1,2-dimethylcyclopro-1(2)-ene. Frey[177] attempted to obtain cyclopropene by the addition of methylene, produced by the photolysis of diazomethane, to acetylene in the gas phase, but only allene, methylacetylene, and a large amount of polymeric products were actually formed. When this reaction is carried out with acetylene labelled with deuterium, the final products are 1,3-dideuteropropyne and 1,1-dideuteropropadiene which suggest the formation of dideuterocyclopropene as an intermediate.



The addition of a dihalogenocarbene to a triple bond was first achieved by Vol'pin *et al.*[178,179] in the reaction between dibromocarbene and tolane:

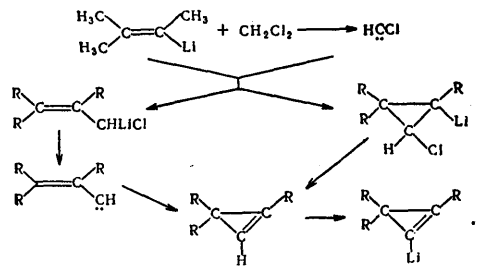
Somewhat earlier Breslow *et al.*[180] obtained diphenylcyclopropenone from phenylchlorocarbene and the acetal of phenylketen. The authors explained the unusual properties of this ketone in terms of the concept of the cyclopropenyl cation as an aromatic species.



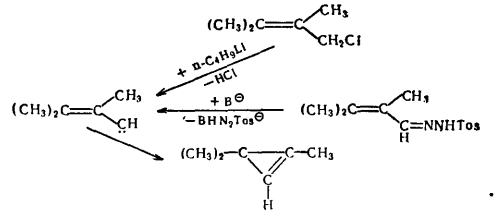
Dipropylcyclopropenone, which Breslow and Peterson[181] obtained from oct-4-yne and dichlorocarbene, proved to be even more stable.

D'yakonov and coworkers[182] showed that enyne hydrocarbons also react with carbenes:

It is reasonable that the electrophilic dichlorocarbene should add to the double bond since the latter is more nucleophilic than the triple bond. This corresponding diadduct could not be obtained. The authors explained this both by the weakening of the nucleophilic properties of the triple bond and the low reactivity of dichlorocarbene. Later Vo-quang and Cadiot[183], who studied the reactions of dichloro- and dibromo-carbenes with other enynes, confirmed that the reaction stops at the stage in which the dihalogenocarbene adds to the double bond of the enyne hydrocarbon.



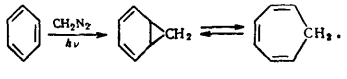
D'yakonov and Danilkina[184] studied the action of ethoxycarbonylcarbene, obtained by the decomposition of diazoacetic ester in the presence of copper or its sulphate, on 2-methylpent-1-en-3-yne. In this reaction the diadduct was obtained in addition to the monoadduct, and it was shown in a separate experiment[112] that the reaction proceeds in two stages as follows:



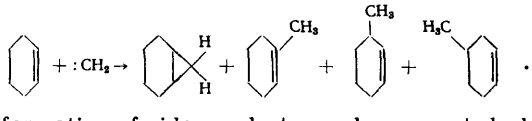
In this reaction ethoxycarbonylcarbene is more reactive and more selective than dichlorocarbene, which is consistent with the comparative characteristics of these reagents established by Skell and coworkers[140,185].

There exist two other possible ways of synthesising cyclopropenes from carbenes: (a) by the reaction between methylene chloride and lithium alkenyls[186] and (b) by intramolecular carbene–olefin addition using vinylcarbene. Let us consider the first of these reactions. In this case the monochlorocarbene formed initially can react with lithium alkenyls in two ways: (1) the carbene can add to the double bond of the lithium alkenyl with $\alpha\beta$-elimination of lithium chloride, and (2) the carbene can be substituted in the C–Li bond with subsequent $\alpha\alpha$-elimination of lithium chloride, resulting in vinylcarbene, which is then converted into cyclopropene by intramolecular addition. Since the

vinyl hydrogen in cyclopropenes is acidic[187], the product of the reaction is the lithium salt of the cyclopropene derivative. Under the given experimental conditions it can react further:

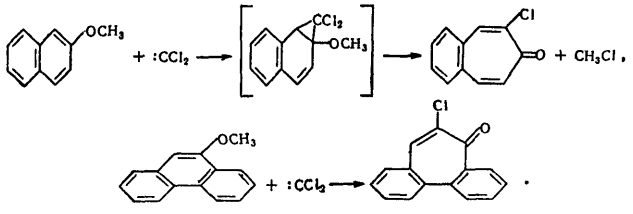


Like bromovinylcarbene, the above vinylcarbene can also be obtained by metal-substitution of mono- and di--halogeno derivatives of the allyl type[188] or from a tosylhydrazone[189] and then converted into cyclopropene:



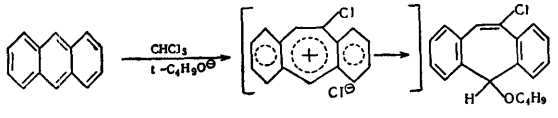
4. Ring Enlargement

The photochemical reaction of benzene with methylene resulting in the enlargement of the ring of the former has been known for a comparatively long time[190]; a mixture of cycloheptatriene and norcaradiene is formed. On heating, norcaradiene can be almost completely converted into cycloheptatriene. Nevertheless the problem of the relation between these two valence-tautomeric structures still cannot be regarded as resolved[191]:

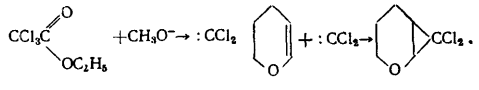


It is interesting that cycloheptatriene can be obtained by the reaction between benzene and diazomethane not only under the action of radiation but also in the presence of catalysts (cuprous chloride and bromide). According to Müller and Fricke[192], in the latter case benzene is subjected to electrophilic attack by the complex $\overset{+}{C}H_2CuBr_2$, formed from diazomethane and cuprous bromide.

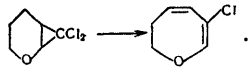
A fairly large number of reactions of carbenes involving the enlargement of other rings are known. However, by no means all of them proceed equally smoothly. Kopecky and coworkers[6] established that the reaction between free methylene and cyclohexene yields a small amount of methylcyclohexene in addition to bicyclo[4,1,0]heptane (norcarane):



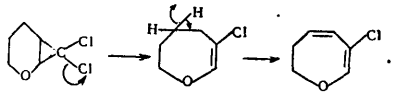
The formation of side-products can be prevented when methylene is produced by photolysis of diazomethane in solution using benzophenone as sensitiser, or by thermal–catalytic decomposition of diazomethane using powdered copper or iron dipivaloylmethide as catalysts.



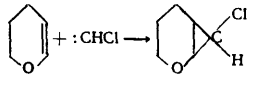
Generally speaking, aromatic double bonds combine with carbenes less readily than olefins. For example, dichlorocarbene does not react with benzene[193]. However, if the aromatic ring contains an electron-donor group, the addition is substantially facilitated. For example, the addition of dichlorocarbene, produced from ethyl trichloroacetate and sodium methoxide, to 1- and 2-methoxynaphthalenes and to 9-methoxyphenanthrene[194] results in the formation of the corresponding chlorotropones:



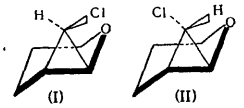
The hydrolysis of chlorotropone yields tropolone. Anthracene, in which certain positions have an enhanced electron density, reacts with dichlorocarbene and undergoes ring enlargement[195]:



Dichlorocarbene, produced from ethyl trichloroacetate, was also used for the enlargement of certain heterocyclic rings. Thus when ethyl trichloroacetate is added to a mixture of dihydropyran and sodium methoxide in pentane, 7,7-dichloro-2-oxanorcarane is formed[158]:

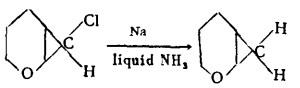


When it is heated with quinoline at 140–150° and a reduced pressure, 6-chloro-2,3-dihydrooxepin is obtained[158]:

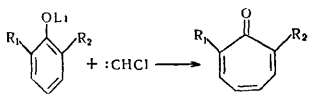


The conversion of 7,7-dichloro-2-oxanorcarane into 6-chloro-2,3-dihydrooxepin proceeds via the allyl carbonium ion, which then loses a proton:

Schweizer and Parham[158] found that chlorocarbene is also suitable for the enlargement of heterocyclic and aromatic rings. For example, when dihydropyran reacts with this carbene, a racemic mixture of the *endo*- and *exo*-forms of 7-chloro-2-oxanorcarane is obtained in 1 : 1.5 ratio:

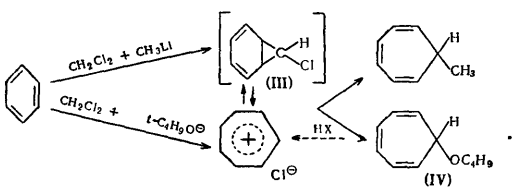


The above workers ascribed the structure (I) to the predominating isomer and structure (II) to the minor isomer, on the grounds that the formation of structure (II) in the activated complex is difficult due to the shielding of the ring by the large chlorine atom of chlorocarbene, whereas the influence of the small hydrogen atom is less marked and isomer (I) forms more rapidly.

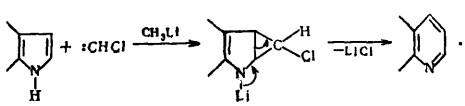


(I) (II)

Consequently isomer (I) is *exo*-7-chloro-2-oxanorcarane while isomer (II) is the *endo*-compound. Isomer (II) distils at atmospheric pressure, while the *exo*-compound decomposes even at 120° and when it is distilled with quinoline at a reduced pressure ring enlargement occurs and 2,3-dihydrooxepin is formed. The ease of conversion of isomer (I) into 2,3-dihydrooxepin is due to the influence of the *trans*-oxygen atom at the instant of the removal of the chlorine atom. Both isomers are readily reduced to 2-oxanorcarane, and in high yield, by sodium in liquid ammonia:

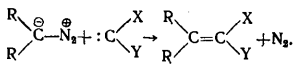


Chlorocarbene, obtained from methylene chloride and methyllithium, yields tropones on reaction with lithium phenoxides [39]:

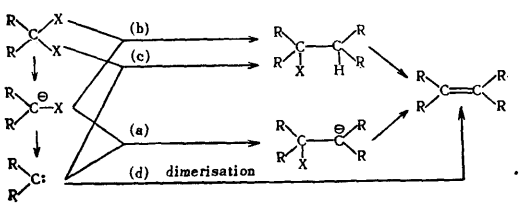


where $R_1$, $R_2$ = H (a), $R_1$ = H, $R_2$ = $CH_3$ (b), and $R_1$ = $R_2$ = = $(CH_3)_3C$ (c). The above synthesis of tropones is an example of the influence of electron-donor substituents on the reactivity of the benzene ring because chlorocarbene obtained in the above way reacts to only a slight extent with the benzene ring itself, the reaction involving, according to Closs and Closs [196], the initial formation of the hypothetical compound (III) which is subsequently converted into the tautomeric tropylium chloride; the latter then reacts with methyllithium to give 7-methylcyclohepta-1,3,5--triene.

When the reaction is carried out in the presence of a weak base, potassium t-butoxide [193], the ether (IV) is formed and subsequently yields the tropylium ion on interaction with acid:



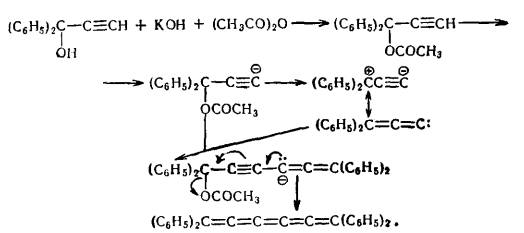
Addition of chlorocarbene to pyrrole and indole also results in the formation of ring-enlargement products, pyridine in 32% yield and quinoline in 13% yield respectively [157]:



5. Carbene Syntheses of Olefins

As already pointed out (see p. 71), the phosphorus atom in triphenylphosphine, which has a free electron pair and is capable of passing to the pentavalent state, readily reacts with carbenes, yielding relatively stable alkylidenephosphoranes. The latter were obtained from dichloro-, difluoro-, and monochloro-carbenes [22,25,197,198]. When such alkylidenephosphoranes are introduced into the Wittig reaction, olefins which are otherwise difficult to obtain can be prepared. Such olefins can also be synthesised by another procedure also involving carbenes. When diazo--compounds are allowed to react with different carbenes, the latter attack the carbon atom of the diazo-compound marked with the minus sign, yielding olefins [95,199]:

A number of reactions are also known in which compounds of the type $R_1R_2CHX$ yield the olefins $R_1R_2C{=}CR_1R_2$ under the action of base. Since it is possible to visualise the participation in this reaction of three different types of species, the molecule $R_1R_2CHX$, the anion $R_1R_2XC^-$, and the carbene $R_1R_2C$, the olefin may form by several different pathways:



In view of the electrophilic properties of most carbenes, pathway (a), i.e. the interaction of the anion and carbene, is very probable. According to literature data, the following reactions proceed by this mechanism [80,200,201]:

$$p\text{-}NO_2C_6H_4CH_2\overset{\oplus}{S}(CH_3)_2 \rightarrow p\text{-}NO_2C_6H_4CH{=}CHC_6H_4\text{-}p\text{-}NO_2$$

(this reaction has already been mentioned on p. 75) and

$$(CH_3S)_3CH \rightarrow (CH_3S)_2C{=}C(SCH_3)_2.$$

As already pointed out in passing on p. 76, tetraphenylhexapentaene is also synthesised by this pathway:

Nucleophilic substitution of the anion in the molecule in pathway (b) should in the first place give ethane derivatives [202], which in fact have been isolated in a few cases but they could have been formed also by the substitution of the carbene in the C–H bond of the molecule by pathway (c).[1]

In recent years dimerisation of carbenes by pathway (d) has been put forward to account for the formation of olefins[203]:

$$p\text{-}NO_2C_6H_4CH_2Cl \rightarrow p\text{-}NO_2C_6H_4CH{=}CHC_6H_4\text{-}p\text{-}NO_2.$$

---o0o---

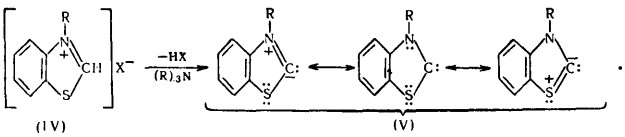
Carbenoids, the electronic analogues of carbenes, are fairly similar to the latter in chemical and certain physical properties. Although the key atoms in these compounds are not of carbon but of other elements, their most characteristic property, like that of carbenes, is the capacity to form two new covalent bonds in reactions. Fairly extensive data are at present available on the carbenoids, but their discussion is outside the scope of the present review.

## ADDED IN PROOF

After our article had been sent to press, a number of interesting papers having direct relevance to the present review appeared, and we therefore felt bound to give at least a brief description of them. Thus we must mention a very thorough French review[204] as well as other review articles[205-207]. Of the experimental investigations, the work of Nefedov *et al.*[208], who proposed a new general method for the synthesis of carbenes, merits considerable attention. This method can be schematically represented as follows:

$$RR'CXX' \xrightarrow[\text{tetrahydrofuran}]{Li} RR'CLiX' \xrightarrow{-LiX'} RR'C:$$

where X and X′ are halogens and R and R′ are hydrogen, halogens, and aryl, alkyl, or alkylidene groups.



Among the latest spectroscopic studies of carbenes, that of Trozzolo *et al.*[209], who investigated *p*-phenylenebis-(phenylmethylene), is interesting. Another interesting paper is that of Russell and Hendry[210], who studied the effect of solvents on the reactions of methylene. The reaction of methylene radicals with acetylene in the gas phase has been investigated by Terao *et al.*[211] Müller *et al.*[212] discovered a reaction in which five-membered aromatic compounds are converted into their homologues by means of diazomethane. Using this reaction, compounds (I), (II), and (III) were obtained from furan and thiophen:

A number of papers have dealt also with the reactions of dihalogenocarbenes. Thus Skattebŏl[213] has continued the study of the reaction mentioned on p. 80. Certain olefins are known to be very inert towards dihalogenocarbenes prepared by the usual methods. For the preparation of *gem*-dihalogenocyclopropane from such olefins, Seyferth *et al.*[214] proposed a procedure involving the use of organomercury compounds: $C_6H_5HgCCl_2Br$, $C_6H_5HgCClBr_2$, and $C_6H_5HgCBr_3$. Landgrebe and Mathis[215] studied several examples of the substitution of dichlorocarbene in the carbon–mercury bond and also the thermal decomposition of compounds obtained in this way. The work of Ohno[216] dealing with the reaction of enamines with dichlorocarbenes is also interesting.

A paper has been published on the reaction of dichlorocarbene with benzofuran and benzothiophen[217]. Krapcho and Huyffer[218] described the thermal decarboxylation of sodium trichloroacetate in the presence of activated carbon and halogeno-compounds.

Kirmse[219,220] recently published two papers on alkylchlorocarbenes. Other communications deal with alkyl-, aryl-, and alkylidene-carbenes[221-224], allylcarbenes[225], and also with the rearrangements of carbenes obtained by the decomposition of 2,2,2-triaryldiazoethanes[226]. Several papers describe the reactions of ethoxycarbonylcarbene[227-229]. We may also mention that Schöllkopf and Küppers[230] obtained a number of phenylselenocyclopropanes starting with phenylselenocarbene and various olefins. In a quite recent paper Wanzlick and Kleiner[231] state that their attempts to find carbenes with "quasi-aromatic resonance stabilisation" have been successful. When *N*-alkylbenzothiazolium halides (IV) are treated with tertiary amines, the former lose the elements of hydrogen halide yielding substances which can be represented by the resonance hybrids (V):

(IV) (V)

The carbene (V) dimerises and also participates in a number of other chemical reactions.

## I. INTRODUCTION

In recent years acid catalysts, among which perchloric acid and its compounds occupy an important place, have been attracting increasing attention. During the past 10–15 years more than 300 papers and patents have appeared, dealing with the use of $HClO_4$ and its compounds in organic chemistry.

Perchloric acid is the strongest mineral acid but at ordinary temperatures its oxidising power is less than that of the other oxygen acids of chlorine, bromine, and iodine[1]. In many organic solvents perchloric acid is readily solvated and this changes the polarity of the bond between the hydrogen atom and the $ClO_4$ residue. In polar organic solvents (acetic acid[2-4], nitromethane[5], nitrobenzene[6], etc.) perchloric acid is ionised to a greater degree than other acids. Comparison of the ionisation constants of mineral acids in anhydrous acetic acid confirms that perchloric acid ($K = 1.6 \times 10^{-4}$) is tens or hundreds of times stronger than hydrobromic ($K = 4 \times 10^{-5}$), sulphuric ($K = 6 \times 10^{-7}$), hydrochloric ($K = 1.4 \times 10^{-7}$), nitric ($K = 4.2 \times 10^{-8}$), and trichloracetic ($K = 2.3 \times 10^{-10}$) acids.

For many years the wide use of perchloric acid in organic synthesis has been hindered by greatly exaggerated ideas about the danger of explosions. However, although work with the anhydrous acid is in fact not without danger, the use of an aqueous solution (30, 60, and 72%) involves practically no risk. Solutions of the anhydrous acid in acetic acid or acetic anhydride containing less than 55% of $HClO_4$ by volume, which are frequently used, are also quite safe[8].

Much experimental data on the use of perchloric acid and its compounds in various fields of organic chemistry has accumulated. This work requires to be correlated and systematised since the published reviews dealing with only parts of the problem are already out of date[8-10].

## II. PERCHLORATES OF ORGANIC COMPOUNDS

The study of organic perchlorates started in the 19th century when crystalline perchlorates of alkaloids were obtained[11]. Later it was found that perchloric acid readily forms perchlorates with ethers, ketones, weakly basic compounds containing nitrogen, and pyridine; this property is used successfully in the purification and identification of many basic organic compounds[12-15]. Organic perchlorates are usually obtained by treating solutions of organic compounds in polar or non-polar solvents (water, alcohols, ether, nitromethane, etc.) with perchloric acid in the cold[16-18].

In their structure the esters of perchloric acid are superficially similar to salts, the metal being replaced by a hydrocarbon radical. The bond between the perchlorate ion and the hydrocarbon radical is covalent or nearly ionic, depending on the degree of polarisation. Nearly all these compounds are unstable and only some of them can be obtained in the pure state. Among the various methods of

synthesising perchloric esters the most widely applicable method is based on the reaction of alkyl halides with silver perchlorate[19-22]:

$$RX + AgClO_4 \rightarrow RClO_4 + AgX.$$

The esters may also be obtained by the interaction of the alcohol with chlorine heptoxide or by the action of diazomethane on aqueous $HClO_4$:[23]

$$ROH + Cl_2O_7 \rightarrow RClO_4 + HClO_4,$$
$$CH_2N_2 + HClO_4 \rightarrow CH_3ClO_4 + N_2.$$

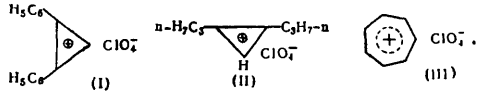
The esters of perchloric acid are widely used as alkylating agents. They are colourless low-boiling oils, miscible with alcohol and insoluble in water, which slowly hydrolyses them[24].

The introduction of aryl residues into the perchlorate molecule has a considerable polarising effect on the C–O ester bond. As the number of aryl groups in an aralkyl perchlorate molecule increases, the C–O bond approaches the ionic type. Aralkyl perchlorates are obtained by the methods used for the preparation of esters.

However, when 72% perchloric acid acts on diphenylmethylmethanol in nitromethane, a mixture of diphenylmethyl ether, diphenylmethane, and benzophenone is obtained instead of the expected diphenylmethyl perchlorate[25].

In the reaction of diphenylmethyl chloride with silver perchlorate in benzene solution diphenylmethyl perchlorate, which has considerable alkylating power, was obtained[26].

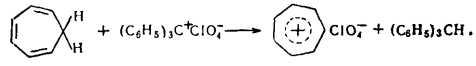
Benzyl perchlorate is also highly reactive but this could not be obtained pure, because it rapidly polymerised at the moment of formation[27-30].



The most interesting of the aralkyl perchlorates are the triarylmethyl perchlorates, as these can be used in hydride displacement reactions.

Experimental data on electrical conductivity[31-33] and absorption spectra[34,35] indicate that the triarylmethyl perchlorates are typical carbonium salts. They are conveniently obtained by the addition of 70% $HClO_4$ to a solution of triarylmethanol in acetic anhydride at room temperature or by the exchange reaction of triarylalkyl chlorides with $AgClO_4$ in a polar solvent[36,37].

Interesting organosilicon perchlorates have been recently obtained by slowly mixing benzene solutions of trialkyl- or triaryl-silicon chloride and silver perchlorate in a stream of dry nitrogen[38,39]. The trialkylsilicon perchlorates ($Alk_3SiClO_4$) were isolated as colourless liquids fuming in air and exploding at 180–200°; they can be distilled under vacuum without decomposition. The triarylsilicon perchlorates are crystalline compounds insoluble in benzene; they evidently have an ionic structure, which was confirmed by a study of their infrared spectra and chemical properties. Recently the synthesis of new heteroorganic perchlorates, $Alk_3\overset{+}{S}ClO_4^-$ and $(CH_3)_3\overset{+}{S}nClO_4^-$, has been reported; they were obtained in the crystalline state[40,41]. Compounds of the first type are easily obtained by the action of perchloric acid on a mixture of thioether and the corresponding alcohol.



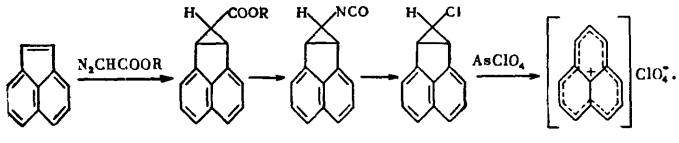
Among diverse carbonium salts[42,43] a special place is occupied by aromatic cations, of which the cyclopropenyl cation is the simplest representative; this cation has the properties of an aromatic system. However, salts of the unsubstituted cyclopropenyl cation are still unknown.

In the reaction of 1,2-diphenylcyclopropene-3-carboxylic acid with 10% $HClO_4$ in acetic anhydride a 70% yield of diphenylcyclopropenyl perchlorate (I) was obtained[44]:

The entirely stable dipropylcyclopropenyl cation (II) has been obtained by this method, acetyl perchlorate in acetic anhydride acting on dipropylcyclopropenecarboxylic acid[45]; this shows that the hypothesis that phenyl groups are required to stabilise the cyclopropenyl cation is untenable.

The properties of cyclopropenyl perchlorates are in many ways similar to the properties of tropylium salts (III). Tropylium perchlorate is easily obtained by the action of triphenylmethyl perchlorate, which is an effective hydride ion acceptor, on cycloheptatriene[46]:

The same method has been used to synthesise some homologues of tropylium salts and vinyltropylium perchlorate[47,48].



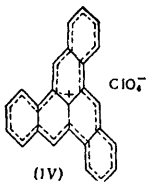
Tropylium perchlorate is also obtained in high yield from cycloheptatriene, phosphorus pentachloride, and 50% perchloric acid in dry carbon tetrachloride solution by the method of Kursanov and Vol'pin[49,50].

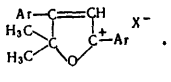
A British patent indicates the possibility of preparing tropylium perchlorate by the acid oxidation with perchloric acid of cycloheptatriene with no more than one substituent at the methylene group[51].

A report on the preparation of tropylium perchlorate by the autoxidation of cycloheptatriene in acetic acid solution in the presence of perchloric acid is noteworthy[52].

The reaction in which fundamental groups R are eliminated from 1-substituted cyclohepta-2,4,6-trienes $C_7H_7R$ (R = COOH, COCl, CN) has been studied with the object of preparing tropylium salts[53]. Tropylium perchlorate was obtained by the action on the latter of silver perchlorate in nitromethane.

Among the various polycyclic systems the perinaphthenyl system has attracted attention; this can exist as a cation, anion, or free radical. The perinaphthenyl cation was obtained[54,55] as the perchlorate from acenaphthylene and diazoacetic ester by the method developed for the synthesis of tropylium salts[53]:





Theoretically it is possible to obtain perinaphthenyl perchlorate by the reaction of silver perchlorate with the perinaphthenyl radical[56]:

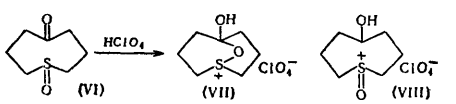
$$C_{13}H_9 + AgClO_4 \rightarrow C_{13}H_9^+ ClO_4^- + Ag.$$

The perinaphthenyl cation is more stable than the triarylmethyl cation but less stable than the tropylium cation. Perinaphthenyl perchlorate is insoluble in non-polar solvents but soluble in strong acids; it is readily hydrolysed

and is unstable in air. Tribenzoperinaphthenyl perchlorate (IV) has similar properties[57]:

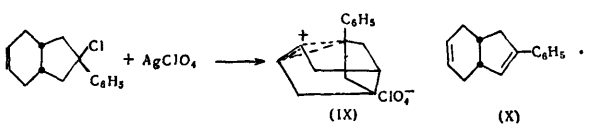
(IV)

(V)



A very interesting synthesis is that of 4,6,8-trimethylazulenium perchlorate, obtained by boiling 4,6,8-trimethylazulene with an excess of 70% $HClO_4$ in acetic acid for a short time[58]. The crystalline perchlorate melts with decomposition at 168–171°; it is stable in air but is decomposed by water.

Kirby and Reid have shown that substituents in positions 4 and 8 are necessary for the formation of azulenium perchlorate.



Dihydrofurylium perchlorate is obtained in almost quantitative yield by the action of an ethereal solution of $HClO_4$ on hydroxydihydrofuran[59]. The product (V) is a yellow compound, insoluble in ether and benzene and slightly soluble in alcohol. A resemblance between dihydrofurylium salts and salts of benzopyrylium, xanthylium, and chromylium has been noted.

The stable 4,5,5-trimethyl-2-phenyldihydrofurylium perchlorate has been prepared[60]; 2,2,3,5-tetramethyl-5-phenyl-2,5-dihydrofuran is obtained by the action of methylmagnesium iodide on this perchlorate. The reactivity of 4-methyldihydrofurylium salts has been studied[61].

The perchlorate of 1-oxo-1-thiacyclooctan-5-one (VI) has been prepared[62,63]; this may have structure (VII) or (VIII).

(VI) (VII) (VIII)

Leal and Pettit obtained a characteristic stable non-classical carbonium ion by the following reaction[64]:

(IX) (X)

Compound (IX) is a yellow saltlike product, insoluble in hexane, chloroform, carbon tetrachloride, and benzene. With water or alcohol it forms the diene (X).

## III. ELECTROPHILIC SUBSTITUTION REACTIONS

### 1. Perchlorylation of Organic Compounds

The electrophilic substitution reaction, which is widely used in organic chemistry, proceeds readily when halogens or mineral acids act on compounds of the aromatic series. However, the introduction of the $ClO_3$ residue into organic compounds by the action of perchloric acid on aromatic compounds is not possible. A direct method of perchlorylation of organic compounds was not developed until 1958.[65,66] Perchloryl compounds of the aromatic series are easily formed by the action of $FClO_3$ in the presence of $AlCl_3$ or $AlBr_3$ on benzene and other aromatic hydrocarbons containing no electron-acceptor groups:

$$ArH + FClO_3 \xrightarrow{AlCl_3} ArClO_3 + HF.$$

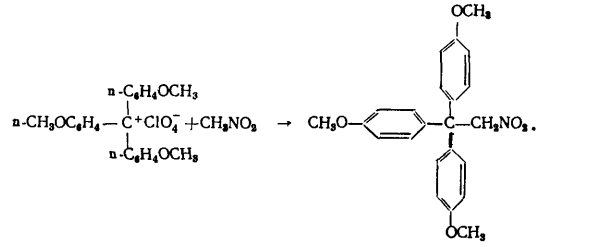
The spectra[65] and chemical properties of the perchloryl compounds confirm that they have the $ArClO_3$ and not the ester structure $ArOClO_2$.[65-68].

Perchlorylation in the *para*-position also proceeds smoothly with anisole[65] and with fluoro-,[65] chloro-,[67] and bromo-benzene[67]. The perchlorylarenes are stable liquids or solid compounds; some of them can be distilled without decomposition. They are entirely stable in neutral and acid media, but are hydrolysed to phenols by concentrated alkali solutions. The perchloryl compounds are detonated by a sharp blow or when the temperature is raised; they decompose explosively. When perchlorylbenzene is hydrogenated by hydrogen in alcoholic solution, the perchloryl group is smoothly eliminated and benzene is formed[68]. Perchlorylbenzene is nitrated in the *meta*-position and its nitro-compound can be reduced to the amine[65]. It is also possible to reduce *m*-nitroperchlorylbenzene completely; the reaction proceeds with the absorption of 7 moles of hydrogen and the elimination of the perchloryl group[68].

The action of nucleophilic reagents on perchloryl compounds has been studied and it has been shown that although perchlorylbenzene does not react with metallic lithium or magnesium, it does react vigorously even at -33° with $NaNH_2$ and $ArNH_2$ in liquid ammonia with the formation of triphenylamine[67]. The formation of dehydrobenzene from perchlorylarenes is confirmed by study of the elimination of the perchloryl group which proceeds readily to the extent of 87% under the action of the $NH_2^-$ anion in liquid ammonia.

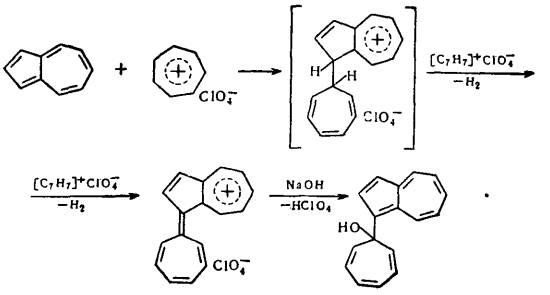
Measurement of the dipole moment of $FClO_3$ has shown that, although the molecule is electrically neutral, the $ClO_3$ group is the electropositive end of a dipole and the fluorine atom is the electronegative end[69]. Therefore, in the presence of Brønsted or Lewis acids (as occurs in the perchlorylation reaction) the organic compound will be attacked by the electrophilic cation $ClO_3^+$. In contrast, in an alkaline medium, because of an inductomeric shift, $FClO_3$ may act as an effective fluorinating agent with electropositive fluorine. Thus, when $FClO_3$ acts on 1-ethoxycyclohexene in pyridine at 0°, 2-fluorocyclohexanol is formed. Compounds with an active methylene group (acetylacetone, diethyl malonate, etc.) are smoothly fluorinated by perchloryl fluoride[70,71].

Perchloric acid and its derivatives may be used in the halogenation[72-76], nitration[77-79], nitrosation[80,81], and diazotization[82-85] of organic compounds.



### 2. Alkylation

Alkyl perchlorates may be used as alkylating agents. Thus, methyl perchlorate, obtained from methyl iodide and silver perchlorate, slowly reacts with anisole at ordinary temperatures to give *p*-methylanisole[86,87]. Methyl perchlorate reacts much less rapidly with benzene. Ethyl, propyl, and n-butyl perchlorates have similar properties.



It is interesting that isobutyl perchlorate isomerises to t-butyl perchlorate, and when anisole and benzene are alkylated with isobutyl iodide and $AgClO_4$, t-butylanisole

(76%) and t-butylbenzene are obtained. There are data on the alkylation of toluene by cyclohexyl perchlorate[88,89].

Aralkyl perchlorates are very reactive. Benzyl perchlorate, prepared in solution of the compound to be alkylated, smoothly reacts with benzene and toluene forming diphenylmethane and *p*-methyldiphenylmethane in good yield[86]. Diphenylmethyl perchlorate readily combines with benzene to give triphenylmethane (65%) in two hours at room temperature[26]. When trityl perchlorate ($Tr^+ClO_4^-$) acts on a mixture of phenol and aniline, *p*-aminotetraphenylmethane is obtained in 78–84% yield[90]. At room temperature $Tr^+ClO_4^-$ converts anisole into *p*-methoxytetraphenylmethane in 63% yield; the same product is obtained from anisole and triphenylmethanol in the presence of 72% $HClO_4$ in nitromethane. Hydroxytetraphenylmethane was obtained from $Tr^+ClO_4^-$ and phenol in nitromethane at room temperature in yields of 23% (8 hours) and 68% (7 days). It is interesting that, when heated with 72% $HClO_4$ in nitromethane for 7 days, tri-*p*-methoxyphenylmethanol forms 1,1,1-tri-*p*-methoxyphenylnitroethane in good yield[26]:

Azulene and triphenylmethyl perchlorate in boiling acetic acid form a mixture of 1-triphenylmethyl- and 1,3-bis(triphenylmethyl)-azulene[91]. The reaction of azulene and its methyl homologues with tropylium perchlorate in dimethylformamide has been studied[81]; it proceeds according to the following scheme:

When unsubstituted azulene is alkylated under the conditions mentioned, a 1,3-dicycloheptatrienyl derivative of azulene is formed.

When an attempt was made to alkylate benzene and anisole with allyl perchlorate, obtained from allyl chloride and silver perchlorate, only resinous products were obtained[29].

Perchloric acid can be used for the alkylation of phenol by different alcohols[25,92-94]. When phenol is alkylated with t-butyl alcohol in 50% perchloric acid, 4-t-butylphenol and 2,4-di-t-butylphenol are formed[92].

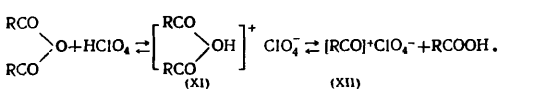
Diphenylmethanol, phenol, and 72% $HClO_4$ give 63% of *p*-hydroxytriphenylmethane or 86% of 2,4,6-tris(diphenylmethyl)phenol, depending on the molecular proportions employed[25,26]. Similarly anisole forms *p*-methoxytriphenylmethane (89%), which is further converted to 2,4-bis-(diphenylmethyl)anisole (93%). Trisubstituted anisole could not be isolated. In the presence of perchloric acid hydroxymethyldimethylamine reacts with azulene to form mono- and bis-(dimethylaminomethyl) derivatives[95].

The patent literature contains references to the use of perchloric acid[96] and its salts[97,98] in the alkylation of phenols by olefins. In the presence of crystalline aluminium or iron perchlorate or aqueous lead perchlorate, *o*-cresol reacts with dodecene to give 4-s-dodecyl-*o*-cresol in excellent yield; similarly octene and aluminium perchlorate gives 4-s-octyl-*o*-cresol[98]. Phenylethylphenols (*o*- and *p*-) have been obtained by allowing styrene and perchloric acid in acetic acid to react with phenol[99].

The interaction of β-acetoxyethylmercury acetate with anisole to form β-(*p*-anisyl)ethylmercury acetate is an interesting case of alkylation[100].

Recently a method of alkylating phenols with ketones using small amounts of perchloric acid has been developed[101,102], and it has been shown that when benzyl phenyl ethers are treated with acetic anhydride and perchloric acid they are smoothly debenzylated[29,103].

### 3. *C*-Acylation

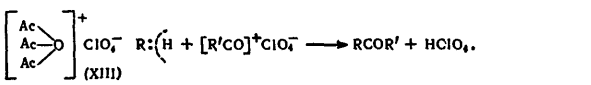


There are a number of serious disadvantages in the use of the usual catalysts such as $AlCl_3$, $ZnCl_2$, HF, etc. in acylation. It is sufficient to mention that the acylation of many organic compounds in the presence of these catalysts is associated with great difficulties arising from resinification of the starting materials, their isomerisation, degradation, and polymerisation. Extremely large amounts of catalyst are required. There are also difficulties in separating the products from the catalysts. Some of these difficulties can be overcome by the use of perchloric acid and its compounds as catalysts.

In 1927 Diels and Alder published the first account of the use of perchloric acid in the acylation of toluene and *o*-xylene by hot acetic anhydride[104].

In 1944 Berlin, who was studying the *N*-acylation of amines difficult to acylate, found that, when pyrrole is heated with acetic anhydride in the presence of catalytic quantities of 30% perchloric acid, a mixture of 1- and 2--acetylpyrroles is formed; he suggested that 2-acetylpyrrole (yield 33%) is a product of the thermal isomerisation of 1-acetylpyrrole[105].

In 1950 Burton and Praill commenced extensive studies of the catalytic properties of 72% perchloric acid, and showed that reactive aromatic compounds (*m*-xylene and anisole) could by acylated by carboxylic acid anhydrides in the presence of half-molar quantities of this catalyst[106-109]. In the same year Foster obtained a patent for the catalytic acylation of aromatic compounds in the presence of perchloric acid[110]. Aqueous (usually 60–72%) perchloric acid is generally employed in acylation.



Perchloric acid reacts with acid anhydrides evidently forming an oxonium ion (XI) which dissociates in solution to form an electrophilic acylium carbonium ion (XII) and a carboxylic acid[106]:

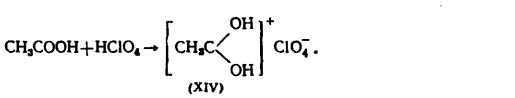
The existence of the triacetyloxonium cation (XIII), obtained from acetyl perchlorate and acetic anhydride, has also been

suggested[111]. The possibility that these ions exist has been confirmed by electrical conductivity measurements of solutions of perchloric acid in acetic anhydride[111,112] and also by kinetic studies[112-114].

Acylium carbonium ions (XII) are effective acylating agents and are therefore used for the acylation of reactive compounds of aromatic character[106-109,115,116].

(XIII)

Acyl perchlorates of various structures are also easily obtained by the reaction of equimolar quantities of acid chlorides with silver perchlorate in solution in nitromethane, absolute ether, or acetonitrile[107-109]:



$$RCOCl + AgClO_4 \rightarrow [RCO]^+ClO_4^- + AgCl.$$

"Pure" acyl perchlorates obtained in this way are more effective acylating agents than those formed from acid anhydrides and perchloric acid[107], since in the latter case the acylating reagent consists of a mixture of carbonium (XII) and oxonium (XI) ions.

When a solution of perchloric acid in acetic anhydride is allowed to stand for a long time, or when freshly prepared acetyl perchlorate is added to acetic anhydride even at 20°, self-acylation occurs, probably in the following way[13]:

$$(CH_3CO)_2O + CH_3CO^+ \rightarrow CH_3COCH_2CO^+ + CH_3COOH.$$

At room temperature perchloric acid reacts with acetic acid to form an acidium complex (XIV) with no *C*-acylating properties[106,116]. This explains the negative results obtained in attempts to acylate a number of aromatic compounds by carboxylic acids in the presence of perchloric acid[116]. However, when a dehydrating agent is added to the complex, it is converted to the acylium cation (XII)[107]:

(XIV)

Since perchloric acid is eliminated in the acylation of organic compounds by acyl perchlorates, the reaction is advantageously carried out with a slight excess of the acid anhydride and very small catalytic quantities of $HClO_4$.[115,116]

Dorofeenko and coworkers made a detailed study of the acylation of a series of reactive aromatic and heterocyclic compounds with carboxylic acid anhydrides in the presence of catalytic quantities of perchloric acid (0.001–0.05 mole of catalyst per mole of compound) and they substantially extended the field of application of this catalyst in the acylation of various organic compounds[115,116,117-127].

When aromatic hydrocarbons are acylated with pure acetyl perchlorate[109,128,129], or with acetic anhydride in the presence of perchloric acid[116,117], the corresponding aliphatic-aromatic ketones are obtained in low yield. Benzene forms only traces of acetophenone[109,116,129], but the yield of substituted alkyl aryl ketones increases considerably as the number of alkyl groups in the benzene nucleus increases[117]. Thus, for example, in the acylation of toluene *p*-methylacetophenone is formed in 5–6% yield[109,116,129], while under the same conditions the yield of ketone from *m*-xylene reaches 22–30%[109,119,128] and the yield of the ketone from mesitylene reaches 45%.[17,119] Naphthalene is also acylated by acetic anhydride, but the yield of α-acetylnaphthalene does not exceed 10–15%.[119]

A slight increase in the nucleophilic properties of the aromatic compounds materially increases the yield of ketone. Good results have been obtained in the acylation of acenaphthene with acid anhydrides in the presence of catalytic quantities of perchloric acid or Anhydrone; the yield of 5-substituted acylacenaphthenes was 50–81%.[119-121] It is interesting that acylation by this method gives mainly ketones substituted in the 5-position; acylation in the presence of aluminium chloride[130] or hydrogen fluoride[131] leads to the formation of a mixture of isomeric ketones.

Cauquil and coworkers found that silver perchlorate is also a good catalyst in the acetylation or aromatic hydrocarbons by acetic anhydride[132,133]. However, this expensive and very light-sensitive compound has no advantages over perchloric acid.

Magnesium perchlorate (Anhydrone)[134,135] and other aprotic or proton-containing derivatives of perchloric acid of the type of inorganic and organic salts, and also aralkyl perchlorates[119], were found to be good catalysts in the acylation of reactive aromatic and heterocyclic compounds by acid anhydrides. In this series of compounds the greatest catalytic activity was shown by magnesium perchlorate, benzyl perchlorate, and triphenylmethyl perchlorate[119].

Magnesium perchlorate has a milder catalytic action than perchloric acid and for this reason its use is preferred in the acylation of acid-labile compounds[134,135]. It may be supposed that the acylating agents in this reaction are acyl perchlorates (XII), i.e. this process proceeds in principle in the same way as the reaction catalysed by perchloric acid.

Detailed studies of the acetylation of anisole by acetic anhydride in the presence of perchloric acid enabled a convenient preparative method to be worked out for the preparation of *p*-methoxyacetophenone in 60–72% yield[106,107,116]. The use of pure acetyl perchlorate in this case has no advantages over the procedure described above[107].

The acetylation of anisole and phenetole in the presence of catalytic quantities of Anydrone gives the same yield (60–66%) as when perchloric acid is employed, but purer ketones are formed[134-136].

Kuhn and Daxner, using the method of Burton and Praill for the acylation of phenyl ethers with the anhydrides of acetic, propionic, and n-butyric acids in solution in the corresponding acid, obtained alkoxyacetophenones in good yield[137].

When anisole and phenetole are acylated with carboxylic acid anhydrides (propionic, n- and iso-butyric, n- and iso-pentanoic, and hexanoic) in the presence of small quantities of perchloric acid, the corresponding *p*-alkoxyphenyl alkyl ketones are obtained in 70–90% yield[138].

Aromatic hydrocarbons (*m*-xylene, mesitylene), phenol ethers (anisole and phenetole), and some heterocyclic compounds (thiophen) may be successfully acylated by carboxylic acid chlorides in the presence of small quantities of perchloric acid or Anhydrone[118,122,125]. However in acylation with aliphatic acid chlorides (from acetic to hexanoic) the yield of the corresponding ketones is as a rule much lower (20–55%) than when acid anhydrides are used. Good

results were also obtained with other acylating agents; mixed anhydrides, silicon anhydrides† and boron anhydrides† of the acids were used[119].

Investigation of the benzoylation of a series of aromatic hydrocarbons and phenol ethers with benzoyl chloride in the presence of small quantities of perchloric acid or Anhydrone enabled a convenient preparative procedure to be developed for the synthesis of *p*-alkyl- and *p*-alkoxy-substituted benzophenones[125,127].

Good results have been obtained in the benzoylation of anisole and thiophen with benzoic anhydride in the presence of catalytic quantities of perchloric acid[139].

The benzoylation of anisole with aromatic acid chlorides (benzoyl, 2,4,6-trimethylbenzoyl, *p*-nitrobenzoyl, and anisoyl) in the presence of equimolar amounts of silver perchlorate in nitromethane solution has been studied; *p*-methoxybenzophenone and its derivatives were obtained in 50–84% yield[108]. Benzoylation of anisole with benzoic anhydride in nitromethane solution gives a lower (27%) yield.

When toluene and anisole are acylated with aralkylcarboxylic acid perchlorates of the type $[C_6H_5(CH_2)_nCO]^+ClO_4^-$ ($n$ = 1–4) [obtained from $C_6H_5(CH_2)_nCOCl$ and $AgClO_4$ in nitromethane solution], ketones of the general formula $C_6H_5(CH_2)_nCOC_6H_4R$ are obtained in good yield[140]. *p*-Allyloxyacetophenone was obtained in 32% yield from allyl phenyl ether[29].

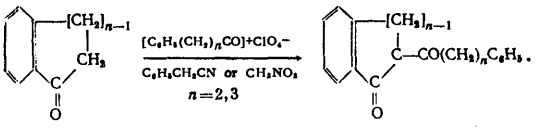
When ethers of mono- and poly-hydric phenols are acylated with a complex acylating agent consisting of molar quantities of acetyl chloride, acetic anhydride, and sodium perchlorate in glacial acetic acid, the corresponding alkoxy-substituted ketones are obtained in 30–50% yield[141]. However, these and other similar ketones are obtained in a higher yield (40–65%) in the acylation of phenol ethers with acetic anhydride in the presence of catalytic quantities of 60% perchloric acid[117].

Acylation of anisole and xylenes with tosyl perchlorate (from $p$-$CH_3C_6H_4SO_2Cl$ and $AgClO_4$ in nitromethane) led to the formation of substituted *p*-tolylphenylsulphones[142].

As already mentioned, in the acylation of phenols *O*-acyl derivatives are obtained in good yield, but hydroxyketones are not formed[106,116,135]. Under the same conditions aromatic amines undergo *N*-acylation[105]; acetylation of dimethylaniline in the presence of Anhydrone gave *p*-dimethylaminoacetophenone[135].

The acylation of azulene and its derivatives with acid anhydrides in the presence of perchloric acid has recently been studied[143].

Good results have been obtained by the acylation of various heterocylic compounds by this method[115,116,122,124,126,134–136,139]. Magnesium perchlorate is more convenient than perchloric acid as a catalyst in the acylation of heterocyclic compounds, because it does not destroy heterocyclic compounds and for this reason only quite small amounts of resinous products and by-products are obtained. Furan and $\alpha$-methylfuran are easily acylated in the presence of traces of perchloric acid or Anhydrone to form 2-acetylfuran, 5-acetyl-2-methyl furan, and other furyl $\alpha$-alkyl ketones in yields of 68–75%.[116,121,126,135,139]. When 2-halogenofurans were acetylated by this method, 5-acetyl-2-halogenofurans were obtained in 85–90% yield[144]. Acylation of thiophen with acid anhydrides proceeds with the same high yield (92–95%) as in the presence of stannic chloride[145], but the method of preparing ketones with perchloric acid is simpler and more convenient[116,126,135,138]. Thiophen is also easily acylated by aliphatic acid chlorides in the presence of Anhydrone to give thienyl $\alpha$-alkyl ketones in 55–65% yield[125].



In the acylation of pyrrole by carboxylic acid anhydrides (from acetic to hexanoic) in the presence of small quantities of $HClO_4$ or $Mg(ClO_4)_2$ alkyl 2-pyrrolyl ketones are formed in 35–55% yield[124]. Even when pyrrole is acylated in the cold, 2-acylpyrrole, which is easily separated after neutralisation of the reaction mixture, is the main product; in the majority of experiments, 1-acylpyrroles have not been found in significant quantities. These results indicate that the conclusion of Berlin on the primary *N*-acylation of pyrrole is erroneous[105].

In the same way, in the acetylation or propionylation of pyrrole derivatives(1-methylpyrrole, 1-phenylpyrrole, and 2,4-dimethylpyrrole) substituted 2-acylpyrroles are obtained in high yield (50–72%)[124]. Indole is also easily acetylated in the presence of perchloric acid[116] or Anhydrone[134] to give 3-acetylindole in 32–50% yield together with some 1-acetylindole.

Alkyl aryl ketones(acetophenone and methylacetophenone) are acetylated by acetyl perchlorate on the methyl group to give the corresponding $\beta$-diketones in up to 20% yield[109].

$$ArCOCH_3 \xrightarrow[CH_3NO_2]{CH_3COCl+AgClO_4} ArCOCH_2COCH_3.$$

Burton and Munday[146] extended this reaction to cyclic ketones (cyclopentanone, cyclohexanone, 1-indanone, and 1-tetralone); acylating with acetyl perchlorate and phenylalkanoyl perchlorates, they obtained cyclic $\beta$-diketones in low yield:

Recently it was shown that it was in principle possible to obtain $\alpha\beta$-unsaturated ketones by acylating olefins by Kondakov's method with acid anhydrides in the presence of perchloric acid and its compounds. Acylation of cyclohexene with acetic anhydride in the presence of perchloric acid[147] or with acetyl chloride and silver perchlorate in nitromethane[126,147] leads to the formation of 2-acetylcyclohex-1-ene in yields of 32 and 42% respectively. Hex-1-ene and triisobutylene are also acetylated by acetic anhydride in the presence of catalytic quantities of perchloric acid, unsaturated ketones being formed in 15–20% yield[119]. In the acylation of vinylaromatic compounds (styrene and vinyltoluene) under similar conditions unsaturated ketones were obtained in 15–20% yield, but the formation of considerable amounts of polymeric compounds was also noted[119,123]. Other arylethylenes (acenaphthylene and indene) alone or mixed with styrene only form polymers and copolymers in quantitative yield under the acylation conditions[148]. As shown by Plesh and coworkers the polymerisation of unsaturated compounds is initiated by acetyl perchlorate and proceeds by the usual cationic polymerisation mechanism[149].

Perchloric acid has also proved an effective catalyst in the acylation of a number of high-molecular-weight compounds containing reactive linkages in the polymer chain[123,148].

† Mixed anhydrides with silicic and boric acids ? (Ed. of Translation).

In particular, the *C*-acylation of polyacenaphthylene and of the copolymer of acenaphthylene with styrene have been carried out by this method[148].

The addition of anhydrides of carboxylic acids to vinyl acetate in the presence of catalytic quantities of perchloric acid or silver perchlorate leads to the formation of acylals of β-ketoaldehydes (10–60% yield), which are widely used in organic synthesis for the preparation of heterocyclic compounds[150,151]:

$$R'CH{=}CHOAc \xrightarrow[HClO_4]{(RCO)_2O} RCOCHCH(OAc)OCOR,\ (R' = H,\ CH_3)$$

where R = $CH_3$, $C_2H_5$, $C_3H_7$; R′ = H, $CH_3$.

Of other cases in which perchloric acid is used in an acylation reaction, the cyclisation of benzoylbenzoic acid to anthraquinone should be mentioned; the components are boiled in acetic acid solution[152].

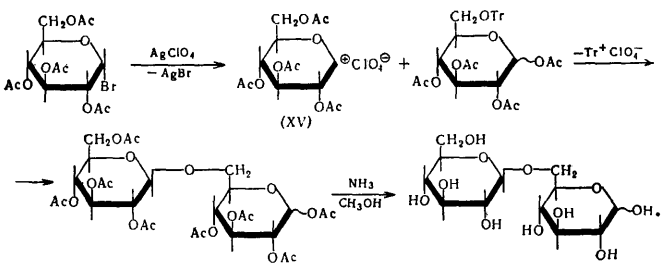
## IV. ACYLATION AND ALKYLATION OF THE HYDROXY--GROUP

Perchloric acid and its salts are widely used for the catalytic acylation of alcohols, phenols, and other hydroxy--compounds, and also for the analytical determination of the hydroxy-group[153]. Alcohols[154] and phenols[106,116] are acylated by acid anhydrides in the presence of traces of perchloric acid or Anhydrone[106,155]. In this way even compounds such as arylnitroalcohols[156] and tertiary alcohols[157], which are sensitive to mineral acids, have been successfully acylated. The acetylation of phenol[116], guaiacol[137], resorcinol[116], hydroquinone[106], and naphthols[114] gives aryl acetates in high yield. Information on the mechanism and kinetics of the *O*-acylation of phenols is given in a paper by Satchell[114].

The catalytic decomposition of 1,3,5-trioxan in acetic anhydride has been described; a mixture of mono-, di-, and (at low temperatures) even tri-oxymethylenediacetates is formed[158].

When $(CH_3CO)_2O$ and $HClO_4$ act on derivatives of 2-phenylcoumarin and tetrahydrofuran, the opening of the heterocyclic ring is accompanied by the formation of *O*-acyl compounds[159].

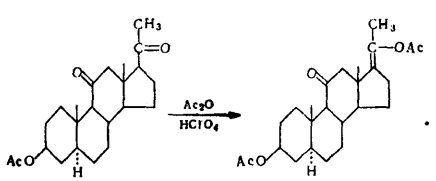
The use of perchloric acid in the acylation of polyhydric alcohols[160], monosaccharides[160,161], and cellulose[162–164] gives particularly good results. Glucose is acetylated rapidly and easily at ordinary temperatures to the α-pentaacetate[161]. Partial acetylation of cotton cellulose, in a continuous-process apparatus, is effected in a heterogeneous medium by a mixture of 85% $CH_3COOH$ + 15% $(CH_3CO)_2O$ and 0.1–0.2% $HClO_4$, or by 50% $(CH_3CO)_2O$, 50% pentyl acetate, and 0.2% $HClO_4$.[165] When acetylated D-glucosides are heated with acetic anhydride and perchloric acid, D-glucoseheptaacetate is obtained[166].



Heating glucose β-pentaacetate with perchloric acid in a solution of $(CH_3CO)_2O$ and $CH_3COOH$ leads to its isomerisation to an equilibrium mixture containing 90% of the α-anomer[113,167].

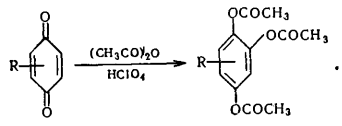
A convenient preparative method has been developed for acetylating polyhydric alcohols, cyclitols, and some monosaccharides and *O*- and *C*-glycosides in the presence of small amounts of magnesium perchlorate, which is more convenient in this reaction than perchloric acid[154,155,168].

For example, with this method polyhydric alcohol polyacetates are obtained in 85–90% yield, and pure D-glucose α-pentaacetate is obtained in 80% yield.



A simple and convenient method has been proposed for deacetylating polyhydric alcohol polyacetates and *C*-glycosides by heating the acetates with small quantities of perchloric acid in methanol solution[168,169]. Hydrolysis of *O*-glycosides with aqueous perchloric acid proceeds through the intermediate glucopyranosylcarbonium cation ("sucronium" cation)[170].

Recently a new method of synthesising oligosaccharides has been proposed[171]. Essentially this method consists in the reaction of acetohalogenose and silver perchlorate in nitromethane to give the sucronium perchlorate, which then reacts with acyl derivatives of 6-tritylmonose. In this way di- and tri-saccharides with 1,1- and 1,6-*O*-glycosidic bonds have been synthesised[172,173] and branching has been introduced into polysaccharide molecules[174]. The synthesis of the disaccharide gentiobiose in 59% yield has been effected according to the following scheme[173,175]:

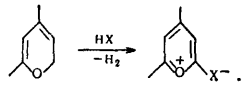


By a similar reaction of (XV) with the trityl derivative of $\Delta^5$-3β-hydroxypregnen-20-one the *O*-glycoside of this steroid has been synthesised[175]. A series of acetylated *O*-glycosides has been synthesised by the interaction of sucronium perchlorates (XV), obtained as unstable colourless syrups from 1-chloro-2,3,4,6-tetra-*O*-acetyl-D-glucose, D-galactose, and D-xylose and $AgClO_4$, with aliphatic and alicyclic alcohols[176].

A method of *O*-acylation previously developed has been applied to the synthesis of fats[171,177]. When mono- and di-trityl ethers of various glycerides react with aliphatic acid chlorides and $AgClO_4$ in nitromethane, homogeneous triglycerides are formed in good yield[177]. There are also reports of the use of perchloric acid in *O*-acylation reactions of some steroids[178,179] and alkaloids[180,181]. Thus when 3-β-acetoxyallopregnane-11,20-dione was treated with acetic anhydride containing traces of perchloric acid in $CCl_4$ solution, the monoenol acetate was obtained in good yield[180]:

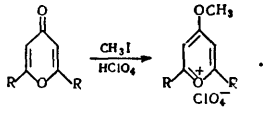
Perchloric acid is the most effective catalyst in the acylation of quinones by Thiele's method, since the tri-

acetates of 1,2,4-trihydroxybenzene and its derivatives can be obtained in yields of 90% and more[112,182]:



When treated with acetic anhydride and perchloric acid, 1,4-naphthoquinone forms 1,2,4-triacetoxynaphthalene in quantitative yield[183].

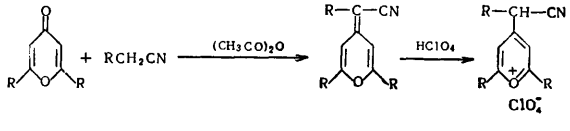
## V. SYNTHESIS OF HETEROCYCLIC COMPOUNDS



The systematic use of perchloric acid in the synthesis of heterocyclic compounds only began in recent years.

Perchloric acid is an effective catalyst and condensing agent in the synthesis of pyrylium salts, which are easily separated and purified as stable perchlorates. Methods of preparing pyrylium salts associated with the use of the acid may be classified according to three general synthetic routes: (a) synthesis from compounds containing the pyran ring; (b) the alkylation of olefins and other unsaturated compounds; (c) condensation reactions of carbonyl compounds. However, even in the latest reviews and monographs dealing with the chemistry of heterocyclic compounds the methods of synthesis and the properties of pyrylium salts are considered very superficially[184-188].

Under the action of strong mineral acids pyran derivatives eliminate a hydride ion and form pyrylium salts[189]:



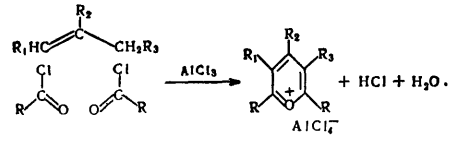
On alkylation with methyl iodide or dimethyl sulphate and subsequent treatment with perchloric acid, the readily accessible 2,6-dimethyl-4-pyrone, 2,6-diphenyl-4-pyrone, and 2,4-dimethyl-2-pyrone form 4(2)-alkoxypyrylium perchlorates[184,185].

2,4,6-Trisubstituted pyrylium salts with different substituents in position 4 of the pyrylium ring may be synthesised by the successive action of organomagnesium compounds and perchloric acid on 2,6-disubstituted 4-pyrones[190,191].

Similarly, in the presence of acetic anhydride or other dehydrating agents disubstituted 4-pyrones react with various nucleophilic compounds (dimethylaniline[192], malonic acid dinitrile, cyanacetic ester[193], etc.) to form substituted pyrylium salts:

Some information on the conversion of pyrones to pyrylium salts is given in a recent review by Dimroth[193].

Data on the second of the aforementioned methods of preparing pyrylium salts, which was discovered almost simultaneously in 1959 by Balaban and Nenitzescu[194,195] and also by Praill and Whitear[157,196], are systematised in a detailed review by the Rumanian workers[197].



When olefins are acylated by Kondakov's reaction in the presence of the usual catalysts ($AlCl_3$, $SnCl_4$, $ZnCl_2$, $HClO_4$, $BF_3$ complexes, etc.), $\alpha\beta$-unsaturated ketones are formed[198]. However, as has been shown in recent work, pyrylium salts are formed in this reaction in addition to $\alpha\beta$-unsaturated ketones; because of their solubility in water, the pyrylium salts remained unnoticed for a long time[195,199-201].

In their study of the carbonylation of t-butyl chloride by carbon monoxide in the presence of ferric chloride, Balaban and Nenitzescu observed a small quantity of crystalline product (~3%) in addition to trimethylacetic acid and t-butyl isobutenyl ketone; this turned out to be 2,6-di-t-butyl-4-methylpyrylium tetrachloroferrate[194]. From this the correct conclusion was drawn that the pyrylium salt is formed from isobutene produced by the decomposition of t-butyl tetrachloroferrate:

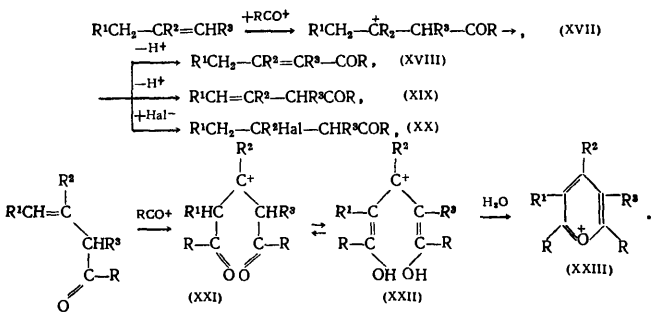
$$(CH_3)_3CCl+FeCl_3 \rightarrow (CH_3)_3C^+FeCl_4^- \rightleftarrows CH_3C(CH_3)=CH_2+HCl+FeCl_3.$$

On bisacylation of an olefin with trimethylacetyl chloride and subsequent cyclisation of the 1,5-diketone formed in the reaction, a pyrylium salt is obtained.

A detailed investigation of the acylation of a series of olefins (isobutene, $\alpha$-methylstyrene, 1,2-diphenylpropene, etc.) with an excess of acid chlorides in the presence of aluminium led to a simple and original method of preparing substituted pyrylium salts in 20–40% yield[195]:

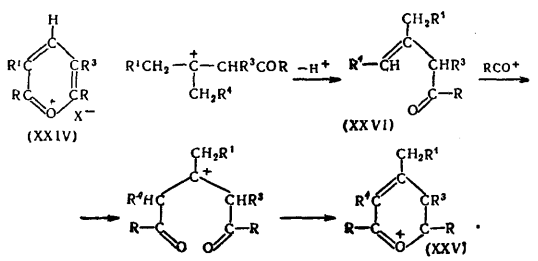
The pyrylium salts formed in the reaction are separated from aqueous solution as slightly soluble perchlorates, chloroplatinates, or derivatives of Reinecke's salt, or they are converted by ammonia to the corresponding pyridine bases.

Tri- and tetra-substituted pyrylium salts may be obtained in 25–50% yield by the acylation of olefins (isobutene, 2-methyl-1-butene, pent-1-ene, $\alpha$-methylstyrene, etc.) with a large excess of acetic or propionic anhydride in the presence of molar quantities of 72% perchloric acid[196]. The structure of the pyrylium salts was established by their conversion into the corresponding pyridine derivatives, which is easily effected by treating the salts with aqueous ammonia or with ammonium acetate in acetic acid solution.



The reaction is obviously a general method of synthesising pyrylium salts from unsaturated compounds, containing the propenyl group, of the general formula (XVI):

$$R_1CH_2-CR_2=CHR_3$$
(XVI)

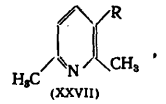


(where $R_1$, $R_2$, and $R_3$ = H, Alk, or Ar).

The mechanism of bisacylation of olefins is discussed

in a series of papers on the synthesis of pyrylium salts and may be represented by the following scheme[197,201,202]:

The first stage of the reaction consists in the addition of an acylium cation to the unsaturated compound (XVI) to form a carbonium ion (XVII), which is stabilised by elimination of a proton, being converted into $\alpha\beta$-(XVIII) or a $\beta\gamma$-unsaturated ketone (XIX), or in the addition of a halide ion to form in the latter case a $\beta$-halogeno-substituted ketone (XX) (if the acylation is carried out by an acid halide). Since the double bond in the $\beta\gamma$-unsaturated ketone (XIX) formed in the reaction is not conjugated with the carbonyl group, it readily reacts with a second molecule of acylium cation to form the dicarbonyl compound (XXI), which is converted into the pyrylium cation (XXIII) by elimination of a molecule of water from the enol form (XXII). The proposed mechanism was further confirmed in work on the bisacetylation of olefins with $CH_3{}^{14}CO^+$.[203] When $R^2 = H$, only one pyrylium salt isomer (XXIV) is formed. When $R^2 = CH_2R^4$, two isomers can be obtained, the pyrylium cation (XXIII) obtained as described above and the isomeric cation (XXV) formed by the following reaction:

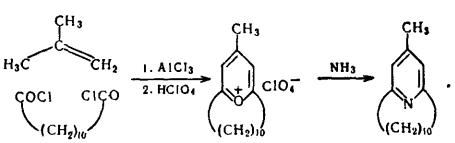


The formation and yield of the isomers (XXIII) and (XXV) is obviously determined by the quantitative ratio of the unsaturated cations (XIX) and (XXVI) and also by thermodynamic and kinetic factors.

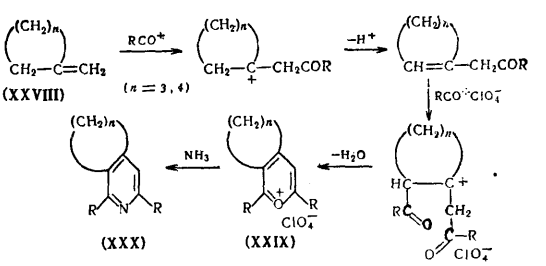
As is to be expected, in the acetylation, propionylation and benzoylation of unsubstituted propene (the simplest compound which can be converted into a pyrylium salt by bisacylation), 2,6-disubstituted pyrylium salts are formed in low yield (0.5–5.7%)[204].

Praill and Whitear have made a detailed study of the acylation of a number of olefins (pent-1-ene, pent-2-ene, 3-ethylpent-2-ene, etc.) and other unsaturated compounds by acetic anhydride in the presence of perchloric acid[201].

Dulenko and Dorofeenko studied the bisacylation of higher olefins (the hex-1-ene, hept-1-ene, non-1-ene, and dec-1-ene) but in this case they did not succeed in separating pyrylium salts as perchlorates; these are difficult to crystallise and very soluble in water[205]. However, treatment of the reaction mixture with ammonia gave the corresponding 2,6-dimethyl-3-alkylpyridines (XXVII) (yield 23–42%), which are difficult to obtain



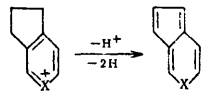
where R = $C_3H_7$, $C_4H_9$, $C_6H_{13}$, and $C_7H_{15}$.



Crystalline pyrylium salts were not obtained when allylbenzene was acetylated in the presence of perchloric acid, but when the final product was treated with ammonia 2,6-dimethyl-3-phenylpyridine and 3-*p*-acetylphenyl-2,6-dimethylpyridine were obtained[206].

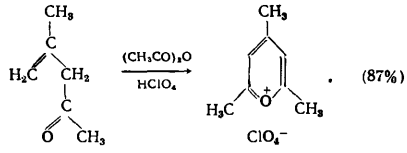
Acetylation of 2-methylpropenylbenzene ($CH_3COCl + AlCl_3$) gave a small amount of 2,6-dimethyl-4-benzylpyridine after the usual treatment[207]. The structure of the olefin materially effects the bisacylation reaction and the yield of pyrylium salts. The best results are obtained in the acylation of di- and tri-alkyl-substituted propenes, and also the "middle" members of the $\alpha$-olefin series containing an activated double bond. When one or two aryl residues are introduced into the propene molecule, the yield of pyrylium salts is appreciably reduced. Attempts to synthesise pyrylium salts from olefins with a deactivated double bond (1,2,3-triphenylpropene and methyl methacrylate) have proved unsuccessful[197]. Attempts to synthesise pyrylium salts by acetylation of allyl halides and isoprene, which immediately polymerise under the reaction conditions, were also unsuccessful[208].

An interesting case of intramolecular bisacylation was observed in the action of decane-1,10-dicarboxylic acid chloride and $AlCl_3$ in nitromethane on isobutene[209]: the bicyclic 4-methyl-2,6-decamethylenepyrylium salt was obtained as perchlorate and this was converted into the corresponding pyridine, as isomer of the natural muskopyridine:



Balaban and Nenitzescu have done interesting work on the bisacylation of methylenecycloalkanes (XXVIII)[200]. Here, too, the pyrylium salts (XXIX) formed in the reaction could not be separated, but when the mixture was treated with ammonia 2,6-disubstituted pyridine, condensed with cycloalkene rings (XXX) were obtained in 18–25% yield

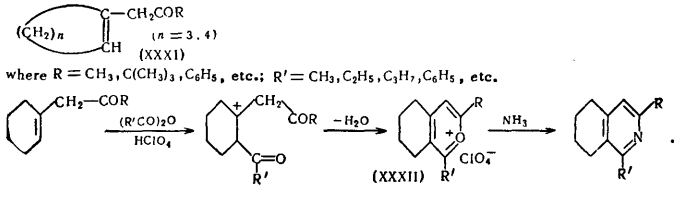
1,3-Dimethyl-5,6,7,8-tetrahydroisochromylium ($n = 4$) perchlorate was obtained in 30% yield by the acetylation of 1-methylcyclohexene, an isomer of (XXVIII) ($n = 4$).[201]



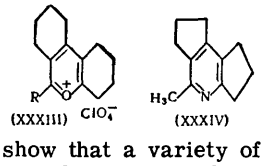
The pyrylium salts condensed with a cyclopentane ring (X = O) are of considerable interest, because they themselves and the quaternary pyridinium (X = NR) salts ob-

tained from them can be used as starting materials in the synthesis of pseudoazulenes:

where X = O or NR.



As is to be expected, $\beta\gamma$-unsaturated ketones (for example 4-methylpent-4-en-2-one), which are intermediates in the bisacylation of olefins, form pyrylium salts in excellent yield under the conditions mentioned[201]

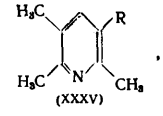


(87%)

The acylation of products of the crotonic condensation of cyclic ketones (cyclopentanone, cyclohexanone, etc.) with aliphatic and alkyl aryl ketones, in one of the isomers of which ($n$ = 4) the double bond is in the $\beta\gamma$-position to the carbonyl group, has been studied with the object of obtaining 5,6,7,8-tetrahydroisochromylium salts[208,211].

$\beta\gamma$-Unsaturated ketones (XXXI) (for example cyclohexenylacetone, cyclohexenylacetophenone, etc.) are acylated very rapidly by anhydrides of carboxylic acids in the presence of perchloric acid, the reaction mixtures becoming hot, and crystalline 5,6,7,8-tetrahydroisochromylium perchlorates (XXXII) can be isolated in good yield (70–90%):

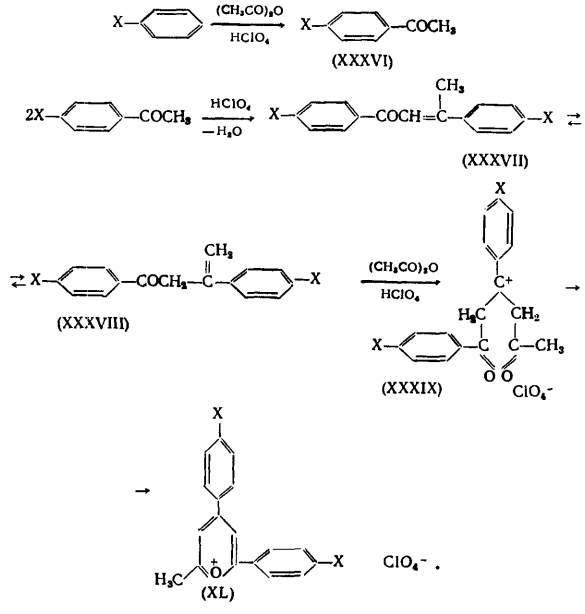
When cyclohexenylcyclohexanone was acylated in the manner described, 2-alkyloctahydrodibenzopyrylium (XXXIII) perchlorates were obtained in high yield (up to 80%)[208]. Attempts to acetylate the product of the autocondensation of cyclopentanone were also successful[208]. Although in this case the crystalline perchlorate was not isolated, treatment of the mixture with ammonia gave 2-methyl-3,4:5,6-biscyclopentadienopyridine (XXXIV) in 30% yield:



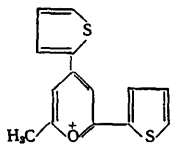
These results show that a variety of 1,3-disubstituted salts of 5,6,7,8-tetrahydroisochromylium can be easily synthesised by this method, and the salts may be used for the preparation of a number of isoquinolines, analogues of isoquinoline alkaloids, and other aromatic compounds difficult to obtain[208,211].

When t-butyl alcohol is acetylated in the presence of molar quantities of perchloric acid[157,199,201,212] or other acid catalysts[199], the final reaction product, obtained in the high yield (55–75%), is 2,4,6-trimethylpyrylium perchlorate. The same product is obtained in 72% yield by acetylating diacetone alcohol, which is evidently converted into a $\beta\gamma$-unsaturated ketone that readily forms a pyrylium salt[201].

Under the same conditions t-pentyl alcohol forms a mixture of pyrylium salts (yield 60%) consisting of 2,3,4,6-tetramethylpyrylium perchlorate (79%) and 2,6-dimethyl-4-ethylpyrylium perchlorate (21%).[157,158,201] Bisacylation of dimethylbenzylmethanol leads to the formation of 2,4,6-trimethyl-3-phenylpyrylium perchlorate[207], and 2,6-dimethyl-4-phenylpyrylium perchlorate is obtained from dimethylphenylmethanol[208]. Studies on the acylation of secondary alcohols in the presence of perchloric acid have shown that the process is accompanied by slow dehydration of the alcohols to the corresponding olefins, which are then diacylated with the formation of pyrylium salts, convertible by ammonia into the corresponding pyridines[208,213]. By this method 2,6-lutidine (11%) has been obtained from isopropanol, and 2,3,6-collidine (15%) has been obtained from butan-2-ol.



Other secondary alcohols (pentan-2-ol, hexan-2-ol, and octan-2-ol) form 2,3,4,6-tetrasubstituted pyridines (XXXV), which are difficult to obtain, in 27–30% yield:

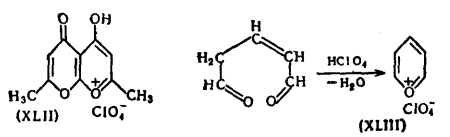


where R = $CH_3$, $C_2H_5$, $C_4H_9$.

However, attempts to extent this reaction to primary alcohols have not been successful[208].

In 1927 Diels and Alder reported on the preparation of pyrylium salts by the acylation of some aromatic compounds (toluene, $o$-xylene) and acetophenone with acetic anhydride in the presence of molar quantities of perchloric acid[104]. Obviously, the first stage in this reaction consists in the acetylation of the aromatic compound to an alkyl aryl ketone (XXXVI). The ketone obtained in this way, or introduced directly, forms a crotonic condensation product (XXXVII). The latter isomerises with a shift of the double bond to form a $\beta\gamma$-unsaturated ketone (XXXVIII), which is acylated again at the double bond with subsequent cyclisation of the diketone (XXXIX) to the pyrylium salt (XL):

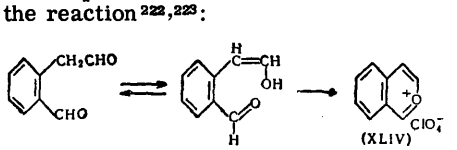
2-Methyl-4,6-di(*p*-alkoxyphenyl)pyrylium salts (and from them substituted pyridines) are formed in good yield by acetylating phenol ethers (anisole and phenetole) or the corresponding *p*-alkoxyacetophenones in the presence of perchloric acid[208,214]. When thiophen or methyl-2-thienyl ketone is acetylated in this way, a pyrylium salt with heterocyclic radicals in the ring (XLI) is obtained in good yield (45%).



(XLI) $ClO_4^-$

It is interesting that, when dibenzyl ketone is bisacetylated under similar conditions, it forms 2,6-dimethyl-3,5-diphenyl-4-pyrone in low yield, because of the high mobility of its methylene group hydrogen atoms[215].

The schemes given for the formation of pyrylium salts from olefins and ketones are confirmed by the fact that $\alpha\beta$-unsaturated ketones of suitable structure also form pyrylium salts[105,195,201,216]. For example, when mesityl oxide is treated with acetyl perchlorate, it forms 2,4,6-trimethylpyrylium perchlorate in 46% yield[105,201]. Acetylation of acetone in the presence of perchloric acid, which catalyses the crotonic condensation reaction as with mesityl oxide, readily gives a good yield (45–50%) of 2,4,6-trimethylpyrylium[214].

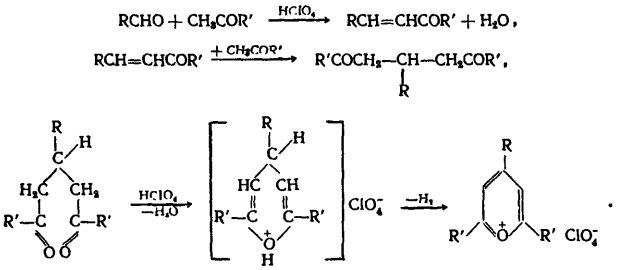


The Diels–Alder method of preparing pyrylium salts is a special case of a general method of synthesising compounds of this class by the bisacylation of olefins and other unsaturated compounds. However, the Diels–Alder method, the synthetic possibilities of which have not been fully elucidated, is very promising since it permits the preparation from readily accessible materials of pyrylium salts that are otherwise difficult to obtain. When a mixture of equimolecular quantities of acetic anhydride and perchloric acid is heated, self-acylation of the anhydride occurs and the acetoacetic acid is subsequently cyclised to the perchlorate of a base to which structure (XLII) has been ascribed[217]; the same compound is obtained when dehydroacetic acid is acetylated:

(XLII) (XLIII)

A third route to the synthesis of pyrylium salts is associated with the condensation of carbonyl compounds and the cyclisation of dicarbonyl compounds in the presence of perchloric acid.

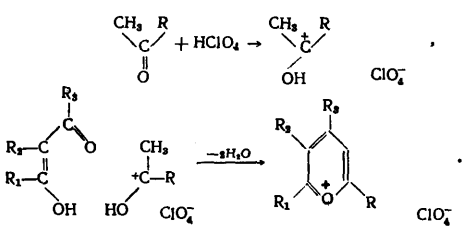
Thus, the unsubstituted pyrylium salt (XLIII) is formed in good yield by the action of perchloric acid on glutaconic dialdehyde[218]. Under the action of dehydrating complexes ($FeCl_3$, $SbCl_5$)[219,220] or trityl perchlorate[221] 1,5-diketones are smoothly converted into 2,4,6-trisubstituted pyrylium salts in 50% yield. Robinson and coworkers obtained salts of the isochromylium cation (XLIV) by treating homophthalic aldehyde with perchloric acid or ferric chloride, which results in the reaction[222,223]:



(XLIV)

The salts formed (XLIV) readily react with ammonia or primary amines to form isoquinoline and various *N*-substituted quaternary isoquinolinium salts.

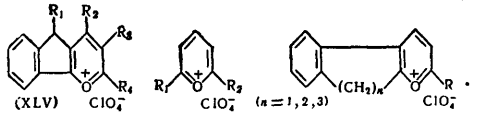
A simple method of preparing 2,4,6-triarylsubstituted pyrylium salts has been developed; these are obtained by the interaction of $\alpha\beta$-unsaturated ketones (chalkones) with alkyl aryl ketones[224–226] or by the direct condensation of aromatic aldehydes with ketones[220,227] in acetic anhydride in the presence of ferric chloride.



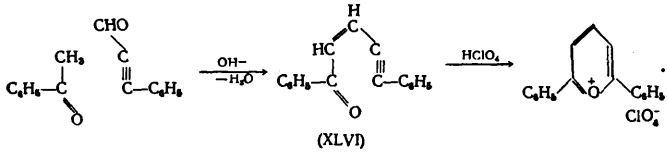
Dorofeenko and Krivun, who studied the condensation of aromatic aldehydes with alkyl aryl ketones in the presence of 70% perchloric acid, have proposed a simple and convenient method for the preparation of pyrylium salts with aryl substituents[228,229]. The synthesis of pyrylium salts appears to proceed through intermediate 1,5-diketones according to the scheme

Pyrylium salts are readily formed by brief heating (1–2 hours) or an aromatic aldehyde and ketone (molar ratio 1 : 2) at 100–110° with or without an inert solvent. In this way 2,4,6-triphenylpyrylium perchlorate (50–60%), 2,6-diphenyl-4-*p*-nitrophenylpyrylium perchlorate (30%), 2,6-diphenyl-4-*p*-dimethylaminophenylpyrylium perchlorate (33–35%), and a number of other pyrylium salts have been obtained[228,229].

The recently described condensation of benzylidenacetophenone and phenacyl acetate to 3-acetoxy-2,4,6-triphenylpyrylium perchlorate is effected in a similar way[230]. When chalkones are condensed with cyclohexanone in the presence of perchloric acid, 2,4-diaryl-5,6,7,8-tetrahydrochromylium perchlorates are formed[231,232].



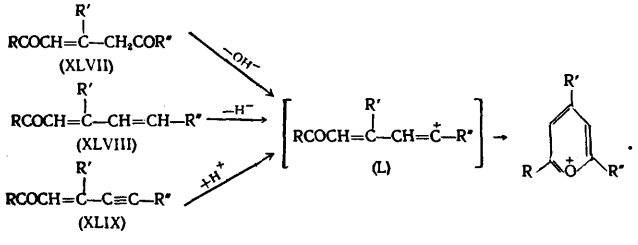
A method has been developed for preparing pyrylium salts in which $\beta$-dicarbonyl compounds are condensed with ketones in the presence of perchloric acid[208,233]:



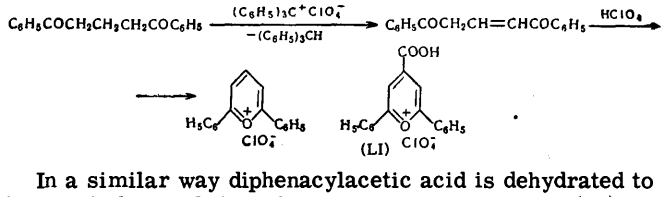
Although the pyrylium salts are obtained in low yield (15–30%) by this method, it appears to have wide possibilities, since it permits the synthesis of pyrylium salts that have not been obtained by other methods.

When 2-indanone and its derivatives are condensed with $\beta$-diketones, indeno[2,3*h*]pyrylium perchlorates (XLV) are obtained[234]; these form dyes when treated with sodium acetate[235]. Condensation of $\beta$-chlorovinyl ketones with

ketones[236] or enamines[237] also leads to pyrylium salts of the following structure:



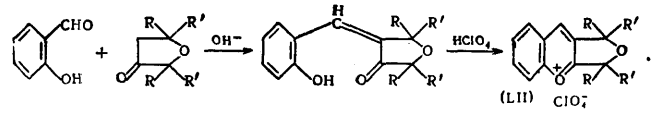
When acetophenone is condensed with phenylpropiolic aldehyde, the chalkone (XLVI) is formed; in the presence of perchloric acid this cyclises to a 2,6-diphenylpyrylium salt in 60% yield[238]:



(XLVI)

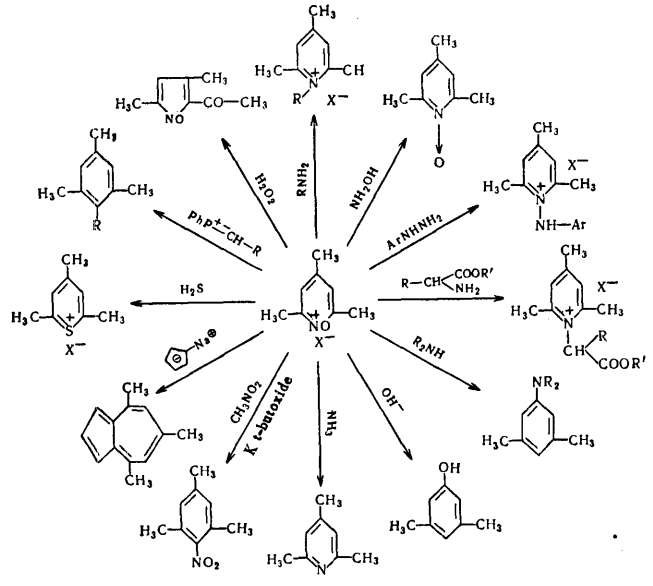
In a paper by Siemiatycki and Fugnitto a general mechanism is proposed for the formation of pyrylium salts from unsaturated δ-diketones (XLVII) and unsaturated ketones (XLVIII) and (XLIX) containing two double bonds, or a double and a triple bond, conjugated with a carbonyl group[221]. According to this interpretation, the formation of a pyrylium ring from ketones of the structure mentioned proceeds through the same carbonium ion (L), which is converted into a pyrylium cation:

This mechanism is confirmed by results in the paper quoted above[238] and by the studies of Siemiatycki and Fugnitto[221], who, showed that when 1,5-diphenylpenta-2,4-dien-1-one reacts with triphenylmethyl perchlorate, which has considerable dehydrating properties, 2,6-diphenylpyrylium perchlorate is formed (23%).[239,240] The same salt is obtained in good yield (88%) by the dehydration of 1,3-dibenzoylpropane with trityl perchlorate:



In a similar way diphenacylacetic acid is dehydrated to form 2,6-diphenyl-4-carboxypyrylium perchlorate (LI) in good yield (85%)[221]; this compound has not been otherwise synthesised.

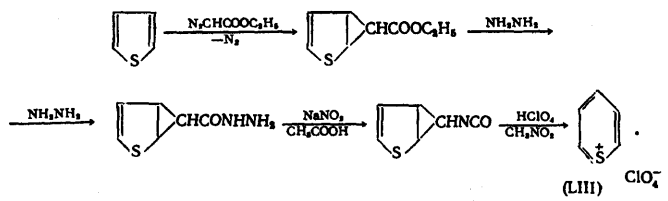
Perchloric acid is frequently used as a condensing agent in the synthesis of benzopyrylium salts[241]. A new method has been proposed for the synthesis of benzopyrylium salts by condensation of various β-chlorovinyl ketones with phenols and naphthols in the presence of ferric chloride or perchloric acid[242-246].



When xanthydrol or its derivatives is treated with perchloric acid in acetic anhydride, xanthylium salts are formed in good yield[247,248]. In this way 9-phenylethynylxanthylium perchlorate was obtained from 9-phenylethynylxanthydrol[249].

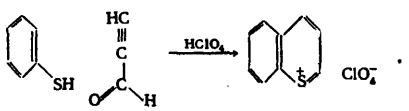
Recently it was shown that benzopyrylium perchlorates could be prepared by treating 2-acylcoumarins with perchloric acid in acetic acid[250]. Perchloric acid has also been used as a condensing agent in the Robinson–Kostanetskii reaction for the synthesis of furanidinobenzopyrylium perchlorates (LII), obtained in 30–65% yield[251].

In recent years pyrylium salts have become of very great importance in organic chemistry because they are easily converted in high yield into alkyl- and aryl-pyridines[191,205], which are difficult to prepare; they also form *N*-alkyl(aryl)pyridinium salts[190,191], thiopyrylium salts[252], pyran derivatives[253-255], azulene derivatives[256,257], aromatic hydrocarbons[258,259], nitro-compounds[260], amines[104], phenols[190], and other aromatic compounds[258,261] that are frequently difficult to synthesise by other methods. Recently a new reaction of pyrylium salts was discovered that permits them to be readily converted into substituted alkyl α-furyl ketones[262] by the action of hydrogen peroxide, catalytic hydrogenation of which gives *sym*-trialkyltetrahydropyrans[212].



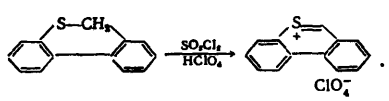
An interesting conversion of pyrylium salts into benzene derivatives by interaction with alkylidenetriphenylphosphoranes was recently discovered by Mark[263]. When pyrylium salts react with esters of α-amino-acids or diamino-acids, quaternary pyridinium salts are formed[264]:

Detailed information on the chemical properties of pyrylium salts and their various reactions is given in an excellent review by Dimroth[193].



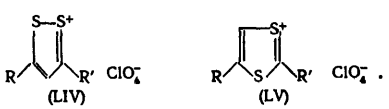
The use of perchloric acid and its compounds in the synthesis of sulphur- and nitrogen-containing heterocycles has also been described.

The preparation of thiopyrylium salts (LIII) by a new and interesting method has recently been described[265]:



(LIII)

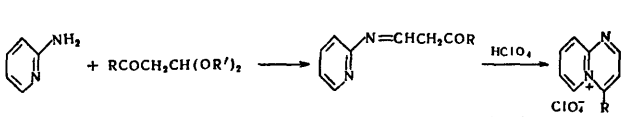
Engelhard and Kolb have proposed a simple single-step synthesis of thionaphththalenium salts; thiophenol or its derivatives is condensed with propargyl aldehyde in the presence of 70% perchloric acid[266].



When thioxanthene is dehydrated with trityl perchlorate in acetic acid, thioxanthylium perchlorate is formed in good yield; with the same reagent 1-thiochromanone forms 1-thiochromone, also in good yield[267].

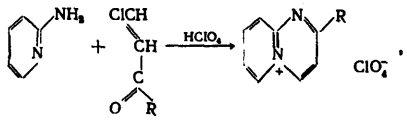
9-Thio-9,10-dihydrophenanthrene is smoothly converted into 9-thiophenanthrenium perchlorate by the action of sulphuryl chloride and perchloric acid in ether solution[268].

Perchlorates of 1,2-dithiolium derivatives (LIV) were obtained in good yield by the interaction of β-diketones with hydrogen sulphide in ether solution saturated with hydrogen chloride, and subsequent treatment with perchloric acid[269].



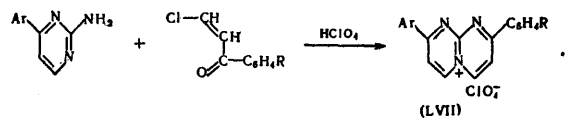
(LIV) (LV)

Similarly, when phenacyl- or acetonyl-carbodithionates were condensed with $H_2S$ in ether solution saturated with HCl, salts of the 1,3-dithiolium cation (LV) were obtained.



There are reports on the use of perchloric acid in Fischer's indole synthesis. When acetophenone phenylhydrazone was heated to boiling in bromobenzene solution with perchloric acid, 2-phenylindole was obtained[270]. Perchloric acid has been used as a condensing agent in the synthesis of *N*-*p*-tolyl-4,6-dimethylquinolinium perchlorate obtained by Bayer's method by the reaction of *pp*-ditolylamine with acetone and formaldehyde in nitromethane solution[271].

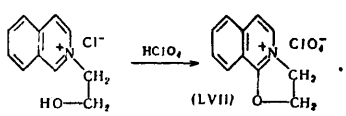
A new method of synthesising salts of 4-alkyl-1-azadehydroquinolizinium cation (LVI) has been developed; this is based on the condensation of α-aminopyridine with acetals of acylacetaldehydes, followed by cyclisation of the condensation products with concentrated acids ($HClO_4$, HBr)[272,273]:



(LVI)

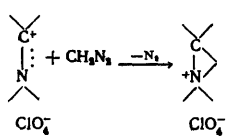
Compounds of this type are obtained easily and in good yield by the reaction of α-aminopyridine with β-chlorovinyl ketones in the presence of 70% perchloric acid[274]:

where R = $CH_3$, $C_3H_7$, $C_6H_5$.



2,8-Diaryl-1,9-diazadehydroquinolizinium{pyrimidino-[1,2-*a*]pyrimidinium} perchlorates (LVII), derivatives of a new heterocyclic system, were synthesised by condensing 4-aryl-2-aminopyrimidines with aryl β-chlorovinyl ketones in the presence of perchloric acid[275]:

(LVII)



where R = H, *o*-Br, *p*-Br, *p*-$NO_2$.

*N*-(Hydroxy)isoquinolinium chloride is almost quantitatively cyclised to 4,9,5,6,7-hexadehydro-1-oxa-7,8-benzoindolizinium perchlorate (LVII) by boiling with 70% $HClO_4$ in alcoholic solution[276]:

(LVII)

When immonium perchlorates react with diazomethane, aziridinium salts, easily isolated in the crystalline state, are formed in good yield[277]:

We have described the most promising and most developed ways of using perchloric acid and its derivatives in organic synthesis. The scope of this review does not allow us to deal with its use in hydrolysis and solvolysis reactions, addition of carboxylic acids to olefins, polymerisation, dehydration with trityl perchlorate and quinone perchlorates, oxidation, isomerisation, and rearrangements, and also in various condensation reactions.

Although perchloric acid and its compounds began to be used only comparatively recently in organic chemistry, the data presented show that it undoubtedly has a wide and promising range of uses.

# ION-EXCHANGE CELLULOSES AND THEIR USE IN CHROMATOGRAPHY

E.G.Davidova and V.V.Rachinskii

CONTENTS

I. Introduction 104
II. Preparation of ion-exchange celluloses 104
III. Properties of ion-exchange celluloses 105
IV. Technique of the application of ion-exchange celluloses 107
V. Uses of ion-exchange celluloses 110

## I. INTRODUCTION

The successful development of sorption technique and chromatography is to a considerable extent dependent on the discovery and utilisation of new types of synthetic sorbents. The production and introduction into sorption technology, particularly chromatography, of a new type of ion-exchange sorbent, the ion-exchange celluloses, is an outstanding achievement of modern chemistry and biochemistry.

The number of papers dealing with the chromatographic use of ion-exchange celluloses has been rapidly growing in recent years, and about 500 have already been published. The use of ion-exchange celluloses in chromatography and other varieties of sorption technology has enabled consider able progress to be made in the resolution of some of the most difficult problems in biochemistry — the separation of proteins, enzymes, nucleic acids, and other high- and low-molecular-weight substances found in living matter.

It is to be expected that ion-exchange celluloses will rapidly find wider application in ever increasing numbers of chemical fields.

The object of this review is to provide an account of current knowledge of the properties and uses of ion--exchange celluloses.

## II. PREPARATION OF ION-EXCHANGE CELLULOSES

We shall not concern ourselves here with the ion--exchange properties of natural and commercial (including chromatographic) celluloses, which may be found in a number of monographs, e.g. those of Rogovin[1] and Hais and Macek[2]. We note only that both natural and the various types of commercial cellulose possess ion-exchange properties mainly because of the presence of carboxyl groups, but their absorption capacity is negligibly small, being only $\sim 0.05$ mg-equiv. $g^{-1}$, which corresponds to about one carboxyl group for 90–130 glucose structural units[3,4].

The use of ion-exchange forms of cellulose for chromatographic purposes already has a history of more than 50 years. Goppelsröder[5] mentioned oxycellulose (a weakly acidic carboxyl-type cation exchanger) as a suitable material for capillary analysis. Oxycellulose is obtained by saponifying the esters present in the initial cellulose and oxidising the primary alcoholic groups present in the 6-position of the glucose structural units[1,2]. Even in this process definite limitations are found in the content of carboxyl groups: there exists a certain critical level for the introduction of these ionogenic groups into cellulose; above this level the cellulose loses the character of an insoluble sorbent. For oxycellulose it was found that the content of carboxyl groups could not exceed 1–4%; with more than 5% (every fifth glucose structural unit then being oxidised in the 6-position) the oxycellulose becomes soluble in water at pH above 9.[2]

The "pioneering" work on the production of different types of ion-exchange cellulose includes that of Lautsch and coworkers[6], Micheel and Albers[7], Sober and Peterson[8,9], and Porath[11]. Lautsch and coworkers obtained a number of ion-exchange cellulose ion exchangers: a carboxyl-type cation exchanger, the ether of glycolic acid containing the $-CH_2OCH_2COOH$ group, by the action of chloroacetic acid in alkaline solution; a strongly acidic cation exchanger containing the $-CH_2OCH_2CH_2CH(SO_3H)CH_3$ group by the action of butane sulphone; and an anion exchange containing $-CH_2\overset{+}{N}R_3X^-$ groups by esterification with *p*-toluenesulphonyl chloride and reaction of the ester with tertiary amines. In each case one ionogenic group could be introduced for each 20–30 glucose structural units; this was the limit of ion-exchange capacity for these ion exchangers, since with more ionogenic groups the cellulose decomposed.

Micheel and Albers[7] obtained a carboxyl-type cation--exchange cellulose in the form of the phthalic acid mono-

ester. This weakly acidic cation exchanger was insoluble in alkalis when containing 5% of carboxyl groups.

Sober, Peterson, and coworkers[8,9] and Porath[11] undertook systematic studies of the production of ion-exchange celluloses for chromatography.

Sober and Peterson[8,9] described the preparation of a series of new cation- and anion-exchange celluloses: CM-cellulose (carboxymethylcellulose); P-cellulose (phosphorylated cellulose); DEAE-cellulose (diethylaminoethylcellulose); and ECTEOLA-cellulose. From DEAE-cellulose, Porath[11] prepared the anion exchanger TEAE--cellulose (triethylaminoethylcellulose), and he also obtained the strongly acidic cation exchangers SE-cellulose (sulphoethylcellulose) and SM-cellulose (sulphomethylcellulose). The abbreviated and full names of some ion--exchange celluloses and their properties are given in Table 1. These are prepared from natural $\alpha$-cellulose.

Sober and Peterson[8,9] used powdered cotton cellulose for the preparation of cation exchangers and powdered wood cellulose for anion exchangers. $\alpha$-Cellulose was found to be the most suitable substrate for the introduction of ionogenic groups.

The absorption capacity of ion-exchange celluloses is limited on the one hand by the need for the sorbent to be insoluble, and on the other by the requirement that the sorbent should have good physical properties suitable for use both in paper and in column chromatography.

The ion-exchange celluloses obtained by the above groups of workers had absorption capacities of less than 1 mg-equiv. $g^{-1}$, which is considerably lower than for ion--exchange resins. However, in most cases this capacity was quite sufficient.

The ion-exchange celluloses are prepared by normal etherification of cellulose; for example, DEAE-cellulose was obtained by heating a mixture of cellulose and $\beta$-diethylaminoethyl chloride in alkaline medium[9], and SM- and SE-celluloses were prepared analogously[11].

TABLE 1. Types of ion-exchange cellulose.

| Abbreviated name | Full name | Ionogenic group | Acidic or basic properties | Total absorption capacity*, mg-equiv. × × $g^{-1}$ |
|---|---|---|---|---|
| Cation exchangers | | | | |
| SE | sulphoethylcellulose | $-C_2H_4SO_3H$ | strong acid | 0.4 |
| P | phosphorylated cellulose | $-PO_3H_2$ | strong acid | 0.8 |
| CE | carboxyethylcellulose | $-C_2H_4COOH$ | moderately strong acid | 0.7 |
| CM | carboxymethylcellulose | $-CH_2COOH$ | weak acid | 0.7 |
| C | carboxycellulose (oxycellulose) | $-COOH$ | weak acid | 0.7 |
| Anion exchangers | | | | |
| PAB | *p*-aminobenzylcellulose | $-CH_2C_6H_4NH_2$ | weak base | 0.6 |
| ECTEOLA | reaction product of cellulose with ethylene chlorohydrin and triethylamine | not known | weak base | 0.5 |
| AE | aminoethylcellulose | $-C_2H_4NH_2$ | weak base | 0.7 |
| TEAE | reaction product of DEAE-cellulose with ethyl bromide | not known | moderately strong base | 1.0 |
| DEAE | diethylaminoethylcellulose | $-C_2H_4N(C_2H_5)_2$ | moderately strong base | 1.0 |
| GE | guanidoethylcellulose | $-C_2H_4NHCNH_2NH_2OH$ | moderately strong base | 0.7 |

* Approximate values are given.

The methods for the production of ion-exchange celluloses have given good reproducibility in the physical properties of the sorbents and in their physicochemical characteristics (absorption capacity, etc.). A considerable part of the work on the uses of ion-exchange celluloses has been carried out on materials produced by the actual investigators. At the present time ion-exchange celluloses are produced by a number of foreign companies, such as Whatman (UK) and Serva (W. Germany), as well as at the Institute of Antibiotics, Academy of Sciences of the USSR (Leningrad) and the Textile Institute (Moscow). Table 1 lists the main known types of ion-exchange cellulose used in chromatography, the cation exchangers in order of decreasing acidity, and the anion exchangers in order of increasing basicity. A whole range of cellulose-based ion exchangers is available, and workers can select those with the required physicochemical properties.

## III. PROPERTIES OF ION-EXCHANGE CELLULOSES

### Structure

In their chemical structure the ion-exchange celluloses are linear polymers comprising long macromolecular chains of $\beta$-glucopyranose units joined by 1–4 $\beta$-glucosidic bonds. At intervals of the order of 50 Å the hydrogen of the cellulose hydroxyls is replaced by the various ionogenic groups. The individual linear macromolecules interact by molecular-type bonds (mainly polar) and by hydrogen bonding[1], the difference in the relative proportions of the two forms of interaction producing the differences in solubility and reactivity between the cellulose and its derivatives. Although the linear cellulose chains are cross--linked, the cross-linking is very weak.

The introduction of groups which cause partial rupture of the hydrogen bonds can increase the solubility. It should also be borne in mind that bonds retained in the ion-exchange celluloses may be broken during chromatography of some materials; thus it has been shown[11] that in chromatography of proteins on ion-exchange celluloses the protein molecules are adsorbed by hydrogen bonding as well as by the formation of ionic and polar bonds. A kind of competition arises for hydrogen bonding between the cellulose macromolecules on the one hand, and between cellulose and protein molecules on the other, which explains the high absorption capacity of ion-exchange celluloses towards proteins and other high-molecular-weight substances. The cellulose macromolecules can also combine with each other by ordinary valence bonds (glucosidic and ester linkages).

### Physical Properties

Because of the irregular thread-like shape of the cellulose particles, it is impossible to obtain an accurate evaluation of their dispersity and dimensions. Direct microscopic measurement of particle lengths has produced distribution curves which show the maximum length to be 350–500 $\mu$m; the maxima on the distribution curves lie in the range 50–100 $\mu$m. The diameter of the particles is 15–20 $\mu$m. The moisture content of air-dried ion-exchange celluloses is 10–15%. The density is 0.1–0.2 g $ml^{-1}$, i.e. like commercial cellulose they are fairly "loose". The

specific volume of ion-exchange celluloses in the swollen state is 10–15 $cm^3 g^{-1}$, and the swelling factor is ~ 2.

Ion-exchange celluloses possess good filtration properties; when they are used in column chromatography, the flow rate of solvent can be controlled within the limits 5–25 ml $cm^{-2} h^{-1}$. No data exist on their combined water content.

## Physicochemical Properties

The extent of dissociation of the ionogenic groups of ion-exchange celluloses and their acidity and basicity can be estimated from their titration curves[19]. Table 1 includes a qualitative indication of the acidic and basic properties of ion-exchange celluloses, and their approximate total absorption capacities.

The total absorption capacity of an ion exchanger, is a sorption constant and is determined by the number of ionogenic groups which have exchangeable ions; in other words, the total absorption capacity as a constant is independent of the composition of the solution in contact with the ion exchanger. However, the utilisation of this total absorption capacity by different ions varies with the energy of the bond produced by the sorbed ions. If the sorption of one ion is studied in the presence of other ions, the distribution follows the ion-exchange isotherm and the law of equivalence of exchange.

The sorbed ions compete for the sorption centres of the ion exchanger in accordance with their bond energies, and of course hydrogen ions (with cation exchangers) or hydroxide ions (with anion exchangers) sorbed by the ion exchangers block part of the total exchange capacity and so also compete; as a result, the real absorption capacity of the ion exchanger depends on the pH of the solution.

The sorption of dissociable high-molecular-weight compounds (polyelectrolytes) and many low-molecular-weight organic compounds by ion exchangers is a complex process, and has been little investigated theoretically or experimentally. Dissociable organic compounds are generally amphoteric substances the ionogenic groups of which differ in their degree of dissociation, and the number of free ionic bonds will vary with the pH of the solution and the presence and concentration of other substances. In addition to polar ionic sorption, organic molecules may also be attached by other types of bond.

In view of what has been said, the laws of ion exchange established for the sorption of inorganic ions will not apply to the sorption of dissociable organic compounds. The absorption capacity of ion-exchange celluloses towards organic compounds cannot be expressed as milliequivalents per gramme of sorbent, nor, in the case of high-molecular-weight compounds of indefinite molecular weight, even as millimoles per gramme of sorbent. In such cases ion-exchange celluloses will have a specific absorption capacity for a specific substance under specific conditions, and this must be expressed as milligrammes of substance per gramme of sorbent. If a more rigorous approach is desired, the universal standard unit of mass of ion exchanger must be taken as 1 g of the ion-exchanger matrix (the mass of the ion-exchanger less the mass of sorbed ions or compounds). At the present time, however, this unit of measurement of the mass of an ion-exchanger has not found widespread use, and the absorption capacity is usually measured per gramme of air-dried (or dry) ion exchanger in the ionic form taken for the experiment.

The sorption properties of ion-exchange celluloses have as yet been very little studied, and there have been no systematic studies of absorption capacity, sorption isotherms, or the kinetics and dynamics of sorption.

Peterson and Sober[9] determined the absorption capacity of some ion-exchange celluloses towards proteins, obtaining the following values:

DEAE 0.498 g of blood serum protein per gramme of sorbent,

ECTEOLA 0.05 g of blood serum protein per gramme of sorbent,

CM 0.98 g of CO-haemoglobin per gramme of sorbent,

P 0.93 g of CO-haemoglobin per gramme of sorbent.

O'Donnell and Thompson[13] investigated the variation of the absorption capacity of ion-exchange celluloses with temperature; for example, a decrease of temperature from 25° to 1° greatly reduces the absorption capacity of DEAE-cellulose towards insulin.

The rate of sorption is known to be determined by the rates of the successive stages of the sorption process, i.e. of diffusion and of actual sorption. The part played by these steps in establishing sorption equilibrium on ion-exchange celluloses has not been investigated. Consideration of the structural features of ion-exchange celluloses suggests that the sorption of various substances on them will be extramicellar in nature; the intradiffusional stage of sorption is practically excluded here.

The extramicellar nature of the sorption and the high degree of dispersion of ion-exchange celluloses (particle diameters of the order of 10–20 μm) should theoretically produce a more rapid sorption than on ion-exchange resins. With inorganic ions and low-molecular-weight organic substances the time required for establishment of sorption equilibrium is probably limited by the time of the extradiffusional stage of sorption. It may well be, however, that with high-molecular-weight substances the time required for the establishment of sorption equilibrium will also depend significantly on the time required for the actual act of sorption.

The literature contains extremely scanty information on the kinetics of sorption of substances on ion-exchange celluloses. When the sorbent is stirred with a solution of calcium ions, the equilibrium for the sorption of $Ca^{2+}$ by SE- and P-celluloses in various ionic forms is attained in 10 s, which corresponds to the time required for the external diffusion of the inorganic ions being exchanged[14]. With DEAE-cellulose equilibrium is established in the exchange of chloride and iodide ions in slightly more than ~ 30 s, i.e. as with ion-exchange resins, sorption by anion exchangers is slower than by cation exchangers. This difference may reflect the influence of the rate of the chemical stage of sorption, which is not always instantaneous. Gusev[15] studied the kinetics of sorption of $Na^+$ and $Fe^{3+}$ ions under somewhat unusual conditions, with sorption of the ions by a dense layer of CM-cellulose, and found the sorption by the surface of the dense cellulose layer to be very rapid, while further sorption inside the layer was very slow, sorption equilibrium being established in 3 h. This result is only comprehensible if, under the conditions indicated, the time required for establishment of the equilibrium is determined by diffusion inside the very dense

layer of sorbent (internal diffusion). However, such conditions do not apply in chromatographic experiments. Gusev also found the rate of sorption to be greater in acid than in neutral media; this effect is also observed with ion-exchange resins, and is associated with the greater swelling of the ion exchangers in acidic media and the greater mobility of the hydrogen ions which participate in the exchange.

Nikolaev[16] has shown that equilibrium is established in 5 min in the sorption of proteins and enzymes on ion-exchange celluloses.

There is very little information available on the sorption isotherms for various compounds on ion-exchange celluloses. Nikolaev[16] investigated the statics of the sorption of asparaginase from 0.08 M NaCl and from buffer solutions of pH 7.0 and 6.5; he obtained a sorption isotherm of convex shape.

There is a little information available on sorption series for some ion-exchange celluloses; for example, Head and coworkers[17] obtained the following sorption series for P-cellulose: $U^{4+} > UO_2^{2+}$; $Th^{4+} > Fe^{3+} > La^{3+} > H^+ > Cu^{2+}$; and $Ca^{2+} > Na^+$. These agree with results obtained for phosphate resins. Veder and coworkers[18] established the following sorption series for anions with ECTEOLA-cellulose:

citrate > formate > $HPO_4^{2-}$ > $SO_4^{2-}$ > phthalate > > salicylate > succinate > glutamate > $NO_3^-$ > > benzoate > $Br^-$ > propionate > tartrate > > caproate > $Cl^-$ > lactate > acetate > $I^-$ > > ascorbate > glycerate.

In investigating the sorption of compounds on ion-exchange celluloses, due account must be taken of the possibility of complex-formation between the ions and the ionogenic groups or other ions in the solution[17,19].

It is evident from this review that the properties of ion-exchange celluloses have been very little studied. Practically no information is available on the mechanisms of the sorption processes or the quantitative laws of sorption of inorganic and organic compounds on cellulose ion exchangers, but this gap in our knowledge will obviously be filled by appropriate studies in the near future.

## IV. TECHNIQUE OF THE APPLICATION OF ION-EXCHANGE CELLULOSES

### Choice of Sorbent

Ion-exchange celluloses are selected on the basis of their properties and the composition of the mixtures to be separated. DEAE-cellulose is usually employed for the separation and analysis of proteins. About 80% of published work on the use of ion-exchange celluloses relates to the chromatographic analysis of proteins, and 75% of this is concerned with the use of DEAE-cellulose, ~ 20% with CM-cellulose, and ~ 3% with TEAE-cellulose; this information is taken from Serva's catalogue[12], and is illustrated in Table 2, which is based on the catalogue but which we have supplemented.

DEAE-cellulose is used for the separation of enzymes and proteins having isoelectric points at a neutral or acid pH, and for the purification of viruses and chromatography of polysaccharides, peptides, and nucleotides; TEAE-cellulose is used similarly, and in some cases gives cleaner separations of proteins and other high-molecular-weight compounds. AE- and GE-celluloses have not yet found wide application. Good separations of nucleic acids and viruses are attained with ECTEOLA-cellulose. CM-cellulose is used for the analysis of neutral and basic proteins.

The strongly acidic celluloses such as SE and P are generally employed for the chromatography of low-molecular-weight substances. PAB-cellulose is in a class of its own. In its primary form it can be used to separate nucleic acids, but it has one important specific property: the amino-group is readily diazotised, and then couples with proteins, enzymes, antigens, and other materials. Because of this, PAB-cellulose can act as a selective sorbent; for example, a PAB-azoantigen selectively absorbs antibodies, PAB-azohistone and PAB-azoguanine selectively absorb nucleotides, and PAB-azotyrosine selectively absorbs tyrosinase. Enzymes attached to PAB-cellulose lose their activity. The discovery of this sorbent opens up new possibilities in chemistry and biochemistry. The production of specific sorbents is extremely important for the development of sorption technology and chromatography.

Ion-exchange celluloses are used in column, paper, and thin-layer chromatography and in drop sorption techniques. The experimental procedure in each of these methods is different, and must be dealt with separately.

### Column Chromatography

Columns of ion-exchange cellulose with a length to diameter ratio of 10 : 1 are usually employed; the size of the column and hence the amount of cellulose are selected in accordance with the amount of mixture to be separated, the separating ability of the column, and the required yields of the separated components of the mixture.

Organic substances are generally separated by displacement or elutive column chromatography, with buffer solutions as eluting solvents. Experience has shown that best results are obtained if the sorbent is first treated with the buffer solution which is to be used as eluent, thus becoming saturated with the ions and other components in equilibrium proportions.

Work with ion-exchange celluloses has shown[20] that in some cases, particularly with concentrated eluate solutions, the chromatography is accompanied by partial dissolution of the cellulose, so that dissolved cellulose fragments. polysaccharides with ionogenic groups, pass into solution; this may lead to errors. This effect can be detected or tested for by analysis of the eluate for polysaccharides[21,22]. The eluate can be readily freed from such impurities, for instance by passage through small columns of ion-exchange resins[23].

Account should also be taken of the possibility of decomposition of the cellulose by the enzyme cellulase[24,25]. Some ion-exchange celluloses are stable towards the action of this enzyme, but some are not[24]; the former group includes P-, SM-, and CM-celluloses, and the latter DEAE-cellulose and the cellulose prepared from Whatman paper.

The cellulose ion exchangers employed in chromatographic analysis can be regenerated by the usual method[26].

Ion-exchange celluloses withstand the not unduly prolonged action of strong acids and alkalis[17].

TABLE 2. Bibliographic index of the applications of ion-exchange celluloses.

| Material | Sorbent | Ref. |
|---|---|---|
| Acetylenemonocarboxylate hydrolase | DEAE | 147 |
| Acetyltrypsin | DEAE | 148 |
| Acetyltrypsinogen | DEAE | 149 |
| Adenosine 5'-phosphate | CM, DEAE | 131 |
| Alanine-activating pH 5 enzymes | DEAE | 132, 133 |
| Albumen (human blood serum) | CM, DEAE | 134–136 |
| Alcohol dehydrogenase | CM, DEAE | 139, 140 |
| Aldehyde dehydrogenase | CM, DEAE | 137 |
| Aldolase | DEAE | 138 |
| L-Amino-acid oxidase | DEAE | 142 |
| Amino-acids | DEAE | 120 |
| Aminoacyl-RNA enzymes from ribosomes | DEAE | 144 |
| Aminoacyl-RNA synthetase | DEAE | 143 |
| γ-Aminobutyraldehyde dehydrogenase | DEAE | 145 |
| Aminoglucosidase | DEAE | 141 |
| Aminooxidase | AE | 84 |
| Antiserum (diphtheria) | SE, SM | 146 |
| Asparaginase | DEAE | 16 |
| Carbamoylphosphate synthetase | DEAE, P-cellulose | 235 |
| Carbonic anhydrase | DEAE | 236 |
| Carboxypeptidase | DEAE | 237 |
| Catalase | DEAE | 238, 239 |
| Cathepsin | DEAE | 239 |
| | DEAE, CM, SM | 240 |
| Cell proteins | DEAE | 241 |
| Cell stimulating hormones | CM | 242 |
| Ceruloplasmin | DEAE | 244, 245 |
| Chloroperoxidase | DEAE | 369, 370 |
| Chymotrypsinogen | CM, DEAE | 371 |
| α-Chymotryptsinogen derivatives | CM | 372 |
| Cobalamine | DEAE | 243 |
| Collagen | CM | 127 |
| Collagenase | DEAE | 246 |
| Corticotropin | DEAE | 247, 248 |
| Creatinine deaminase | DEAE | 249 |
| Creatinine transaminase | DEAE | 249 |
| Cytochrome c | CM | 82, 373 |
| DNA | ECTEOLA | 96, 98, 99, 212–218 |
| DNA polymerase | DEAE | 219, 220 |
| Deoxyribonuclease | DEAE | 225, 226 |
| Deoxyribonucleotides | CM | 171, 227 |
| Diaphorase | DEAE, ECTEOLA | 221–224 |
| Dihydroxydehydrase | DEAE | 229 |
| Diphosphogalactose-4-epimerase | DEAE | 228 |
| Elastase | CM | 230 |
| | | 60, 374, 375 |
| | DEAE | 233, 375 |
| Enolase | SM | 376 |
| Enzymes of calf thymus | DEAE | 351 |
| Ferritin | DEAE | 352 |
| Fibrinogen | DEAE | 353 |
| Flavin nucleotide | DEAE | 300 |
| Flavone | CM | 354 |
| Folic acid derivatives | TEAE | 299 |
| β-Galactosidase | DEAE | 167 |
| | TEAE | 168 |
| Gelatin | CM | 231 |
| γ-Globulin | CM | 154, 186 |
| Glucopeptides | DEAE | 202 |
| α-Glucoprotein | DEAE | 203 |
| Glucose-6-phosphate | DEAE | 190 |
| Glucose-6-phosphate dehydrogenase | DEAE | 187–189 |

In the chromatographic separation of mixtures of substances on ion-exchange celluloses by displacement chromatography with buffer solutions, the distribution constants or sorption factors of the components, the differences in which determine the success of the chromatographic separation, depend on the pH of the solution and the concentration of salts present in it. Optimum conditions for the separation can be found by proper selection and control of the pH and the concentration of salts and other components in the eluent. Experience with various sorbents, including ion exchangers, has shown that the effective separation of mixtures of organic substances by displacement column chromatography requires the use not of a single eluent, but of several eluents in succession, or an eluent of continu-

ously varying composition. This has brought into use such methods of chromatography as single-stage, multistage, and continuous gradient elution.

Several devices exist for setting up concentration gradients [12], differing in how the eluent concentration varies with time.

Elution gradients, their theoretical prerequisites, and practical methods for obtaining them have been actively discussed in the literature, particularly in connection with the use of ion-exchange celluloses [20,27-34].

The choice of eluent and the forms of gradient are greatly dependent on the mechanism of sorption of the dissociable organic substances on the ion exchangers. Unfortunately, this has been very little investigated, either theoretically or practically. In this Review we can only touch upon some of the general theories relating to this type of sorption.

Dissociable organic compounds are usually amphoteric, i.e. according to the pH of the solution they dissociate predominantly by scission of acidic (hydrogen ions) or basic (hydroxide ions) from ionogenic radicals. The organic molecules will exist as neutral molecules and anions in the former case, and as neutral molecules and cations in the latter, the relative amounts of neutral and ionic molecules depending on the degree of ionisation of the ionogenic radicals in the molecule. At a certain pH — the isoelectric point — the dissociation of both types of ionogenic group is equally probable, and the dissociating molecule takes on the properties of a dipolar ion (zwitterion).

The sorption of dissociable organic compounds on ion exchangers is a complex process which may involve all types of bonding.

Since ion exchangers are polar sorbents containing ionogenic groups having ionic bonds, one of the main mechanisms of sorption of dissociable substances on ion exchangers is that of ion-exchange sorption. As in the case of inorganic substances, ion-exchange columns can be used to find the nature of organic compounds, their ionic constitution, etc.; for example, at a given pH "basic" compounds will be firmly sorbed on cation exchangers and loosely held on anion exchangers.

The sorption of dissociable organic compounds is greatly influenced by the nature of other ions present in the solution; these include hydrogen and hydroxide ions, the concentrations of which define the pH of the solution. The ions will combine both with the sorbent and with the dissociating organic ions in the solution.

The distribution of other ions present between the sorbent and the organic molecules in solution depends on the corresponding bond energies and the ionic concentrations. These ions and the ions of the organic compound will compete for the sorption sites in the ion exchanger, and changing the concentration of the former ions will therefore alter the distribution coefficients for the organic material being sorbed. One general feature is observed in this process: the sorption of the dissociating organic compound will decrease as the concentration of other ions is increased, because the latter will utilise more and more of the available ionic bonds in the ion exchanger and in the dissociating organic molecules. The other ions present thus act as a barrier which hinders the sorption of the dissociating organic compound. For this reason, solutions of electrolytes, such as buffer solutions, are used to elute the sorbed organic substances. Experience with the chromatography of organic substances has shown that some are not eluted, after introduction into the column of sorbent (or onto the paper). This means that such organic materials do not dissolve in the eluent employed. However, if the concentration of salts in the eluent is slowly raised, a certain "critical" concentration is reached when the organic material becomes almost completely soluble and begins to move at the flow rate of the eluent. Because each component has its own critical elution concentration, gradient elution can achieve an efficient separation of a mixture of organic substances. This method of chromatographic separation was discovered by Tiselius [35,36] in the chromatographic analysis of proteins, and has sometimes been called the "all or nothing" method or "salting-out" chromatography.

One further application of gradient elution must be mentioned. One of the negative effects in the chromatographic separation of mixtures of substances is the spreading of the fronts of the chromatographic zones, and gradient elution is one of the methods available for overcoming this. In gradient elution the forward and rear boundaries of the chromatographic zones occur at different eluent concentrations, lower at the forward edges and higher at the rear edges, so that at the rear boundary regions the conditions are such that the sorption of the substance is less than at the forward boundary. This means that desorption will be greater at the rear than at the front, and the chromatographic zones will become narrower and form sharp peaks, so improving the efficiency of the chromatographic separation.

## Paper Chromatography

Ion-exchange chromatographic paper is also used analytically. A detailed bibliography and description of working with ion-exchange paper can be found in a Czech monograph [2]. Several firms produce ion-exchange paper for chromatography in addition to powdered ion-exchange cellulose.

Two methods are used for chromatography on ion-exchange paper [37]: with a "dry" and with a "wet" start. In the former, which is generally used in paper chromatography, the eluting solvent is absorbed by the dry paper, and in the latter the paper is first impregnated with the buffer solution and is then used similarly to an ion-exchange column.

Knight has shown that the "dry" start method gives a better separation of amino-acids [38].

## Thin-Layer Chromatography

In recent years much success has been achieved by the use of the so called thin-layer chromatography, first suggested by Izmailov and Shraiber [39] and developed by Stahl [40,41]. Nikolaev [42] has reviewed this field in detail.

The essence of the method is that the sorbent is mixed with some cementing or binding material (such as gypsum), and the resulting paste is then deposited in a thin layer ($\sim 0.5$ mm) on a glass plate. This thin layer is the analogue of the column or sheet of chromatographic paper. One- or two-dimensional chromatograms can be obtained. The main advantage of thin-layer chromatography is that, because of the fine dispersion ($< 25$ $\mu$m) of the sorbing material deposited on the glass plate, there is very rapid

capillary uptake of the solvent, and the chromatography takes very little time. Clean separations of mixtures can be achieved on 10 × 10 $cm^2$ or 15 × 15 $cm^2$ plates. Ion-exchange celluloses can be used as sorbents in thin-layer chromatography, and the Serva company provides prepared mixtures of ion-exchange cellulose powders with cementing material, specially designed for thin-layer chromatography [12].

The following procedure is recommended for the preparation of the plates. 10 g of the sorbent is mixed with 60–80 ml of water, and the paste is spread in a thin even layer on the plate with a special frame or other device. The success of the chromatography depends very much on the preparation of the thin layer, and it is very important to have an even thickness. The glass plate must have a good plane and even surface. The deposited sorbent layer is dried in the air at room temperature. The sample is introduced on to the sorbent layer with a micropipette, and the plate is placed vertically with its edge in the eluting solvent. The eluent front moves at a rate of 10 cm in 15 min.

As in paper chromatography, a very convenient method for developing the chromatograms, in addition to the use of indicator reagents, is to use ultraviolet light; for example, nucleotides show up as dark spots in ultraviolet light ($\lambda$ = 253 m$\mu$m), and proteins can be detected in ultraviolet light after heating the moist chromatogram for several minutes at 150°.

### Fractional Sorption

Hess and Walter have shown [43] that selective separation of individual components from the test material can in some cases be achieved simply by adding the ion-exchange cellulose to the substrate; for example, certain dehydrogenases have been selectively extracted from plasma proteins. This procedure has been called fractional sorption, and has found application as a rapid method in clinical diagnostics, specially standardised DEAE- and CM-cellulose being available for this purpose [12].

## V. USES OF ION-EXCHANGE CELLULOSES

### Chromatography of Proteins

The first systematic studies in the development of the chromatography of proteins on ion-exchange celluloses were made by Sober, Peterson, and their coworkers [8-10,44], who used column chromatography to analyse the proteins of human and horse blood plasma on the anion-exchange DEAE-cellulose, by means of the gradient elution method. The protein content of the individual fractions was found spectroscopically. In addition the fractions were further subjected to electrophoretic separation. It was found that with a decreasing pH gradient and an increasing salt concentration the proteins generally left the column in the order of decreasing isoelectric points. The column of anion exchanger was saturated to the extent of 170 mg of protein per gramme of sorbent. The new method gave a considerably better separation than electrophoresis. The Sober–Peterson method was later applied to the separation of blood serum proteins by many other workers [45-50], using gradient elution with DEAE-cellulose [10,46,49] or CM-cellulose [45,47,50].

Kogent and Broda [46] evolved a chromatographic separation of the high-molecular-weight compounds contained in blood serum and not precipitated by sulphosalicylic acid, using DEAE-cellulose in a phosphate buffer. In their study of normal and pathological blood serum they found these compounds to be mucopolysaccharides.

Morrison and Cook [45] showed that good results in the separation of proteins can be obtained with CM-cellulose. Hess and Walter [43] used ion-exchange celluloses for the analysis of blood proteins in clinical diagnostics. Sober and coworkers [51] used chromatography on ion-exchange celluloses to show that human and horse CO-haemoglobin is less homogeneous in protein composition than dog haemoglobin.

CO-haemoglobin has been analysed chromatographically several times, using CM-cellulose the eluent being 0.01 M phosphate buffer with a "convex" pH gradient from 6 to 8. [52-54] In addition to the chromatographic separation of the proteins, pure globulin was obtained in preparative quantities. Blood haemoglobin has also been analysed by chromatography on ion-exchange celluloses by many other workers [55-58], and the method has been used for the chromatographic analysis of various other proteins: meromyosin [59,60], *l*-myosin [61], insulin [62], $\beta$- and $\gamma$-casein [63], $\gamma$-globulins [64], $\beta$-lactoglobulin [65], and others.

Complex biological materials such as egg protein [66,67] and milk proteins [68,69] have also been analysed chromatographically. Previously unknown proteins have been discovered by chromatography on ion-exchange celluloses, for example in egg protein by Rhodes and coworkers [67] using elutive chromatography on CM-cellulose.

Several papers have been published on the separation of plant proteins [70,72]. As yet unidentified protein fractions have been found in soya bean proteins [71], and six protein fractions have been detected in barley proteins [70].

### Chromatography of Enzymes

Chromatography on ion-exchange celluloses has been successfully used for the separation and isolation of enzymes. Arne [73] used a column of TEAE-cellulose to analyse gastric invertase and maltase; the latter consists of three components, while the former is a single enzyme.

Taborsky [74] separated ribonuclease into four components by chromatography on CM-cellulose.

Ispolatovskaya et al. [75,76] used DEAE- and ECTEOLA-cellulose for the separation and preparative isolation of leucitinase, pologenase, and hyaluronidase of bacterial toxin.

Others have also analysed enzymes by chromatography [77,78].

Many papers have been published on the purification of enzymes by means of ion-exchange celluloses [79-88]; for instance, the dehydrogenase isolated from rat liver was purified with DEAE-cellulose, its activity increasing 250 times [86], and the alkaline phosphatase activity of the enzyme isolated from human intestines and liver was increased 15–140 times [87].

A 50-fold purification of yeast carboxylase on a column of CM-cellulose has been described; the resulting enzyme retained its activity at 5° for a prolonged period. Ion-exchange celluloses have been used to purify hormones [89-91], antigens [92,93], and plasmogen [94].

Brown[95] has developed a procedure for the preparative isolation of pure myoglobin from crude muscle extracts using large columns of ion-exchange cellulose, and Nikolaev has shown that proteins may be concentrated by means of columns of DEAE-cellulose[16].

## Chromatography of Nucleic Acids and Nucleotides

Bendich and coworkers[96] were the first to use ion-exchange celluloses for the separation and analysis of nucleic acids; they tested a number of celluloses, and obtained best results with ECTEOLA-cellulose. They achieved chromatographic fractionation of DNA differing in the composition of the heterocyclic bases. Other workers have also carried out chromatographic fractionation of DNA with ECTEOLA-cellulose[97-99] or DEAE-cellulose[100].

Staehelin and coworkers[101,102] used DEAE-cellulose in their investigation of the nucleotide sequence in RNA. By chromatography of the hydrolysate of yeast RNA treated with pancreatic RNA-ase, they observed a whole range of different mono- and poly-nucleotides: the mononucleotides uridylic and cytidylic acids; the dinucleotides AC, AU, GC, and GU; the trinucleotides AAC, AAU, GAC, AGC, GAU, AGU, GGU, and GGC; and some tetranucleotides. Even the nucleotide isomers GAC and AGC were readily separated.

Mihalyi and coworkers[103] have used ECTEOLA-cellulose for the removal of RNA from muscle myosin; the chromatography separates the RNA from the protein, the RNA/protein ratio being 1.3 before and 0.02 after. In some experiments the protein content of the RNA fraction was reduced by a factor of 50–60. Ward and Putch[104] used ECTEOLA-cellulose to separate a mixture of DNA and RNA.

Reference may also be made to other work in which ion-exchange celluloses have been used for the separation of nucleic acids and nucleotides[105-108].

ECTEOLA- and DEAE-celluloses have also been used for separating and purifying viruses[109-113]. Thus Hayer and Bolton[111] separated and purified certain animal viruses in this way. The prospects of this method for virology and in particular for the production of vaccines are obvious.

Randerath[114] separated a mixture of nucleotides by thin-layer chromatography in 5 minutes using ECTEOLA- and DEAE-cellulose.

## Chromatography of Low-Molecular-Weight Organic Substances

Rouser and coworkers[115] used columns of DEAE-cellulose to separate the lipids isolated from whole beef brain and found the composition to be cholesterol 20.3%, ceramide 0.3%, cerebroside 16.8%, cerebroside sulphate 3.5%, lecithin 11%, phosphatidylethanolamine 17%, and other constituents.

Heri and Neukom[116] carried out a successful separation of the pectins isolated from beet and apples on DEAE-cellulose, obtaining fractions differing in their content of arabinose and galactose and in the degree of etherification and polymerisation. The greater the degree of polymerisation and the lower the degree of etherification, the more firmly were the pectins retained on the DEAE-cellulose.

Elutive chromatography on a column of DEAE-cellulose was used by Muller and coworkers[117] to separate five polysaccharide fractions, differing in their content of uronic acids, from soil. Ion-exchange celluloses have been employed for the isolation of seromucoids from blood serum[118].

Pawelkiewicz[119] used an ion-exchange cellulose for the isolation and purification of vitamin $B_{12}$.

The use of ion-exchange celluloses for the separation of amino-acids has been investigated[38,120,121]. Ion-exchange celluloses have no particular advantages over ion-exchange resins in the column chromatography of amino-acids[120].

Ion-exchange celluloses have been successfully employed for the separation of AMP, ADP, and ATP,[101] peptides[122] and sugarphosphates[17].

## Chromatography of Inorganic Ions

Head's work on the analysis of inorganic substances by chromatography on ion-exchange celluloses has already been mentioned. He found that $Fe^{3+}$, $Ce^{4+}$, $UO_2^{2+}$, $U^{4+}$, $Th^{4+}$, and $ZrO^{2+}$ ions are strongly absorbed from acid solutions by P-cellulose, which is not observed with resins of the sulphonic acid type. These ions can be eluted with reagents which form stable complexes with them, for example $Th^{4+}$ and $UO_2^{2+}$ are quantitatively eluted with 10% $(NH_4)_2CO_3$ solution, $Fe^{3+}$ with chloroacetic acid, $ZrO^{2+}$ with ammonium fluoride, etc.

Head and coworkers also successfully separated mixtures of Bi and Pb, Cu and Pd, Cu and Co, and Cu and Ni; for example, Bi and Pb were separated by eluting Pb with 1 *N* $HNO_3$ and Bi with 1 *N* HCl, in which it forms anionic complexes; and Cu was separated from Cd, Co, and Ni by elution of these with 1 M $MgCl_2$, followed by desorption of the copper remaining on the column by passing HCl.

Cerrai and Testa[19] prepared a new type of anion-exchange cellulose, TOAC (tri-n-octylaminocellulose), with the very high capacity of $\sim 1$ mg-equiv. $g^{-1}$; with this they separated a mixture of $Fe^{3+}$, $Co^{2+}$, and $Ni^{3+}$, using 0.8 M HCl as eluent. Iron and cobalt form anionic complexes in HCl and are sorbed by the anion exchanger, while nickel does not form complexes and moves with the eluent. The Co and Fe are separated by elution with 3 M HCl, which desorbs Co but not Fe. Differences in ion-exchange sorption and complex-forming ability have also been used to separate a mixture of Th, Zr, and U, and such mixtures as La and Th, Zr and La, and Zr and Hf have also been successfully separated.

## Use of Ion-Exchange Paper and Thin-Layer Chromatography

Ion-exchange paper chromatography has been successfully used to separate amino-acids[38], barbiturates[123,124], organic acids[125], proteins[126], inorganic ions[127-129], and other materials.

Curtain[126] separated blood serum proteins on DEAE-cellulose of ion-exchange capacity $\sim 0.003$ mg-equiv. $cm^{-2}$, using gradient elution with pH and ionic strength gradients, established with a programmed photoelectric device. Albumin and $\beta$- and $\gamma$-globulins were separated on a paper strip.

Street [123,124] used DEAE-paper to separate a mixture of 5,5-substituted barbiturates, with t-$C_5H_{11}OH$–0.1 M EDTA disodium salt (1 : 1) as eluent, by circular chromatography. He was able to separate a mixture of phenobarbitone, barbitone, butanobarbitone, and quinobarbitone. The chromatographic zones were inspected in ultraviolet light.

Myhre [125] has described the separation of organic acids on CM-paper, using butanol–ethanol–water (4 : 1 : 5) as the mobile phase. Gluconic and glucuronic acids are better separated on a more acid cellulose.

Kember and coworkers [127] used phosphorylated paper for the separation of cations, and paper treated with 2-aminoethanesulphonic acid for the separation of anions.

Cerrai and Testa [128] have investigated the behaviour of inorganic cations on ICBL1 paper treated with 0.02 *N* tri-n-octylphosphine oxide in cyclohexane. As the mobile phase they employed HCl, $HNO_3$, and $H_2SO_4$ solutions of various concentrations, and they indicated the dependence of the $R_F$ value on the acid concentration for 50 metal cations. Mixtures such as Sr–Y, Bi–Hg–Pt, U–Mo–Y–La, Th–Y–La–Ca, and U–Tl–Fe–Ge were successfully separated.

An anion-exchange paper prepared by treating Whatman paper with tri-n-octylamine has been used to separate the mixtures Fe–Co–Ni and Zn–Co–Mn–Ni, making use of the ability of these metals to form anionic complexes in HCl [22].

By thin-layer chromatography on ion-exchange celluloses, Randerath and Struck [37] were able to separate complex mixtures of heterocyclic bases and nucleotides. They used 10 g of ECTEOLA, CM-, or DEAE-cellulose in a thin-layer on a plate, with ~ 2–5 μg of material taken for the chromatography. Water was used as the mobile phase, the front moving at a rate of 10 cm in 3 min.

The following $R_F$ values were obtained for a number of bases: adenine 0.30, adenosine 0.53, hypoxanthine 0.55, inosine 0.70, guanine 0.37, guanosine 0.58, uracil 0.72, and uridine 0.81. Nucleotides were separated with butanol–acetone–acetic acid–5% $NH_4OH$–water (4.5 : 1.5 : 1 : 1 : 2); the rate of movement of the front was ~ 10 cm in 1 min. The following $R_F$ values were obtained: AMP 0.38, CDP 0.22, UTP 0.13, ADP 0.26, and ATP 0.16.

Randerath has published a fuller review of the uses of thin-layer chromatography on ion-exchange cellulose [130].

IV. Applications of monodisperse aerosols 127

## I. INTRODUCTION

Almost all the properties of aerosols depend to a marked extent on the particle dimensions, and the establishment of these relationships is the chief aim of many aerosol studies. Since all real aerosols are more or less polydisperse, it is necessary, in the experimental study of these relationships, that the quantity to be determined in a polydisperse aerosol with a mean particle radius $\bar{r}$ coincides with the corresponding quantity in a monodisperse aerosol with the same particle radius. The error thus introduced increases with increase in the polydispersity of the aerosol, so that in the last twenty years there has been an ever-increasing tendency in aerosol studies to use aerosols which are as far as possible monodisperse.

In one extremely important case, however, namely in the study of various processes of aerosol deposition, for example in filters, breathing apparatus, etc., it is also possible to use polydisperse aerosols. In this case the total concentration of particles and their distribution with respect to dimensions in the original aerosol and in the aerosol which has passed through the filter or been deposited on it are determined, and the efficiency of the filter for all the particle dimensions of the aerosol is calculated. The precise determination of the total concentration of particles and their distribution with respect to dimensions, even within a fairly narrow range of the latter, is a complex and extremely tedious task, however. This method can thus be recommended only for preliminary measurements, and for accurate studies it is best in most cases to work with an aerosol with the maximum degree of monodispersity attainable by modern methods of preparation. Such aerosols may be described as "practically monodisperse", and it is to these that we shall be referring in the present review.

The degree of monodispersity is conveniently characterised by the magnitude of the coefficient of variation $\alpha$, i.e. the ratio of the standard deviation of the particle radii $\sigma$ to the mean radius $\bar{r}$:

$$\alpha = \frac{\sigma}{\bar{r}} = \left[\frac{\sum_i^N (r_i - \bar{r})^2}{N}\right]^{1/2} \Big/ \bar{r}. \qquad (1)$$

Since the distribution of particles with respect to dimensions in aerosols usually deviates appreciably from the normal gaussian distribution and approximates to a logarithmic-normal distribution, the degree of monodispersity, at values of $\alpha$ which are not too small, is conveniently expressed by the value of the logarithm of the geometric mean square deviation:

$$\sigma_g = \left[\frac{\sum_i^N \left(\ln \frac{r_i}{r_g}\right)^2}{N}\right]^{1/2}, \qquad (2)$$

where $r_g = \left[\prod_i^N (r_i)\right]^{1/N}$ is the geometric mean radius of the particles. For low values of $\alpha$, when $\bar{r} \simeq r_g$, $\ln(r_i/r_g) \simeq (r_i - r_g)/r_g$ and

$$\sigma_g \simeq \left\{\frac{\sum_i^N [(r_i - r_g)/r_g]^2}{N}\right\}^{1/2} \simeq \alpha. \qquad (3)$$

Fig. 1 gives the logarithmic-normal distribution curves for $\sigma_g = 0.1$ and 0.2, and also the normal distribution curves for $\alpha = 0.1$ and 0.2. The choice of criterion for "practical monodispersity" is of course arbitrary. The present review deals with aerosols with $\alpha \leq 0.2$ or $\sigma_g \leq 0.2$. Not all authors have calculated $\alpha$ for the aerosols which they have prepared. Sometimes only the distribution curves or histograms are given, and in some cases only the range of radii containing a certain percentage of the particles. In these cases we calculated $\alpha$ with the accuracy assumed for the data given in the work cited.

Here mention must be made of the methods used to determine the degree of monodispersity of aerosols. The most reliable methods naturally involve the direct determination of the dimensions of a large number of individual particles by means of an optical or electron microscope, ultra-microscope (from the rate of sedimentation of the particles), photoelectric counter, or other methods, followed by statistical treatment of the results of the measurements. Unfortunately, these methods are not always applicable, particularly for aerosols from volatile liquids, whose particles undergo appreciable volatilisation during the removal of the specimens and the actual measurements. It is extremely difficult to eliminate evaporation. Moreover, in the measurement of liquid droplets by means of an optical microscope, it is necessary to make allowance for their spreading over the support, and only preliminary studies of the measurement of droplets with the electron microscope have been made. The measurement of the rate of sedimentation of particles or the rate of movement in an electric field by means of the ultra-microscope is possible[1] only for a particle radius greater than 0.15 $\mu$m, and the errors in the determination of the dimensions of individual particles, associated with brownian movement, lead unavoidably to high values of $\alpha$.

Another method for estimating the monodispersity of aerosols, which has been widely employed, is the optical method based on the fact that the scattering of white light in more or less monodisperse systems of spherical particles produces spectral colours which are purer the higher the degree of monodispersity. If the observer looks through the aerosol towards the light beam, he sees, surrounding the light source, a "halo" consisting of coloured rings whose angular diameter is simply related to the particle dimensions and the length of the corresponding light

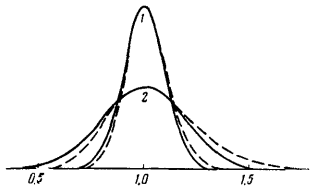

Fig. 1. Normal (solid line) and logarithmic-normal (broken line) distribution curves.

waves. The "halo" method is applicable at $\bar{r} > 1$ μm and is used in the study of fogs formed by the adiabatic expansion of air containing the vapour of water or other volatile liquid and also in the study of natural clouds and fogs. In the latter case the sun or moon is the light source.

When $\bar{r} < 1$ μm, the aerosol is introduced into a vertically-arranged cylindrical vessel with transparent walls and a narrow beam of white light is passed in a direction perpendicular to the axis of the cylinder. In the case of an aerosol which is monodisperse and has a sufficiently high concentration, spectral colours, which show a periodic variation with change in the angle of observation, are visible in the vessel. These diffraction spectra, which were first observed in monodisperse sols of sulphur by Ray[2] and were studied in detail by La Mer and coworkers[3-5], have been called "higher-order Tyndall spectra". A horizontal viewing-tube, focussed on the axis of the vessel and capable of rotating around it, is used to measure $\theta$, the angle of deviation of the red rays, for which $\alpha$ is obtained with the highest accuracy. The spectra are made more distinct by using a polaroid plate, which transmits only the component of the scattered light polarised in a vertical plane. The number of spectra increases with increase in the particle dimensions and is approximately equal to the particle radius in tenths of a micrometer. By means of special tables calculated on the basis of the Mie theory, it is possible to determine $\bar{r}$ from the values of $\theta$ corresponding to spectra of different orders; the position of the spectra depends comparatively little on the refractive index of the particles. This method is applicable for the approximate range $0.15\ \mu m < \bar{r} < 1.2\ \mu m$. The measurement of $\theta$ becomes impossible at lower values of $\bar{r}$, since the spectrum becomes indistinct, and becomes impossible at higher values of $\bar{r}$, because the spectra of different orders are crowded together[6]. The instrument used has been named the Owl.

It is impossible to give a precise answer to the main problem — at what degree of monodispersity do distinct Tyndall spectra appear? It first of all follows from the theory of the phenomenon that with increase in the degree of monodispersity the spectra should appear not immediately but gradually, so that different observers may disagree on the question of whether the spectra are present or absent. Moreover, the clarity of the spectra is influenced by a number of factors: the optical density of the system[7], the mean dimensions of the particles and their refractive index, the conditions of the observation — the thickness of the illuminating beam[8], stray light in the instrument, the shading in the laboratory, the unique features of the observer's vision, etc. The use of a polaroid plate has a marked effect on the clarity of the spectra. For a given value of $\sigma$ and $\bar{r}$, the possibility of observing the spectra also depends on the nature of the distribution curve, since the scattering of the light increases rapidly with increase in the particle dimensions. By using the ultramicroscope method to study the distribution with respect to dimensions for droplets of various non-volatile liquids in fogs produced in a Sinclair–La Mer generator (see below) with $\bar{r} = 0.3$–$0.9$ μm, Kitani[9-11] established that determination of $\theta$ for the red band is possible only for $\sigma \leqslant 0.12$ μm. According to Berner[12], who determined the dimensions of droplets in dioctyl phthalate fogs in the same range of values of $\bar{r}$ using Goetz's Aerosoloscope[13], the first red band can be observed at $\sigma \leqslant 0.14$ μm and the whole spectrum only at $\sigma \geqslant 0.10$ μm. From the data given by Goyer and Pidgeon[14], it follows that in an aqueous fog with $\bar{r} = 0.45$ μm, Tyndall spectra appear only at $\sigma \leqslant 0.09$ μm. In other papers the limiting value of $\sigma$ was not determined, but the quoted values of $\sigma$ at which the Tyndall spectra were or were not observed agree with the above data, with the following two exceptions.

La Mer's report[5] that the spectra disappear when equal volumes of two monodisperse hydrosols of sulphur with $\bar{r} = 0.467$ μm and $0.476$ μm are mixed is undoubtedly based on some major error, since mixing in this way can lead to an increase in $\sigma$ of only $0.004$ μm. In actual fact, according to Maron and Elder's observations[7], the Tyndall spectra are preserved when monodisperse latexes of polystyrene with $\bar{r} = 0.164$ μm and $0.196$ μm are mixed, although in this case the calculated value of $\sigma$ increases by $0.016$ μm. An analogous result was obtained by Petro[15], by mixing monodisperse hydrosols of sulphur with $\bar{r} = 0.310$ μm and $0.385$ μm.

According to Martius[16], who prepared condensation aerosols of dioctyl phthalate with $\bar{r} = 0.34$–$0.67$ μm, Tyndall spectra are observed in these aerosols only at $\sigma \leqslant 0.003$–$0.006$ μm. Such monodisperse aerosols cannot, however, be prepared by a condensation method, and this result is due to the elementary error which Martius made in making allowance for the influence of brownian movement on the scatter of the particle-radius values found by the ultramicroscope method.

Thus the appearance of Tyndall spectra is related to the value of not the relative ($\alpha$) but the absolute ($\sigma$) standard deviation. This is apparently due to the fact that the increase in monodispersity with increase in $\bar{r}$ at constant $\sigma$ is compensated by the simultaneous crowding together of the spectra of different orders.

The qualitative method of estimating monodispersity from the Tyndall spectra can also be developed quantitatively. The most accurate method is the "polarisation ratio" method, based on the measurement of the ratio $k$ of the intensities of the components of the light scattered by the aerosol and polarised in horizontal (parallel to the plane of scattering) and vertical planes. Here it is possible to illuminate the aerosol with monochromatic light of constant wavelength $\lambda$ and measure $k$ as a function of the angle $\theta$ of scattering (Kerker *et al.*[17-19]), or to carry out the measurements at constant $\theta$ (usually 90°) and varying values of $\lambda$ (Heller *et al.*[20,21]). This gives sinusoidal curves, which become flatter (the maximum and minimum values of $k$ approach) with increase in the polydispersity. For a given distribution of the particles with respect to dimensions, for example the logarithmic-normal law, these curves are calculated on the basis of the Mie theory, by means of computers, for different values of $\bar{r}_g$ and $\sigma_g$, and the results are compared with the experimental curves. The distribution parameters can be determined in this way with sufficient accuracy. For a constant value of the product $r_g \sigma_g$, close to the value of $\sigma$ given by formula (3), the nature of the curves changes little with increase in $\sigma_g$.[17] This agrees with the above condition for the production of the Tyndall spectra.

To enable the Tyndall-spectra method to be applied to particles with $\bar{r} < 0.2$ μm, La Mer[5,22,23] suggested that the particle size be increased by using solvent vapour which is in equilibrium with a solution of the aerosol material in the same solvent. The increase in size is determined by the concentration of the solution. The same concentration is also rapidly established in the aerosol droplets (if the Kelvin effect is neglected, see below). In this way La Mer was able to increase the particle size by a factor of 5–10

and to obtain Tyndall spectra in aerosols with an initial value of $\bar{r} \geq 0.02$ μm. In this "cultivation" of the aerosols, the value of $\alpha$, as a first approximation, should not change, but because of the Kelvin effect, it is necessary, in order to maintain equilibrium, that the concentration in the finer droplets be slightly greater than that in the larger droplets, i.e. the latter grow more than the former, so that $\alpha$ should increase slightly during "cultivation"[24]. At the same time the value of $\sigma = \alpha\bar{r}$ increases considerably during the "cultivation", and this possibly explains La Mer's observation[25] that the sulphuric acid fogs with $\bar{r} \geq 0.20$ μm, obtained in his generator, give Tyndall spectra, whereas highly-dispersed fogs with $\bar{r} < 0.1$ μm do not give these spectra on "cultivation".

## II. PREPARATION OF MONODISPERSE AEROSOLS BY CONDENSATION METHODS

A number of conditions must be observed in order to obtain monodisperse aerosols by condensation methods. Since the monodispersity decreases on coalescence, it is necessary to eliminate coalescence as far as possible during the preparation of monodisperse aerosols. From this it follows that the concentration given by the count (the number of particles in unit volume) of the aerosols generated should not be too high, or else they should be diluted considerably immediately after their formation. The maximum permissible concentration naturally depends on the time for which the aerosol being studied should remain unchanged under the conditions of the experiment. Since the aerosol coalescence constant under normal conditions has values of about $3 \times 10^{-10}$ cm$^3$ s$^{-1}$, we find that if the count concentration is to be decreased by not more than 5% after an experimental time $t$, the concentration should not exceed $1.7 \times 10^8$ cm$^{-3}$ for $t = 1$ s, $0.85 \times 10^7$ cm$^{-3}$ for $t = 20$ s, and $3 \times 10^5$ cm$^{-3}$ for $t = 10$ min.

The question of the conditions of formation of monodisperse "primary", i.e. non-coalesced, aerosols during the bulk condensation of a vapour is more complex. In this case it is obviously necessary that formation of all the aerosol particles should take place under exactly identical conditions, and in particular that the supersaturation be the same throughout the whole volume in which the condensation is taking place. This condition can be realised in practice only by producing the supersaturation by the adiabatic expansion of a vapour–gas mixture in a sufficiently large chamber, in which it is possible to neglect the decrease in supersaturation close to the walls, or by a homogeneous gaseous chemical reaction. In ordinary methods of generating condensation aerosols — by cooling a gas–vapour mixture in a heat exchanger or by mixing it with a cold gas — variations in the degree of supersaturation at different points in the gas stream and hence fluctuations in the size of the particles formed are unavoidable.

In spontaneous condensation of vapour, another unfavourable factor is introduced — the nuclei are not formed simultaneously, even when the supersaturation is constant throughout the volume. According to the general theory of new-phase formation, the rate of spontaneous formation of nuclei increases extremely rapidly with increase in supersaturation. Thus if the supersaturation were created instantaneously, the rate of production of new nuclei would decrease extremely rapidly as the supersaturation was eliminated, i.e. all the particles would have approximately the same age. Under real conditions, however, the supersaturation is produced at a finite rate and continues to increase for some time after the start of formation of the nuclei, passing through a maximum. The slower the increase in supersaturation, the less distinct this maximum, and the longer the time interval within which new nuclei may be produced. Thus spontaneous condensation generally leads to the formation of more or less polydisperse aerosols.

As in the case of colloidal solutions, aerosols with a much higher monodispersity are obtained by the "nucleus" method, i.e. by condensation on prepared (extraneous) condensation nuclei, which may be gaseous ions or highly dispersed aerosols of non-volatile substances. If these nuclei exhibit more or less identical activities, i.e. if the condensation of vapour on these nuclei begins at approximately the same supersaturation, an aerosol with an extremely high monodispersity should be formed.

In addition to the above factors which do not favour monodispersity in the formation of aerosols by condensation, there is a factor which effectively increases the monodispersity, namely the equalisation of particle dimensions during condensation growth. The rate of growth (increase in dimensions) of particles with a radius much less than the mean free path of the vapour molecules $l$ is independent of $r$, whereas when $r \gg l$ the rate of growth[26] is inversely proportional to $r$. Thus in the initial stage of the growth of nuclei of different ages the absolute difference in their dimensions remains constant, and later even begins to decrease. As a result, the relative difference in the size of the particles decreases appreciably as they grow. From this it follows, *inter alia*, that the degree of monodispersity of condensation aerosols should, generally speaking, increase with increase in the particle dimensions, as is observed experimentally. In this discussion we have neglected the increase in vapour pressure above very fine particles, but in the initial stage of the growth of the particles the supersaturation is usually fairly high, so that this factor is of no significance.

### 1. Preparation of Monodisperse Aerosols by the Adiabatic Expansion of a Vapour–Gas Mixture

From the above it follows that the most favourable conditions for the formation of monodisperse aerosols are achieved by condensing a vapour on prepared nuclei or by adiabatic expansion of a vapour–gas mixture. Unfortunately, this method has up to the present been used only to prepare fogs of volatile liquids, chiefly water, and the determination of the degree of monodispersity of the resulting fogs by direct measurement of the droplets is extremely difficult. For this purpose, only the optical methods described above can be used.

In the adiabatic expansion of moist atmospheric air containing a large quantity of condensation nuclei with widely differing activities, an extremely polydisperse fog is formed. If, however, this fog is allowed to disappear, partly by deposition of the droplets and partly by evaporation, the largest and most active (hygroscopic) nuclei will be removed, the total number of nuclei will be reduced considerably, and when the expansion is repeated a fog with a larger particle size and hence a higher monodispersity is formed. After several expansions, the purity of the halo colours indicates that extremely monodisperse fogs are produced[27].

2. Preparation of Monodisperse Condensation Aerosols in Generators of the Heat-Exchange Type

The nucleus method for preparing monodisperse aerosols from high-boiling substances was first applied by Sinclair and La Mer [28-31]. The generator which they designed in 1941 rapidly received extensive acceptance in aerosol studies. In this generator (Fig. 2) the liquid is placed in the vaporiser ($A$) — a 2 litre Pyrex flask placed in an air thermostat. Filtered air or nitrogen enters the vaporiser at a rate of not more than 4 litre $min^{-1}$, partly through a generator of condensation nuclei ($B$) and partly through a tube immersed in the liquid. The gas containing the vapour of the liquid, spray, and condensation nuclei passes through two narrow nozzles into a superheater ($C$) — a similar but empty flask placed in another thermostat at a slightly higher temperature. In the superheater the spray is vaporised, the contents of the flask are mixed, and the gas mixture passes into a condenser ($D$), 50 cm long and 2 cm in diameter, with air jacket, where the gas is slowly cooled and the vapour condenses, partly on the walls and partly in the space within the condenser, forming an aerosol. On leaving the condenser, the aerosol is diluted in the mixing vessel ($E$) with 10–100 times its volume of filtered air, to prevent coalescence.

Let us consider what happens in the condenser of the generator. In the vapour–gas mixture entering the condenser, the vapour is unsaturated, so that in the lower section of the condenser, only gradual cooling of the gas takes place under conditions of laminar flow, since the temperature of the gas near the axis of the condenser is higher than that at the walls. At a certain height, the dew point is reached at the walls and the vapour begins to condense there; the concentration of the vapour at the walls becomes less than that at the axis. In the absence of condensation nuclei (or when the rate of flow is too low), it is frequently found that almost all the vapour condenses on the walls, since the supersaturation is insufficient for spontaneous condensation in space. With an increase in the concentration of nuclei $n$, the ratio of the quantity of vapour condensed in space to that on the walls increases. Thus although the mean volume $v$ of the resulting droplets decreases, the product $nv$ increases. The dimensions of the droplets subsequently increase with increase in the concentration of vapour (at constant $n$), i.e. with increase in the temperature of the vaporiser. This makes it possible to control the particle size within certain limits. The temperature of the superheater has comparatively little influence on $\bar{r}$, however.

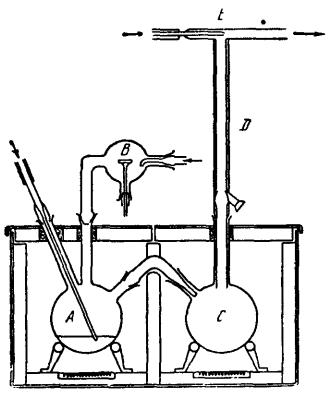

Fig. 2. Sinclair–La Mer generator.

To obtain aerosols with a low degree of dispersion corresponding to $\bar{r} > 1-2$ μm, a low concentration of nuclei and a high concentration of vapour are thus required. Since increase in temperature in the vaporising liquid may lead to its decomposition, it is recommended that the degree of vapour saturation of the gas be increased by bubbling the gas through a porous plate and by decreasing the rate of flow of gas through the nucleus generator [32-34]. Moreover, in the preparation of large droplets it is necessary to increase the duration of their growth, i.e. to use a longer condenser and to direct it not upwards but downwards, so that the rapidly-settling large droplets can leave the condenser. In this way it was possible to obtain monodisperse fogs of tetralin with $\bar{r}$ up to 27 μm. [33] On the other hand, La Mer used the generator to prepare an aerosol with $\bar{r} = 0.006$ μm; [35] but he was able to verify the monodispersity (by "cultivation") only for $\bar{r} > 0.02$ μm.

To obtain monodisperse aerosols with mean particle dimensions which do not change with time, a number of conditions must be satisfied in the Sinclair–La Mer generator. The temperature of the vaporiser should be constant to within 0.2 deg, otherwise, as we have seen above, the dimensions of the aerosol particles will change continuously. Because of the high heat capacity of the generator, the establishment of constant operating conditions requires about 6 h.

The purity of the vaporising liquid is extremely important — volatile impurities are particularly undesirable, since the dimensions of the particles decrease continuously as these are removed from the liquid. Since the liquid undergoes prolonged heating in the generator, it gradually decomposes, particularly when air is passed through; the walls of the vaporiser and superheater become covered with a deposit of decomposition products and the aerosol is no longer monodisperse [24]. It is therefore necessary to change the liquid and wash the generator at intervals. The decomposition is inhibited considerably in an inert gas atmosphere.

Thus the monodispersity of aerosols, generally speaking, increases with increase in $\bar{r}$, but it sometimes decreases sharply when a definite value of $\bar{r}$ has been reached [36]. This is probably due to the fact that spontaneous condensation of the vapour begins when the concentration of nuclei becomes too low. The same is observed when the vapour–gas mixture is cooled too rapidly in the condenser, for example when the flow rate in the condenser is too high [31].

It is also extremely important to have a constant concentration of condensation nuclei. Thus in the usual method of generating the nuclei, by the sublimation of sodium chloride or other substances, it is necessary to maintain the sublimation temperature and the rate of gas flow through the generator constant, since this affects the conditions of both the volatilisation and the condensation.

In agreement with theory, almost all authors report that aerosols obtained in the absence of nuclei are polydisperse (except for sulphuric acid aerosols, see below). The observations of Matijevich *et al.* [37] that in the production of AgCl aerosols the introduction of AgCl nuclei has no influence on the polydispersity of the aerosols ($\alpha$ = 0.20–0.25) are simply explained by the fact that these nuclei

were able to volatilise before condensation of the vapour on the nuclei had begun.

In most cases the nuclei are provided by highly-dispersed sodium chloride aerosols obtained by sublimation of the salt or, less frequently, by atomisation of dilute NaCl solutions followed by drying of the resulting fog [35,38]. Sometimes other salts, for example AgCl, [39] or metals [10] are sublimed; in the latter case a spark or arc discharge between metallic electrodes is frequently used [10,35,38]. In one method widely employed — sublimation of NaCl deposited on the surface of a nichrome wire which is made incandescent — allowance must be made for the fact that the salt recrystallises with the passage of time, so that the rate of its volatilisation and hence the concentration and dimensions of the nuclei decrease considerably [40]. It is therefore necessary either to "condition" the NaCl deposit for a prolonged period or to sublime the salt under conditions where the gas is saturated with its vapour [41].

Polydisperse aerosols containing large particles should not be used to provide nuclei. The use of an AgCl aerosol of this type gave polydisperse linolenic acid fogs [39], but when aerosols containing no large AgCl particles were used the monodispersity of the fogs increased considerably. Particularly unfavourable conditions are created when the condensation nuclei dissolve in the droplets of the fog being generated, decreasing the vapour pressure above the droplets. Petro [15] prepared a fog from aqueous NaCl solution by passing the NaCl aerosol through the vaporiser of a Sinclair–La Mer generator filled with water at room temperature. Since the walls of the condenser were very wet with water, the growth of the solution droplets took place in an atmosphere saturated with water vapour. Thus in the case of polydisperse NaCl aerosols containing large particles, a fairly polydisperse fog was obtained, but when an NaCl aerosol in which the radii of all the particles were less than 0.1 $\mu$m was used, it was possible to obtain fogs which gave Tyndall spectra.

It has not been possible to find condensation nuclei for all vapours. Thus mercury vapour does not condense on the nuclei usually employed [42]. Some gases, for example $NO_2$, bring about the condensation of mercury vapour, but monodisperse aerosols are not obtained in this way. Indigo vapour shows analogous behaviour [43].

On the other hand, $H_2SO_4$ vapour obtained from the 98–99% acid not only does not require the presence of nuclei for condensation but even condenses spontaneously in the presence of condensation nuclei [25]. The spontaneous condensation of these vapours makes it possible to obtain aerosols with $\overline{r}$ = 0.1–0.4 $\mu$m, giving Tyndall spectra [25,44].

Until recently, the Sinclair–La Mer generator was used to obtain monodisperse aerosols only from organic substances, sulphur, and sulphuric acid. Recently, Movillat [36] used a slightly modified generator to prepare a cadmium aerosol with $\overline{r}$ = 0.28 $\mu$m and $\alpha < 0.17$.

A considerably simplified generator is used in Kerker's laboratory [17,45]. The substance to be volatilised is placed in a boat in a long tubular furnace through which helium is passed. The gas, saturated with the vapour of the substance, leaves the furnace and passes through a tube, which apparently acts as an air condenser, into the chamber for examination. Since condensation nuclei are not used, aerosols with a fairly high polydispersity are obtained.

Rapaport and Weinstock [46] developed a fundamentally different design of heat-exchange generator (Fig. 3).

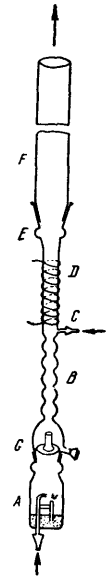

Fig.3. Rapaport and Weinstock's generator.

Filtered air passes at a rate of ~ 4 litre $min^{-1}$ into a pneumatic atomiser ($A$), which gives an extremely polydisperse fog. Large particles are deposited on the walls of the vaporiser, which acts as a screen. When the fog is passed through the column ($B$), further deposition of the large droplets takes place, and only droplets with $\overline{r} \leqslant$ $\leqslant$ 1 $\mu$m remain in the fog. Where necessary, the fog is diluted with air supplied through the side arm ($C$). The fog then passes into the volatiliser ($D$) (2.0 cm in diameter and 25 cm long), heated with a nichrome spiral, and the temperature is raised to a value at which all the drops volatilise. This is verified by the absence of a Tyndall cone at the point $E$. The gas–vapour mixture then enters the condenser ($F$) (2.5 cm in diameter and 120 cm long), where the vapour condenses on the nuclei which remain after volatilisation of the droplets and consist of the non-volatile impurities present in the liquid. The liquid which has not volatilised flows downwards over the walls into the ring ($G$) and leaves the generator.

This generator gives the same degree of monodispersity as the Sinclair–La Mer apparatus, but it has a number of important advantages: steady-state operating conditions are attained in times of the order of 10 min instead of several hours; the cost of the generator is much lower; decomposition of the substance has no effect, since the spent liquid is removed and fresh liquid is supplied continuously to the generator; and the quantity of liquid used is very small.

Another characteristic feature of this generator is that the temperature of the vaporiser need not be strictly constant, since under the condition that volatilisation of the primary drops is complete the concentration of the vapour is independent of temperature. Moreover, since the concentrations of both the vapour and the condensation nuclei are proportional to the concentration of primary drops, change in the latter again has no significant effect on the

particle dimensions of the aerosol generated. In order to decrease $\bar{r}$, air is introduced as diluent through the side arm (C), but this permits a change in $\bar{r}$ only within comparatively narrow limits.

As shown by Lassen[47], it is possible, by varying the distance from the atomiser to a special screen, to alter considerably the dimensions and number of primary droplets and hence $\bar{r}$. In this way Lassen was able to change $\bar{r}$ in a dioctyl phthalate aerosol from 0.15 μm to 0.7 μm at constant vaporiser temperature and constant rate of flow of air.

According to Berner's experiments[12], the purity of the liquid used is of considerable importance in the production of monodisperse aerosols in a Rapaport–Weinstock generator. Very pure liquids or liquids appreciably contaminated with high-boiling impurities give fogs with a greater polydispersity than those given by liquids with a low concentration of these impurities: in the first case, the nuclei remaining after the evaporation of the primary droplets are so fine that their growth requires a high supersaturation, at which spontaneous condensation is possible; in the second case, large polydisperse nuclei are formed.

Martius' generator[48], which is intermediate between the two assemblies described above, consists of a glass tube, 30 mm in diameter and 2 m long, arranged at an angle of 30° to the horizontal. The lower half of the tube is heated with a nichrome spiral and the upper part is fitted with a jacket and acts as condenser. Dry filtered air is passed into the tube at a rate of 0.3–3 litre $min^{-1}$. In the centre of the heated section of the tube there is a side arm containing a syringe, which is operated from a servo-motor and passes the fog-forming liquid to the lower wall of the tube at a controlled rate within the range $10^{-3}$–$10^{-2}$ ml × × $min^{-1}$. The air–vapour mixture is then superheated and passes to the condenser, in the jacket of which water at a controlled temperature is circulated (for dioctyl phthalate a temperature of 17° is recommended).

In this generator the products of the thermal decomposition of the liquid being vaporised are not removed from the heated zone. It is thus hardly possible to maintain steady-state generating conditions over more or less prolonged periods. Martius does not mention this, and the data which he gives[16] do not indicate the monodispersity of the fog generated.

The generator of Fuks and Sutugin[49] is a modification of Kogan and Burnasheva's mixer-generator[50] (see below). The gas containing the condensation nuclei, before being mixed with the hot gas containing the vapour of the liquid, is heated to the temperature of the hot gas, after which the mixture is passed to the condenser. In the ultramicroscope study of dibutyl phthalate fogs with $\bar{r}$ = 0.61–1.3 μm and $\alpha$ = 0.02–0.12, obtained in this generator, it was found that the distribution of the droplets with respect to dimensions approximates more or less satisfactorily to the normal distribution. It was later found that, with decrease in the concentration of nuclei $n$, the mean radius of the particles increases only to a certain limit and then remains constant. Thus, at a vaporiser temperature of 95° and a flow rate of gas equal to 2.8 litre $min^{-1}$, the maximum value of $\bar{r}$ is 0.9 μm (at $n = 1.5 \times 10^3$ $cm^{-3}$). Calculation showed that for this value of $n$, only ~ 2% of the total vapour condensed on the nuclei, while the rest condensed on the walls of the condenser. Thus under these conditions, the supersaturation of the vapour inside the condenser is determined almost entirely by the rate of condensation of the vapour on the walls and is independent of the concentration of nuclei.

## 3. Preparation of Monodisperse Condensation Aerosols in Generators of the Mixer Type

A generator of the mixer type was designed by Kogan and Burnasheva[50]. Filtered gas passes at a rate of ~ 1 litre $min^{-1}$ through a vaporiser (A) (Fig. 4), which is placed in a thermostat and is filled with large-pore silica gel impregnated with the liquid to be evaporated; the gas then passes in a narrow stream into the conical nozzle (B) of the mixer. Cold gas containing condensation nuclei passes at a rate of ~ 4 litre $min^{-1}$ through the tube (C) and a narrow annular gap (whose width can be varied) into the same nozzle. The degree of supersaturation in the mixture depends on the nature of the liquid, the velocity of the two gas streams, the temperature of the mixer, the concentration of nuclei, and the width of the annular gap; it is controlled in such a way that the supersaturation is not so high that spontaneous condensation begins, or so low that all the vapour condenses on the walls of the mixer. For liquids with a high boiling point (dioctyl sebacate), it was possible to use gaseous ions as condensation nuclei. In this generator the mean dimensions of the particles cease to depend on the concentration of nuclei $n$ at high values of $n$, of the order of $10^4$ $cm^{-3}$, probably because the ratio of the quantities of vapour condensing on the nuclei and on the walls is even lower than that in heat-exchange generators. At a higher concentration of nuclei ($n > 10^6$ $cm^{-3}$) the volume of the particles is approximately inversely proportional to $n$. The methods used to vary $\bar{r}$ are the same as those for the Sinclair–La Mer generator. The degree of monodispersity and the shape of the curves giving the distribution of the particles with respect to dimensions in the aerosols obtained in this generator and in the Fuks–Sutugin generator are approximately the same.

Fig. 5 shows a typical distribution of droplets with respect to dimensions (on a probability graph) in dibutyl phthalate fogs which we prepared in a Kogan–Burnasheva generator[49]. The distribution approximates to the normal distribution given by the straight line.

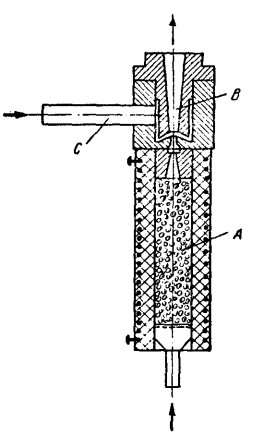

Fig. 4. Kogan and Burnasheva's generator.

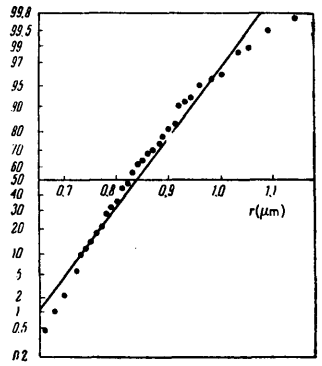

Fig.5. Distribution of particles with respect to dimensions in dibutyl phthalate fog.

In some cases, mixer-generators give fairly monodisperse aerosols even without extraneous condensation nuclei, for example from sulphuric acid (see above). In some cases atmospheric condensation nuclei appear to have been used, although no reference was made to these. Nuclei of this type are probably responsible for the production of dioctyl phthalate aerosols with $\overline{r}$ = 0.1–0.2 μm, giving Tyndall spectra, in mixer-generators [51,52].

### 4. Formation of Monodisperse Condensation Aerosols as a Result of a Chemical Process

There are very few data on this subject. An extremely promising method involves the preparation of monodisperse aerosols by photochemical or radiochemical gas reactions. When nitrogen containing methyl acrylate or methyl methacrylate vapour but no condensation nuclei was passed through a quartz tube illuminated with ultraviolet light, polymer aerosols with $\overline{r}$ = 0.05–1 μm, giving Tyndall spectra, were obtained [53]. When sufficiently fine condensation nuclei were introduced, it was possible in this way to obtain an aerosol with an extremely high monodispersity, since in this case it is possible to achieve constant supersaturation of the polymer vapour throughout the whole period of growth of the particles.

Fogs of aqueous ammonium chloride solution, with $\overline{r}$ = 0.15–0.40 μm and $\alpha \simeq 0.10$, were prepared by mixing $NH_3$ and HCl, in a long vertical tube, with air which had been saturated with water vapour and freed from gaseous-ion condensation nuclei [54].

In concluding this section we would point out that the particles of condensation aerosols obtained at low temperatures, at which no thermoelectronic emission takes place, are uncharged or very weakly charged (as a result of capture of atmospheric ions).

## III. PREPARATION OF MONODISPERSE AEROSOLS BY DISPERSION METHODS

The extremely varied dispersion methods for preparing monodisperse aerosols can be divided into three groups: (1) atomisation of liquids; (2) atomisation of monodisperse suspensions; and (3) atomisation of monodisperse powders.

### 1. Preparation of Monodisperse Aerosols by Atomising Liquids

The mechanical atomisation of liquids in jets, nozzles, etc. is used in many branches of technology and generally produces extremely polydisperse fogs. The mechanism of atomisation in all cases involves the action of hydraulic pressure or centrifugal or aerodynamic forces which draw the liquid out into a fine stream or film [55] which then breaks down to form droplets under the influence of surface tension. The finer the liquid stream or film, the smaller the resulting droplets, but the degree of polydispersity is always high.

On the other hand, it is known that, when a liquid is drawn slowly from a capillary tip, drops with constant dimensions are formed, although these are accompanied by very fine droplets or satellites. The latter are formed from the fine thread of liquid joining the droplet to the rest of the liquid before the actual rupture. The radius $r$ of the main drops is determined from the condition that the force of gravity on the drop $G$ and the capillary force $H$ are equal at the moment when the neck of the drop begins to narrow

$$G = \frac{4}{3}\pi r^3 \gamma g = H = 2\pi\rho s k, \qquad (4)$$

where $s$ is the surface tension, $\gamma$ the density of the liquid, $\rho$ the radius of the neck when it begins to narrow, approximately equal to the radius of the capillary from which the liquid is flowing, and $k$ is a numerical constant of the order of unity. It can readily be shown that only droplets of the order of 1 mm can be obtained in this way, even from very fine capillaries.

To obtain finer droplets, it is necessary to increase considerably the force causing the drop to break away. Lane [56] suggested that this be done by blowing a fine stream of air downwards against the capillary (syringe needle with an internal diameter of 0.45 mm). When the needle was placed exactly along the axis of a short tube (diameter 2.5 mm) through which the air was blown, it was possible to obtain water droplets with values of $r$ in the range 0.15–0.50 mm, depending on the velocity of the air and the rate of supply of liquid $V$. The value of $\alpha$ decreased from 0.012 to 0.005 with increase in $\overline{r}$, i.e. the degree of monodispersity was very high. Finer droplets could be obtained by using finer needles or by placing wires inside the needles, and by decreasing $V$.

Other workers [57], unlike Lane, did not allow the liquid to flow spontaneously [under the action of gravity (Ed. of Translation)] into the needle but forced the liquid into the needle by means of a micro-plunger. In spite of this, the degree of monodispersity was slightly lower than that obtained by Lane: the value of $\alpha$ varied in the range 0.11–0.05 for values of $\overline{r}$ in the range 22–220 μm.

Lane's generator has a very low output. When an attempt was made to increase the output by means of a battery of 169 needles with an internal diameter of 0.22 mm, the degree of monodispersity decreased sharply, the decrease being greater, the smaller the droplets [58]. For $\overline{r}$ = 0.45 mm, $\alpha$ = 0.22. The reason for the polydispersity was the small difference between the internal and

external diameters of the needles, the latter determining the flow-rate profile in the surrounding stream; moreover, the drops obtained in the middle of the battery were larger than those obtained at the edges. The output of the battery was 200 g of water per minute for $\overline{r}$ = 0.5 mm and 20 g per minute for $\overline{r}$ = 0.1 mm. The monodispersity of the fog generated in the battery could probably be increased considerably if it were constructed with greater precision.

Much finer droplets can be obtained by centrifugal force in the so-called disc atomisers consisting of a horizontal disc rotating around a vertical axis passing through its centre. The liquid supplied to the disc flows to the tapered edge of the disc. At a high flow rate of liquid the latter forms a thick ring on the edge of the disc from which streams or films are drawn out to give a polydisperse fog.

Walton and Prewett[59] discovered, however, that when the flow rate of liquid is sufficiently low, so that it forms a very thin layer on the surface of the disc and a narrow ring at the edges, individual droplets are torn from the latter. If the liquid is supplied to the exact centre of the disc and its surface is effectively wetted by the liquid, the thickness of the ring is constant over the whole perimeter and droplets with equal dimensions are formed (together with much finer satellite droplets).

From the theory of the breaking away of drops from a wall which they are wetting, it follows that in this case the quantity $\rho$ in Eqn. (4) should be replaced by a quantity close to the radius $\overline{r}$ of the actual drop. Further replacement of $g$ by $\omega^2 D/2$, where $\omega$ is the angular velocity of the disc and $D$ its diameter, and of $r$ by $d/2$, where $d$ is the diameter of the drops, gives

$$d\omega (D\gamma/s)^{1/2} = C. \qquad (5)$$

The value of the constant $C$ is $\sqrt{12} = 3.47$.

In Walton and Prewett's experiments at low rates of rotation the values of $C$ were in fact close to 3.47 for organic liquids which effectively wetted the surface of the disc; the value was slightly lower for water, which did not wet the disc effectively. At very high values of $\omega$, equal to several hundred rev $s^{-1}$, the liquid is unable to acquire the tangential velocity of the disc, the drop dimensions are greater than the theoretical, and the values of $C$ reach 5.

Water droplets with $\overline{r}$ = 0.1–1.5 mm were obtained on a disc rotating at 10–50 rev $s^{-1}$, and droplets of non-volatile liquids with $\overline{r}$ down to 8 $\mu$m were obtained at 1500 rev $s^{-1}$. Methyl salicylate droplets with $\overline{r}$ = 0.9 mm were obtained with a disc diameter of 4 cm and a velocity of 15 rev $s^{-1}$. At a flow rate of liquid $V \leq 0.4$ ml $s^{-1}$, the mass of the main droplets is greater by several orders of magnitude than the mass of the satellite droplets, but increase in $V$ leads to an increase in both the relative number and dimensions of the satellite droplets, and at $V$ = 2.8 ml $s^{-1}$ an obviously polydisperse fog is formed. The greater the rate of rotation and the smaller the diameter of the disc, the smaller should be the value of $V$ necessary to obtain a monodisperse fog. Since the droplets fly further from the disc the greater their dimensions, it is possible, when the satellite droplets are much smaller than the main droplets, to separate the two by surrounding the disc with a jacket sectioned to allow the passage of the main droplets.

In May's experiments[60], the flow rate of liquid was very low ($\leq$ 1 ml $min^{-1}$) and more attention was paid to the application of the liquid exactly in the centre of the disc and to the determination of the degree of monodispersity of the fog generated. For dibutyl phthalate fog with $\overline{r}$ = 32 $\mu$m, $\alpha$ = 0.014, and for a water fog with $\overline{r}$ = 22 $\mu$m, $\alpha$ = 0.031, i.e. in the second case the monodispersity was slightly lower, in agreement with what was said above. The value of $\alpha$ changes little with the mean dimensions of the droplets, but increases appreciably as $\overline{r}$ approaches the height of the irregularities on the disc surface. It is therefore recommended that the disc be polished and treated with wetting agents to improve its wettability with water.

Boshoff[61], working with a large disc ($D$ = 35 cm) at 2.7–27 rev $s^{-1}$, found that monodisperse fogs with $\overline{r}$ = = 0.35–1.15 mm are formed only at $6 < V < 22$ ml $s^{-1}$. The existence of the lower limit for $V$ is undoubtedly due to rupture of the layer of liquid when it becomes very fine (the actual thickness is not stated) on the surface of the disc. Ryley[62], working at $D$ = 5 cm, $V$ = 0.4–0.8 ml $s^{-1}$ and a velocity of 1000 rev $s^{-1}$, obtained water droplets with $\overline{r}$ = 11 $\mu$m, but no data on the degree of monodispersity are given. Monodisperse fogs can also be obtained on conical dishes with tapered edges, rotating about a horizontal axis[55].

The output of disc atomisers is higher than that of other monodisperse-fog generators; a slight inconvenience associated with their use is that the drops fly in all directions.

The mechanism of operation of a generator with a vibrating capillary, proposed by Dimmock[63], is not quite clear. A glass tube is drawn out at one end to form a 20 cm long capillary with an external diameter of 0.6 mm. A piece of steel needle from a syringe is fixed to the capillary at a distance of 2–5 cm from its base. An electromagnet supplied with alternating current is used to vibrate the capillary and the liquid fed to the latter is atomised to give drops of identical dimensions. The dimensions of the capillary are chosen in such a way that it is brought into resonance with the forced vibrations. From the diagram published in the paper, it is evident that the liquid is thrown not from the tip of the capillary, as stated in the text, but from the side opening, and individual droplets are torn away. Since 100 drops per second were torn from the capillary, the frequency $\nu$ of the vibrations was evidently 50 c $s^{-1}$. The maximum acceleration of the capillary tip is $(2\pi\nu)^2 a$, where $a$ is the amplitude of the vibrations, with an order of magnitude in any case not more than 1 cm. Thus according to Eqn. (4), only water drops with $\overline{r}$ = 0.5 mm could be obtained in these experiments. In actual fact, Dimmock obtained drops with $\overline{r}$ = 5–150 $\mu$m, and this is extremely difficult to explain. All other workers[64–66] working with a generator of this type obtained drops with $\overline{r} \geq 150$ $\mu$m. Ryley[62] pointed out that a quite different mechanism of drop formation is possible. By using a syringe needle with an internal diameter of 0.14–0.61 mm and a tip polished at right angles to the axis, and by making this needle vibrate at a frequency of 200–3000 c $s^{-1}$, Ryley obtained a fine sinusoidal stream of liquid, which broke down to form droplets at a certain distance from the capillary. In order to obtain a monodisperse fog with $\overline{r}$ = = 0.15–0.68 mm, the stream had to be broken down into fragments with a length equal to the total period of the sinusoid $\lambda$. In agreement with Rayleigh's theory, breakdown in this way is favoured when the ratio of $\lambda$ to the thickness of the stream has the value 4.5 or a multiple of this figure. In this case the volume of the drops formed is directly proportional to the linear velocity of the stream. The capillary may be vibrated extremely simply by directing over it a narrow stream of compressed air[67].

In Mason's laboratory[68] needles with an internal diameter of 0.1 mm and a frequency of vibration equal to 1000 c $s^{-1}$ were used to obtain water drops with $\overline{r}$ = 15 $\mu$m.

In the same laboratory use was made of the phenomenon of reflection of water droplets falling on the surface of water at a definite velocity and at a definite angle. When an electric potential is applied to the vibrating needle, the drops which are torn away are charged, and lose some of their mass when reflected from water, the quantity lost being greater, the higher the potential. Thus the drops leaving the water are identical and smaller than the primary drops; moreover, their dimensions can be controlled within certain limits. When the potential is sufficiently high, the drops falling on the water surface are completely absorbed, but by applying an additional pulsating voltage to the needle it is possible to vary at will the frequency of formation of the secondary droplets and the distance between them, and this is very convenient in certain studies [69].

In the work cited transverse vibrations of the capillary were used; analogous results are obtained with longitudinal vibrations. If pressure pulsations are applied to a liquid in a vessel with a narrow side-tube, large drops with a high degree of monodispersity are ejected from the tube [66], and in this case, unlike the case of the vibrating-capillary generators, no satellite droplets are formed. Drops with $\overline{r}$ = 1–4 mm were prepared in this way; with increase in $\overline{r}$, $\alpha$ decreased from 0.005 to 0.002.

A similar method is based on the following principle. When a point is rapidly immersed in a liquid and then removed, a connection is formed between the point and the liquid surface and is drawn into a fine thread. This thread breaks away first from the liquid and then from the point, and forms a drop which flies in the direction of movement of the point. This process is repeated periodically by using a vibrating point. The size of the drops is determined by the nature of the liquid, the shape and dimensions of the point, the frequency and amplitude of the vibrations, the wettability of the point, and, more particularly, the depth of its immersion in the liquid. It is extremely convenient to work with a liquid which flows slowly from a capillary. In this case the depth of immersion of the point and the dimensions of the droplets generated increase with increase in the dimensions of the drop hanging from the capillary. As a result, the rates of flow and atomisation (ml $s^{-1}$) are equalised automatically and the dimensions of the droplets are determined only by the flow rate. Drops with $\overline{r}$ = 25–200 μm can be obtained in this way, at 100 vibrations $s^{-1}$. [70,71]

In Wolf's experiments [72] the point (a rod with a diameter of 10–50 μm) was immersed not in a hanging drop but in the meniscus of a liquid filling a horizontal slit cut in a piece of porous glass, through which the liquid was passed. At a frequency of 120 c $s^{-1}$, drops of water and aqueous solutions with $\overline{r}$ = 5–100 μm, and drops of molten wax and paraffin with $\overline{r}$ = 2–20 μm, were obtained. In the latter case the rod was immersed vertically in the free surface of a melt, held accurately at a constant level.

The vibrating rod may be replaced by a 3 mm broad, 0.5 mm thick plate with a tapered end, cut from a safety razor blade and rotating at 10–20 rev $s^{-1}$. [73] Drops with $\overline{r}$ = 40–350 μm were obtained in this way from aqueous solutions and Diesel fuel flowing from a capillary. To obtain monodisperse drops, it is important that the capillary and blade be effectively wet by the liquid. In contrast to the work with a vibrating point, where the monodispersity was estimated visually from photomicrographs of the droplets, the work cited gave numerical data: $\alpha$ = 0.012–0.22 for $\overline{r}$ = 50–60 μm.

The electrostatic atomisation of liquids, now used for painting manufactured articles, depends on the repulsion forces between the electric charges on the liquid surface. These forces decrease the surface tension of the liquid, and when they are sufficiently high the surface of the liquid becomes unstable. In small protuberances formed randomly on the surface, the charge density increases, the repulsion forces become greater than the surface tension, and the raised section is drawn out into a thread, rupture of which produces a drop.

In accordance with the foregoing, the immersion of an electrode into a vessel containing a liquid flowing through a capillary, and the application of a voltage of constant sign and increasing magnitude to the electrode lead to a decrease in the surface tension, and the dimensions of the droplets decrease, in accordance with Eqn. (4), while the frequency of their formation increases. In this way it is possible to obtain several hundred drops (accompanied by satellite drops) of identical dimensions per second, with $\overline{r}$ varying from 50 μm to several hundred μm. [74,75]

At a certain critical voltage the nature of the process changes sharply; in addition to a stream of comparatively large drops, a broad beam of highly-dispersed fog giving Tyndall spectra begins to be formed. At the critical voltage, the above-mentioned process of liquid-thread formation evidently begins. It cannot yet be stated with certainty why the threads give a monodisperse fog.

In most work using this method glass apparatus was employed, and it was found that a highly-dispersed fog can be obtained only when the sign of the voltage applied to the electrode is positive and when the conductivity of the liquid lies between $10^{-13}$ $\Omega^{-1}$ $cm^{-1}$ and $10^{-5}$–$10^{-6}$ $\Omega^{-1}$ $cm^{-1}$. Distilled water, alcohol, and other polar liquids lie in this range [76]. When the conductivity is very low (non-polar liquids) the charges evidently accumulate too slowly on the liquid surface. When the conductivity is high (electrolyte solutions), atomisation is apparently accompanied by a corona discharge from the regions of the surface with high curvature, and this prevents the formation of threads.

When a metal capillary — a syringe needle connected to a voltage source, with tip polished at right angles [77,78] — is used and an earthed metallic plate is set up parallel to the needle at a short distance from it, the atomisation becomes much easier; fairly highly-dispersed fogs of any liquid, including non-polar liquids and dilute electrolyte solutions, could be obtained, irrespective of the sign of the potential. The dimensions of the droplets decreased with increase in the voltage, and drops with $\overline{r}$ = 1 μm could be obtained.

Unfortunately, there are very few data on the degree of monodispersity of the fogs obtained by means of an electric field: it is known only that in highly-dispersed fogs obtained in this way, Tyndall spectra are observed, and there are no data for larger drops. The drops have high charges, with the same sign as the electrode, and in a number of cases this limits their application.

Mention must be made of some less important methods. When air is bubbled from narrow capillaries through distilled water or sea water, a polydisperse fogs forms from the bursting bubbles, but segregation of the droplets according to size takes place in the ascending current of air and collection of the droplets at a definite height makes it possible to obtain monodisperse drops with $\overline{r}$ = 1–250 μm. [79]

Ultrasonic atomisation appears to give fogs with fairly high polydispersity [80].

## 2. Preparation of Monodisperse Aerosols by Atomising Suspensions

When non-aggregated monodisperse suspensions in water or other volatile solvent are atomised under conditions where not more than one particle is present in each drop, drying of the resulting fog should obviously produce monodisperse aerosols. This method of generating aerosols was first used by microbiologists, who prepared bacterial aerosols in this way. The atomisation of suspensions acquired practical importance as a method for generating monodisperse aerosols with the introduction of monodisperse polystyrene latexes with accurately spherical particle shape, developed by the Dow company. In these latexes, $\alpha$ is equal to $\sim 0.09$ at $\bar{r} = 0.044$ μm, $\sim 0.04$ at $\bar{r} = 0.07$–$0.09$ μm, 0.015–0.023 at $\bar{r} = 0.13$–$0.28$ μm, and $\sim 0.012$ at $\bar{r} = 0.4$–$0.6$ μm.[81]

The latexes contain $\sim 7\%$ of polymer and before atomisation are diluted extensively with distilled water. The resulting fog is dried by mixing with dry filtered air. In the first experiments on the preparation of monodisperse aerosols with $\bar{r} = 0.17$–$0.49$ μm by this method it was found that the degree of monodispersity is much lower than that of the latexes themselves[82], and in most cases $\alpha$ varied from 0.11 to 0.16 (the dimensions of the particles were determined with a photoelectric counter). This phenomenon may be due to the presence of more than one particle in the drops, leading to the formation of twins, etc., when the drops are dried, and to the presence of the water-soluble non-volatile emulsifier in the latexes ($\sim 30\%$ of the weight of polymer). Thanks to the emulsifier, the latex particles do not aggregate even on extensive dilution of the suspension, but with complete removal of the emulsifier, coagulation of the suspensions is unavoidable. The probability that the drop contains more than one particle depends on the concentration of the suspension and on the dimensions of the drops and particles. If it is assumed that a concentration of 5% of twins in the aerosol is permissible (in this case the number of triplets, etc. will be negligible), we find from Poisson's formula that, for the mean drop radius of $\sim 1$ μm attainable in practice by means of special atomisers, the concentration of the suspension should not exceed 1% for a particle radius $\bar{r} = 0.5$ μm, $\sim 0.1\%$ for $\bar{r} = 0.25$ μm, and $\sim 0.01\%$ for $\bar{r} = 0.1$ μm. These conditions have obtained in most work.

The greatest difficulty is due to the presence of emulsifiers in the suspension; we have already seen that its complete elimination is impossible. The emulsifier is apparently extremely hygroscopic, and when the above method is used to dry drops containing polymer particles, a coating of concentrated emulsifier solution is deposited on the particles; when drops containing no particles are evaporated, "blanks" of the same solution are left. Moreover, it follows from Poisson's formula that when the number of twins is low, the number of "blanks" should be much greater than the number of droplets with polymer particles.

This was observed particularly clearly in work by Langer and Lieberman[83]. In the atomisation of a suspension prepared by tenfold dilution of a latex with $\bar{r} = 0.407$ μm, into a chamber containing air with a moisture content of 4%, study of the resulting aerosol by means of a photoelectric counter showed that the concentration of particles was 25 times the calculated value, because of the presence of the "blanks". The radius of the "blanks" varied from the limit of sensitivity of the counter ($\bar{r} \simeq 0.25$ μm) to 1.5 μm, the mean radius of the aerosol particles was 0.7 μm, and the value of $\alpha$ was 0.39.

When the fog was heated to 165°, the number of particles recorded by the counter decreased by a factor of 10–100; the radius of most of the completely dried "blanks" was evidently less than 0.25 μm and was not recorded by the counter. The maximum particle radius decreased to approximately 0.5 μm, approaching the true radius of the polymeric granules. An analogous effect was observed for hundredfold dilution of the latex: in the aerosol dried at room temperature, $\bar{r}$ decreased to 0.55 μm and $\alpha$ to 0.22; the number of "blanks" recorded decreased considerably, because of their smaller size.

It must be emphasised that in the microscopic measurement of the particles the emulsifier solution, which effectively wets the support, flows over the latter in a very thin film and cannot be seen. Thus the authors who studied these aerosols only by the microscope method concluded that the aerosols had a high monodispersity[84,85]. However, the presence of a large number of "blanks" could also be detected under the microscope in the deposit from an aerosol with $\bar{r} = 0.407$ μm, obtained in an electrostatic sorter, in which the particle dimensions are determined from their position in the deposit[86]. In other work[87] with an aerosol prepared from the same latex and deposited in a centrifugal sorter (conifuge) in which the particle dimensions are determined in analogous fashion, the value found for $\bar{r}$ corresponded to the dimensions of the particles in the latex, and the influence of the emulsifier was revealed only in the increase in the value of $\alpha$ from $\sim 0.012$ to 0.11. In the second case the degree of dilution was probably greater and the drop dimensions smaller, than in the first case.

Aerosols have also been prepared by atomising extremely highly monodisperse AgI suspensions[88]. Since coagulation took place during purification of the suspensions from the salts present, the monodispersity of the aerosols was probably low.

A monodisperse aerosol with very fine particles was prepared by atomising suspensions, thoroughly freed from all impurities, of *E. coli* bacteriophage T3 with $\bar{r} = 17.5$ mμ and $\alpha = 0.07$. Electron-microscope study of the suspension and the aerosol prepared from it showed that the particle distribution with respect to dimensions was the same in each[89].

## 3. Preparation of Monodisperse Aerosols by Atomising Powders

The chief disadvantage of the above method for generating monodisperse aerosols, associated with the presence of dissolved substances in the suspensions, is obviously eliminated in the atomisation of dry monodisperse powders, but in this case other difficulties arise. Powders with $\bar{r} > 5$ μm are comparatively readily atomised by compressed air, with the formation of aerosols containing completely disaggregated particles, but with decrease in the particle size the atomisation becomes more difficult and for powders with $\bar{r} < 0.5$ μm, complete atomisation has not yet been achieved. Important factors, in addition to particle size, are the shape, elastic properties, and moisture content of the particles. Lamellar or acicular particles are more difficult to atomise than spherical particles. Powders of hard materials are more readily atomised than those from soft materials. Increase in the moisture content of the particles leads to a sharp decrease in the ease of atomisation, but powders which have been

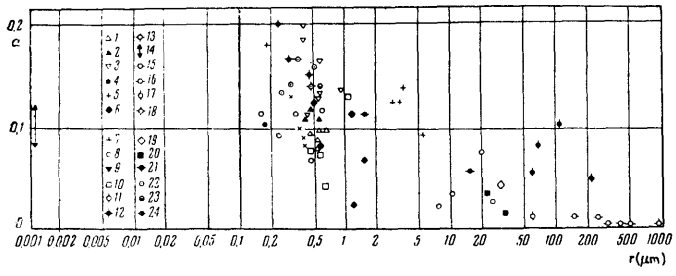

Fig. 6. Characteristics of monodisperse aerosols prepared by different methods, from published data.
Condensation method: aerosols from:
1) dioctyl phthalate[46]; 2) dioctyl phthalate[120]; 3) dioctyl phthalate[10,11]; 4) dioctyl phthalate[138]; 5) dioctyl phthalate[119]; 6) dibutyl phthalate[49]; 7) glycerol[125]; 8) tetralin[33]; 9) stearic acid[36]; 10) stearic acid[143]; 11) linolenic acid[39]; 12) linoleric acid[19]; 13) sodium chloride[45]; 14) sodium chloride[41]; 15) cadmium[36].
Atomisation of liquids:
16) blow capillary, water[56]; 17) rotating blade, mineral oil[73]; 18) pulsating pressure, water[66]; 19) rotating disc, water[126]; 20) dibutyl phthalate[60]; 21) electrostatic atomisation, butyl benzoate[78].
Atomisation of suspensions:
22) latex[82]; 23) spores of *B. globulis*[144].
Atomisation of powders:
24) lycopodium[105].

over-dried are also difficult to atomise, because of the high triboelectric charges.

Elutriation under the influence of gravity or in a centrifuge can be used to obtain powders with any degree of monodispersity, but the method is time-consuming. The well-fractionated glass powders consisting of spherical particles, supplied by some Non-Soviet firms, are very convenient. Powders with extremely high monodispersity are also found in nature. Thus in lycoperdon spores $\bar{r}$ = = 2.09 μm and $\alpha$ = 0.08;[90] in maize-rust spores $\bar{r}$ = 3.9 μm and $\alpha$ = 0.038;[91] and in clover pollen $\bar{r}$ = 26 μm and $\alpha$ = = 0.04.[92] Because of its availability, lycopodium spores with $\bar{r}$ = 15 μm and $\alpha$ = 0.10 have been most widely used[93].

In concluding this section we would point out that in all aerosols obtained by dispersion methods, with the exception of fogs formed by non-polar liquids, the particles have fairly high charges of either sign. In some studies this property is extremely undesirable.

Fig. 6 gives data on the particle size and degree of monodispersity of aerosols obtained by condensation and dispersion methods.

## IV. APPLICATIONS OF MONODISPERSE AEROSOLS

The titles of most papers describing the use of monodisperse aerosols for different purposes do not mention the application. In many cases the application is mentioned only in a few lines in the text of a paper. Moreover, monodisperse aerosols are used in the solution of an extremely varied range of problems, and the appropriate papers may be found in specialised journals of the widest range. All this makes a search of the literature on this subject extremely difficult, and cannot but be reflected in the completeness with which it is covered in a review.

Monodisperse aerosols have been used in the study of various optical properties of aerosols (condensation aerosols[24,31,39,94-96] prepared from latexes[85,97] or lycopodium[98]); the absorption of sound in aerosols (lycoperdon[99]); the vibrations of particles in a sonic field (condensation[100]); deposition of aerosols on obstacles from a stream (condensation[101-103], latex[104], and lycopodium[105]), on the walls of tubes from a turbulent stream (lycopodium[106]), in impactors (condensation[101], lycopodium[107], and latex[142]), in thermal precipitators (condensation[108], disc atomiser[109]), in electrostatic precipitators (latex[84]), and in breathing apparatus (condensation[110], atomisation of bacterial suspensions[111]); methods for sampling aerosols (condensation[112], fractionated powders[113]); diffusion deposition during flow in narrow channels (condensation[114]); sedimentation and diffusion in a cell (condensation[115]); filtration of aerosols through fibrous filters (condensation[24,31,115-122], latex[123], bacterial and virus suspensions[124,144]) and granular filters (condensation[121]); the efficiency of collisions between drops and solid walls (condensation[125], vibration atomiser[70]), liquid surfaces, and one another (vibration[64,65] and disc[126] atomisers); the charges of particles in condensation aerosols during their formation[127] and during charging by an ion beam[119,128]; the elution of aerosols by rain (lycopodium[129]); the dependence of the efficiency of insecticides and herbicides on drop dimensions (condensation[32], disc atomiser[130,131]); the supercooling of droplets[132] and their vapour pressure (condensation[38]); the ice-forming power of AgI particles (atomisation of a suspension[88]); the movement of coarse dust in tubes (glass spheres[133]); the activation of aerosols by radioactive gases (condensation[134], latex[134]); the chemical reaction of aerosols with gases (condensation[44]); and the lubrication of ball bearings with oil fogs (disc atomiser[135]). They have also been used to verify Stokes' law (lycoperdon[90]) and Kelvin's law (condensation[22,23]), to prepare monodisperse emulsions (condensation[136], electrostatic atomisation[78]); for the calibration of instruments used for the dispersion analysis of aerosols — photometers (latex[137]), photographic[138], photoelectric (condensation[139]), and thermoelectric (vibration atomiser[67]) counters (sorters), and electrostatic (condensation[128]) and centrifugal (condensation[140], latex[87,141]) sorters.

## I. INTRODUCTION

Interesting properties of technetium have been discovered in recent years. Unlike its nearest analogue, the perrhenate ion, the pertechnate ion exhibits exceptional anti-corrosion properties[1], greatly superior to those of $CrO_4^{2-}$ ions. For example, iron which has been immersed in ammonium pertechnate solution with a technetium concentration of only 5 $\mu g\ ml^{-1}$ undergoes no rusting over a period of several years. This reveals promising possible applications of technetium compounds as effective inhibitors of the corrosion of iron and steel. These compounds may prove particularly useful for preventing the corrosion of homogeneous boiling reactors[2], certain submarine parts, etc.

Metallic technetium and its alloys (for example an alloy containing 50% Tc and 50% Mo) are superconductors at low temperature[3,4] and can be used to replace super-purity niobium in inertial control systems in rocket technology[2], as memory elements in electronic machines[5,6], and in thermonuclear-synthesis assemblies for the production of magnetic fields of high intensity[6]. Many fundamental properties of this element have not been studied, since large quantities are not available. When larger quantities are produced, new properties of technetium and extensive possibilities for its use in industry may be revealed.

Thus the problems of preparing large (kilogramme) quantities of technetium and separating it from the neighbouring elements rhenium, molybdenum, and ruthenium are now of pressing importance. It is therefore of interest to examine the latest achievements in the analytical chemistry of technetium, since recent reviews on the chemistry of technetium[6-12] devote little space to this topic, and there are no special reviews on the subject.

## II. METHODS OF ISOLATING AND CONCENTRATING TECHNETIUM

A large number of technetium isotopes with mass numbers from 92 to 107 and half-lives from several seconds to $2 \times 10^6$ years are now known. The most important isotopes of technetium, their radioactive characteristics, and methods of preparation are given in Table 1.[13]

Four of the isotopes given in Table 1: $^{95m}Tc$, $^{96}Tc$, $^{97m}Tc$, and $^{99m}Tc$, are used as tracer atoms in the study of the chemical properties of technetium. The most readily available for this purpose is the nuclear isomer $^{99m}Tc$, which is formed with high specific activity from molybdenum irradiated with neutrons. The other three isotopes: $^{97}Tc$, $^{98}Tc$, and $^{99}Tc$ are long-lived, with half-lives $>10^5$ years, and can be used for the study of the chemistry of technetium in ponderable quantities. The last of these isotopes is the most readily available, since it is formed by the fission of uranium and plutonium nuclei or by the prolonged irradiation of molybdenum in a reactor.

TABLE 1. Most important isotopes of technetium.

| Isotope | Half-life | Decay type | Energy of radiation, MeV | | Method of preparation |
|---|---|---|---|---|---|
| $^{95m}Tc$ | 60 days | e.c. ~96%<br>i.t. ~3%<br>$\beta^+$ ~0.4% | $\beta^+$<br>$\gamma$ | 0.4<br>0.201 | $^{95}Mo(p,n)^{95m}Tc$ |
| $^{96}Tc$ | 4.2 days | e.c | $\gamma$ | 0.77–0.84 | $^{96}Mo(p,n)^{96}Tc$ |
| $^{97m}Tc$ | 91 days | i.t. | $\gamma$ | 0.096 | $^{97}Mo(p,n)^{97m}Tc$ |
| $^{97}Tc$ | $2.6 \times \times 10^6$ years | e.c. | $\gamma$ | | $^{97}Mo(d,2n)^{97}Tc$ $^{97m}Tc \rightarrow {}^{97}Tc$ |
| $^{98}Tc$ | $1.5 \times \times 10^6$ years | $\beta^-$ | $\beta^-$<br>$\gamma$ | 0.30<br>0.66; 0.75 | $^{98}Mo(p,n)^{98}Tc$ |
| $^{99m}Tc$ | 6.04 h | i.t. | $\gamma$ | 0.14 | $^{98}Mo(n,\gamma)^{99}Mo \xrightarrow{\beta} {}^{99m}Tc$ |
| $^{99}Tc$ | $2.12 \times \times 10^5$ years | $\beta^-$, no $\gamma$ | $\beta^-$ | 0.296 | fission products from uranium and plutonium; daughter $^{99m}Tc$ |

1. Isolation of Technetium from Irradiated Molybdenum

The best method for obtaining relatively large quantities of technetium is by isolating it from the mixture of uranium fission products or from the waste products of the atomic [energy] industry. Because of the high level of radiation, however, all operations involved in the isolation of technetium from these materials must be carried out in special radiochemical laboratories using apparatus with remote control. When small (milligramme) quantities are required, technetium can also be obtained by the prolonged neutron irradiation of very pure molybdenum in a nuclear reactor, according to the reaction

$$^{98}Mo(n,\gamma)^{99}Mo \xrightarrow[67\ h]{\beta^-} {}^{99m}Tc \xrightarrow[6.1\ h]{i.t.} {}^{99}Tc\ (\text{long-lived, } 2.12\times10^5 \text{ years}).$$

When the $^{99}Mo$ has decayed, the technetium can be isolated in ordinary radiochemical laboratories.

The first ponderable quantities of technetium were obtained by irradiating 5.7 kg of pure metallic molybdenum powder in a nuclear reactor for 130 h with a neutron beam at $5\times10^{11}$ neutrons $cm^{-2}\ s^{-1}$.[14,15] In this case, according to calculations, 2.8 mg of technetium, i.e. only $5\times10^{-5}$%, was formed.

A variety of methods have been described for extracting small quantities of technetium from molybdenum irradiated with neutrons, protons, or deuterons. After dissolution, the main bulk of the molybdenum was removed by precipitating silver molybdate[16] or lead molybdate[17] or by precipitation with 8-hydroxyquinoline from ammonium acetate solution[18]. Technetium can be extracted from an ammoniacal solution of molybdenum by coprecipitating the pertechnate ion with sparingly-soluble crystalline $MgNH_4PO_4$ and $MgHPO_4$ [19] After dissolution of the precipitate in 6 M HCl, the technetium was reduced to a lower valency by passing $H_2S$, after which $MgNH_4PO_4$ or $MgHPO_4$ was again precipitated from ammoniacal solution. Under these conditions, technetium remained in solution. Further concentration and purification was achieved by coprecipitation with certain sulphides ($Re_2S_7$, $PtS_2$, CuS, etc.[15]) or by ion-exchange[15,20] or electrochemical[15,16,21,22] methods. A chromatographic method for the isolation of technetium using strongly-basic anion-exchange resins (Dowex I-X8, IRA-400, etc.)[23] has also been developed. The metallic molybdenum which had been irradiated with neutrons was dissolved in a 10% NaOH + 30% $H_2O_2$ mixture, the solution was boiled to remove $H_2O_2$, and passed through a chromatographic column containing the resin. Molybdenum was weakly absorbed by the resin and eluted with 3 M NaOH solution, after which the technetium was eluted with 1 M $HClO_4$ or $NH_4ClO_4$ solution. When technetium is being isolated from kilogramme quantities of molybdenum, however, precipitation methods are unsuitable, because of the large volumes of solution and precipitate involved. Ion-exchange chromatography is also inapplicable, so that methods have been developed for isolating technetium by extraction and distillation.

Extraction methods are based on the extraction of pertechnate ions from alkaline media by means of chloroform in the presence of tetraphenylarsonium chloride[24,25] or with pyridine or methyl derivatives of pyridine[26-28]. Another effective method involves the extraction of technetium by ketones from 3–5 *N* solutions of alkalis or alkali metal carbonates[28-32]. The last method is used fairly frequently to isolate the nuclear isomer $^{99m}Tc$ for analytical purposes from molybdenum trioxide irradiated with neutrons. The molybdenum trioxide $MoO_3$ is dissolved with heating in 3–4 *N* KOH or NaOH solution in the presence of small quantities of hydrogen peroxide, after which the technetium is extracted from the solution by ethyl methyl ketone, by treatment for 5–10 min. The organic phase is washed 2–3 times with small volumes of 3–4 M $K_2CO_3$ solution to remove traces of molybdenum and radioactive impurities. The technetium is then re-extracted into the aqueous phase using chloroform or other non-polar solvents.

To isolate the short-lived isomer $^{99m}Tc$, use is made not only of the above extraction methods but also of chromatographic methods with synthetic anion-exchange resins[33] or inorganic sorbents such as alumina[34,35] and zirconium hydroxide[36]. As the $^{99m}Tc$ from the molybdenum, adsorbed on the inorganic sorbents, accumulates on the column, the technetium is eluted at intervals with 0.1 M $HNO_3$ or $H_2SO_4$ in the case of alumina or 2 M $HNO_3$ in the case of zirconium hydroxide. Methods based on the electrochemical separation of $^{99m}Tc$ from non-aqueous media[37,38] and on the irradiation of certain carbonyl compounds of molybdenum[39-41] have also been proposed. These methods have not been widely used in analytical chemistry, however, because of the time required for the electrochemical separation and the complexity of preparation and low stability to irradiation shown by the carbonyl compounds of molybdenum.

The most effective methods for separating technetium from very large quantities of molybdenum are the distillation methods. A method based on the codistillation of technetium and perchloric acid has been described[22]. To prevent the distillation of molybdenum dissolved in the $HClO_4$, phosphoric acid was added to form the non-volatile molybdophosphate complex.

Boyd and coworkers[15] showed that the distillation of technetium with concentrated sulphuric acid provides a fairly effective method for separating technetium from molybdenum. Thus when 6 ml of acid were taken per gramme of metallic molybdenum, 75% of the technetium passed into the distillate, and this figure increased to 90% when the quantity of acid was doubled. After two distillations, more than 98% of the technetium is extracted. This method was used to isolate milligramme quantities of technetium from 5.7 kg of molybdenum. As an example, we can describe a method developed[15] for the isolation and concentration of technetium from molybdenum. The molybdenum, irradiated with neutrons, was left for 6 weeks until the $^{99}Mo$ had decayed, after which it was dissolved in concentrated $H_2SO_4$. The sulphuric acid was then distilled from solutions containing approximately 190 g of the metal. The resulting distillate was diluted to a concentration of 4 M with respect to sulphuric acid, heated to boiling, and treated with bromine water. Platinum was then added to the solution (1 mg per 200 ml) and platinum sulphides were precipitated. The precipitate was filtered off, dissolved in an $NH_4OH + H_2O_2$ mixture, the solution was evaporated to dryness, the residue was treated with concentrated $H_2SO_4$ or $HClO_4$, and the technetium was distilled into a flask cooled with ice. After 4-fold dilution, the sulphides were precipitated from the solution. Spectroscopic analysis of the resulting concentrate showed the presence of technetium, together with fairly large quantities of molybdenum. The methods used to purify technetium from molybdenum and also from rhenium, which is present in traces in molybdenum and is concentrated with the technetium, will be described below.

The milligramme quantities of technetium isolated from molybdenum irradiated with neutrons have played an important part in the study of the chemical and physical properties of this element. The further development of research and the practical application of technetium require large quantities (tenths of a kilogramme) of the element, however, and these cannot be obtained from molybdenum. At the present time, therefore, increasing attention is being paid to the isolation of technetium from uranium fission products.

## 2. Isolation of Technetium from Uranium Fission Products

The nuclear reactor gives, in addition to other fission products, one of the most long-lived isotopes of technetium — $^{99}$Tc. The yield of this isotope in the fission of $^{235}$U with thermal neutrons amounts to ~6.2%. When the reactor has operated for a prolonged period, however, considerable quantities of $^{239}$Pu and $^{241}$Pu accumulate, and the fission of these isotopes provides an additional source of technetium. According to calculations[42], considerable quantities of $^{99}$Tc accumulate in the fuel elements of the first atomic power-station. Thus the consumption of 50% of the $^{235}$U gives 600 mg of $^{99}$Tc per kg of $^{235}$U. According to other data[43], the production of 10 kg of Pu in the nuclear reactor leads to the accumulation of 150 g of $^{99}$Tc. Thus the development of atomic power provides an opportunity for the production of technetium in large quantities. Particularly suitable materials for this purpose are the waste solutions from atomic plants. Treatment of these solutions makes it possible, for example, to obtain 400 g of technetium per month[3].

Ponderable (milligramme) quantities of technetium were first isolated from uranium fission products by Parker *et al.*[44] A rod of metallic uranium which had been irradiated in a nuclear reactor was dissolved in 37% HCl and the $UCl_4$ formed on dissolution was oxidised with $H_2O_2$ and bromine water to $UO_2Cl_2$. The technetium was then coprecipitated with $PtS_2$ using hydrogen sulphide, the precipitate was dissolved in a mixture of $H_2O_2$ and $NH_4OH$, and the solution was evaporated to dryness. The subsequent purification of the technetium was carried out by distilling $Tc_2O_7$ from 18 *N* $H_2SO_4$.

The first gramme of technetium was obtained in 1952 from the waste products from plutonium production[45]. Because of the high concentration of nitrate ion in the solution used, it was impossible to concentrate the technetium in the form of sulphides. Use was therefore made of the organic base tetraphenylarsonium chloride, which forms sparingly soluble precipitates with perchlorate ions added to the waste solutions and coprecipitates the structurally-similar pertechnate ion. The precipitate was dissolved in concentrated $H_2SO_4$ and the technetium was deposited electrolytically on platinum electrodes. The resulting black deposit of $TcO_2$ was dissolved in 18 M $H_2SO_4$, the technetium was distilled off, and technetium sulphide was precipitated from the distillate. The use of electrolysis in this procedure makes it impossible to regenerate the expensive tetraphenylarsonium chloride. A method was therefore developed[46] to avoid the decomposition of this reagent. The mixture of tetraphenylarsonium perchlorate and pertechnate was dissolved in alcohol and the solution was passed through a column of anion-exchange resin in the $Cl^-$ form. The perchlorate and pertechnate were absorbed on the resin and the tetraphenylarsonium cation passed through the column. The technetium was then eluted with 2 *N* NaOH solution.

Technetium has also been concentrated and isolated by precipitation and coprecipitation methods from the waste products from the processing of atomic fuel[47,48]. Technetium and ruthenium were coprecipitated on iron hydroxide in the presence of hydrazine hydrate at a controlled pH of 2–3, the precipitate was dissolved in $HNO_3$, and tetraphenylarsonium pertechnate was precipitated and reprecipitated several times. $Tc_2S_7$ was then precipitated from 2 *N* HCl. The precipitate was dissolved in an $NH_4OH$ + + $H_2O_2$ mixture and pure $KTcO_4$ was isolated. Technetium can also be isolated from alkaline solutions of uranium fission products by coprecipitating $Tc^{IV}$ with $Fe_3O_4$.[49]

The chromatographic and extraction methods for isolating and concentrating technetium from fission products appear to be the most effective. One of the earliest extraction experiments was carried out by Tribalat and Beydon[24,50], who extracted technetium with a solution of tetraphenylarsonium chloride in chloroform. The equilibrium constant for the extraction reaction

$$(C_6H_5)_4As^+(aq.) + TcO_4^- \rightleftarrows (C_6H_5)_4AsTcO_4(org.),$$

is $\sim 3 \times 10^6$. The isolation was carried out as follows. Irradiated uranium trioxide $UO_3$ was dissolved in $H_2SO_4$ and the solution was treated with ammonium persulphate to oxidise $I^-$ ions to elementary iodine, which was extracted with toluene. The aqueous solution was boiled to remove traces of iodine, neutralised with $(NH_4)_2CO_3$, and treated again with ammonium persulphate. $TcO_4^-$ was then extracted with a solution of tetraphenylarsonium chloride in chloroform.

In the isolation of technetium from industrial solutions, extensive use has recently been made of extracting agents such as amines and ketones, which give high distribution constants for $TcO_4^-$.[28,51-55] For example, the extraction of technetium with pyridine from alkaline media makes possible selective and almost quantitative separation of technetium from nitrate and other solutions. This can be seen from Tables 2 and 3,[28] which give the distribution constants for technetium and certain other elements obtained by the fission of uranium, for extraction with pyridine from alkaline $NaNO_3$ and $Na_2CO_3$ solutions.

High distribution constants for technetium are given by methyl derivatives of pyridine. For example, the distribution constants for technetium in extraction from 2 M $(NH_4)_2CO_3$ solution using pyridine and 2-methylpyridine are 7.5 and 242 respectively. 3-Methyl- and 4-methyl-pyridines give even higher values of *E* than 2-methylpyridine. 2,4-Dimethylpyridine has proved particularly effective for the isolation of technetium from solutions with high nitrate ion concentration (for extraction from 4 *N* $NaNO_3$–0.5 *N* NaOH, *E* = 50). The technetium is usually recovered by distillation of the pyridine and its methyl derivatives, which can be used again. Another convenient method involves the re-extraction of technetium with non-polar solvents: chloroform, hexane, kerosene, and petrol, which also purify the technetium solution from organic impurities.

Amines have recently been used[3] to isolate kilogramme quantities of technetium from industrial wastes remaining after the fluorination of uranium irradiated in reactors. The technetium was recovered by repeated extraction with 2,4-dimethylpyridine, followed by purification by extraction with trioctylamine in petrol and repeated crystallisation as ammonium pertechnate from $NH_4NO_3$ solution.

TABLE 2. Distribution constants ($E$) for technetium in extraction with pyridine from alkaline $NaNO_3$ solutions of different concentration.

| $NaNO_3$, M | $E$ | |
|---|---|---|
| | 2 $N$ NaOH | 0.25 $N$ NaOH–2.0 M $Na_2CO_3$ |
| 0 | 54 | 740 |
| 0.25 | — | 110 |
| 0.50 | 19 | 89 |
| 0.75 | — | 71 |
| 1.0 | 16 | 58 |
| 1.5 | 12 | 52 |
| 2.0 | — | 42 |

TABLE 3. Distribution constants ($E$) for various uranium fission products in extraction with pyridine from 0.25 $N$ NaOH–2.0 M $Na_2CO_3$ solution.

| Fission product | $E$ |
|---|---|
| $^{99}Tc$ | 740 |
| $^{137}Cs$ | $2.87 \cdot 10^{-3}$ |
| $^{106}Ru$ | $1.27 \cdot 10^{-1}$ |
| $^{95}Zr$, $^{95}Nb$ | $6 \cdot 10^{-4}$ |
| $^{152-155}Eu$ | $6 \cdot 10^{-3}$ |
| $^{90}Sr$ | $3.48 \cdot 10^{-3}$ |

Another effective method[52,54] for the isolation of technetium in this case is by extraction with a 0.3 M solution of trilaurylamine in an organic solvent. After the removal of uranium with 0.5 $N$ $HNO_3$ and of neptunium with 0.1 $N$ $H_2SO_4$, the technetium was re-extracted with 1 $N$ $NH_4OH$ or 4 $N$ NaOH.

An extraction method using tributyl phosphate in kerosene has been developed for isolating technetium from sulphuric acid solutions[56]. Tributyl phosphate has not found wide application, however, because of the poor extraction of technetium from nitrate solutions by this solvent (the distribution constants for extraction from 0.5 M and 4 M $HNO_3$ are 1.36 and 0.04 respectively).

Chromatographic methods are based on the extensive sorption of pertechnate ion from weakly acidic, neutral, and alkaline media by strongly basic anion-exchange resins; most other fission elements ($^{137}Cs$, $^{90}Sr$, $^{152-155}Eu$, etc.) are not absorbed by anion-exchange resins. Appreciable sorption of $TcO_4^-$ takes place even from solutions with high concentrations of nitrate ion, which is usually present in the waste solutions from the atomic industry. Table 4 [28] gives the distribution constants for technetium between Dowex-1 resin and $NaNO_3$ solutions of different concentration.

According to data obtained by other workers[57], who carried out experiments under factory conditions and in plant assemblies, $TcO_4^-$ is readily absorbed by strongly basic anion-exchange resins from solutions with nitrate ion concentrations up to 7.5 $N$. This has made it possible to develop an effective and economic chromatographic method for isolating technetium from neutral industrial solutions ("Purex wastes")[57]. The solution was passed through a chromatographic column containing 5 litres of anion-exchange resin, and after desorption the technetium was separated from traces of ruthenium by oxidising the latter to $RuO_4$ and sorption on a cation-exchange resin. The technetium was then precipitated as the sulphides.

TABLE 4. Distribution constants ($E$) for technetium between Dowex-1 anion exchange resin and alkaline (0.25 $N$ NaOH) $NaNO_3$ solutions of different concentration.

| $NaNO_3$, M | $E$ |
|---|---|
| 0 | 4500 |
| 0.5 | 575 |
| 1.0 | 340 |
| 2.0 | 190 |
| 3.0 | 142 |
| 4.0 | 125 |
| 5.0 | 121 |
| 6.0 | 122 |

The method makes it possible to obtain in one stage a high yield (> 80%) of technetium with a chemical and radiochemical purity >99%.

In one of the latest improved chromatographic methods[58] acidic nitrate solutions of uranium fission products were treated with NaOH and the alkaline solutions were passed through a column of strongly basic anion-exchange resin. The technetium was then eluted with $HNO_3$, alkali was added to the solution, and the technetium was extracted with ethyl methyl ketone.

A new method for the production of technetium was recently developed in the USA[2,59]. In the processing of atomic fuel from gas-diffusion plants, technetium is separated from uranium hexafluoride by passing their heated mixture through a column packed with magnesium fluoride, in which the technetium is retained. The mechanism of the absorption of the technetium has not been studied in detail, but data which have been obtained suggest that the phenomenon is based on physical adsorption.

## 3. Methods of Isolating Technetium from Minerals in the Search for the Element in Nature

The detailed study of the chemical and physicochemical properties of technetium and its production in ponderable quantities have made it possible to undertake intensive searches for technetium in nature, and these have led to the detection of technetium in the sun's atmosphere and in young stars[60]. The question of the possible discovery of technetium in terrestrial materials is important in the geochemistry of this element[61-66]. Boyd and coworkers' searches[62] for technetium in various minerals showed that some of the minerals contained extremely small traces of the element.

Recently, Kenna and Kuroda[64-66] isolated appreciable quantities of technetium ($10^{-9}$ g) from pitchblende obtained in the Congo. Like Boyd, Kenna and Kuroda considered that the presence of technetium in the minerals results from the spontaneous fission of uranium or the activation of molybdenum, ruthenium, and niobium by powerful cosmic radiation.

A variety of methods, depending on the mineral studied, are available for the isolation and determination of technetium in natural materials. Chromatography, distillation, and coprecipitation have been used[62] in the analysis of minerals such as $MoS_2$ and yttrotantalite. The mineral was fused with five times its weight of $Na_2O_2$ in a zirconium or iron crucible. To control the chemical process, radioactive technetium (usually $^{96}Tc + {}^{95m}Tc$) was added

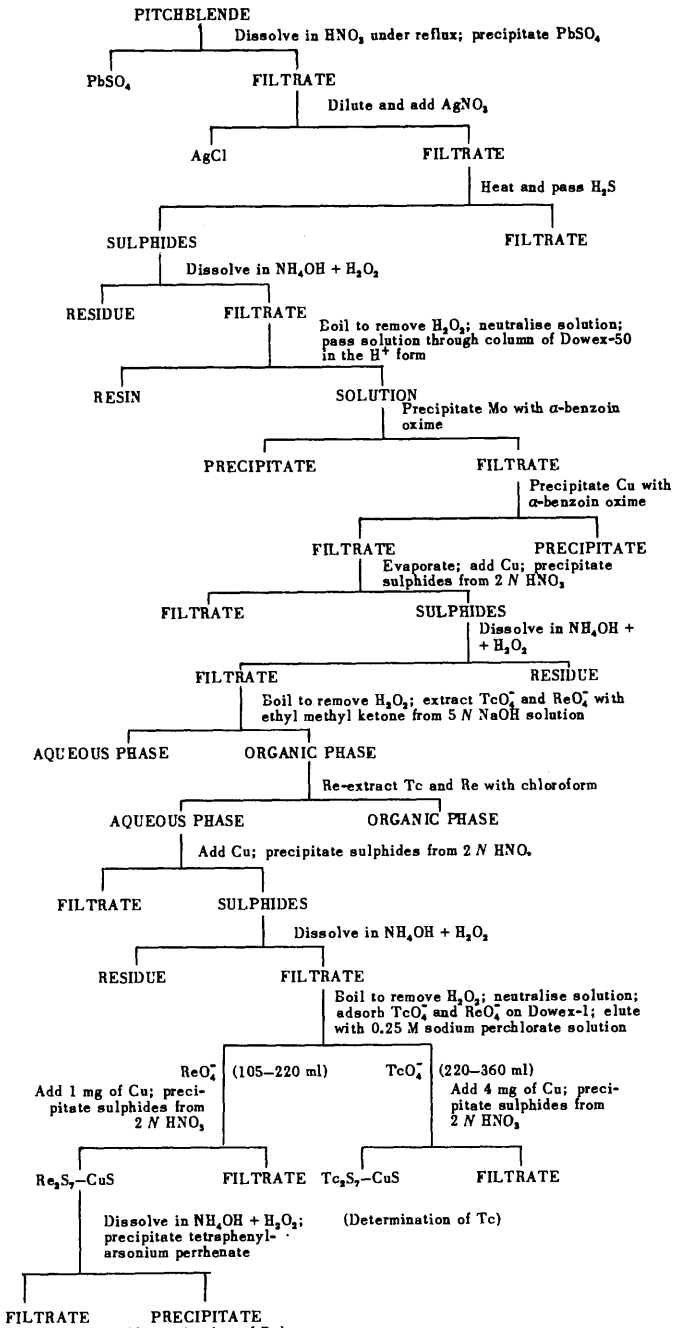

Fig. 1. Scheme for separating technetium from pitchblende.

at each stage to the material being studied. The melt was dissolved in water, the solution was boiled and cooled, and iron was precipitated as the hydroxide, 1–45 litres of the filtrate was passed through a 22 cm × 9.6 cm column of strongly basic anion-exchange resin (Dowex-2 or Amberlite IRA-410). The anion-exchange resin absorbed all the technetium, rhenium, and a small proportion of molybdenum, ruthenium, sulphate, etc. Sodium, copper, nickel, etc. cations passed through the column. Molybdates and other anions were then eluted with 1 M $NaNO_3$ at pH 10 or with 2 N NaOH, after the column had been washed with distilled water. Technetium and rhenium were eluted with 2 N $HClO_4$ or $NaClO_4$. The solution was acidified, heated, and treated with bromine water, after which rhenium and technetium sulphides were precipitated. The precipitate was dissolved in an $NH_4OH + H_2O_2$ mixture, the solution was evaporated to dryness, and the residue was dissolved in 10 M HCl. The main bulk of the rhenium was separated from technetium by precipitating rhenium sulphide with hydrogen sulphide in this medium. Further separation of technetium from rhenium was achieved by the methods of ion-exchange chromatography described below. Finally, technetium was coprecipitated with copper sulphide (1–1.5 mg Cu) and this "technetium concentrate" was treated by one of a number of methods for quantitative determination of technetium.

In addition to the above methods, methods involving the extraction of technetium have been used in the analysis of pitchblende[66]. A scheme illustrating the analytical operations involved in the isolation and purification of technetium from this mineral is shown in Fig. 1.

## III. METHODS OF SEPARATING TECHNETIUM FROM RHENIUM, MOLYBDENUM, AND RUTHENIUM

The most difficult task in the isolation of technetium from irradiated products is its separation from the neighbouring elements rhenium, ruthenium, and molybdenum. In the isolation of technetium from irradiated molybdenum it is necessary to separate it quantitatively not only from molybdenum, but also from rhenium, which is usually present in traces in the molybdenum and is concentrated with the technetium. In the extraction of technetium from fission products it is necessary to separate it from ruthenium isotopes, which, although formed in approximately the same yield as $^{99}Tc$, exhibit a very much higher specific activity.

Technetium is separated from these elements by methods involving distillation, extraction, precipitation and crystallisation, anion-exchange chromatography, etc.

### 1. Distillation Methods

Since the oxide $Tc_2O_7$ is volatile, heptavalent technetium can be codistilled with certain strong acids. Acids can be divided into three groups according to the extent to which codistillation of technetium with the acid takes place (Fig. 2 [15]): (1) with acids such as $HClO_4$ codistillation is quantitative, up to 75% of the technetium codistilling with the first 20% of distillate; (2) with $HNO_3$, aqua regia, $H_2SO_4$, and fuming $H_2SO_4$, codistillation is incomplete, appreciable quantities of technetium beginning to codistil only when more than half of the acid has been transferred to the distillate; (3) with acids such as HCl, HBr, and HI, technetium is not codistilled, since these acids reduce technetium to non-volatile compounds.

The degree of codistillation of technetium is influenced chiefly by the oxidising power of the acid, temperature, and the stability of the volatile oxide. The addition of oxidising agents to acids such as $H_2SO_4$ and $H_3PO_4$ increases appreciably the degree of codistillation of technetium, as can be seen from the curves in Fig. 2. The lower extent of the codistillation of this element with $H_2SO_4$ is due to the possible presence of reducing impurities.

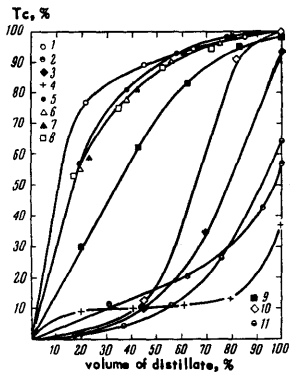

Fig.2. Codistillation of technetium with various acids.
1) $HClO_4$; 2) $H_2SO_4$; 3) fuming $H_2SO_4$; 4) $HNO_3$; 5) $H_2SO_4 + KIO_4$; 6) $H_2SO_4 + K_2Cr_2O_7$; 7) $H_2SO_4 + Na_2S_2O_8 + AgNO_3$; 8) $H_2SO_4 + KBrO_3$; 9) $H_2SO_4 + Na_2S_2O_8$; 10) $H_3PO_4 + KMnO_4$; 11) aqua regia.

The ability of technetium to undergo ready reduction in hydrochloric acid solutions has been used to develop a distillation method for separating technetium from rhenium[9,15,67]. The distillation is carried out at 180–200° from a mixture of sulphuric and hydrochloric acids. In this case an appreciable proportion of the rhenium (~95%) enters the distillate, whereas almost all the technetium is reduced to the tetravalent state by the hydrochloric acid and remains in the solution. The separation factor is equal to 50. This process was recently made the basis of another method[68] involving the reduction of pertechnate ion with hydroxylamine (the perrhenate ion is not reduced in the process). The rhenium is distilled from sulphuric acid containing hydroxylamine. The method can be used to separate 10 mg of rhenium from microquantities of technetium.

A method has been described for separating technetium and rhenium by distillation of the elements as the chlorides[69]. The distillation is carried out from a mixture of metallic technetium and rhenium or their sulphides, in a current of chlorine. Rhenium is then distilled from the distillate at 300° *in vacuo*; the technetium chloride decomposes, leaving metallic technetium.

Partial separation of these two elements can be achieved by codistillation with perchloric acid[9], but in this case ruthenium distils with the technetium.

Codistillation of technetium with sulphuric acid has been used to separate technetium and ruthenium[9]. In this case separation factors of the order of $10^5$ and above are obtained. In the absence of oxidising agents, however, the degree of codistillation of technetium is often very low, because of its reduction by impurities present in the acid[9,15]. (A detailed study[70] of the distillation of technetium with $H_2SO_4$ showed that technetium can be distilled quantitatively with $H_2SO_4$ if highly pure acid and scrupulously clean distillation apparatus are used.) In practice, therefore, complete distillation of technetium is best achieved by adding oxidising agents, which should moreover be non-volatile, stable in boiling sulphuric acid, sufficiently powerful to retain technetium in the heptavalent state, but incapable of oxidising lower valency states of ruthenium to the volatile $RuO_4$. It is very difficult to select oxidising agents satisfying these requirements, and $Ce^{IV}$ and $CrO_3$ are usually employed. In the distillation of technetium in the presence of oxidising agents some ruthenium distils as $RuO_4$, so that for the quantitative separation of technetium from ruthenium, the $RuO_4$ is reduced to insoluble $RuO_2$ by boiling the distillate with alcohol for 1–2 min.

Technetium and ruthenium can be separated from alkaline solutions by distillation of the $RuO_4$ in a current of chlorine[71].

## 2. Methods of Separation Based on Precipitation and Crystallisation

A convenient method for separating large quantities of rhenium from technetium involves the fractional precipitation of rhenium sulphide from concentrated hydrochloric acid solutions. Under these conditions technetium is not precipitated and remains in solution. Curves illustrating the dependence of the coprecipitation of microquantities of technetium and rhenium with platinum sulphide on the hydrochloric acid concentration at 90° are shown in Fig. 3.[15] Almost no technetium is coprecipitated at an HCl concentration 9 M and above, whereas rhenium is coprecipitated up to 10 M HCl. This difference in coprecipitation is due to the reduction of the pertechnate ions by hydrochloric acid to a lower valency state in which technetium is not coprecipitated with metal sulphides. An interesting feature is that complete coprecipitation of technetium with sulphides is observed from other acidic media (for example 24 *N* $H_2SO_4$) exhibiting no reducing properties. The separation by the above method is not quantitative, however (some Re remains in the solution), and the complete purification of Tc from Re requires the use of more refined methods (for example chromatography).

Satisfactory separation of Tc from Re can be achieved by reducing $Tc^{VII}$ with HCl and coprecipitating $Tc^{IV}$ with $Fe(OH)_3$.[29,72] The technetium can then be oxidised to the heptavalent state by oxidising the precipitate in concentrated $HNO_3$ or dilute $H_2SO_4$ in the presence of $H_2O_2$, and precipitating the iron from solution with ammonia.

The separation of ponderable quantities of Tc and Re can be achieved by fractional crystallisation of potassium pertechnate and perrhenate (Fig. 4)[15], and small quantities of ruthenium can be separated by recrystallising $KTcO_4$.[8]

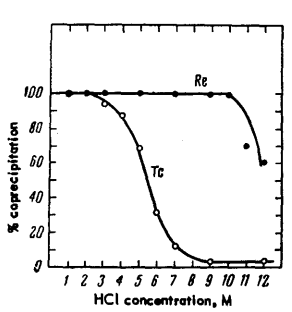

Fig.3. Coprecipitation of technetium and rhenium with $PtS_2$ at different HCl concentrations (90°).

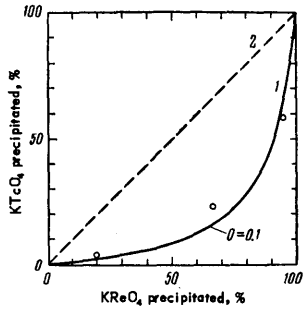

Fig. 4. Separation of $KTcO_4$ from $KReO_4$ by fractional crystallisation:
1) experimental data; 2) calculated data.

Precipitation methods for separating technetium and molybdenum have been described above. These involve the precipitation of molybdenum with 8-hydroxyquinoline or $\alpha$-benzoin oxime or as silver or lead molybdate. On the other hand, the pertechnate ion can be separated from an alkaline solution containing molybdenum or ruthenium, by coprecipitation with tetraphenylarsonium perrhenate or perchlorate. The latter is more convenient, since the technetium is subsequently more readily separated.

### 3. Extraction Methods

Extraction methods are very effective for the recovery of technetium from various materials and its separation from most elements of the Periodic System, but they generally do not give quantitative separation of this element from its analogue rhenium. Some extraction methods are fairly effective for the separation of technetium from molybdenum and ruthenium, however. As noted above, appreciable separation of technetium from molybdenum and ruthenium can be achieved by extraction with pyridine[26-28] from alkaline media and by ketones[28-32] from 3–5 $N$ solutions of alkalis or alkali metal carbonates. In this case the technetium can be re-extracted in the aqueous phase with chloroform or other non-polar solvents. Another effective method for the separation of technetium and molybdenum is that based on the extraction of tetraphenylarsonium pertechnate with chloroform[24,25,50]. Before extraction it is best to add small quantities of oxidising agent such as $H_2O_2$ to prevent the reduction of $TcO_4^-$ by impurities in the organic reagents. During washing, the solution should contain a sufficient concentration of tetraphenylarsonium ion ($\sim 5 \times 10^{-5}$ M) to prevent the premature re-extraction of $TcO_4^-$ into the aqueous phase. The technetium is re-extracted with 0.2 $N$ $HClO_4$ or 12 $N$ $H_2SO_4$. Finally, technetium and molybdenum can be separated by extracting the molybdenum with ether from hydrochloric acid solutions[8,67,73]. In this case the best results are obtained[73] by extracting the molybdenum with ethyl ether from 1 M HCl–1 M $NH_4NCS$ solution. Radiochemically pure technetium is left in the aqueous phase in ~80% yield.

An effective extraction method for the separation of technetium and ruthenium was developed in the Geochemical Institute of the USSR Academy of Sciences[74]. It is based on the extraction of technetium as triphenylguanidinium pertechnate from sulphuric acid by means of chlorex ($\beta$-chloroethyl ether). The technetium can be re-extracted with 3 $N$ $NH_4OH$ solution.

It has been suggested[75] that in the separation of a mixture of technetium and ruthenium in uranium fission products the extraction be first carried out with pyridine from 4 $N$ NaOH in the absence of oxidising agent. In this case only technetium, which is present in solution as $TcO_4^-$, is extracted. NaOCl is then added to the aqueous phase, the Ru is oxidised to $RuO_4^{2-}$, and extracted with pyridine.

Partial separation of technetium from rhenium can be achieved by extraction of the cupferron complex of technetium after reducing the latter to a lower valency state[76]. In this connection, mention may be made of the need for study of the extraction separation of technetium and rhenium using ethyl methyl ketone, from alkaline solutions containing reducing agents, such as hydrazine or hydroxylamine.

Extraction methods are widely used in the analytical chemistry of technetium for separation, isolation, and determination. Table 5 gives data on the extraction of technetium compounds with different organic solvents and the fields in which they are used.

TABLE 5. Extraction of technetium compounds by various organic solvents.

| Technetium compound | Extracting agent | Applications | References |

### 4. Chromatographic Methods of Separation

The most effective method for the quantitative separation of technetium from rhenium and molybdenum is ion-exchange chromatography. In the isolation of technetium this method is generally used in the last stage of the purification of technetium from these elements, when the main bulk of the impurities have been removed by other methods, such as distillation, extraction, precipitation, etc. As already noted, the chromatographic method is based on the extremely strong sorption of the pertechnate ion by strongly basic anion-exchange resins, from which it can be eluted only by ions with a high affinity for the resin. The nature of the eluent thus plays an extremely important part in methods for the chromatographic separation of technetium, rhenium, and molybdenum. The eluents used in analytical practice are solutions containing the anions $SCN^-$,[90,91] $NO_3^-$,[91] and $ClO_4^-$.[62,92]

Atteberry and Boyd[90] separated $TcO_4^-$ and $ReO_4^-$ on Dowex-2 resin in the $SO_4^{2-}$ form, using as eluent a mixture of ammonium sulphate and thiocyanate, with pH 8.3–8.5. Rhenium was first eluted with a 0.1 M solution of these salts, after which technetium was extracted by increasing the concentration of the salts in the eluent to 1 M. Technetium and rhenium were also separated by successive elution from a column of Amberlite IRA-400 resin in the $Cl^-$ form using $NH_4CNS$ and $HNO_3$ solution[91]. Rhenium was eluted with 5% $NH_4CNS$ solution and technetium with 4 M $HNO_3$.

A more effective separation of $TcO_4^-$ and $ReO_4^-$ was achieved by using perchloric acid or ammonium perchlorate as eluent[62,92]. The separation was carried out[92] on a 23 cm × 0.204 cm column filled with Dowex-1-X4 anion-exchange resin in the $ClO_4^-$ form (200–400 mesh); 0.2 M $HClO_4$ was used as eluent. The elution of rhenium required 23.6 free column volumes and the elution of technetium 47.7 free column volumes (Fig. 5). The same quantities of eluents are used when ammonium perchlorate solution is taken for this purpose. The volumes of eluents used to extract rhenium and technetium are inversely proportional to the perchlorate ion concentration.

In the development of a method for the chromatographic separation of $TcO_4^-$ and $ReO_4^-$, it was found[92] that the efficiency of separation of the anions is influenced considerably by effects such as the possible partial reduction of technetium by the anion-exchange resin or the formation of radio-colloids; this often leads to indistinct peaks and less effective separation. To eliminate these effects, it would be useful to study the anion-exchange separation of technetium and rhenium by means of concentrated solutions of hydrochloric acid, which selectively reduces $Tc^{VII}$ to $Tc^{IV}$ with the formation of the complex anions $TcCl_6^{2-}$. Some anion-exchange resins, particularly the AV-17 resin produced in the Soviet Union, have a high absorbing power for complex anions from acidic media[93]. This can apparently be used for the effective separation of technetium and rhenium.

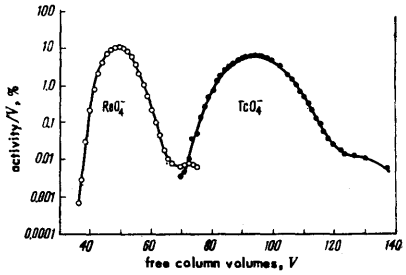

Fig. 5. Chromatographic separation of technetium and rhenium on Dowex-1-X4 anion-exchange resin. Rate 0.75 cm $min^{-1}$.

Chromatographic methods for the separation of Tc and Mo have been based on the successive elution of $MoO_4^{2-}$ with 1 M HCl [94] or 3 M NaOH [23] and $TcO_4^-$ with 4 M $HNO_3$ or 1 M $HClO_4$ respectively.

Lederer and coworkers[95-97] developed a method for separating technetium and molybdenum by paper chromatography, and Garvalho[98] developed a method using electrophoresis. The separation of Tc and Re by these methods was not efficient, but more effective separation was achieved by the selective reduction of $TcO_4^-$ with HCl,[99] HI, or $NH_2NH_2$.[98]

### 5. Electrochemical and Other Methods

Electrochemical methods are based on the selective electrolytic reduction of Tc to $TcO_2$ under definite conditions and its deposition on electrodes, while Re and Mo remain in solution. Rogers[21] developed a method for the electrolytic deposition of Tc on a Pt cathode from 2 M NaOH solution at a controlled cathode potential of 1.1 V.

Boyd *et al.*[15] studied the electrodeposition of technetium under different conditions and showed that the optimum deposition is achieved from neutral media containing $10^{-3}$ M $F^-$ ion. The small quantity of $F^-$ ions apparently increases the hydrogen overvoltage and improves the electrodeposition of Tc. The deposition is also improved by replacing the Pt cathode with polished Ni or Cu electrodes.

A method based on complex formation by technetium with phthalocyanine has also been developed for separating small quantities of technetium and rhenium[61]. Rhenium does not form these complexes. In the separation it is best to use copper phthalocyanine as carrier.

## IV. METHODS OF DETERMINING TECHNETIUM

### 1. Gravimetric Methods

Large quantities of technetium are readily and conveniently determined by gravimetric methods. Two methods for the determination of technetium are known: (1) precipitation of technetium(VII) sulphide and weighing as $Tc_2S_7$;[15,100] (2) precipitation and weighing as tetraphenylarsonium or nitron pertechnates[46].

Technetium sulphide is often the final product in general schemes for the purification of technetium. The concentration process is usually completed by the precipitation of $Tc_2S_7$. The precipitation is carried out from 2–4 M HCl or $H_2SO_4$ using hydrogen sulphide. The precipitate is washed carefully several times with carbon disulphide to remove the sulphur formed. A necessary condition for maximum precipitation of technetium is that the element be in the heptavalent state. This method can be used to determine technetium concentrations down to 3 $\mu g$ $ml^{-1}$.

In the precipitation of tetraphenylarsonium pertechnate, the sensitivity of the determination is reduced to 5 $\mu g\ ml^{-1}$. The precipitation is usually carried out from hot alkaline solution at pH 8–9 by adding 0.05 M $(C_6H_5)_4AsCl$ solution. The resulting precipitate is washed several times with cold distilled water, dried at 110°, and weighed as tetraphenylarsonium pertechnate $(C_6H_5)_4AsTcO_4$. Permanganate, perrhenate, perchlorate, iodide, and bromide ions interfere.

## 2. Spectrophotometric Methods

Aqueous solutions of the pertechnate ion absorb strongly in the ultraviolet range (Fig. 6). Careful measurement of the absorption spectra reveals characteristic peaks with maxima at 247 mμm and 285 mμm.[8,101-104]. It was also found that for these wavelengths Beer's law is obeyed to a pertechnate ion concentration $10^{-3}$ M. This makes it possible to determine 1 μg of technetium spectrophotometrically[62,108]. This method is particularly convenient for the simultaneous determination of technetium and rhenium (Fig. 6).

Spectrophotometric methods based on the measurement of the absorption of technetium complexes are more sensitive. In Crouthamel's method[82], the absorption of the red complex formed by technetium(V) with thiocyanate ions was measured at 510 mμm. The method is very sensitive but certain elements such as uranium and iron interfere. Moreover, the complete development of the colour, which is produced by the slow reduction of $Tc^{VII}$ to $Tc^{V}$ by thiocyanate, requires a considerable time (~3 h), and this is a disadvantage.

In Howard and Weber's work[83] on the development of a rapid method for determining technetium in uranium materials, particular attention was paid to increasing the rate of the reduction process. The use of ascorbic acid for the reduction of $Tc^{VII}$ to $Tc^{V}$ was recommended for rapid development of the colour. Iron(III) was added to the solution to prevent further reduction to $Tc^{IV}$. The red thiocyanato-complex of technetium(V) was extracted from 3 *N* HCl with butyl acetate, and the extract was washed twice with 30% $NaH_2PO_4$ solution to remove iron. The spectrophotometry was then carried out at 585 mμm ($\epsilon$ = 16 500) in the presence of molybdenum or at 510 mμm ($\epsilon$ = 50 000) when molybdenum was absent. This method can be used to determine 0.3 μg of technetium in 5 g of uranium. The accuracy of the method is ±0.07 μg in the determination of 0.5 μg and ±0.2 μg in the determination of 30 μg of technetium. The determination requires 15 min.

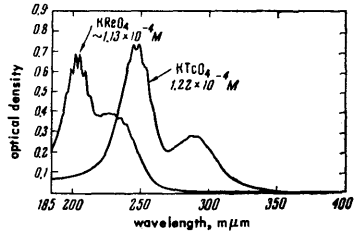

Fig. 6. Absorption spectra of aqueous $KTcO_4$ and $KReO_4$ solutions.

Miller and Thomason[105] developed a method for the spectrophotometric determination of technetium using thioglycollic acid as the complex-forming reagent. The absorption of the coloured solution was measured at 655 mμm. The method is rapid, but insufficiently sensitive. Moreover, many elements such as uranium, iron, etc. interfere in the determination. Later, the same authors developed another method[87], in which the complex formed by technetium with toluene-3,4-dithiol was extracted with carbon tetrachloride and the absorption was measured at 450 mμm. This method is more sensitive than that in which thioglycollic acid is used, but many elements again interfere in the determination and the extraction equilibrium is established only slowly.

Miller and Zittel[86] recently proposed a new method for the spectrophotometric determination of microgramme quantities of technetium using diphenylcarbazide (1,5-diphenylcarbohydrazide). The determination was carried out in 1.5 M $H_2SO_4$, in which diphenylcarbazide reduces $Tc^{VII}$ to $Tc^{IV}$ and forms a stable complex with the latter. The molar extinction coefficient of solutions of this compound is 48 600. Complete development of the colour requires 35–40 min, after which the absorption of the solution is measured at 520 mμm. $VO_3^-$, $MoO_4^{2-}$, $ReO_4^-$, and $Hg^{2+}$ cause little interference in the determination, but $Fe^{3+}$, $Ce^{4+}$, and $CrO_4^{2-}$ should be removed from the solution. Thus in the determination of technetium in the presence of $Cr^{VI}$, technetium diphenylcarbazide was extracted with chloroform (the corresponding $Cr^{VI}$ compound is not extracted) and the optical absorption of the extract was measured.

A convenient method for the determination of microgramme quantities of technetium in the presence of rhenium using *p*-thiocresol has been described[84]. *p*-Thiocresol does not react with $Tc^{VII}$ and and $Re^{VII}$, but reacts with these elements in lower valency states to form coloured complexes which are readily soluble in $CCl_4$, benzene, and ether. In acetic acid solutions, *p*-thiocresol reduces technetium to the tetravalent state with the formation of a complex with absorption maxima at 320–325 mμm and 410 mμm. The maximum at 410 mμm is used for the determination of technetium. The molar extinction coefficient of the solutions of the compound at this wavelength is 7350. $Re^{VII}$ is not reduced under these conditions and does not interfere in the determination. $WO_4^{2-}$, $Sn^{2+}$, $Cd^{2+}$, $Bi^{3+}$, $Pb^{2+}$, $Ni^{2+}$, $Cr^{3+}$, $VO_3^-$, $UO_2^{2+}$, $S^{2-}$, and $MoO_4^{2-}$ do not interfere but ions of elements of the platinum group react with the reagent to form coloured complexes which are readily extracted by chloroform.

The ability of technetium to undergo comparatively ready reduction by concentrated HCl with heating, and to form the anionic complexes $TcCl_6^{2-}$, was used by the author of the present review to develop a new method for the spectrophotometric determination of technetium in the presence of microgramme quantities of molybdenum and rhenium[106]. The molar extinction coefficient of solutions of the chloro-complex of technetium(IV) is 32 000. The method is simple, has a high sensitivity (0.2 μg), and low experimental error (~ 2%).

α-Furyl dioxime can also be used for the spectrophotometric determination of technetium[88,107]. The determination is carried out in the presence of $SnCl_2$ in 1 M HCl. The light absorption is measured at 520 mμm ($\epsilon$ = 13 181). The presence of a 10-fold excess of molybdenum ($10^{-4}$ M) relative to technetium ($10^{-5}$ M) does not interfere in the determination. The sensitivity of the determination is not high, however (~1 μg), and the time required is fairly long (~2 h).

Methods have also been proposed for the determination of technetium with thiourea and dimethylglyoxime[86], potassium hexacyanoferrate(II), and sulphosalicylic and α-picolinic acids[89].

### 3. Radiometric Method

The simplest and earliest method for determining $^{99}Tc$ is the radiometric method, based on the measurement of the β-activity of this isotope on a proportional β-counter[108]. The specific activity of technetium is fairly high (37 800 counts $min^{-1}$ $\mu g^{-1}$), so that this method can be used to estimate 0.1 μg of technetium. The low energy of the β-particles from $^{99}Tc$ (~0.3 MeV) introduces a number of difficulties into the measurement, associated with self-absorption in the specimen, back β-scattering, etc. Despite these disadvantages, the radiometric method in some cases makes possible more accurate determination of the technetium content than chemical methods.

Geiger–Muller counters are often used for the identification and determination of the activity of the nuclear isomer emitting soft γ-quanta (~0.3 MeV), but it is better to carry out the measurements on a γ-scintillation counter or spectrometer[9,109].

### 4. Spectroscopic Method

The spectrochemical method provides a sensitive method for the determination of technetium. It is based on the use of the resonance lines in technetium at 4297.06, 4262.26, and 4238.19 Å and Tc-1 at 4031.63 Å. The method can be used to determine 0.1 μg of technetium[62].

Milligramme quantities of technetium and rhenium can be determined by infrared spectroscopy[110]. Tetraphenylarsonium pertechnate is pressed with sodium bromide into a disc and the infrared absorption is measured at 11.09 mμm. $MoO_4^{2-}$, $WO_4^{2-}$, $SO_4^{2-}$, $PO_4^{3-}$, $Br^-$, $NO_3^-$, $NCS^-$, $IO_3^-$, $UO_2^{2+}$ ions and the ions of organic acids do not interfere, but $ReO_4^-$ and $MnO_4^-$ ions absorb infrared radiation in an adjacent region and should be removed before the determination of technetium.

### 5. Polarographic Method

Traces of technetium can also be determined polarographically[111-113] from the waves produced in the polarographic reduction of $Tc^{VII}$ at at dropping mercury electrode (Fig. 7)[113]. The first wave at pH 2, corresponding to the four-electron reduction of technetium, together with the first and second waves at pH 13, due to the three- and one-electron reductions respectively, can be used for the determination of technetium in the presence of rhenium. Measurement of the third catalytic wave gives maximum sensitivity and has been used[113] for the determination of very small quantities of technetium.

In neutral solutions with 1 M $NaClO_4$ as the supporting electrolyte a distinct diffusion wave with a half-wave potential $E_{1/2}$ = -0.8 V is observed[114], corresponding to the three-electron reduction. This has made it possible to determine technetium fairly accurately. In the range $5 \times 10^{-3}$–$8 \times 10^{-2}$ M, the technetium concentration is directly proportional to the magnitude of the limiting current.

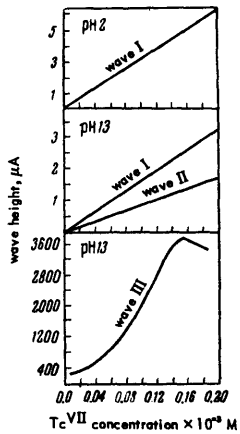

Fig. 7. Dependence of the height of the polarographic wave on the $Tc^{VII}$ concentration.

Miller *et al.*[111] developed methods for determining technetium in buffer solution at pH 7, and White and Thomason[115] determined milligramme quantities of this element by potentiometric titration with chromium sulphate.

A recent paper[112] described a simple rapid method for determining technetium by coulometric titration at controlled potential (-0.70 V) in an acetate-buffer tripolyphosphate solution. The relative error in the determination of 0.5–5 mg of technetium is ±1%. Many ions, for example $ReO_4^-$, $MnO_4^-$, $CrO_4^{2-}$, $Ce^{4+}$, $Cu^{2+}$, $Zn^{2+}$, $Cl^-$, $ClO_4^-$, and $SO_4^{2-}$, do not interfere, but ions such as $Fe^{3+}$, $MoO_4^{2-}$, $Ru^{4+}$, $UO_2^{2+}$, $VO^{2+}$, $F^-$, and $NO_3^-$ cause interference. Technetium can be separated from interfering elements by codistillation with sulphuric acid.

For the rapid determination of $^{99m}Tc$ in a mixture of uranium fission products, Love and Greendale[116] used the method of amalgam polarography. Technetium was concentrated in the mercury drop, after which its activity was measured. The coefficient of purification was $10^5$ and the accuracy of the determination was ~1%.

### 6. Mass-Spectrometric Method

The mass-spectrometric method has been used for the identification of technetium in the isolation of the latter from the fuel elements of the reactor in the first atomic power-station[117] and, in conjunction with isotopic dilution methods, for quantitative determination[62].

The determinations were made on mass-spectrometers with a 60° magnetic field and chamber radius 15–20 cm. Technetium was deposited on the iridium emitter in the form of aqueous ammonium pertechnate solution from a micropipette[117], or electrolytically[62]. After the emitter had been heated at 400° in an atmosphere of hydrogen to reduce the technetium to the metal, the ion source of the specimen was placed in the mass-spectrometer, in which $Tc^+$ ions were produced at 1600–1800°.

In the quantitative determination of $^{97}Tc$ and $^{98}Tc$ in minerals[69] by this method a known quantity of $^{99}Tc$ was

TABLE 6. Sensitivity of methods for determining microgramme quantities of technetium.

| Method | Sensitivity, g |
|---|---|
| Gravimetric | $(3—5)\cdot10^{-6}$ |
| Spectrophotometric | $3\cdot10^{-7}$—$10^{-6}$ |
| Radiometric | $10^{-7}$ |
| Spectroscopic | $10^{-7}$ |
| Polarographic | $5\cdot10^{-6}$ |
| Mass-spectrometric (using isotopic dilution method) | $5\cdot10^{-9}$ |
| Neutron-activation | $2\cdot10^{-11}$ |

introduced into the solutions containing the technetium to be determined, before deposition on the emitter; the $^{99}$Tc served as isotopic diluent. The quantitative determination was made by the isotopic dilution method from the change in the isotopic composition on mixing[118]. The sensitivity of the determination is $5 \times 10^{-9}$ g, which is much higher than the methods previously described.

### 7. Neutron-Activation Method

The most sensitive method for the determination of traces of technetium is neutron-activation analysis, which has been used successfully by Boyd and Larson[62] in the search for technetium in natural materials. The determination of the $^{99}$Tc content by the neutron-activation method is based on irradiation of the specimen with slow neutrons and the formation, as a result of an $(n,\gamma)$-reaction, of the radioactive $^{100}$Tc, with a half-life of 15.8 s. $^{99}$Tc has a fairly high thermal-neutron capture cross-section (20 barn), and this makes it possible to determine down to $10^{-11}$ g of technetium by this method. Because of the fairly short half-life of $^{100}$Tc, however, this method has not been widely applied.

The sensitivities of all the above methods of determination are compared in Table 6.

## V. FUTURE DEVELOPMENTS

One of the main tasks in the analytical chemistry of technetium is the development of new, effective, and economic methods for concentrating technetium from its extremely dilute solutions containing high concentrations of various salts. A promising method in this connection is ion-exchange chromatography with strongly basic anion-exchange resins, which make it possible, for example, to extract and purify technetium from concentrated nitrate solutions. Study of the sorption capacity and selectivity of a variety of synthetic anion-exchange resins and inorganic sorbents for technetium ions in various media is therefore of interest.

The development of extraction methods for concentrating technetium from various materials is desirable. Of particular promise are extraction methods for isolating and purifying technetium from fairly concentrated technetium solutions, and also for the preliminary concentration of the element for subsequent spectrophotometric, spectroscopic, or polarographic determination.

Studies of the lower valency states (less than seven) of technetium with a view to their utilisation in analytical chemistry are necessary. In these valency states, technetium forms a variety of complexes which may be used for the selective concentration, separation, and determination of technetium in extraction, chromatographic, spectrophotometric, and other methods of analysis. The study of the varied analytical properties of this element, which exhibits both metallic and non-metallic character, and also the investigation of new possible applications in science and technology, are of interest.

## 1. INTRODUCTION

Molten salts form a large class of the liquids which exhibit electrolytic conductivity. The principal structural units in molten salts are ions, they are therefore also terms ionic liquids.

The practical importance of molten salts has increased considerably in recent years in connection with the development of new branches of metallurgy and energetics. Molten salts are widely used for the electrolytic production of various light and rare metals[1,2], used in nuclear technology as heat transfer media or reactor fuels[2,3], employed as electrolytes in fuel cells[4], etc. Recently there has been a sharp increase in the number of publications — both research papers and review articles. Reviews and monographs on various aspects of the physics and chemistry of molten salts have been published by Belyaev *et al.*[5], Voskresenskaya[6], Delimarskii and Markov[7], Morachevskii[8-10], and many other authors[2,3,11-20]. The earlier investigations have been critically discussed and reviewed[1,21].

Electrolytic conductivity and other properties of molten salts are explained if the salts are considered to be composed of charged structural units — ions. In characterising the properties of molten salts and comparing them with the properties of ionic crystals, reference is sometimes made to dissociation on melting. However, here the term "dissociation" has only conventional significance, since during fusion there is no decomposition of neutral molecules into ions. The fusion of a salt is essentially the destruction of the crystal lattice, usually accompanied by an increase in volume. The extra volume produced ensures freer movement of ions, so that it is more logical to speak of the disordering or disintegration of the crystal lattices than of dissociation. The condensation of salt vapours, which consist of neutral molecules, is accompanied by self-dissociation, as a result of which ions, earlier bound in pairs, are socialised, are collectivised, to form an ionic liquid. In this respect there is a definite analogy between salts and metals, since in the condensation of metal vapours there is the collectivisation of the electrons[22].

It is natural for properties of molten salts such as electrical conductivity, viscosity, diffusion, surface tension, heats of phase transformations, and so forth to depend on the characteristics of the ions forming the melt — their dimensions, masses, polarisability, and charge. However, in considering this dependence it is necessary to take into account that the ions in the melt form a single collective, exhibiting a definite structure. Just as the properties of ionic crystals are determined not only by the properties of the individual ions, but also by the properties of their set, that is, the crystal lattice, the properties of molten salts can be understood only by studying their structure. In turn, a study of the properties of salt melts permits assessment of their structure and makes possible their quantitative characterisation.

The development of the theory of the liquid state as applied to molten salts shows that their principal properties are due to the structural peculiarities more than to

the properties and interaction of the individual ions. This is shown especially clearly by the example of electrical conductivity of molten salts. Most of the ions in a melt are vibrating at each moment of time at definite equilibrium positions analogous to the nodes of a crystal lattice; these ions cannot participate in forward motion even in very strong fields, and consequently cannot take part in the transport of electricity. Forward motion becomes possible for a given ion only when a neighbouring equilibrium position becomes vacant, that is, as a result of fluctuations in the structure.

In the present review an attempt is made to consider the experimental data available about the properties of pure molten salts in the light of contemporary theoretical views about their structure and molecular constitution.

Until recently the ionic–molecular composition of molten salts had been studied solely by cryoscopic methods. Not long ago spectroscopy and X-ray diffraction became widely used for this purpose. The essence of the cryoscopic method lay in the use of the Raoult–van't Hoff law, according to which the freezing point depression $\Delta T$ on dissolution of a foreign salt in a given melt is

$$\Delta T_f = \nu \frac{RT_f}{L_f} \times \frac{M}{1000} \times m = \nu m k_f, \qquad (1)$$

where $M$ is the molecular weight of the solvent, $L_f$ its heat of fusion, $m$ the molarity of the solution, $k_f$ a cryoscopic constant, and $\nu$ the number of particles, foreign with respect to the solvent, which are formed from one molecule of the solute salt. Naturally, study of the freezing point depression not only permits confirmation of the ionic structure of the salt but also provides concrete information about the ionic composition of the melt.

The number of cryoscopic investigations is very large. The older works on the cryometry of molten salts were discussed by Hoenen[23] and contemporary investigations in the review of Janz *et al.*[11] The earlier works on cryometry (Zakura and others[21,23]) were not distinguished by exceptional accuracy. In later years Janz and coworkers[24,25], Kordes and coworkers[26–28], and others[29–52] made careful measurements of freezing point depressions. As an example Fig. 1 gives $\Delta T_f = f(m)$ curves for molten $AgNO_3$, and shows that Eqn. (1) is obeyed satisfactorily. Some deviations can be related to the formation of solid solutions or with the non-ideality of the system[29].

The scheme of "dissociation" of salts, as follows from the cryometric results, usually corresponds with the ionic structure of the crystals. The particles bound in the crystal, mainly by electrostatic forces, form relatively free ions in the melt, for example, $Na^+$, $Cl^-$, $NO_3^-$, etc. Complex ions, between the structural constituents of which covalent forces act ($NO_3^-$, $CO_3^{2-}$, $SO_4^{2-}$) behave as integral units and there are no signs of their decomposition into their individual constituents. In certain cases the fusion of ionic crystals leads to the formation of new, more complex ions. Thus it follows from cryoscopic measurements that in the dissolution of NaF in $PbF_2$ $\nu = \frac{1}{2}$, and in the dissolution of NaF in NaCl $\nu = 1$.[16] These results can be explained by assuming that a complex ion is formed during the fusion of sodium fluoride:

$$2NaF \rightleftarrows Na_2F^+ + F^-.$$

The formation of such autocomplexes during fusion is also possible in several other instances.

## 2. OPTICAL PROPERTIES OF MELTS

More complete information about the ionic composition of molten salts can be obtained by the study of optical properties.

Many authors have studied the absorption spectra of molten salts[53–65], and it has been shown that they usually absorb in the ultraviolet region. Their absorption spectra are essentially different from those of salt vapours. The latter usually exhibit absorption bands spaced over a rather wide range of frequencies and which consist of many closely spaced spectral lines. The molecular absorption spectra of melts consist of wide bands with one or two maxima. This diffuseness is linked with the small distance between the ions and the strong excitation of the electron clouds of the absorbing particles by the neighbour ions.

The absorption band of a molten salt is connected with the excitation of the outer electron in the anion and its transfer to an orbital in the field of neighbouring cations. Ionic crystals give similar spectra (Fig. 2).

The energy corresponding to maximum absorption is

$$\varepsilon_{max} = \varepsilon_i - h^2/8mr_0, \qquad (2)$$

where $\epsilon_i$ is the ionisation potential of the anion, $m$ the mass of an electron, and $r_0$ the radius of the excited orbital, equal to the inter-ionic distance less the radius of the cation[63–65]. In the absorption band the optical density is usually very

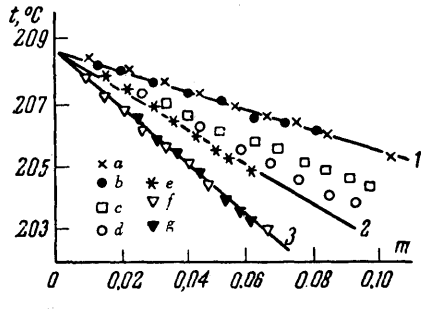

Fig. 1. Depression of the freezing point of $AgNO_3$ [26] on dissolution of: *a*) $Ag_2SO_4$; *b*) $KNO_3$; *c*) $ZnSO_4$; *d*) $PbSO_4$; *e*) $KClO_4$; *f*) $PbCl_2$; *g*) $K_2Cr_2O_7$. 1), 2), and 3) calculated curves for $\nu = 1$, 2, and 3 respectively.

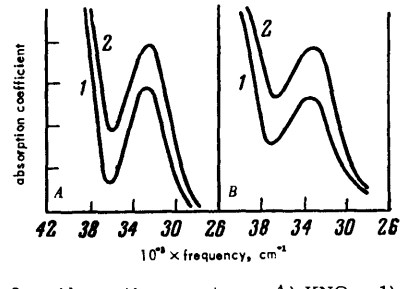

Fig. 2. Absorption spectra. *A*) $KNO_3$: 1) 338°, melt; 2) 333°, crystal. *B*) $NaNO_3$: 1) 308°, melt; 2) 304°, crystal.

great[59,60], so that the structure of the spectrum cannot always be established. Therefore some authors characterise the spectra by the parameters of the absorption edge ($\epsilon_{edge}$, $\lambda_{edge}$) and not by the energy or wavelength at the absorption maximum ($\epsilon_{max}$, $\lambda_{max}$).

There is little information about the dependence of the absorption spectrum on the nature of the salt. For the alkali metal halides, on going from Cs to Li there is a displacement of the absorption band into the violet, and on going from Cl to I, into the red side. The absorption limit of the alkali metal halides near their melting points lies at about 250–350 mμm and that of the halides of the metals of the auxiliary subgroups in the 500–600 mμm region[53,60]. A quantitative relation has been found for the alkali metal nitrates between the spectra and the cation radius:

$$\varepsilon_{max} = 3.81 + 0.33/r_+, \text{ eV}. \quad (3)$$

Probably, analogous relations exist for other salts.

A temperature dependence of the absorption spectra is predicted by Eqn. (2) and is expressed by the formula:

$$\varepsilon_{max} = \varepsilon_0 - \kappa t, \quad (4)$$

in which the coefficient $\kappa$ is proportional to the coefficient of thermal expansion of the salt[55,58,60,63]. It is also noted, that for many salts the $\epsilon_{max}(t)$ curves do not have inflections near the melting point, showing that there is no complex formation[54-58,63].

There is another important parameter of molten salts — their refractive indices. Both the old work[66-68] and the more recent investigations of Bloom[13,14,69,70], Thurmond[58], and Murgulescu[71] show that the refractive indices of melts decrease linearly with rise in temperature:

$$n_t = n_0 - bt. \quad (5)$$

The dependence of the refractive indices on the nature of the salt is shown in Table 1.

It is more convenient to characterise a melt by its molecular refraction:

$$R = \frac{n^2 - 1}{n^2 + 2} \times \frac{M}{\rho}, \quad (6)$$

TABLE 1. Refractive indices of molten salts for the sodium D line[13,14].

| Salt | $n_0$ | $10^4 b$ | $\Delta t$, °C |
|---|---|---|---|
| LiCl | 1.590 | 1.60 | 620—750 |
| KCl | 1.667 | 3.50 | 780—810 |
| AgCl | 2.148 | 2.10 | 480—656 |
| $CdCl_2$ | 1.735 | 0.35 | 590—700 |
| $PbCl_2$ | 2.244 | 3.67 | 515—620 |

TABLE 2. Molecular refractions of salt melts ($cm^3$) for the sodium D line[13,70,72]

| Salt | $t$, °C | $R_{melt}$ | $R_{crystal}$ | $R$ for infinitely dilute solution |
|---|---|---|---|---|
| LiCl | 650 | 8.20 | 7.59 | 8.42 |
| NaCl | 850 | 9.48 | 8.52 | 8.88 |
| KCl | 800 | 11.68 | 10.85 | 10.93 |

which for most salts is almost independent of temperature and is, to a known degree of approximation, the sum of the refractions of the individual ions. This follows, in particular, from the fact that the molecular refractions of molten salts, crystals, and infinitely dilute aqueous solutions are close to one another (Table 2).

## 3. RAMAN SPECTRA AND INFRARED SPECTRA OF MOLTEN SALTS

An investigation of Raman spectra and infrared spectra provides a possibility of obtaining important information about the structure of molten salts. As is well-known, in the molecular spectra produced by transitions between vibrational or rotational energy levels, there are lines which correspond to these transitions. These frequencies, which correspond to the molecular vibrational levels, determine the value of the Raman frequencies, which are equal to the sums $\nu_0 \pm \nu_i$, where $\nu_0$ is the frequency of the exciting radiation and $\nu_i$ is that of a natural vibration of the molecule, which can be excited in scattering a beam of frequency $\nu_0$.

Raman and infrared spectra of molten salts have been investigated only in recent years[73-81]. Bues[73-75] and Walfaren *et al.*[80] obtained Raman spectra for alkali metal nitrates, phosphates, pyrophosphates, and hydrogen sulphates, and also for zinc and cadmium chlorides, and Janz and McIntire[81] obtained those for mercury halides. Wilmshurst[76-78] and Bradbury[79] studied the vibrational spectra of various nitrates, chlorates, phosphates, and other salts with complex anions.

As an example let us consider work devoted to alkali metal nitrates. The $NO_3^-$ ion forms a planar equilateral triangle of oxygen atoms with a nitrogen atom at the centre. Here, symmetric and antisymmetric vibrations along the bonds, giving Raman frequencies $\nu_1$ and $\nu_3$, two-dimensional vibrations leading to destruction of the symmetry, with frequency $\nu_4$, and out-of-plane Raman-inactive vibrations of frequency $\nu_2$, are possible (Fig. 3). Table 3 gives the Raman frequencies of the $NO_3^-$ ion for crystals, aqueous solutions, and molten salts.

The values of frequencies $\nu_1$, $\nu_3$, and $\nu_4$ are always very close. The spectra of melts do not contain any new frequencies. The line $\nu_3$ for $LiNO_3$ (and $AgNO_3$) is split, which is due to the marked deformation of the $NO_3^-$ ion. Bues[73] established that the frequency $\nu_1$ is directly determined by

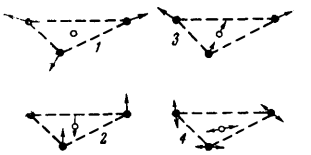

Fig. 3. Diagram of the vibrational motion of the oxygen and nitrogen atoms in the $NO_3^-$ ion. 1) Symmetric stretching vibrations with frequency $\nu_1$; 2) out-of-plane vibrations with frequency $\nu_2$; 3) antisymmetric stretching vibrations with frequency $\nu_3$; 4) bending vibrations with frequency $\nu_4$.

TABLE 3. Combination frequencies of the $NO_3^-$ ion.

| Frequency \ Salt | $LiNO_3$ | | | $NaNO_3$ | | $KNO_3$ | |
|---|---|---|---|---|---|---|---|
| | solution | crystal | melt | crystal | melt | crystal | melt |
| $\nu_4$ | 718 | 728 | 724 | 728 | 722 | 714 | 715 |
| $\nu_3$ | 1392 | 1391 | 1366, 1476 | 1387 | 1386 | 1361 | 1382 |
| $\nu_1$ | 1047 | 1086 | 1061 | 1069 | 1053 | 1050 | 1048 |

the free volume of the salt, which is calculated as the difference

$$V_f = V - \omega N, \qquad (7)$$

where $N$ is Avogadro's number, $\omega$ the sum of the volumes of the anion and cation, and $V$ the molar volume of the salt. The displacement of $\nu_1$ during the fusion of the salt is explained by its expansion.

Other work on Raman and infrared spectra also showed that the structure of complex anions in a melt is analogous to their structure in crystals and aqueous solutions. The existence of complex ions in halide melts has been demonstrated[74,81].

## 4. SCATTERING OF X-RAYS AND NEUTRONS IN MOLTEN SALTS

During passage through a thin layer of liquid the X-rays scattered by any atom interfere with the rays scattered by its nearest neighbours, and since the number of these neighbours and the distance between them alter due to thermal motion the diffraction picture which can be observed is the result of some mean distribution of atoms and is independent of which atom was chosen at the start of the reading.

Usually the distribution of the atoms in the liquid is characterised by the function $\rho(r)$, defined as the mean number of atoms in unit volume at a distance $r$ from the central atom. The number of atoms in the spherical layer from $r$ to $r + dr$ equals $\rho(r)4\pi r^2 dr$.

Since in a liquid there is not a strict ordering in the position of the atoms, function $\rho(r)$ gives a continuous curve with maxima corresponding to the most probable distances. As the distance from the central atom increases, all distances become equally probable and the maxima disappear from the $\rho(r)$ curve.

Zernicke and Prins[82] and Debye[83] found a relation between the experimental scattering curve in a monatomic liquid and the radial distribution function $4\pi r^2\rho(r)$ or $\rho(r)$. This theory, which enabled an averaged picture of the distribution of particles in the liquid to be obtained from the experimental results on scattering of X-rays, was then developed by Warren *et al.*[84] for polyatomic liquids. The method of X-ray scattering was used successfully in the case of molecular liquids, particularly $CCl_4$ (Fig. 4). The radial distribution function for carbon tetrachloride has two narrow isolated peaks at 1.74 and 2.92 Å, corresponding to the distances between the atoms C–Cl and Cl–Cl in the $CCl_4$ molecule, and a series of subsequent maxima (3.5, 5.0, and 6.4 Å), corresponding to the most probable distance between the atoms of carbon and chlorine in the neighbour molecules. The form of the first two maxima shows that the $CCl_4$ molecule is not dissociated in the liquid. Ritter and coworkers[86-88] obtained similar results in investigating molten salts such as $AlCl_3$ and $SnI_4$, which are

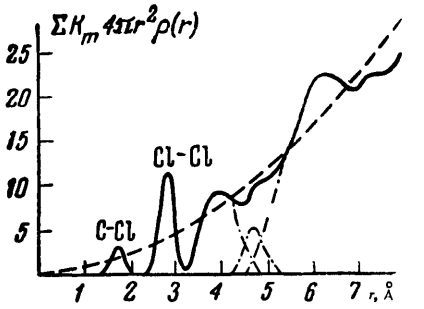

Fig. 4. Radial distribution function for $CCl_4$ at 25°.[85]

not electrolytes†. Experiments with molten $CdI_2$ showed that the coordination number 6 characteristic for the crystal‡, is retained here, but two of the iodine atoms are situated somewhat closer to the cadmium atom than are the others. This shows that $CdI_2$ molecules are formed in the melt as well as $Cd^{2+}$ and $I^-$ ions. Similarly, the distribution curve for $InCl_3$ shows that the ions $In^{3+}$ and $Cl^-$ and the dimer $In_2Cl_6$ can be formed in the melt.

In recent years there have been investigations of the scattering of X-rays in typically ionic liquids — halides, nitrates, and carbonates of the alkali metals, etc.[90-107] Fig. 5 shows a typical radial distribution curve for these melts. Despite some quantitative discrepancy between the results of different workers, they all obtained quantitatively similar results. There have been studies[89-91,96-104] devoted to the structure of alkali and alkaline earth metal halides, both with X-ray diffraction and also by neutron diffraction[102]. Alkali metal nitrates[94,95,105], molten NaOH and KOH,[93] and alkali metal carbonates and sulphates[107] have been studied. Furukawa[106] attempted to generalise the results of these investigations.

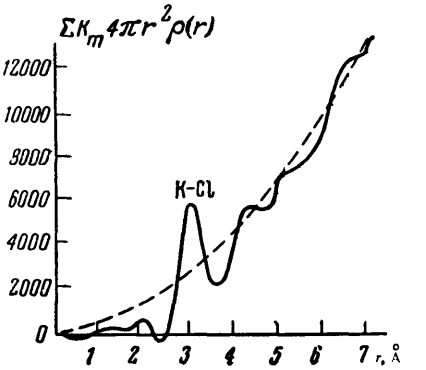

Fig. 5. Radial distribution function for molten KCl.[92]

† On fusion these salts not only give no ions but even also form dimeric molecules, for example, $Al_2Cl_6$.

‡ The coordination number is calculated from the area under the given peak of the radial distribution curve.

TABLE 4. Characteristics of the first coordination sphere — the $M^+-X^-$ interaction — in melts and crystals of alkali metal halides [101,102].

| Salt | Melts | | Crystals | | |
|---|---|---|---|---|---|
| | $r'_{max}$, Å | $N_1$ | $r'_{crit}$, Å (t°) | $r'_{crit}$, Å (20°) | $N_1$ |
| LiCl | 2.47 | 4.0 | 2.66 | 2.57 | 6 |
| LiI | 2.85 | 5.6 | 3.12 | 3.00 | 6 |
| NaCl | 2.88 | 4.7 | 2.95 | — | 6 |
| NaI | 3.15 | 4.0 | 3.35 | 3.23 | 6 |
| KCl | 3.10 | 3.7 | 3.26 | 3.14 | 6 |
| CsCl | 3.53 | 4.6 | 3.57 | 3.57 | 6(8) |
| CsI | 3.85 | 4.5 | 3.94 | 3.95 | 6(8) |

The maxima on the radial distribution curve were in all cases close to the corresponding inter-ion distances in the crystals ($r_{cryst}$), but the coordination numbers in the first ($M^+-X^-$) and second ($M^+-M^+$, $X^-X^-$) coordination spheres ($N_1$, $N_2$) are considerably less than in the crystal lattices (Table 4).

It is interesting that the values of $r'_{max}$ for melts are usually somewhat less than in crystals close to the melting point — the ions in melts are more closely packed on account of the break-down of the symmetry of the field. The considerable breadth of the first peak shows that the true distance between the ions $M^+-X^-$ can be also much greater and less than $r'_{max}$. The closest possible distance between ions in melts is close to the $M^+-X^-$ distance in gaseous molecules.

The absence of accurately determined values of the inter-ion distances in melts implies that the ions associate in separate groups, between which are distributed unoccupied voids and vacancies. In the small groups the ions are more closely packed, as in gaseous molecules; the coarse groups represent as it were fragments of the crystal lattice. These groups are in dynamic equilibrium, continuously forming and decomposing.

The second peak on the radial distribution curves is still more diffuse than the first. The sharpest second peak, that is, the greatest indication of uniformity in $M^+-M^+$ and $X^-X^-$ distances and the degree of ordering of the melt structure are observed for salts with a small cation (lithium and sodium halides). In potassium and caesium salts the second peak is very diffuse, which is evidence of a less regular structure.

There are interesting prospects in studying the structure of molten salts, not only by the methods considered above, but also by $\gamma$-radiation absorption [108] and nuclear magnetic resonance [79,109]. However, there has not yet been proper development in these directions.

## 5. DENSITY AND MOLAR VOLUME

Investigation of the nature of molten salts and their practical application necessitate a knowledge of their physical properties, including density.

Melt densities are measured either pyknometrically or by hydrostatic weighing [5,2]. The results obtained before 1939 — and particularly the work of Jaeger [110,111], Klemm [112,113], and others [114-119] cannot now be considered sufficiently reliable. The most reliable data on densities of the alkali metal halides have been published by Yaffe and van Artsdalen [120]; they fit (see Table 5) Mendeleev's linear equation:

TABLE 5. Densities of molten alkali metal halides in g $cm^{-3}$ — parameters of Eqn. (8).

| Salt | a | $10^3 b$ | Salt | a | $10^3 b$ | Salt | a | $10^3 b$ |
|---|---|---|---|---|---|---|---|---|
| LiCl | 1.7660 | 0.4328 | NaI | 3.3683 | 0.9191 | RbBr | 3.4464 | 1.0718 |
| LiBr | 2.8878 | 0.6520 | KCl | 1.9767 | 0.5831 | RbI | 3.6377 | 1.1435 |
| LiI | 3.5397 | 0.9176 | KBr | 2.7333 | 0.8252 | CsCl | 3.4782 | 1.0650 |
| NaCl | 1.9911 | 0.5430 | KI | 3.0985 | 0.9557 | CsBr | 3.9109 | 1.2234 |
| NaBr | 2.9518 | 0.8169 | RbCl | 2.8799 | 0.8832 | CsI | 3.9179 | 1.1834 |

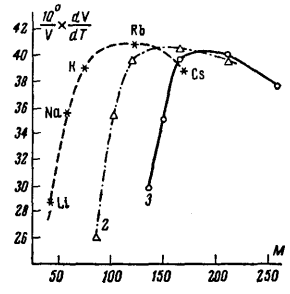

Fig. 6. Dependence of the volume coefficient of expansion of molten salts at the melting point on the molecular weight [120]: 1) chlorides; 2) bromides; 3) iodides.

$$\rho = a - bt. \qquad (8)$$

Careful measurements have been made [121,122,130,131] of the density of alkali metal nitrates and carbonates. There is less systematic information about the density of salts of the alkaline earth metals and the metals of the auxiliary subgroups, particularly $MgCl_2$, [123,124] $CaCl_2$, [125] and $BaCl_2$, [126] mercury halides [81,128], alkaline earth fluorides [127], and various other salts [132-135]. In all cases Eqn. (8) is obeyed.

The volume coefficients of thermal expansion of molten salts:

$$\alpha = \frac{1}{V}\times\frac{dV}{dt} = -\frac{1}{\rho}\times\frac{d\rho}{dt} = \frac{b}{\rho}, \qquad (9)$$

and their molar volumes:

$$V = M/\rho. \qquad (10)$$

are entirely determined by their internal structure. In particular, it is characteristic of the alkali metal halides that the coefficients of thermal expansion of the lithium and sodium salts are relatively small, whereas those of the potassium, rubidium, and caesium salts are relatively large and almost independent of the nature of the salt (Fig. 6). This difference is probably connected with the above-mentioned expanded structure for salts with a large cation.

Comparison of the molar volumes of molten salts [5,16,21] shows that those of typically ionic melts are relatively small, whereas those of molecular liquids ($CCl_4$, $SiCl_4$, etc.) are large. It is also noted that salts formed by metals of auxiliary subgroups have smaller molar volumes than are usually associated with complex formation on melting.

## 6. COMPRESSIBILITY

The compressibility of molten salts has been determined in practice from measurements of the velocity of ultrasonic waves ($u_L$), which is related with the adiabatic compressibility by the relation:

$$\beta_s = -1/V(\partial v/\partial p)_s = \rho^{-1}u_L^{-2}. \quad (11)$$

To calculate the isothermal compressibility information about the isobaric ($C_p$) and isochoric ($C_V$) heat capacities of the melt:

$$\beta_T = -\frac{1}{V}\left(\frac{dV}{dp}\right)_T = \beta_s \times \frac{C_p}{C_V}, \quad (12)$$

is required.

There have been several measurements of ultrasonic velocity in molten salts[136,142] and it has been shown that melt compressibilities depend on temperature and increase with it (Table 6). For salts of a given type the compressibility also increases with the molecular weight.

The information about compressibility and ultrasonic velocity in salt melts obtained by Bockris and Richards[136] and other authors[139-141] differ considerably. In particular,

TABLE 6. Isothermal compressibility of alkali metal halides, $10^{12}$ cm$^2$ dyn$^{-1}$.[136]

| Salt | 700° | 800° | 900° | 1000° | Salt | 700° | 800° | 900° | 1000° |
|---|---|---|---|---|---|---|---|---|---|
| LiCl | 21.1 | 24.7 | 28.6 | 33.0 | KCl | — | 38.4 | 45.7 | 54.7 |
| LiBr | 25.8 | 29.4 | 33.6 | 38.4 | KBr | — | 43.8 | 52.1 | 62.1 |
| NaCl | — | 28.7 | 33.8 | 40.0 | KI | 49.9 | 59.9 | 72.0 | 87.3 |
| NaBr | — | 33.6 | 38.6 | 44.9 | CsCl | 42.9 | 51.2 | 62.7 | 76.3 |
| NaI | 40.0 | 47.3 | 65.6 | 65.6 | CsBr | 55.8 | 67.1 | 82.7 | 103.1 |

Bockris and Richards[136] state that the ultrasonic velocity is a linear function of $T^{\frac{1}{2}}$, whereas others[139,140] give $T$. The reason for this discrepancy is unexplained.

## 7. SURFACE TENSION

The surface tension of molten salts at their phase boundary with a vacuum or inert gas has been measured by the methods of lifting a ring, maximum bubble pressure, etc.[143]. The temperature dependence of surface tension is usually expressed by the linear equation[111]:

$$\sigma = a - bt, \quad (13)$$

although in some cases a quadratic interpolation formula has to be used. The measurements of the surface tension of molten salts made between 1900 and 1930 (for example, Jaeger[111], Arndt and Löwenstein[114]) are inaccurate, since the methods used in these works are not completely reliable. However, the results of later investigations often differ considerably from one another. Of work in recent years, reference may be made to measurements of the surface tension of halides[145-157,161], carbonates[122], and nitrates[145,158-160]. Table 7 summarises the most reliable results and shows that the surface tension depends greatly on the nature of the salt. According to Semenchenko's

TABLE 7. Surface tension of molten salts — coefficients of Eqn. (13).

| Salt | $a$ | $b$ | Reference | Salt | $a$ | $b$ | Reference |
|---|---|---|---|---|---|---|---|
| NaCl | 168.4 | 0.068 | 147 | $CaBr_2$ | 153.1 | 0.0459 | 154 |
| NaBr | 140.9 | 0.056 | 153 | $CaI_2$ | 98.7 | 0.0174 | 154 |
| NaI | 147.4 | 0.090 | 145 | $SrBr_2$ | 178.0 | 0.0439 | 154 |
| KCl | 156.3 | 0.075 | 147 | $SrI_2$ | 134.8 | 0.0383 | 154 |
| KBr | 142.2 | 0.072 | 145 | $BaCl_2$ | 225.0 | 0.078 | 156 |
| KI | 138.7 | 0.087 | 145 | $PbCl_2$ | 192.1 | 0.110 | 145 |
| $MgCl_2$ | 74.0 | 0.01 | 147 | $CdCl_2$ | 95.6 | 0.021 | 153 |
| $CaCl_2$ | 178.0 | 0.038 | 149 | AgCl | 202.2 | 0.052 | 153 |

theory, the surface tension of melts should be determined by the electrostatic interaction of the particles, that is, in the final reckoning, on their generalised moment $\mu = z/r$.[162,163] This probably explains the decrease in the surface tension of the alkali metal halides with increasing radii of cation and anion[163,164]. Salts of the alkaline earth metals show the reverse relation, which is thought[163] to be usually explained by the formation of autocomplexes on melting. However, this explanation cannot be considered exhaustive.

The parachor, the equation for which is given by Bachinskii[165]:

$$\Pi = \frac{M}{\rho_{liq} - \rho_{solid}}\sigma^{1/4}, \quad (14)$$

for molten salts usually varies only slightly with temperature. The problem whether the parachors of salts are the sums of the parachors of the individual ions has not been studied.

## 8. HEAT CAPACITY

The molar heat capacities of molten salts at constant pressure are almost independent of temperature. Values of $C_p$ have been tabulated by Kubaschewski and Evans[166] and elsewhere; more recent values are available[167-169]. Table 8 gives values of $C_p$ and the change of heat capacity on melting:

$$\Delta C_p = (C_p^{liq})_f - (C_p^{solid})_f. \quad (15)$$

It is seen that the heat capacity of molten salts is (within an accuracy of 5–10%):

$$C_p \approx 8\nu \text{ cal deg}^{-1} \text{ mole}^{-1}, \quad (16)$$

where $\nu$ is the number of ions formed by one molecule of salt.

However, this rule is inapplicable to salts with polyatomic anions. At the same time it is valid for salts such as $MgCl_2$, $PbCl_2$, etc., and this does not agree with the assumptions about the formation of autocomplexes in these melts.

TABLE 8. Heat capacity $C_p^{liq}$ and change in heat capacity during fusion $\Delta C_p$ for salts (cal deg$^{-1}$ mole$^{-1}$).[166-169]

| Salt | $C_p$ | $\Delta C_p$ | Salt | $C_p$ | $\Delta C_p$ | Salt | $C_p$ | $\Delta C_p$ |
|---|---|---|---|---|---|---|---|---|
| LiCl | 15.5 | 1.5 | $MgCl_2$ | 22.1 | 2.0 | $PbCl_2$ | 24.9 | 2.6 |
| NaCl | 15.9 | 0.6 | $CaCl_2$ | 24.7 | 4.35 | $PbBr_2$ | 26.3 | 5.6 |
| KCl | 16 0 | 1.35 | $SrCl_2$ | 26.2 | 5.1 | $PbI_2$ | 32.3 | 11.7 |
| RbCl | 15.3 | 1.3 | $CdCl_2$ | 26.7 | 4.9 | $BiCl_3$ | 34.3 | 8.2 |

For salts of one type there is also some increase in heat capacity with molecular weight. There is only approximate information about the jumps in heat capacity on melting. It must also be taken into account that the rise starts much below the melting point of the salt[170].

## 9. HEATS OF VAPORISATION AND VAPOUR PRESSURE

Usually the heat of vaporisation and boiling point of salts are known only approximately. The heat of vaporisation is determined either calorimetrically or by measuring the temperature dependence of vapour pressure[171]. Heats of vaporisation of salt melts have been published[166,172-176].

Salts with a strongly ionic type of bond (alkali metal halides) are typified by a higher boiling point and heat of vaporisation, and those with a considerable covalent bond fraction (for example, $BeCl_2$, $ZnCl_2$) by a lower one.

The alkali metal halides have been most fully studied. The entropy of vaporisation of these salts ($\Delta S^\circ_{vap} = L^\circ_{vap}/T_{boil}$) is 25–30 cal deg$^{-1}$ mole$^{-1}$, which is evidence that they have similar degrees of ordering. Pauling[177] showed that the heats of vaporisation and melting and the melting and boiling points of the alkali metal halides should exhibit a regular dependence on the inter-ionic distance in the crystals, since all these properties are associated with the lattice energy and this is determined by the sum of the ionic radii. However, the properties of real salts depart considerably from the expected relation. Pauling considers that these anomalies are due to the mutual repulsion of large anions which play a considerable part in lattices with small cations (Li and Na salts).

Investigations of the vapour pressure of molten salts have been reviewed[166,173,178], but recently new results about the composition of the vapours of inorganic salts have been obtained which compel critical consideration of the earlier measurements. Thus it was shown[179-185] that in alkali metal halide vapours there is a large proportion of dimers $(MX)_2$ and trimers $(MX)_3$. Formation of polymers was also found in $ThF_4$,[176] $FeCl_2$,[186] CuCl,[187] AgCl,[188] and other salt vapours. The heats of dissociation of the polymeric molecules are comparable with the heats of vaporisation.

The polymerisation in the salt vapours leads to a change in their molecular weight, a knowledge of which is necessary if the vapour pressure is determined by the vaporisation method, the effusion method, etc. Therefore the old data obtained by such methods[189,190] are incorrect. The most reliable absolute methods of determining vapour pressure — the static and the boiling point[171,191] methods — were used in references 192–203 and 174, 176 respectively.

TABLE 9. Vapour pressures of molten salts in mmHg[166,179,198].

Applying the Clausius–Clapeyron equation under conditions far from the critical, and assuming that the vapour will behave as an ideal gas, but that the temperature dependence of the heat of vaporisation is expressed by the relation $dL_{vap}/dT = \Delta C_p$, it is easy to obtain

$$\log p = \frac{A}{T} + B \log T + D, \qquad (17)$$

where $A = -L_{vap}/4.575$, $B = \Delta C_p/R$, $\Delta C_p$ is the difference between the heat capacities of liquid and vapour, $L^\circ_{vap}$ is the heat of vaporisation at the boiling point, and $D$ a constant. In some instances the term $B \log T$ can be neglected§.

Eqn. (17) is usually employed to express the experimental results, the coefficients $A$, $B$, and $D$ being determined empirically. Table 9 gives their values for several salts.

In certain cases[179] attempts have been made to calculate theoretically the coefficient $B = \Delta C_p/R$ from the experimental values of $C_p^{liq}$ and the calculated $C_p^{vap}$. In this, the values of $B$ should evidently be close within a particular series of salts. As Table 9 shows this requirement is fulfilled in many instances.

## 10. HEATS OF FUSION OF IONIC CRYSTALS

The fusion of crystals and the thermodynamic parameters of this process ($T_f$, $L_f$) are determined by the lattice energy, and thus in the end by the radii, polarisability, ionic charges, and the structure of the electron clouds of the ions. Heats of fusion are determined by calorimetric and cryoscopic methods and by measurement of the temperature coefficients of the e.m.f. of chemical cells[166,205,206]. The melting points and heats of fusion of salts are given in various reviews[166,172,207,208]. Recently these quantities have been determined[167,169,192,209-215], but the results obtained are often quite contradictory.

Table 10 gives the parameters for the fusion of alkali metal halides. An analysis of it and of the other available data suggests the following conclusions[5]:

TABLE 10. Heats (kcal mole$^{-1}$) and entropies (e.u.) of fusion of alkali metal halides[209].

| Salt | $L_f$ | $\Delta S_f$ | Salt | $L_f$ | $\Delta S_f$ | Salt | $L_f$ | $\Delta S_f$ |
|---|---|---|---|---|---|---|---|---|
| LiF | 6.47 | 5.77 | NaBr | 6.24 | 6.12 | RbF | 6.15 | 5.76 |
| LiCl | 4.76 | 5.39 | NaI | 5.64 | 6.04 | RbCl | 5.67 | 5.70 |
| LiBr | 4.22 | 5.13 | KF | 6.75 | 5.97 | RbBr | 5.57 | 5.77 |
| LiI | 3.50 | 4.72 | KCl | 6.34 | 6.08 | RbI | 5.27 | 5.73 |
| NaF | 7.78 | 6.14 | KBr | 6.10 | 6.06 | CsF | 5.19 | 5.23 |
| NaCl | 6.69 | 6.23 | KI | 5.74 | 5.02 | CsCl | 4.84 | 5.27 |
| | | | | | | CsBr | 5.64 | 6.20 |
| | | | | | | CsI | 5.64 | 6.27 |

§ Eqn. (17) can be derived from kinetic considerations[204]. Since the number of vacancies in a crystal[22] is $N = \alpha n_0 \exp(-L^\circ_{vap}/RT)$, where $n_0$ is the number of pairs of ions in 1 cm$^3$ and $\alpha$ a constant, we obtain for the density of the vapour

$$\rho = NM/N_A = \alpha \rho_{crit} \exp(-L^\circ_{vap}/RT),$$

where $\rho_{crit} = n_0 M/N_A$. And since $p = \rho_n RT/M$ and $\rho/M = 1/V$, then $\ln p = \ln \alpha RT - \ln V - L^\circ_{vap}/RT$, where $p$ is expressed in bars and $R$ in J mole$^{-1}$ deg$^{-1}$.[204]

1. Crystals with doubly-charged ions melt at a higher temperature than those formed by similar singly-charged ions.

2. In a series of salts with the same cation, the melting point falls as the anion radius increases.

3. The melting points of crystals containing cations with 18-electron and incomplete clouds are lower than those of crystals with ions of similar radii but having inert gas shells.

4. As the bond covalency increases the melting point of the salt decreases. In particular, crystals with layer lattices ($CdI_2$, $MgCl_2$, $ZnCl_2$) have low melting points. The fall in melting point on going from the fluorides to the iodides of the alkaline earth metals is also explained by the increase in the degree of covalency of the bond.

5. Salts with molecular lattices have very low melting points and are not electrolytes, for example $SiCl_4$($t_f$ = 68°), $TiCl_4$ (-30°), $PbCl_4$ (-15°), etc. However, the same elements in a lower oxidation state give ionic salts with high melting points: $TiCl_2$ (400°), $PbCl_2$ (501°), etc.

6. The melting point of salts is greatly dependent on the crystal lattice structure. Pauling[117] noted that the low melting points of lithium salts are explained by the small radius of the $Li^+$ ion, as a result of which anion–anion contact occurs in the lattice and the mutual repulsion of the anions reduces the lattice energy. A linear relationship between the melting point and the ratio of the radii of the ions has been reported[216] for alkali metal halides.

The entropies of fusion for the alkali metal halides $\Delta S_f = L_f/T_f$ are close to 6 e.u. mole$^{-1}$, which corresponds to 3 e.u. g-ion$^{-1}$. Remembering that the entropy of fusion of the monatomic noble gases is also close to 3 e.u. × × g-atom$^{-1}$, this can be considered as confirmation of the purely ionic structure of the melts. The marked departure from this value for some salts is usually considered as an argument in support of the hypothesis concerning the formation of autocomplexes in the fusion of the salts.

## 11. VISCOSITY

The viscosity of molten salts has been determined by use of both static (falling sphere[217,218]) methods, the capillary flow method[217,219], and also dynamic methods (for example, measurement of the damping of harmonic oscillations of a body of rotation suspended in the melt by an elastic filament[217-220]). Dynamic methods usually introduce errors on account of the impossibility of allowing for all the factors which affect the measurement[217]. Static methods are generally more reliable but serious difficulties are encountered when working with melts. Hence completely reliable and systematic data on the viscosity of molten salts are still lacking.

The temperature dependence of viscosity is usually expressed by the equation[22,221-223]:

$$\eta = A_\eta \exp(E_\eta/RT). \qquad (18)$$

In the theory of absolute reaction rates[221,224] the preexponential factor is given by:

$$A_\eta = 1.09 \times 10^{-3} \rho^{2/3} T^{3/2} / M^{1/2} \Delta E_{vap}, \qquad (19)$$

where $\Delta E_{vap} = L_{vap} - RT$ is the energy of vaporisation, and $M$ the molecular weight. Panchenkov[225,226], starting from the assumption that the transfer of momentum between the particles of the liquid takes place during separation of the particles from one another, deduced the equation:

$$\eta = A\rho^{4/3} T^{1/2} \exp(2\Delta E_{vap}/\gamma RT)[1 - \exp(-2\Delta E_{vap}/\gamma RT)], \qquad (20)$$

where $\gamma$ is the coordination number and $A$ a constant.

Panchenkov's equation was applied successfully to the viscosity of melts of NaCl and $NaNO_3$, the constants $\gamma$ and $A$ being determined empirically[225].

Equation (18) is usually employed in practice[19,227], the coefficients being found empirically. Table 11 gives values of the viscosity at $1.1T_f$ °K and the parameters $A\eta$ and $E\eta$, calculated for various salts from published results.

TABLE 11. Viscosity of molten salts.

| Salt | $10^4 A_\eta$, P | $E_\eta$, kcal × × mole$^{-1}$ | $10^2 \eta_{1.1T_f}$, P | Reference | Salt | $10^4 A_\eta$, P | $E_\eta$, kcal × × mole$^{-1}$ | $10^2 \eta_{1.1T_f}$, P | Reference |
|---|---|---|---|---|---|---|---|---|---|
| LiCl | 1.64 | 8.35 | 1.27 | 274 | AgI | 15.8 | 5.13 | 2.90 | 230 |

| KCl | 4.29 | 7.40 | 1.10 | 228 | $CaCl_2$ | 86.3 | 3.70 | 4.34 | 150 |
| LiBr | 7.07 | 5.30 | 1.38 | 227 | $CdCl_2$ | 22.9 | 3.98 | 2.04 | 231 |
| NaBr | 2.85 | 8.00 | 1.06 | 229 | $CdBr_2$ | 21.9 | 4.30 | 2.30 | 232 |
| KBr | 2.92 | 7.96 | 1.14 | 229 | $PbCl_2$ | 5.37 | 6.77 | 3.05 | 231 |
| RbBr | 12.07 | 4.73 | 1.15 | 227 | $PbBr_2$ | 7.95 | 6.25 | 3.47 | 232 |
| AgCl | 7.64 | 5.30 | 2.13 | 230 | $AgNO_3$ | 18.2 | 3.08 | 2.06 | 234 |
| AgBr | 11.7 | 4.85 | 2.71 | 220 | | — | — | — | — |

Equation (18) is usually employed in practice[19,227], the coefficients being found empirically. Table 11 gives values of the viscosity at $1.1T_f$ °K and the parameters $A\eta$ and $E\eta$, calculated for various salts from published results.

The relation between viscosity and the nature of the salt has been insufficiently studied. Several investigators[223,235] note a relation between the activation energy for viscous flow $E\eta$ and the melting point. In particular, for alkali metal halides the ratio $E\eta/L_f$ is close to 1.2. Melts of the halides of bivalent metals have a much greater viscosity, which is probably due to the appreciable fractions of covalent and van-der-Waals interactions. Bachinskii[236] considers that viscosity is not a direct function of temperature but is connected with the molar volume of the liquid:

$$\eta = \frac{C}{V - \omega}, \qquad (21)$$

where $C$ and $\omega$ are constants, $V - \omega$ having the physical interpretation of the volume available for the motion of the particles in the liquid, that is, the free volume. The applicability of Eqn. (21) to molten salts has been demonstrated[19,237], the difference $V - \omega$ usually being 2–6 cm$^3$ × × mole$^{-1}$, and $\omega$ always considerably exceeding the volume of the solid at the melting point. The constant $C$ depends on the radii of the ions[19]. Ideas about the relation between viscosity and the free volume of a molten salt have also been developed elsewhere[139,140].

## 12. DIFFUSION

Information about coefficients of self-diffusion in molten salts have only been obtained in recent years thanks to the use of radioactive isotopes. Table 12 gives the values of the empirical coefficients of the exponential equation:

$$\Delta = \Delta_0 \exp\left(-\frac{E_\Delta}{RT}\right), \qquad (22)$$

calculated from the experimental results of various authors. Many investigators[238-240,242,248] have tried to apply to salts the Stokes–Einstein equation:

$$\Delta = \frac{kT}{6\pi\eta r_i}, \qquad (23)$$

TABLE 12. Coefficients of self-diffusion of ions in molten salts.

| Salt | $10^5\Delta_0^+$, $cm^2\ s^{-1}$ | $E_\Delta^+$, kcal $mole^{-1}$ | $10^5\Delta_0^-$, $cm^2\ s^{-1}$ | $E_\Delta^-$, kcal $mole^{-1}$ | Reference |
|---|---|---|---|---|---|
| NaCl | 3.36 | 7.65 | 3.02 | 8.37 | 238, 239 |
| RbCl | 2.51 | 8.00 | 1.67 | 7.42 | 238 |
| CsCl | 1.73 | 7.30 | 2.46 | 7.82 | 238 |
| NaI | 0.63 | 4.00 | 0.43 | 4.41 | 238 |
| TlCl | 0.76 | 4.60 | — | — | 244 |
| $ZnBr_2$ | 79.0 | 16.0 | — | — | 243 |
| $PbCl_2$ | 0.773 | 6.75 | 0.895 | 7.10 | 241, 242 |
| $LiNO_3$ | 2.47 | 5.50 | 1.95 | 6.32 | 246 |
| $NaNO_3$ | 1.29 | 4.96 | 0.90 | 5.07 | 245, 246 |
| $KNO_3$ | 1.32 | 5.52 | 1.42 | 5.75 | 246 |
| $CsNO_3$ | 1.13 | 5.60 | 1.78 | 6.27 | 246 |
| $AgNO_3$ | 0.49 | 3.72 | 0.31 | 3.84 | 246 |
| $Na_2CO_3$ | 0.192 | (900°) | 0.279 | (900°) | 247 |

where $r_i$ is the ionic radius. However, comparison of Tables 12 and 11 shows that Eqn. (23) is scarcely applicable, owing to the absence of the required equality between the activation energies for the diffusion of cations and anions and a regular connection between $\Delta_0$ and the radii of the ions¶.

The Nernst–Einstein equation:

$$\Lambda = \frac{F^2}{RT}(\Delta^+ + \Delta^-), \qquad (24)$$

where $\Lambda$ is the molar conductivity, is also probably inapplicable to melts. This question has been studied[238-240,248] and the inapplicability of Eqn. (24) was attributed to the interaction of ions in the diffusion of ion pairs.

Recently Panchenkov[249] derived an equation connecting the diffusion coefficients with the molar volume, heat of vaporisation, and coordination number of the liquid. The possibility of using this equation for molten salts has not been verified.

Several investigators[22,250-252] link the coefficients for the diffusion of ions with the free volume of the liquid. In particular, Cohen and Turnbull[250] derive the equation:

$$\Delta = gau\exp(-\gamma V/V_f), \qquad (25)$$

where $g$ and $\gamma$ are constants, $a$ is the diameter of the molecule, $u$ the gas kinetic velocity, $V$ the molar volume, and $V_f$ the free volume. This equation has been verified for melts[238,251], but the results of various authors contradict one another. Bockris[238] considers that the Fürth–Frenkel' vacancy theory is more applicable to salts (see below).

## 13. ELECTRICAL CONDUCTIVITY

There have been many papers devoted to the electrical conductivity of molten salts; a review of the early investigations was given in monograph by Lorenz[253]. The later works, including those of Jaeger and Kapma[254], Sandonini[117], Goodwin and Mailey[255], and Arndt[256,257], were discussed by Biltz and Klemm[258] and then by Drossbach[259] and Antipin *et al.*[21] The results of these workers can now be considered only as approximate.

The method of measuring the electrical conductivity of salt melts has been described[120,125,260-268]. The most important point here is the necessity of using a very sensitive a.c. bridge which permits the compensation of both ohmic and capacitative components of the cell impedance over a wide range of frequencies. The electrical conductivity of the alkali metal halides was determined[120,149,150,254,258,261,269-278], but the results often do not agree with one another. The most reliable values have been given[120]. The electrical conductivity of the alkaline earth halides has been measured[123,126,149,150,279-283] and the halides of the auxiliary subgroup metals[81,125,130,279,284-288] have been studied. Bockris *et al.* give the most reliable data[279]. The electrical conductivity of nitrates[130,131,134,268,285,289-292], carbonates[122], pyrophosphates[133], etc. have also been studied.

The temperature dependence of the electrical conductivity of molten salts is usually expressed by Kohlraush's formula[293]:

$$\kappa = a + bt + ct^2, \qquad (26)$$

which usually fits the experimental data well, often without the quadratic term (that is, with $c = 0$). However, this formula has no physical basis.

Frenkel'[22] showed that the equation:

$$\Lambda = \kappa M/\rho = A_\Lambda \exp(-E_\Lambda/RT), \qquad (27)$$

should hold for molar conductance. This idea was developed by Eyring, who used the theory of absolute reaction rates to derive the relationship[120]:

$$\Lambda = 5.18\times10^{18}(D+d)d_i^2\exp(\Delta S^*/R)\exp(-\Delta H^*/RT), \qquad (28)$$

where $D$ is the dielectric constant of the melt, $d_i$ half the inter-ion distance, and $\Delta S^*$ and $\Delta H^*$ the entropy and heat of activation of the migration. For the alkali metal halides $\Delta S^*$ is 6.0–8.5 cal $mole^{-1}\ deg^{-1}$. Formula (26) corresponds to the conductance of a single ion. In the general case, according to Frenkel'[22]:

$$\Lambda = a_1\exp(-E_1/RT) + a_2\exp(-E_2/RT), \qquad (29)$$

and this transforms into (26) when $E_1 \simeq E_2$, $E_1 \gg E_2$, or $E_1 \ll E_2$. Analogously to (26) we can write:

$$\kappa = A_\kappa\exp(-E_\kappa/RT), \qquad (30)$$

in which[294]:

$$E_\Delta = E_\kappa + RT^2\alpha. \qquad (31)$$

The measurements of Yaffe and van Artsdalen[120] showed that at least for the alkali metal halides $\Delta H^* = f(T)$ and Eqns. (26) and (30) are not obeyed. For example, the true relations are:

for LiBr,

$$\Lambda = \exp(5.5709 - 694.83/T + 0.43261\times10^{-3}T),$$

and for CsBr,

$$\Lambda = \exp(9.4173 - 3980.3/T + 1.1528\times10^{-3}T),$$

etc., but these have no theoretical basis. At the same time many authors consider that Eqns. (26) and (30) are obeyed by most molten salts, at least in the range of temperatures studied[122,131,284].

The relation between $\Lambda$ or $\kappa$ and viscosity is interesting. Walden's well-known rule[295]:

$$\Lambda\eta = \text{const}, \qquad (32)$$

evidently does not apply to molten salts. This was shown, for example, by Erdey-Gruz[296], who attributed the inapplicability of Eqn. (32) to the possibility of a Grotthus mechanism of migration. Such an explanation cannot withstand criticism, since the electrical conductivity of a molten salt

¶ It is possible, however, that this discrepancy is due to experimental errors (for example, see Bockris and coworkers[238-240]).

calculated by the Nernst–Einstein equation (24) is always greater than the actual value. For the same reason the hypothesis of Abraham and Brenet[297] about the existence of considerable electronic conductivity in pure molten salts cannot be accepted.

Barzakovskii[21] considers that since the Stokes–Einstein equation (23) forms the basis of the Walden formula, the inapplicability of formula (32) is explained by the inapplicability of (23) for melts. Actually the matter is complicated because the mechanisms of viscous flow and migration in molten salts are not identical. As Frenkel' notes, in the first case the large ions play the chief part, and in the second the smaller ions.

Several investigators have discussed the applicability to melts of the formula[275,298-301]:

$$\Lambda^n\eta = \text{const}, \qquad (33)$$

but as Delimarskii and Markov showed[7], Eqn. (33) is the simple consequence of the exponential temperature dependence of $\Lambda$ and $\eta$ and completely fails to reveal a connection between these quantities.

Comparison of the data shown in Tables 14 and 13 shows a significant relation between the conductivity of melts and the nature of the salt. Biltz and Klemm[258] associate the value of $\Lambda$ at an appropriate temperature (for example, at a temperature equal to 1.1 $T_f$, °K) with the position of the cation of the salt in Mendeleev's table. The electrical conductivity of the melt increases with the ionic nature of the bond. On the other hand, salts with a high fraction of covalent bonding (such as the mercury halides) are poor conductors. Biltz[302] noted that the temperature coefficient of conductivity also increases with the covalency of the bond.

* $\chi$ is given for $MgI_2$ at 800°, $CaI_2$ at 900°, $SrI_2$ at 700°, $BaI_2$ at 800°, and $ZnI_2$ at 490°.

The low electrical conductivity of molten salts is often considered as an index of the formation in the melt of low-mobility autocomplexes and neutral molecules. However, this type of hypothesis requires confirmation by analysis of all the properties of the molten salt.

## 14. TRANSPORT NUMBERS

Various methods based on the use of radioactive isotopes are employed in determining the transport numbers of the ions in molten salts, but the analysis of the results thus obtained presents difficulties if one is speaking of the transport numbers in the pure salt. The transport numbers in an inert solvent are determined as the ratios:

$$\left.\begin{aligned} t_+ &= \frac{\Lambda^+}{\Lambda_+ + \Lambda_-} = \frac{u_+}{u_+ + u_-} \\ t_- &= \frac{\Lambda_-}{\Lambda_+ + \Lambda_-} = \frac{u_-}{u_+ + u_-} \end{aligned}\right\}, \qquad (34)$$

where $\Lambda_i$ are the ionic conductivities, $u_i$ the mobilities, that is, the rates of movement of the ions under unit potential gradient. In aqueous solutions the rate of motion of the ions is considered relative to the immovable mass of solvent. Understandably, it is more difficult to determine the rate in a melt. In this connection several authors[303-305] have generally denied the possibility of determining transport numbers in molten salts on account of the absence of a "coordinate system", whose part in solvents and crystals is played by the solvent or the lattice. Sundheim[304], starting from the principle of conservation of momentum and applying it to the electrolysis process, derived a formula relating the transport numbers to the masses of the ions:

$$t_- = \frac{M_+}{M_+ + M_-}, \quad t_+ = \frac{M_-}{M_+ + M_-}. \qquad (35)$$

This theory was supported by various investigators[306-308] but disputed in other papers[11,309]. Esin *et al.*[310] showed the fallibility in Sundheim's theory, pointing out that in molten salts the change in momentum is not zero[311] because of internal friction. Esin showed further that in the melt the transport of charges is effected not by the whole mass of the ions, but only by the small fraction of them which have sufficient energy (the activation energy of migration). These ions at any particular moment move relative to the melt, which acts as the same "coordinate system" as the crystal lattice in solid salts. Laity[312] developed a formal theory of migration and diffusion in molten salts based on a consideration of the inter-ion coefficients of friction.

Mulcahy and Heymann[313] proposed an empirical equation for the molar conductance of alkali metal halides close to the melting point†:

$$\Lambda = 105(1/r_+ + 1/r_-), \qquad (36)$$

where $r_i$ is the ionic radius. From this equation the relationship found by Duke[314,315]‡ can be easily obtained:

$$t_- = \frac{r_+}{r_+ + r_-}; \quad t_+ = \frac{r_-}{r_+ + r_-}, \qquad (37)$$

which often agrees well with experiment.

† Markov and Delimarskii[316] showed that another relationship is more accurate:

$$\Lambda = \text{const}\,(1/r_+^2 + 1/r_-^2).$$

‡ Duke obtained his equations by comparing the force of internal friction and the electric field $zeE = kr_i u_i$, whence $r_+/r_- = u_-/u_+$.

| | — | — | — | | 0.40 | 0.92 | 319 | | | | |

There have been several investigations of transport numbers in salt melts[317-336]. The methods of measurement have been discussed[337]. Almost all the investigators used a cell with a diaphragm separating the electrode spaces, and the decrease in volume of the melt in one of the compartments during electrolysis was compensated for by the constant addition of salt to it. The absence of a flow of salt under the action of gravity is usually verified by the position of a bubble in a capillary joining the two parts of the vessel, or by some other means.

The most reliable results of the measurements of transport numbers are given in Table 15.

Most authors consider that transport numbers are almost independent of temperature but Duke *et al.*[329] have found a considerable increase in $t_-$ for AgCl on raising the temperature from 650° to 925°. An analysis of the results given in Table 15 shows that in many instances Eqn. (37) agrees well with experiment. There are considerable deviations only for lead and zinc halides and for silver and thallium nitrates.

Characteristically, most solid states exhibit unipolar conductivity. Thus, the transport numbers of the cation in NaCl and KCl decrease from 1.00 to 0.93 and 0.88 respectively as the temperature is raised from 400° to 600°, whereas in the melt $t_+$ for both salts is 0.38. Lead chloride exhibits anionic conductivity in the solid state ($t_- = 1.0$) but in the melt $t_- \simeq 0.70$. Hence, fusion changes the mechanism of electrical conductivity, and the widely-held opinion that the conductivity of molten salts is also unipolar is incorrect.

## 15. THERMAL CONDUCTIVITY

Bloom[13], Gambill[338], and Turnbull[339] have investigated the thermal conductivity of molten salts. The thermal conductivity of potassium and sodium nitrates is $11.25 \times 10^{-4}$ and $13.50 \times 10^{-4}$ cal $cm^{-1}$ $s^{-1}$ $deg^{-1}$ respectively. According to Turnbull, the thermal conductivity of molten salts is made up of vibrational $\mu_{vib}$ and diffusion $\mu_{dif}$ constituents:

$$\mu_{vib} = 2.85 \times 10^{-3} (T_f \nu / M)^{1/2} (V_{solid}/\nu)^{2/3}, \quad (38)$$

$$\mu_{dif} = 2\Delta C_V / V, \quad (39)$$

where $C_V$ is the heat capacity and $\nu$ the number of ions in a salt molecule.

To a first approximation thermal conductivity can be calculated by Vargaftik's formula[340]:

$$\mu = 4.28 \times 10^{-3} C_p \rho^{4/3} / M^{1/3}, \quad (40)$$

where $M$ is the molecular weight of the salt.

## 16. VOLUME CHANGE DURING FUSION OF IONIC CRYSTALS

The fusion of ionic crystals is characterised by the following features:

1. The volume of the salt increases sharply during melting.

2. The anisotropy of the properties of the crystals disappears during fusion, this being the direct consequence of the disappearance of ordering in the position of the particles. As X-ray analysis shows, in the liquid state ordering is retained only in the nearest surrounding particles (short-range order). There is no order at greater distances (long-range order).

3. During fusion there is a marked change in electrical conductivity, heat capacity, diffusion coefficients, and other properties of the salt[18,234,341], which is evidence of the break-down of structure. It is characteristic that these changes start below the melting point (premelting effect) and are greatly dependent on the nature of the salt.

All these features permit a liquid to be considered as a disordered crystal and the melting process as one of partial breakdown of the crystal lattice. In crystals of the inert gases, alkali metal halides, and similar materials, there is probably a single possible means of breakdown of the lattice — the transfer of ions from the lattice positions into the interstices and to the surface of the crystal. For more complicated crystals with polyatomic complex anions or ions with easily distorted shells the destruction of order can proceed by a change in the orientation of the complex ions, the formation of new types of molecular packing, and also the formation of autocomplexes owing to the degeneration of the ionic bond and the increase in polarisation interactions[342-347].

The most important characteristic of the fusion process is the volume change. The increase in molar volume during fusion can be termed the surplus volume of the melt, and this has been measured in several studies[347-355]. Table 16 gives Schinke and Sauerwald's results[348], recalculated with allowance for other data[120], and calculated values of $\Delta V$, derived using the latest data on the coefficients of linear expansion of crystals[356] at room temperature (in parentheses).

Table 16 shows that the surplus volume depends markedly on the nature of the salt. For alkali metal halides, as for crystals of inert gases, it is 20–25%; for Ca, Sr, and Ba

halides it is only a few per cent, just as for nitrates, and this is due to the degeneration of the ionic bond and reorientation.

The "surplus" volume is in general not the "free volume of the liquid", if by this term we understand that part of the volume available for the translational and vibrational motion of the ions, since part of the surplus volume is screened by the force fields of the neighbour particles[357]. The value of the "free volume" of the liquid can be determined as follows[358]. It is known that the statistical partition fnnction of a system with particles oscillating in closed micro-cells which they cannot vacate has the form:

$$\Phi_m = \left[\frac{(2\pi mkT)^{3/2}}{h^3} \times \frac{V_f}{N}\right]^N [\Phi_{int} \exp(-E/RT)]^N, \quad (41)$$

where $V_f$ is the total free volume, $N$ Avogadro's number, $m$ the mass of the particle, $h$ Planck's constant, $\Phi_{int}$ the internal partition function, and $E$ the potential energy, determinable as the energy for the transformation of the system into ideal gas at 0°K.

Virtually, this partition function corresponds to a crystal expanded to the volume of the liquid. The difference between the crystal and the liquid is that in the latter the particles are not localised in their cells and therefore:

$$\Phi_{liq} = \frac{1}{N!}\left[\frac{(2\pi mkT)^{3/2}}{h^3} \times V_f\right]^N [\Phi_{int} \exp(-E/RT)]^N. \quad (42)$$

When this equation is combined with the known relation:

$$p = RT(\partial \ln \Phi/\partial V), \quad (43)$$

an equation of state of the liquid, similar to the van der Waals equation, is obtained

$$V_f[p + (\partial E/\partial V)_T] = RT, \quad (44)$$

where the derivative $\partial E/\partial V$ has the significance of the internal pressure of the system. To calculate the free volume, another well-known relationship can be used:

$$(\partial E/\partial V)_T = T\frac{\alpha}{\beta} - p, \quad (45)$$

which in combination with (44) gives:

$$V_f = R\beta/\alpha. \quad (46)$$

Another method of calculating the free volume involves the determination of the entropy of vaporisation of the liquid, which equals[359,360]

$$\Delta S_{vap} = R \ln(V_{gas}/V_f), \quad (47)$$

and

$$L_{vap} = -RT \ln(V_b/V_{gas}), \quad (48)$$

but since for a gas $V_{gas} = RT/P$, then:

$$V_f = \frac{RT}{p}\exp\left(-\frac{L_{vap}}{RT}\right) = \frac{RT}{P_b}\exp\left(-\frac{L^\circ_{vap}}{RT_b}\right). \quad (49)$$

TABLE 17. Free volumes of alkali metal halides at 800°, $cm^3\ mole^{-1}$.

| Salt | $V_f$ (Ref. 46) |
|---|---|
| LiCl | 6.84 |
| NaCl | 6.84 |
| KCl | 8.26 |
| CsCl | 10.50 |

However, the results of calculations by Eqns. (46) and (49) usually differ by an order of magnitude.

We note that the physical significance of the concept of free volume has not been finally determined and is still the subject of discussion, so that some authors understand other quantities as free volume[360-362].

## 17. THEORY OF THE FUSION OF IONIC CRYSTALS

The important theories of fusion can be classified into a few groups. The vibrational theories of fusion link the crystal → liquid change with the vibrational motion of the particles[363-376]. The basis of the vibrational theories is the idea of the mechanical instability of the crystal lattice, which appears with increase in the amplitude of the vibrations of the ions. Lindemann[363], by considering the collision of the vibrating particles as a criterion of fusion, obtained a formula for the melting point:

$$T_f = \text{const}\, V/\beta. \quad (50)$$

In later works Born[367,368], Fürth[370-373], Patrushev[376], and Thompson[369] also developed different variants of the vibrational theory. As Mott showed[374,375] Born's concept of the melting point as the temperature for the disappearance of the elastic properties of a crystal due to the vibration of the atoms is erroneous. However, there is also a grain of truth in the vibrational theories. In particular, this applies to Patrushev's theory which connects the increase in volume during fusion with the heats of fusion and sublimation:

$$L_f/L_s = \text{const} \times \Delta V/V_{solid}. \quad (51)$$

The theory of disordering is seen as the basis of the melting process in the disappearance of the order peculiar to the crystal. Frenkel'[22] and Bresler[377] have considered this question most fully. To characterise the order in the system they introduce the concepts of degree of short- and long-range order. In a crystal MX the long-range order is expressed by the cations and anions occupying completely determined ("cationic and anionic") positions, and short-range order by each ion $M^+$ being surrounded by six $X^-$ ions and vice versa. The breakdown of long-range order signifies that a fraction $N''_+$ of the cationic places, out of the total number $N_+ = N'_+ + N''_+$, is occupied by anions. The Bragg–Williams criterion[378]

$$\gamma = \frac{N'_+ - N''_+}{N'_+ + N''_+} = \frac{2N'_+ - N_+}{N_+} \quad (52)$$

serves as a measure of the long-range order. For the ideal crystal $N'_+ = N_+$, $N''_+ = 0$, $\gamma = 1$. With complete disorder, $N'_+ = N''_+$, $\gamma = 0$. When out of the total number $p$ of nearest neighbours the mean number of neighbours of the same kind is $n$, and that of the other kind is $m$, then the degree of short-range order can be characterised by Bethe's criterion[379]:

$$\xi = \frac{m-n}{p} = \frac{m-n}{m+n} = \frac{2m-p}{p}. \quad (53)$$

For the ideal crystal $n = 0$, $m = p$, and $\xi = 1$; with complete disorder, $m = n = p/2$, and $\xi = 0$.

Frenkel' gives[22] the following assumptions: (a) melting corresponds to complete disappearance of long-range order; (b) the probability of transfer of an ion to a "foreign" site is determined by the Boltzmann relation, that is,

$$N''_+ = N'_+ \exp(-\varepsilon/kT), \quad (54)$$

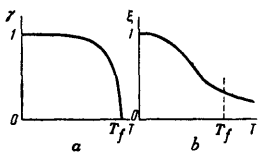

Fig. 7. Change in the degrees of long-range ($\gamma$) and close-range ($\xi$) order with rise in temperature[22].

in which $\epsilon = \gamma\epsilon_0$; (c) the probability of differently charged ions occupying neighbouring positions is determined by the relation:

$$n = m\exp(-\Delta\epsilon/kT), \quad (55)$$

where $\Delta\epsilon$ is the mean difference in energies of interaction of the pairs $M^+-M^+$, $X^--X^-$. In this case we can obtain:

$$\gamma = \tanh(\epsilon_0\gamma/2kT), \quad (56)$$

$$\xi = \tanh(\Delta\epsilon/2kT). \quad (57)$$

Graphs of these functions (Fig. 7) show that long-range order disappears by a sharp jump at a definite temperature $T_f$, at which an appreciable fraction of short-range order is retained.

Despite the qualitative agreement with experiment, this theory is not completely accurate since the change in volume during melting is not taken into account, that is, in the final reckoning the part played by "holes" in the destruction of order§ is not considered. An attempt to allow for this feature was made by Bresler[377], who determined the degree of short-range order as the probability of the coordination number $p$ and of disorder as reduction in the coordination number to $(p - 1)$, which gives:

$$\xi = [1 + p\exp(-\epsilon/kT)]^{-1}, \quad (58)$$

where $\epsilon$ is the energy of the system.

A more detailed statistical theory of fusion has been developed[383-389]. Kurosawa[390] and Karpachev and Karasik[391] attempted to create a quantitative theory of fusion of ionic crystals. The former considered the liquid as a solution of holes in an ionic medium and the application of the Debye–Hückel theory to the interaction of holes enabled several properties of molten salts to be calculated (melting point, etc.). The entropy of fusion of ionic crystals has been calculated[391] as the result of the expansion of the crystal and the appearance in it of unoccupied sites (vacancies). The relation finally obtained was:

$$\Delta S_f = -\frac{\alpha}{\beta}\Delta V + 4.6R[\log(1 + \Delta V/V_{solid}) + (\Delta V/V_{solid})\log(1 + V_{solid}/\Delta V)]. \quad (59)$$

## 18. THEORY OF MOLTEN SALTS

The theory of ionic liquids has been developed in the last few years as part of the general theory of the liquid state. Its first considerable success was connected with the development of the hole theory (Frenkel'[22], Fürth[392,393] and others[394,395]) which is based on the concept of a liquid as a quasi-crystal with a large number of vacant sites – the holes. The holes are attributed with the ability to migrate and a spherical form, and the liquid itself is regarded as a continuous medium. The energy of formation of a hole of radius $r$ is[393]:

$$e_g = 4\pi r^2\sigma, \quad (60)$$

and the mean volume of a hole is:

$$v_g = 0.68(kT/\sigma)^{3/2}. \quad (61)$$

Frenkel'[22] and Kurosawa used the idea of hole theory to explain the diffusion and viscosity of molten salts. Bockris and coworkers[136,238] used the same viewpoint in handling their experimental results on diffusion and ultrasonic velocity in melts.

One of the first theories of the liquid state[396] considered a liquid as a dynamic combination of microregions with an ordered structure (sibotaxic group), situated in mobile equilibrium internally and with the molecules forming irregular transition regions. A development of this theory is the theory of significant structures[397-400], according to which in a liquid there coexist regions with a crystal lattice structure, regions containing "gaslike" molecules, and also dislocations, vacancies, holes, and other defect structures. The degree of bonding of the molecules in the liquid is characterised by the ratio $V_{solid}/V_{liq}$, and the statistical sum of states is determined as the product of the partition functions of the "gaslike" and "solidlike" particles. By applying the theory of significant structures to molten alkali metal halides, Eyring and others[399,400] found for the partition function:

$$\Phi = \left\{\frac{\exp(E/2RT)(V_{liq}/V_{solid})^{1/3}}{[1-\exp(-\theta/T)]^3}\left[1 + N_g\exp\left(-\frac{aE}{2N_gRT}\left(\frac{V_{liq}}{V_{solid}}\right)^{1/3}\right)\right]\right\}^{2NV_{solid}/V_{liq}} \times$$

$$\times\left\{\frac{(2\pi mkT)^{3/2}}{Nh^3}eV_{liq}\frac{8\pi^2IkT}{h^2}[1-\exp(-h\nu/kT)]^{-1}\right\}^{(1-V_{solid}/V_{liq})N}, \quad (62)$$

where $E$ is the potential energy of the salt at $T_f$, $\theta$ is the Einstein characteristic temperature, $m$, $I$, and $\nu$ are the mass, moment of inertia, and fundamental vibration frequency of the halide molecule, $a$ is an empirical parameter, $N$ Avogadro's number, and $N_g \simeq 10(V_{liq} - V_{solid})/V_{solid}$ the concentration of holes. A comparison of the fusion parameters, calculated by Eqn. (62), with the experimental values shows good agreement (Table 18). However, unfortunately Eqn. (62) contains the empirical coefficient $a$.

Eyring[383] and Lennard-Jones and Devonshire[384] developed a theory representing a liquid as an expansion of a crystal in which each molecule can move freely in a certain volume, equal to $\omega/N$, where $\omega$ is the total free volume of the cell. Assuming it to be equal to the free volume of the liquid and using Eqns. (40), (41), and

$$S = k\{\ln\Phi + T(\partial\ln\Phi/\partial T)_V\}, \quad (63)$$

TABLE 18. Comparison of theory of significant structures with experiment[399].

§ Samoilov[380-382] considered the decrease in coordination number during fusion.

we can obtain the change in entropy due to the removal of the prohibition for movement of a molecule from one cell to another:

$$\Delta S^* = k \ln (N^N/N!) \simeq kN = R. \quad (64)$$

This quantity was termed the communal entropy of the liquid and identified with the entropy of fusion. The latter, of course, is incorrect, since Eqn. (40) relates to a conventional crystal and the complete freedom of mixing of the particles is reached only in vaporisation of the liquid[385].

The quantity $\omega$ in the Eyring-Lennard-Jones and Devonshire theories is determined as follows[401]. In a three-dimensional cubic lattice let only a central molecule move and six of its neighbours be immovably fixed; the volume bounded by these neighbours for all $N$ molecules is

$$\omega = 8N[v^{1/3} - \sigma]^3, \quad (65)$$

where $\sigma$ is the diameter of the molecule, and $v^{\frac{1}{3}} = (V/N)^{\frac{1}{3}}$ is the distance between the centres of neighbouring molecules. The quantity $\omega$, calculated for molten salts[136], is 0.5–1.0 cm$^3$ mole$^{-1}$ for alkali metal halides, which is much smaller than the actual free volume (compare Table 18).

The ideas of Lennard-Jones and Devonshire were applied to salt melts and developed by McQuarrie[402] who obtained, in particular, an equation for vapour pressure:

$$\log p = \frac{0.434\,(D_0 - \alpha\epsilon^2/a)}{kT} + 0.217 \log T + \log \left\{ \frac{\left(\frac{M}{M_+M_-}\right)^{\frac{3}{2}} (8\pi k)^{\frac{1}{2}} hI \times 7.6 \times 10^4}{V_f^2 \epsilon^2} \right\}, \quad (66)$$

where $M$ is the mass of diatomic molecules, $M_+$ and $M_-$ are the masses of the cation and anion, $I$ is the moment of inertia, $\epsilon$ the charge of the ions, $D_0$ the energy for the decomposition of the molecule into ions, and $\alpha$ the Madelung constant. The values of $V_f$ obtained from Eqn. (66) were of the order of 0.05 cm$^3$ mole$^{-1}$ for the alkali metal halides. However, McQuarrie's calculations of the entropy of fusion of NaCl and KCl (2.84 and 2.40 cal deg$^{-1}$ g-ion$^{-1}$) were close to the experimental values.

The progress in the statistical theory of the liquid state associated with the use of the methods of Kirkwood, Bogolyubov, and Green[403-408], based on the calculation of molecular distribution functions permits these methods to be applied to molten salts. Calculation of the correlation functions with allowance for both coulombic forces and short-acting repulsive forces:

$$U(r) = \epsilon^2/r + U_0(r), \quad (67)$$

still meets with insuperable mathematical difficulties. Bogolyubov[405] proposed, as a first approximation, the use of smoothing coulombic potentials

$$U(r) = \epsilon^2 [1 - \exp(-\alpha r)]/r. \quad (68)$$

This idea was employed in several works[409-411], which related, however, to aqueous solutions of electrolytes. Works on the theory of ionic liquids[412-419] were all based on a model in which the ions were represented by rigid charged spheres. The question as to how far this model is suitable for describing the properties of molten salts is still not solved. Undoubtedly some successes have been achieved in this direction. In particular, mention can be made of works[417,418] in which a formula was derived for the surface tension of melts:

$$\sigma = \frac{kT}{4\pi a^2} \left[ \frac{12y}{1-y} + \frac{18y^2}{(1-y)^2} \right], \quad (69)$$

| | | expt. | calc. |
| NaCl | 1000 | 98 | 111 |
| KCl | 900 | 90 | 96 |
| RbCl | 828 | 89 | 81 |
| CsCl | 830 | 78 | 79 |
| $BaCl_2$ | 1000 | 157 | 152 |

where $y = \pi a^3 \rho/\sigma$, $a$ is the mean diameter of the ions, and $\rho$ the density. This formula agrees well with experiment (Table 19). Satisfactory results were also obtained by Rice[419] in calculating the diffusion coefficients, viscosity, and thermal conductivity of melts.

All the theories considered relate only to molten alkali metal halides. With other molten salts the matter is more complicated. As already noted, in many instances the formation of autocomplexes of the type $BeCl^+$, $BeCl_3^-$, etc.[316] on melting is assumed. However, it is possible that in addition to autocomplexes the melt retains fragments of the crystal lattice in several instances, for example, $ZnBr_2$.[240] Finally, in melts of the mercury halide type the equilibrium

$$HgX_2 \rightleftarrows HgX^+ + HgX_3$$

is probably established, with a strong displacement towards the side of formation of neutral molecules[421]. Naturally the construction of a theory for such complicated ionic-molecular systems is encountering great difficulties.

# ALCOHOL DERIVATIVES OF THE ALKALI AND ALKALINE EARTH METALS, MAGNESIUM, AND THALLIUM(I)

N. Ya. Turova and A. V. Novoselova

CONTENTS

I. Classification of the alcohol derivatives of the elements 161

II. Alkoxides of the alkali and alkaline earth metals, magnesium, and thallium(I) 162

A. Methods of preparation 162

B. Physical properties of alkoxides and certain structural problems 167

C. Chemical properties of alkoxides and their main applications in organic and inorganic preparations 171

1. Addition reactions 171

2. Substitution reactions 174

3. Oxidation reactions 176

4. Thermal decomposition of alkoxides 176

5. Catalytic action of alkoxides 176

III. Phenoxides of the alkali and alkaline earth metals, magnesium, and thallium(I) 177

A. Methods of preparation 177

B. Properties of phenoxides 179

## I. CLASSIFICATION OF THE ALCOHOL DERIVATIVES OF THE ELEMENTS

Alcohol derivatives of the type $E(OR)_n$ are now known for almost all the elements of the Periodic System. Even as long ago as 1899, Tishchenko noted that "the form of alcoholates is as general and besides much more stable (in respect of thermal stability) than the hydroxide form"[1]. However, the alcohol derivatives of many rare metals have been prepared and studied intensively only recently — the difficult-to-prepare compounds of the multivalent elements of Groups IV, V, and VI, and also the alkoxides of the platinum group metals and actinides.

The properties of the alcohol derivatives — unlike hydroxides — are not determined solely by the nature of the element, but depend also on the nature of the alcohol radical in the $E(OR)_n$ molecule. Therefore the acidity of the alcohol (that is, the lability of the hydrogen atom of the hydroxyl group) and the electronegativity of the element obviously must be taken as the basis of the classification of the alcohol derivatives of the various elements of the Periodic System. From this standpoint the following groups of compounds of type $E(OR)_n$ can be distinguished:

1. Compounds formed by elements with sharply expressed metallic properties and the radicals from alcohols having a strongly acid character ($K_{diss} \geqslant 10^{-10}$). This group includes the derivatives of the alkali and alkaline earth metals and thallium(I) with phenols, naphthols, anthrols, etc. Subsequently we will term them phenoxides. These compounds are saltlike, and as "salts of strong bases and acids of medium strength" are capable of existing in aqueous solution. They are insoluble in organic solvents (even in absolute ethanol), have usually a definite melting point, exhibit a high thermal stability, and evidently do not exist in the gaseous state.

2. The other boundary case consists of the derivatives of non-metallic elements and alcohols whose acid function is weakly expressed — the esters of inorganic acids. Low melting and boiling points, high vapour pressure, solubility in organic solvents, and instability with even traces of water are characteristic here. The molecules of esters are of very low polarity, usually strongly associated, and tend to form complexes. As characteristic examples of esters we may mention the alkyl borates, whose properties have been reviewed in detail[2,3]. However, it should be noted that the above-mentioned general features of the compounds

of this group are also distinctive of the alcohol derivatives of the metals of Groups III–VIII of the Periodic System.

3. The characteristic representatives of the compounds of the third group — the alkoxides (into whose composition there enter an active metal and the alkoxy radical of an alcohol with an acid dissociation constant $\ll 10^{-10}$) — are the derivatives of the metals of the principal subgroups of Groups I and II and thallium(I) with the aliphatic alcohols. From the character of the M–OR bond they occupy an intermediate position between the polar phenoxides and the non-polar esters. This is evidently fundamental and determines their unique properties. The alkoxides, like the esters of inorganic acids, are extremely sensitive to the action of moisture, are sometimes (as in the case of Li) associated, and tend to form complexes. By analogy with phenoxides, alkoxides are capable of electrolytic dissociation (in alcoholic solutions they exhibit appreciable electrical conductivity and sometimes react in an ionic form), and are insoluble in organic solvents (with the exception of alcohols). However, unlike the compounds of the first two classes, the alkoxides do not melt or sublime, but undergo thermal decomposition at 200–300°.

These three classes of alcohol derivatives of elements are only boundary cases, since their characteristic representatives are the compounds of elements which exhibit clearly expressed metallic or non-metallic character. At the same time the vast majority of metals of the main subgroups (starting with beryllium and Group III) and the elements of all the auxiliary subgroups form alcohol derivatives combining simultaneously the properties of alkoxides and esters of inorganic acids.

The present review is devoted to the alcohol derivatives of the alkali and alkaline earth metals, magnesium, and thallium(I), which are characteristic representatives of two of the classes mentioned above: the alkoxides and phenoxides. Most of the compounds considered have been known for over a century, but the most important investigations devoted to their synthesis and also to their chemical and most physicochemical properties were only completed in the last 20–30 years. This is due on the one hand to the improvements in experimental techniques, which permit work with substances that decompose in the presence of traces of moisture, oxygen, or carbon dioxide, and on the other to the important part which alkoxides and phenoxides play in the technology of contemporary organic and inorganic syntheses. This review will not deal with the rather large group of inner complex (chelate) compounds of the elements mentioned, which are only formal analogues of alkoxides and phenoxides†. There have been other reviews devoted[4-9] mainly to the use of sodium alkoxides in organic syntheses. The reactions of mixed magnesium halide alkoxides was considered in detail in a monograph by Ioffe and Nesmeyanov[10], published in 1963. In Bradley's reviews[11,12] attention was mainly directed towards the alkoxide compounds of multivalent metals‡.

† This refers to the metal derivatives of polyfunctional organic molecules (hydroxyketones and diketones, ketoenols, alkyl salicylates, nitro- and amino-phenols, hydroxy-pyridines, -quinolines, etc.) and also to most "acid" phenoxides — the incompletely substituted derivatives of polyhydroxy-compounds.

‡ After this review had been prepared for publication, there appeared a volume of Houben ("Houben–Weyl: Methoden der organischen Chemie. 4. Aufl. Band VI. Spezielle chemische Methoden. Teil 2. Sauerstoffverbindungen I. 2", Thieme, Stuttgart, 1963) containing a review of the literature on alcohol derivatives of metals.

## II. ALKOXIDES OF THE ALKALI AND ALKALINE EARTH METALS, MAGNESIUM, AND THALLIUM(I)

### A. METHODS OF PREPARATION

#### Method I. Reaction of Metals with Alcohols

The action of potassium and sodium on ethanol was first observed by Liebig in 1837; in 1840 Kuhlmann (who proposed the term "alcoholate"), on the basis of this reaction, considered compounds of type MOR to be alkali metal salts in which an alcohol plays the part of an acid[1].

The alkali and alkaline earth metals react very readily with at least the first members of the series of aliphatic alcohols but nevertheless the reaction goes to completion only with a large excess of the absolute alcohol or on continuous heating[13]. As a result alkoxide solvates of the type $M(OR)_n.xROH$ ($x$ = 2 or 3) are formed, which lose the alcohol of crystallisation only on heating (sometimes to 150–200° in a stream of inert gas). To obtain the unsolvated alkali metal alkoxides at low temperatures (such preparations exhibit the greatest reactivity), Brühl[14] suggested carrying out the reaction using the stoichiometric quantity of the alcohol with finely dispersed Na or K in a medium of hydrocarbon or diethyl ether[15,16]. Fisher and MacElvain[17] perfected this method: the metal (in a massive state) was put in the filter in a Soxhlet apparatus and a mixture of high-boiling inert solvent (xylene or dioxan) with the calculated quantity of the alcohol was put in the flask. Utilising the insolubility of unsolvated alkoxides in hydrocarbons or ethers, the alcohol was quantitatively converted into the alkoxide. In a similar way Mamedov[18] synthesised disodium ethylenedioxide, which is not readily available (aniline was the reaction medium). In all cases the syntheses (as in general work with alkali and alkaline earth metal alkoxides) were carried out under nitrogen or hydrogen.

This reaction (in the synthesis of derivatives of higher aliphatic alcohols or magnesium alkoxides) has often been catalysed by mercury(II) chloride (or directly with the metal amalgam)[20-26], and also with iodine (first employed by N.D. Zelinskii in 1903), bromine[19,27,28], or with mercury(II) chloride and iodine together[27,29-31]. Nevertheless, reaction between magnesium amalgam and tertiary alcohols has not been achieved, even on heating to 100°.

In Germany in 1932 a commercial scheme was worked out for the production of aliphatic, aromatic, and hydroaromatic alkoxides of sodium — important intermediates in organic synthesis. It was based on an electrolytic process for the decomposition of an aqueous NaCl solution usually employed for the production of chlorine and alkali (the chlorine is liberated at a graphite anode, and the sodium is discharged at a moving mercury cathode and is removed from the cell as an amalgam). The next stage of the process was the decomposition of the sodium amalgam with an absolute alcohol; it was effected in reactors and then in columns filled with pieces of graphite, and the countercurrent principle was employed to ensure that the reaction went to completion. Subsequently this scheme was perfected: the decomposition of the amalgam by the alcohol was accelerated considerably by using a contact electrode not susceptible to amalgamation (of graphite or stainless steel)§. The economics of the process were improved

§ A recent patent claims[32] carrying out the reaction between the amalgam and alcohol in the presence of graphite containing 2–3% iron.

because of the greater utilisation of the sodium: the residues of amalgam contained in the spent mercury were decomposed with water and then the mercury and solution of alkali were recycled to the electrolyser. The heat set free in the formation of NaOH was used to raise the temperature of the reaction between Na/Hg and the alcohol. This method was used in the USA in 1944 by the Mathieson Alkali Works for the production of sodium methoxide on an industrial scale. The purity of the unsolvated $NaOCH_3$ (obtained after vacuum distillation of methanol) was $\leqslant 95\%$, the main impurities being 2% NaOH + $Na_2CO_3$ and < 3% $CH_3OH$.[5,8,9,33].

The rate of reaction of a particular metal with various alcohols can serve as a measure of the lability of the hydrogen atom in the ROH molecule. Using the reaction of magnesium[34] and aluminium[1] amalgams it was found that the acid function of alcohols are in the order primary > secondary > tertiary, and in each of these the values of $K_{diss}$ decrease along the homologous series. Fig. 1 gives values of the enthalpies of formation of the alkali metal alkoxides of a series of alcohols, after Forcrand[35-37] plotted against the logarithm of the reciprocal of the acid dissociation constant of the alcohols[38]. The thermal effect for the replacement of the first hydrogen atom in molecules of polyhydric alcohols considerably exceeds $\Delta H$ for the replacement of subsequent H atoms (thus the value shown in Fig. 1 for $\Delta H$ of the reaction of Na with glycerol relates to the monosodium salt and is 1.5 times that of the corresponding value for the disodium salt)[40].

## Method II. Reaction of Ammines of Metals with Alcohols in Liquid $NH_3$ as Solvent

The solubility of the alkali and alkaline earth metals in liquid ammonia, permits their homogeneous reaction with alcohols (unlike the previous reaction). On account of the liberation of hydrogen and precipitation of the alkoxides

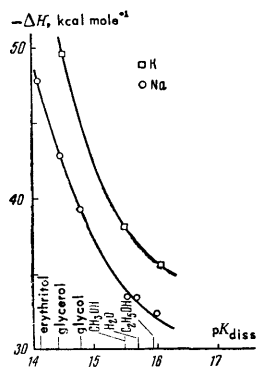

Fig. 1. Relation between the acidity function of alcohols and the heats of formation of the alkali metal alkoxides by the reaction:

$$M_{solid} + ROH_{liquid} = MOR_{solid} + \tfrac{1}{2}H_{2\,gas}.$$

The value of $\Delta H$ of formation of the sodium salt of erythritol was calculated from Forcrand's data on the heat of reaction of solid erythritol with allowance for the heat of fusion of $C_4H_{10}O_4$ (10.2 kcal mole$^{-1}$).[39]

(which are usually insoluble in ammonia[41]), the equilibrium of the ionic reaction:

$$M(NH_3)_6 + nROH \xrightleftharpoons{NH_3} M(OR)_n + n/2\,H_2 \ (n=1 \text{ or } 2),$$

is almost instantaneously shifted to the right for primary alcohols; with secondary and tertiary alcohols the rate is somewhat less[42]¶.

This method was proposed in 1905 by Chablay for the synthesis of sodium alkoxides[42], but he subsequently extended it to the other alkali metals[43] and the alkaline earth metals[44,45]. The field of application of this reaction now extends to the higher, unsaturated, and polyhydric alcohols[43,45-47] — including the mono- and poly-saccharides, cellulose[48-50], poly(vinyl alcohol)[51], etc.

## Method III. Decomposition of Hydrides, Organometallic Compounds, Carbides, Nitrides, Amides, or Sulphides by Alcohols

This reaction is based on the alcoholysis of compounds which are sensitive to the action of "active hydrogen", and leads to the formation of alkoxides and gaseous products according to the scheme: MX + HOR → MOR + HX↑, where X = H, R, C≡C, ≡N, $NH_2$, or SH.

Judging by the patent literature, the reaction of various alcohols with NaH,[52,53] $Na_2S$,[54] calcium carbide[55-56], and magnesium carbide[57] is now a cheap industrial method for the production of alkoxides. White et al.[47,58] proposed to carry out the alcoholysis of alkali amides by alcohols of the aromatic series (whose acidity function is very low) in solution in liquid $NH_3$, where the equilibrium is shifted to the right, owing to the precipitation of the alkoxides.

The reaction described has found wide application in the field of organometallic compounds (mainly Grignard complexes). As Grignard showed, the alcoholysis of alkylmagnesium halides leads to the formation of alkoxymagnesium halides and the liberation of gaseous hydrocarbons. This reaction forms the basis of the method of quantitative determination of "active hydrogen" developed by Tserevitinov[59]. However, in recent years in the determination of active hydrogen simple and double hydrides have begun to displace the less readily available $CH_3MgI$.[60] Among the reactions of the hydro-derivatives is the recently described methanolysis of ethoxymagnesium hydride, leading to the formation of an unsymmetrical alkoxide, $CH_3OMgOC_2H_5$.[61]

## Method IV. Double Decompositions of Salts with Alkoxides

To effect the synthesis of alkoxides by the scheme: $EX + nM^{I}OR \rightarrow E(OR)_n + nMX$, it is necessary for one of the products to be removed from the sphere of reaction (usually by insolubility in the corresponding non-aqueous solvent). This method is widely used in the synthesis of the alkoxy-derivatives of multivalent elements, but has only limited application for the metals of the main subgroups of Groups I and II. Thus in 1923 Jones and Thomas[62] brought about the reaction $LiCl + NaOC_2H_5 = LiOC_2H_5 + NaCl$ by making use of the lower solubility of NaCl (compared with LiCl) in absolute alcohol.

¶ A side-reaction — the decomposition of the ammines with formation of metal amides, $MNH_2$ — can be disregarded because of its slowness under these conditions.

Menzies[63], and then Abbott[64] alkoxylated the dialkylthallium(III) halides with ethylsodium and ethylthallium(I) (in absolute alcohol):

$$R_2TlX + M^IOC_2H_5 = R_2TlOC_2H_5 + MX\downarrow.$$

The patent literature contains descriptions of the synthesis of KOR, by the reaction of KOH or $K_2CO_3$ with sodium or potassium alkoxides. The success of the reaction is decided by the choice of solvent, in which only one of the products should be soluble[56,65]. The double decomposition of a sodium alkyl carbonate with $Ba(OCH_3)_2$ (formed in a boiling methanol suspension of BaO) is interesting, and leads to the formation of $NaOCH_3$ and the precipitation of $BaCO_3$.[66]

Chablay made wide use of the double decomposition of sodium alkoxides with alkaline earth metal or thallium(I) nitrates in solution in liquid ammonia, utilising the fact that the alkoxides are usually precipitated but $NaNO_3$ is soluble in liquid ammonia. Alkoxy-derivatives of Ca, Sr, Ba, and $Tl^I$ with many mono-, di-, and poly-hydric alcohols were obtained in this way[44,45].

Jander and coworkers[67] succeeded in bringing about the double decomposition: $K_2SO_3\downarrow + (C_2H_5)_2SO = KOC_2H_5\downarrow + 2SO_2$ in liquid sulphur dioxide solution, because under these conditions the potassium ethoxide formed was less soluble than the original sulphite. The reaction:

$$NaH + B(OCH_3)_3 \longrightarrow Na[BH(OCH_3)_3] \xrightarrow{250^\circ} NaBH_4 + NaOCH_3 + B(OCH_3)_3\uparrow$$
$$Na[BH(OCH_3)_3] \xrightarrow{+NaH} NaBH_4 + NaOCH_3,$$

is used in the preparation of sodium and lithium tetrahydroborates[60,68] and is interesting in that the alkoxylating agent in this instance is trimethyl orthoborate (and not NaOR, as usually). The sodium and lithium methoxides which remain in large amounts after extraction of $NaBH_4$ with amines apparently find no use at present.

## Method V. Reaction of Oxides or Hydroxides with Alcohols

The oxides and hydroxides of the alkali and alkaline earth elements are much cheaper raw materials than the corresponding metals, therefore their use for the production of alkoxides on an industrial scale is especially promising. However, reactions (1) and (2) are reversible

$$M^IOH + ROH \rightleftarrows M^IOR + H_2O, \quad (1)$$

$$M^{II}O + 2ROH \rightleftarrows M^{II}(OR)_2 + H_2O, \quad (2)$$

and special conditions are required to separate the alkoxides from the reaction mixture in a particular case. As long ago as 1840 Kuhlmann[1] obtained $KOC_2H_5$ by the action of ethanol on "Gay-Lussac pyrophor" (a mixture of $K_2O$, $K_2S_n$, and carbon). Obviously the equilibrium is close to the alkoxide side on account of the reaction of water with the dipotassium polysulphide. Subsequently similar syntheses of alkoxides were repeatedly described in the patent literature. To remove the water from the reaction zone, calcium carbide[70] and oxide[71,72], and benzene (giving an azeotrope with water at atmospheric[73] or elevated pressure[74]) were used. The last of these methods was employed in Germany in the 1930's in the industrial production of sodium ethoxide and methoxide[8]. In 1946 a patent was taken out on the production of compounds of Ba and Sr with the higher aliphatic alcohols by the alcoholysis of hydroxides in a mineral oil medium[75].

Another way of shifting the equilibrium to the right is to precipitate the alkoxides. In particular, there has been a proposal[76] to carry out the reaction of alkalis with ethanol in the presence of anhydrous acetone, which probably "salts out" the sodium and potassium ethoxides.

The method described is used much more frequently under laboratory conditions for the synthesis of alkoxides of polyhydric alcohols (the water is then removed because of the high reaction temperature and its greater volatility in comparison with the reacting alcohols). The synthesis of sodium 2-hydroxyethoxide and disodium ethylenedioxide (by the reaction of NaOH with ethylene glycol in a vacuum at $\leq 110^\circ$) was patented[77] in 1926. Cross and Jacobs[78] obtained monopotassium and monosodium glycerolates analogously, and in 1891 Forcrand had obtained mono- and di-sodium derivatives of 1,2,3,4-tetrahydroxybutane[79]. Ushakov and his coworkers[51] synthesised in this way sodium poly(vinyl oxide) (the alkoxidic nature of which was demonstrated by infrared spectroscopy and also by a counter-synthesis by method II). The low solubility of the alkalis in the higher alcohols for long restricted the use of alcoholysis for synthesising the alkoxides[8]. However, in 1957–58 patents were taken out on the production of alkoxides in the reaction of solid NaOH or KOH[80] or their aqueous solutions[81] with higher alcohols (aliphatic, hydroaromatic, and aromatic). In the last case the reaction is brought about in countercurrent flow in a distillation column at high temperatures[81].

Here it is pertinent to mention the decomposition of alkali carbonates by glycol, as a result of which the corresponding 2-hydroxyethoxides are formed[54]. This reaction takes place at the boiling point of ethylene glycol (198°); in it the considerably weaker acid (ethylene glycol) displaces $H_2CO_3$ (whose dissociation constant at 25° exceeds that of ethylene glycol by a factor of over $10^9$).

According to the literature, this method plays the main part in the synthesis of thallium alkoxides. Owing to its low standard electrode potential, metallic thallium hardly reacts with alcohols (or with water). The reaction can be brought about only in a continuous stream of dry oxygen‡. Hence the essence of the method consists in the reaction of $Tl_2O$ (formed by oxidation of the metal and with properties similar to those of the alkali oxides) with the alcohol:

$$Tl + O_2 \rightarrow [Tl_2O] \xrightarrow{+ROH} TlOR + TlOH,$$
$$TlOH + ROH \rightleftarrows TlOR + H_2O.$$

After repeated treatment of TlOH with small portions of alcohol the solid is completely converted into a heavy oily liquid to which Menzies[63] and other authors after him[64,83–85] ascribe the formula $TlOC_2H_5$ (quoting at best only results

† The thermal decomposition of the alkoxyboron complexes — formed in the alcoholysis of $M[BH_4]_n$ or on dissolution of the metal in an alcohol in the presence of the corresponding $B(OR)_3$ (compare p. 172): $M[B(OR)_4] \rightarrow M(OR)_n + B(OR)_3\uparrow$) — can in turn serve as a convenient method of synthesis of unsolvated alkaline earth and alkali metal alkoxides[32,69].

‡ According to Forcrand's results[82] the hypothetical reaction of Tl with alcohols and water should be endothermic, for the difference of their $\Delta H$ and the $\Delta H$ of the analogous reactions of sodium is constant at 58.52 kcal mole$^{-1}$. Nevertheless the reaction of $Tl_2O$ and TlOH with ethanol has a weak exothermic effect ($\Delta H$ is respectively -2.742 and -1.132 kcal per mole alkoxide).

of determinations of the metal). Yet as long ago as 1919, Freudenberg[86] showed that the concentration of carbon in this oily product is approximately one-half that calculated for $TlOC_2H_5$. In Brauer's handbook[87] this method is even proposed as a method for preparing thallium hydroxide, not alkoxide. Hence despite the many results which relate supposedly to $TlOC_2H_5$, we are speaking in the present case not about an individual compound but about a mixture (or possibly a complex compound) of thallium hydroxide and ethoxide. It must be noted that the structure of the molecular associates of thallium alkoxides quoted in several reviews[11,12,88] and monographs[89,90] were proposed by Sidgwick and Sutton[83] on the basis of cryoscopic and ebullioscopic investigations of the oily product (in this, the molecular weight of the monomer was calculated for the formula $TlOC_2H_5$). In view of the absence of a complete chemical analysis of other thallium(I) alkoxides obtained by this method, the problem of the composition of these compounds must at present be considered open.

In conclusion, mention must be made of the special importance of this type of reaction in making alcohols absolute — since the position of equilibrium (2) (p. 164) determines the maximum possible degree of dehydration of the alcohol concerned. Thus the equilibrium in the reaction $NaOC_2H_5 + H_2O \rightleftharpoons NaOH + C_2H_5OH$ lying considerably to the left[91-93] does not permit sodium to be used for making alcohols absolute§. A series of authors up to the present day have recommended that alcohol should be made absolute with alkaline earth oxides[96]. Moreover, in 1938 Berner[97], and subsequently Scholder and Kreutz[98], showed conclusively that the equilibrium

$$MO + 2\,CH_3OH \rightleftarrows M(OCH_3)_2 + 2H_2O \rightleftarrows M(OCH_3)(OH) + CH_3OH + H_2O,$$

where M = Ca, Sr, Ba, which exists in the solution, leads to the appearance of water in the absolute alcohol put in contact with the alkaline earths. This conclusion is confirmed by an investigation of the isotopic exchange in the $CaO-C_2H_5OH-D_2O$ system[99]. Nevertheless under these conditions both alkoxides were isolated in an individual state. The normal methoxides of Ca, Sr, and Ba are formed when the reaction is carried out with a large excess of alcohol — they are precipitated on heating the solutions. The hydroxide methoxides are obtained as sparingly soluble crystalline powders on treating the oxides with a little alcohol (see also p. 174).

Most methods for making alcohols absolute employ metallic Mg or Ca (sometimes Ba)[96], but the expediency of using them has only been demonstrated preparatively[100] by the determination of the water concentration after distillation over the corresponding alkoxide. Thermodynamic data, which determine the equilibria in these important reactions, have not been published.

## Method VI. Double Decompositions of Alkoxides with Alcohols Leading to the Synthesis of New Alkoxides

This method is of rather limited application among the elements of the main subgroups of Groups I and II. The equilibrium of the double decomposition $M(OR)_n + nR^IOH \rightleftharpoons M(OR^I)_n + nROH$ usually lies to the right on account of the removal of the more volatile alcohol. Therefore this method is used mainly for the synthesis of the alkoxides of polyhydric alcohols, and alkali metal methoxides or ethoxides are used as starting materials. This is the only method for the preparation of the trisodium salt of glycerol (reaction of the monosodium glycerol salt with sodium ethoxide): the reaction of glycerol with metallic Na or with alkoxides of monohydric alcohols does not yield such highly substituted products[180].

As Forcrand showed, the first stage of an exchange reaction of this type is the formation of addition compounds, which decompose with liberation of alcohol only on prolonged heating:

$$C_3H_5(OH)_3 + KOC_2H_5 \longrightarrow C_3H_5(OH)_2(OK)\cdot C_2H_5OH \xrightarrow[-C_2H_5OH]{120^\circ} C_3H_5(OH)_2(OK)^{\P},$$

$$C_3H_5(OH)_2(ONa) + NaOC_2H_5 \longrightarrow C_3H_5(OH)_2(ONa)\cdot NaOC_2H_5 \P \xrightarrow[-C_2H_5OH]{180^\circ-190^\circ}$$

$$\xrightarrow[-C_2H_5OH]{180^\circ-190^\circ} C_3H_5(OH)(ONa)_2. \text{ (Ref. 101)}$$

According to Geiger and Nobs[102], the equilibrium of the reaction between the alkali metal derivatives of cellulose and an excess of methanol is almost completely in favour of formation of $NaOCH_3$.

## Method VII. Certain Reactions of Organometallic Compounds Leading to the Formation of Alkoxides

In this section we consider the reactions which form the basis of several important methods of synthesis in organic chemistry. Alkoxides are intermediate products of reactions, almost never liberated in the free state. This explains the absence from the literature of any physicochemical characteristics whatsoever for most alkali metal alkoxides or the unsymmetrical alkoxymagnesium halides, despite the large number of reactions leading to their formation which have been described.

(a) Oxidation of alkyl derivatives of metals by oxygen. The example of the alkyllithium compounds showed[103] that in the first stage of the reaction peroxides are formed, which give alkoxides on further reaction with LiR:

$$LiR + O_2 \longrightarrow R-O-OLi \xrightarrow{+LiR} 2\,[LiOR].$$

The compound is enclosed within square brackets to denote that its formation is inferred only from the hydrolysis products.

In the case of the Grignard complexes this reaction is only one of the possible oxidation paths[10]. On prolonged storage of ethereal solutions of ethylmagnesium iodide in dry air Meisenheimer succeeded in isolating crystals of $C_2H_5OMgI.(C_2H_5O)_2O$, and sometimes also more oxidised (and probably, partly hydrolysed) products of composition $3[C_2H_5OMgI.(C_2H_5)_2O].MgO$.[104] †

(b) Reduction of carbonyl-containing compounds. This class includes, firstly, many reduction

§ According to Caldin and Long[94] and to Murto[95] the equilibrium constant of the reaction: $C_2H_5OH + OH^- \rightleftharpoons C_2H_5O^- + H_2O$ is 0.68 at 25°, that is, in a 0.1 M solution of NaOH in 99% ethanol 96% of the sodium is present as $NaOC_2H_5$.

¶ Obviously it is more correct to consider such compounds as alcohol addition compounds of disubstituted glycerol salts, $C_3H_5(OH)(ONa)_2.C_2H_5OH$.

† This reference is incorrect. References to Meisenheimer's work in this area are to be found in "Grignard Reactions of Nonmetallic Substances" by M. S. Kharasch and O. Reinmuth, Constable, London, 1954, pp. 1264–1276 (Ed. of Translation).

reactions of Grignard complexes which are accompanied by the formation of alkoxymagnesium halides — derivatives of secondary and tertiary alcohols:

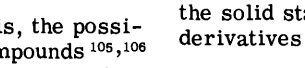
That the products of this reaction were alkoxides was finally decided only in 1941 by Nesmeyanov and Sazonova. Until then many authors had considered them to be addition compounds of RMgX and oxo-compounds [10].

After the discovery of the Grignard synthesis, the possibility of using alkylsodium and alkyllithium compounds [105,106] as reductants for carbonyl compounds was demonstrated. The reaction of organolithium compounds with carbon dioxide, described by Gulman, must be mentioned. As a result of addition of LiR at both double bonds, derivatives of the hydrate forms of ketones are produced [106]:

In 1927 Gomberg and Bachmann [107] employed unusual reductants, magnesium monoiodide and monobromide, obtained by the reaction: $2Mg + X_2 \xrightarrow{ether} 2MgX$. Their reaction with ketones, which is accompanied by an intense coloration (due to the formation of free radicals — metalketyls), led to the pairing of the radicals and the synthesis of pinacolates:

An alkoxide of a special type, an enolate of structure

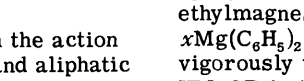
was obtained in the reduction of the $\alpha$-diketone, benzil, as a colourless solvate with two molecules of ether. The solutions of this compound are always coloured (probably on account of the equilibrium between the ketyl and the dimer) [108].



The formation of metalketyls occurs also in the action of metallic sodium or potassium on aromatic and aliphatic ketones [109,110]. The reaction of dialkyl and diaryl carbonates with sodium takes place quantitatively and serves for the production of extremely pure carbon monoxide. In this case, alkoxides are only side-products of the synthesis [111].

There is great interest in the reduction of bis-2-oxoethylmercury with alkali metals (lithium and sodium) in a solution of liquid ammonia. In this way Nesmeyanov et al. [112] synthesised lithium and sodium enolates which were derivatives of vinyl alcohols; for example,

The products form colourless hygroscopic crystals; the existence of a double bond and the absence of a carbonyl group in the molecules were shown convincingly by their infrared spectra [113].



The reaction of carbon monoxide with the alkali and alkaline earth metals also belongs formally to this class of reactions. The pyrophoric "carbonyls" formed as a result have attracted the attention of chemists since the time of Liebig. Until very recently it was thought that they were salts of hexahydroxybenzene — for example $(COK)_6$ is $C_6(OK)_6$ [114] — or derivatives of glyoxal — of the type O=C–Cs
| . [115] However, in 1963–64 Weiss and Büchner [116,117]
O=C–Cs
found, in an X-ray investigation of the potassium, rubidium, and caesium "carbonyls", that the distance between the carbon atoms in them corresponds to a triple bond and the metal is bound to the carbon through oxygen, as in ordinary alkoxides. Hence it can obviously be considered as proved that in the reaction between the alkali metals and CO (in the solid state or in solution in liquid $NH_3$), disubstituted derivatives of the hypothetical acetylenediol are formed:

(c) Cleavage of the C–O bond in ethers with the aid of metal alkyls (Shorygin reaction). In 1910 Shorygin [105], in attempting to carry out in ethereal solution the exchange reaction of sodium with a dialkylmercury, obtained sodium ethoxide instead of the organosodium compound expected. The instability of ethers in relation to an alkyl derivative of alkali metals was thus observed for the first time.

Wittig [118] succeeded in carrying out the Shorygin reaction with tetrahydrofuran (the ether bond in which is usually unreactive). In the reaction with $(C_6H_5)CNa$, tetrahydrofuran was introduced as a complex with diphenylberyllium (in the molecule of which the C–O bond was weakened by coordination). It was shown subsequently that this reaction takes place much more vigorously with organolithium compounds [119].

An interesting compound — a lithium organotinethoxide [the alkoxide of 2-hydroxyethyltriphenyltin (Ed. of Translation)] — is formed by the action of an organotin complex on epoxyethane [120]:

Among the organomagnesium compounds, particularly the Grignard complexes, the Shorygin reaction was known until recently only for the least stable cyclic ethers — epoxyethane and oxetan [10,121]. Bauer [122] observed that ethylmagnesium hydride — obtained by the reaction: $x\mathrm{Mg}(C_6H_5)_2 + SiH_4 = HMgC_2H_5 + SiH_{4-x}(C_2H_5)_x$ — reacts vigorously with diethyl ether. The reaction product HMgOR is insoluble in ether and exhibits quite considerable thermal stability. Huston [123] made a detailed investigation of the mechanism of the reaction of epoxides with symmetrical and unsymmetrical alkylmagnesium compounds. The formation of a series of magnesium alkoxides and halide alkoxides was established. Compounds of analogous type were also obtained in reactions of epoxyethane and its homologues with $MgBr_2.2(C_2H_5)_2O$. [124] However, the compounds synthesised were characterised in the best instance solely by chemical analyses.

## Method VIII. Electrochemical Methods of Synthesising Alkoxides

Numerous instances of the formation of alkoxides in electrochemical processes are noted, particularly in the anodic oxidation of metals during the electrolysis of alcoholic solutions. Szilard [125] isolated pure magnesium ethoxide (and also $Pb^{II}$ and $Cu^{II}$ methoxides) during the electrolysis of alcoholic solutions of sodium alkoxides with various anodes (at low current densities).

The reaction of metals with alcohols (with the aim of obtaining alkoxides) can be considerably accelerated by the setting up of an internal e.m.f. (by the introduction of a second — platinum — electrode)[126] or by connection to a source of current (reacting metal–anode)[127].

The electrolysis of $MgCl_2$ solutions[128] (and various other chlorides)[129] leading to the formation of magnesium alkoxides at the cathode is obviously not of interest from the synthetic aspect.

## B. PHYSICAL PROPERTIES OF ALKOXIDES AND CERTAIN STRUCTURAL PROBLEMS

The alkali metal and alkaline earth metal alkoxides are white, infusible substances, very sensitive to oxygen, moisture, and carbon dioxide (however, $CsOC_2H_5$, $CsOC_3H_7$, and $KOC_3H_7$ are completely liquid by the time decomposition starts[13]). Oxidation, hydrolysis, and carbonation are accompanied by such an appreciable liberation of heat that in air the spontaneous ignition of unsolvated alkali metal alkoxides is possible[5,130]. The potassium and caesium alkoxides are the least stable in this respect (alcohol derivatives of rubidium are still unknown): even in an atmosphere dried by phosphorus pentoxide they rapidly darken and liquefy. To prevent oxidation of solid alkoxides and also of their alcoholic solutions, the patent literature proposes the use of antioxidants: imines, iminium chlorides, and amides[132]. Thallium(I) alkoxides — derivatives of primary normal alcohols (with the exception of methoxide) — are heavy liquids, readily soluble in alcohols and hydrocarbons (Tables 1, 4, and 5).

Most authors refer to the amorphous nature of the alcohol derivatives of the alkali and alkaline earth metals, but adequately sharp reflections are present on the X-ray powder diagrams of all the alkoxides yet studied, including $LiOCH_3$,[133,134] $NaOCH_3$, $NaOCH_3.2CH_3OH$,[133] $KOCH_3$,[133,135] $KOCH_3.nCH_3OH$ ($n$ = 1 or 3)[133], $NaOC_2H_5$,[136] $Sr(OCH_3)_2$.[97]

In 1960–63 the first structural investigations of alkoxides were completed: lithium[133,134], potassium[135], and thallium(I)[88] methoxides. According to Wheatley's results[133], $LiOCH_3$ has a layer structure, analogous to LiOH, of the type ABCBA/AB, . . . . , where A = $CH_3$, B = O, C = Li. Each Li atom in this lattice is surrounded by a distorted tetrahedron of oxygen atoms; the coordination polyhedron of the oxygen is a pyramid with four Li atoms for the base and a $CH_3$ group for the vertex. Hence the basis of the bridge structure of lithium methoxide consists of polymeric chains of $[LiO_4]$ tetrahedra.

Potassium methoxide also crystallises in a layer structure (the space group of both methoxides is $P4nmm$), in which the linear $KOCH_3$ molecules are situated perpendicular to the plane of the layers. The coordination number of potassium is five and the oxygen atom is at the centre of a distorted octahedron, five of the vertices of which are occupied by $K^+$ and the sixth by a methyl group [135].

Lithium alkoxides retain their polymeric nature in solutions and even in the vapour. The degree of association of LiOR, soluble in organic solvents, varies from 3 to 9. [149,157] For insoluble LiOR with radicals of normal structure the association should be even greater [139]. Because the position of the Li–O stretching vibration frequency in the infrared spectra of $LiOBu^t$ vapour (at 200°) is almost the same as that for the solid alkoxide‡, Simonov and coworkers [183] suggested that there was association in the gas phase.

‡ The association of the LiOR molecule leads to a great reduction in the frequency of the Li–O stretching vibrations by ~ 1000 $cm^{-1}$ compared with the value calculated for the isolated molecule [139].

The explanation of such a marked intermolecular interaction for LiOR (in relation to other alkali and alkaline earth alkoxides for which the question remains open) is as follows: (1) the possibility of the formation of "tricentric bonds" from the Li *p* orbital of one molecule and electrons of the Li–O σ bond of another; (2) donor–acceptor interaction between the free *p* orbital of an Li atom and the oxygen lone pair of a neighbouring molecule [139].

A recent investigation of the nuclear magnetic resonance spectra showed that the nature of the bonding of LiOR trimers in n- and t-butoxides is essentially different up to values of $\alpha$ of 6 and 9 respectively§. Whereas in the first case the interaction is of a donor–acceptor character, in the second the formation of multicentre orbitals has the main role [157]. The authors assume that [157] elementary associates, $(LiOR)_3$, form almost planar six-membered rings of alternating lithium and oxygen atoms.

As Table 5 shows, thallium(I) alkoxides are also associated, with formation of tetramers. However, as already indicated on pp. 164–165, the absence of reliable data on the individuality of the products investigated reduces considerably the value of the molecular weight determinations here [83,184]. The existence of tetramers in the $TlOCH_3$ crystal lattice was recently established by X-ray diffraction. Following Sidgwick [83], the authors assume that such a molecular associate is a distorted cube at the vertices of which are four Tl atoms and four oxygen atoms [88]. Unfortunately in this work also only the analyses for the metal are given.

The most important characteristic, which influences all the physicochemical properties of the metal alkoxides being considered, is the considerable polarisation of the M–O bond. However, direct measurement of the dipole moments of the most polar alkoxides is impossible, owing to their insolubility in dipole-free liquids and their involatility. In addition, the published information about the negligible dipole moments of $NaOC(C_6H_5)_3$ ($\mu$ = 1.62 D) [165] and $LiOBu^t$ ($\mu$ = 0.74 D) [139] — compounds which are readily soluble in non-polar solvents — cannot be considered as evidence of the covalent character of the M–O bonds in alkoxides in general (as is done, for example, by Nazarova [165]), in view of the fact that the constants of acid dissociation of $(C_6H_5)_3COH$ and $t\text{-}C_4H_9OH$ are three orders of magnitude less than the corresponding values for the first members of the aliphatic series of alcohols.

Of all the compounds of the class considered, volatility (in a high vacuum) is distinctive for only lithium secondary and tertiary alkoxides [149], potassium tertiary t-butoxide [159], and thallium(I) pentyl oxide [184] — the least polar of the aliphatic alkoxides.

Unsolvated alkoxides, as a rule, are insoluble in most organic solvents (with the exception of alcohols, in which dissolution is effected by the formation of solvates), in liquid ammonia, sulphur dioxide, etc. With increase in size and complexity of the radicals the solubility of MOR in non-polar solvents usually increases. As already mentioned, the LiOR products of normal primary alcohols are insoluble even in the "parent" alcohols, whereas alkoxides with iso-radicals are soluble in any organic solvent (including alkane, hydroaromatic, and aromatic hydrocarbons) except alcohols [149]. Sodium normal alkoxides are readily soluble in alcohols, but as the branching of the radicals is increased the solubility of NaOR in the corresponding alcohols falls considerably (Table 2).

§ $\alpha$ is the degree of association (Ed. of Translation).

* See pp. 164–165.

The solubility of alkali metal alkoxides in liquid $NH_3$ increases with the size of R; [41] with potassium ethoxide it is somewhat greater than with sodium ethoxide [47] (almost insoluble), but Chablay [45] noted a further decrease in solubility on going from the alkali to the alkaline earth alkoxides.

The higher sodium alkoxides — primary isopentyl oxide, triphenylmethoxide — are, unlike the derivatives of alcohols of normal chain structure, readily soluble in benzene, dioxan, etc. (see Table 1). According to McEwen [185], the solubility of $NaOCH_3$ in benzene at room temperature is $3–9 \times 10^{-4}$ M.

The alkaline earth and magnesium alkoxides are much more inert towards organic solvents — even in alcohols their solubility is very restricted and falls on heating (probably owing to a decrease in the solvation of $M^{2+}$ ions with

the alcohols). The solubility of $Mg(OCH_3)_2$ in methanol is given by Bjerrum[186] as 0.9 M at 18°, but Quinet[25] gives 0.118 moles per 100 g at 20°, or ~0.99 M, taking the density of $Mg(OCH_3)_2$ as 1.34.

The polar nature of the M–O bond in alkoxides is responsible for their capability of electrolytic dissociation and consequently their appreciable conductivity in polar solvents. Table 3 gives the equivalent conductance of alkoxides in alcoholic solutions (at infinite dilution). The corresponding quantities for aqueous alkalis and aluminium ethoxide (molten) are also given for comparison.

Thus the electrical conductivity of the alkali metal alkoxides in alcohols is only a few times less than the solubility of such strong electrolytes as NaOH and KOH; it is of the same order as $\lambda_\infty$ of an aqueous solution of sodium acetate and exceeds the electrical conductivity of $Al(OC_2H_5)_3$ by ~6 orders of magnitude, $Al(OC_2H_5)_3$ being a compound whose properties lie at the boundary between typical alkoxides and the esters of inorganic acids.

Grenier and Westrem[141] determined the main thermodynamic functions of sodium methoxide (Table 1); such data are not available for other alkoxides. The variation of heat capacity with temperature, measured between 5° and 340°K, had an anomaly at 34°K, for which the surplus entropy was ~0.43 e.u.

## C. CHEMICAL PROPERTIES OF ALKOXIDES AND THEIR MAIN APPLICATIONS IN ORGANIC AND INORGANIC PREPARATIONS

### 1. Addition Reactions

(a) Complex formation. Meerwein's "alkoxysalts" crystalline alcohol addition compounds. Magnesium halide alkoxides. The tendency of the alkali metal and alkaline earth metal alkoxides to various complex-forming reactions is due to the acceptor and donor abilities of their molecules. A clear demonstration of this "dual" function is the polymerisation of molecules of alkoxides (see p. 169).

The most studied class of oxonium compounds of the alkoxides are their complexes with alcohols. Although the formation of such compounds is due mainly to valence bonds, intermolecular interaction also plays a significant part here, as was shown above. The results of Forcrand's thermochemical investigations (Table 6) suggest that for a single alkoxide the heats of formation of its oxonium complexes from the components decrease along the homologous series of alcohols.

TABLE 6. $\Delta H$ of formation of the crystalline alcohol addition compounds (after Forcrand's results)[166,178,197,220,221]

| Alkoxide | Addend | Composition of complex | $-\Delta H$, kcal (mole complex)$^{-1}$ | | |
|---|---|---|---|---|---|
| | | | Na | K | Ca |
| $MOCH_3$ | $CH_3OH$ | 1:1 | 8.84 | — | — |
| $MOC_2H_5$ | $C_2H_5OH$ | 1:2 | 8.06 | — | 8.5 |
| $MOC_2H_5$ | $C_2H_5OH$ | 1:3 | 8.64 | — | — |
| $MOCH_2-CH_2OH$ | $(-CH_2OH)_2$ | 1:1 | 7.02 | — | — |
| $CH_2-OM$ \| $CH-OH$ \| $CH_2-OH$ | $CH_3OH$ | 1:1 | 5.04 | 3.65 | — |
| | $C_2H_5OH$ | 1:1 | 4.58 | 2.69 | — |
| | n-$C_3H_7OH$ | 1:1 | 4.67 | 3.76 | — |
| | iso-$C_3H_9OH$ | 1:1 | 2.71 | — | — |
| | iso-$C_5H_{11}OH$ | 1:1 | 2.80 | 1.78 | — |

A still more definite conclusion can be drawn from Chelintsev's results[207] on the heats of formation of the compounds of type $C_2H_5OMgI.3ROH$. On plotting the total thermal effects for addition against the dielectric constants of the alcohols (Fig. 2) we observed a relation very close to a straight line (there is a departure only for the first member of the series, $CH_3OH$). A comparison of the thermal effects for the addition of the first molecules of ligand made by Chelintsev is incorrect, since there is no information about the existence of products of an intermediate composition other than 1 : 3 (see, for example, Tolstopyatov[104]). Since in the series of alcohols there is almost no change in the chemical nature of the molecule or the donor properties of the oxygen atom, the observable effect can evidently be ascribed to interaction of entire molecules, not individual atoms (donor and acceptor). The principal role in this interaction is obviously played by the dispersion effect. (In view of the constancy in the dipole moments throughout the homologous series the orientation interaction cannot be great. The induction effect must also be negligible, since in the case under consideration $\mu$ and the polarisability of the donor and acceptor molecules differ little from one another.)

All this at first seems to be contradicted by the results of Frölich[142] and Thomas[13] on the thermal stability of the sodium and caesium alkoxide–alcohol compounds shown in Table 7.

In the examples quoted the desolvation temperatures rise along the homologous series of alcohols, but it must be borne in mind that the acceptor-molecules are different.

For the derivatives of a single alcohol, the enthalpy of formation (Table 6) and thermal stability (Table 1) of the compounds with alcohol of crystallisation decreases from

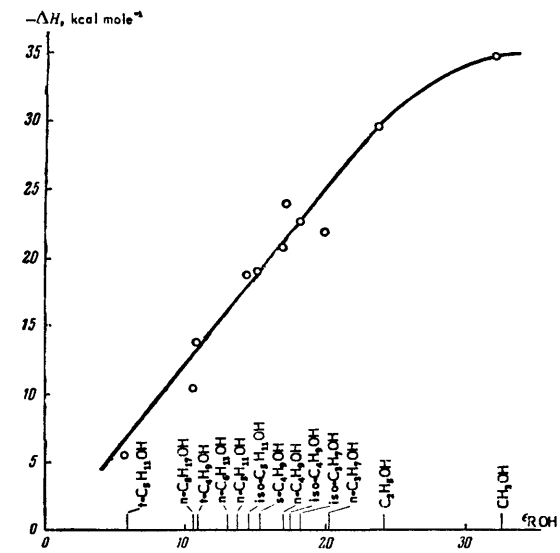

Fig. 2. Relation between the heats of formation of the alcohol addition compounds by the reaction:

$$C_2H_5OMgI + 3ROH = C_2H_5OMgI.3ROH$$

and the dielectric constant of the ligands.

TABLE 7. Temperatures of desolvation of the crystalline alcohol addition compounds.

| | R | | |
|---|---|---|---|
| | $CH_3$ | $C_2H_5$ | $n\text{-}C_3H_7$ |
| $NaOR \cdot 2ROH$[143] | 170° | 200° | 220° |
| $CsOR \cdot ROH$[13] (decomp. in a vacuum) | 20—30° | 50° | 100° |

sodium to potassium. However, Thomas[13] thinks that the tendency of CsOR to solvation by alcohols is somewhat greater than that of KOR.

The coordination compounds of alkoxides with alcohols obviously exist in solution as well as in the solid state. In 1963, Kęcki and Witanowski showed[222] that solutions of Li and Na methoxides in $CH_3OH$ do not give the splitting of the NMR signal of the OH group and linked this with the rapid transfer of protons along the chain of a solvate macromolecule; they also considered the solutions to be systems in which strong intermolecular interaction led to a deficiency of protons.

Besides alcohols, the alkoxides are capable of forming "onium" compounds with many other organic molecules. In particular, the literature mentions the existence in solution of 1:1 and 1:2 complexes of $NaOCH_3$ with $HCOOCH_3$ (from electrical conductivity)[223], and complexes of KOR with dimethoxyethane and ethylenediamine. In the last two cases complex formation with the solvent determines the catalytic activity of alkali metal alkoxides in reactions of anionic polymerisation[224].

A special place among the complex formation reactions of the alcohol derivatives of the alkali and alkaline earth metals is taken by their interaction with formal analogues — the esters of inorganic acids. Even in the last century thanks to the work of Kopo and later Cambi[225] it became known that stable saltlike compounds of the type $M[B(OR)_4]$ were formed during crystallisation of alcoholic solutions containing borate esters and Li, Na, K, or Ca alkoxides.

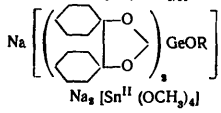
Meerwein and Bersin observed[226] that the alkoxy-derivatives of most of the elements of Groups III–VI undergo alcoholysis in alcoholic solutions with formation of "alkoxy--acids" of type $H[E(OR)_n]$. Their reaction with the "strong bases" $M^IOR$ is analogous to neutralisation:

$$H[E(OR)_n] + M^IOR \longrightarrow M[E(OR)_n] + ROH.$$

The complexes which are formed have acquired the name "Meerwein's alkoxy-salts". In many cases these authors[226] succeeded in titrating with alcoholic solutions of $M^IOR$. Subsequently synthesis of alkoxy-salts progressed and now compounds of the type $M[E(OR)_n]$ and also the mixed salts $M[EX_m(OR)_{n-m}]$ (where X is H, halogen, $NH_2$, OH, OR′, or R′) are known for almost every element in the Periodic System. Table 8 gives brief information about them.

These complex alkoxides crystallise readily and are much less reactive than their components. The most stable of them even shows some stability towards water and does not react with methyl iodide; in their alcoholic solutions the inversion of methone does not take place — in other words, the most characteristic reactions of the alkali metal alkoxides do not occur[226,230]. Meerwein notes that the instability constant of the complex anion depends on the nature of the alkoxy-group to an even greater extent than on the central atom. As might be expected, under strictly equal conditions it decreases as the "acidity" of the alcohol increases; therefore maximum stability is shown by the compounds of the polyhydric alcohols and phenols; these are usually inner complexes which do not even decompose in aqueous solutions.

Just as in some respects the alkoxides behave like the hydrides of the corresponding metals (tendency to solvation, polymerisation, extreme sensitivity to moisture, oxygen, $CO_2$, etc.), their "alkoxy-salts" show in several properties a similarity with double hydrides (by the alcoholysis of which they can readily be obtained). A consideration of the physicochemical properties of the complex alkoxides enables them to be classified roughly (by analogy with the double hydrides) into molecular and saltlike. It is interesting that the nature of the metal–complex anion bonds in the $M[EX_n]$ molecules which contain atoms of the same elements obviously do not change significantly on going from hydrides to alkoxides. The considerable difference in the polarity of the E–O and M–O bonds in the components leads to the formation of saltlike complex alkoxides, characteristic representatives of which are the alkali and alkaline earth metal methoxyborates. These compounds (like the corresponding hydroborates[68]) are insoluble in non-polar organic solvents but their alcoholic solutions exhibit considerable electrical conductivity; their thermal decomposition takes place at high temperatures and is accompanied by the detachment of $B(OR)_3$. Meanwhile $M[B(OC_2H_5)_4]_2$ (where M is an alkaline earth metal) are soluble in (as well as alcohols) tetrahydrofuran, benzene, cyclohexane, and ether, their solubility falling in this order of the solvents[69]. At the same time, $Mg[Al(OC_2H_5)_4]_2$ or the recently described $Li[AlH(OBu^t)_3]$ and $Ca[U(OC_2H_5)_6]_2$ are readily soluble in ethers and hydrocarbons and distil without decomposition — the b.p. of $Mg[Al(OC_2H_5)_4]_2$ is 235–237°/1 mmHg,[238] and the sublimation temperatures of $Li[AlH(OBu^t)_3]$ is 280°/1 mmHg,[237,242] and of $Ca[U(OC_2H_5)_6]_2$ 200°/0.01 mmHg.[255]



Hence their molecules, by analogy, for example, with $Al[BH_4]_3$, appear entirely covalent and it can be assumed that there is something in common between the molecular structures of "alkoxy-salts" and the corresponding double hydrides. In connection with this, there is the interesting question of the nature of the reaction of barium and titanium methoxides. According to the patent literature[259], on boiling an alcoholic solution of these alkoxides $Ba_2TiO_4$ is precipitated, and this can be explained only by the instability of the double methoxide which is probably formed in the first stage.

In the last 15–20 years interest in the complex alkoxides has grown considerably, in connection with their possible use as efficient catalysts. Thus, the "amphoteric" nature of $Mg[Al(OR)_4]_2$ determines the peculiar catalytic action of this alkoxy-salt[260]. The "strong base" $Mg(OR)_2$ present in the molecule brings about the aldol condensation, but the "acid" $Al(OR)_3$ leads to the Tishchenko reaction between the hydroxyaldehyde formed in the first stage and a molecule of the original aldehyde (to a glycol ester)[261]:

$$RCH_2CHO + CH_2CHO \longrightarrow \underset{\displaystyle R}{RCH_2CH}\!-\!\underset{\displaystyle OH}{CH}\!-\!\underset{\displaystyle R}{CHO} \xrightarrow{+RCH_2CHO} \xrightarrow{+RCH_2CHO} RCH_2COOCH_2\!-\!\underset{\displaystyle R}{CH}\!-\!\underset{\displaystyle OH}{CH}\!-\!CH_2R.$$

Hydroalkoxy-complexes — for example, $Li[AlH(OBu^t)_3]$ — are valuable reductants. They differ from $LiAlH_4$ by

* According to our observations[258], this compound could not be prepared, either under the conditions described by Meerwein[226] or on reaction of the two alkoxides.

** This is the probable formula, judging from the properties of the complex carbonyl described by Feigl and Krumholz[256].

their gentler and more selective reducing action for certain classes of organic compounds and also for metal halides [242,262].

A second, much wider field of use of alkoxyborates is connected with the synthesis of hydroborates, for example:

$$M[B(OCH_3)_4] \text{ or } Na[BH(OCH_3)_3] + B_2H_6 \longrightarrow M[BH_4] + B(OCH_3)_3$$

M = Li, Na, K, Mg, Ca, Sr, Ba, [60,68,69,263]

$$Na[BH(OCH_3)_3] \xrightarrow[\text{(diglyme)}]{} NaBH_4 + \downarrow Na[B(OCH_3)_4]^{263}.$$

A much less studied class of complex alkoxides comprises the products of addition to inorganic halides. At present such compounds (given the formula X–M–OR) are known only for magnesium among the group of elements covered by this review (see p. 165). By common crystallisation of alcoholic solutions of $MgCl_2$ and $Mg(OC_2H_5)_2$, Meerwein and Schmidt [29] separated a 1 : 1 addition product, which could be recrystallised with partial decomposition from boiling alcohol. On carrying out the reaction with magnesium methoxide under similar conditions, Quinet [264] obtained the crystalline complex $3Mg(OCH_3)_2.MgCl_2.11CH_3OH$, which easily loses its alcohol of crystallisation.

Tolstopyatov and coworkers [104], in a detailed investigation of the alcoholysis of the alkylmagnesium halides, proposed a convenient method for isolating crystalline ROMgI: precipitation as a complex with benzophenone or benzaldehyde. It was shown simultaneously that the higher alcohols (starting with n-propanol) do not form stable magnesium alkoxides. The equilibrium of the symmetrisation: $ROMgX \rightleftharpoons Mg(OR)_2 + MgX_2$, which the authors [104,265] think exists in ether solutions is easily shifted to the right by the precipitation of $MgI_2.3(C_6H_5)_2CO$ (which is insoluble in ether). The scanty data [266,267] suggest that the crystalline magnesium bromide alkoxides (obtained on the alcoholysis of RMgBr) are considerably less soluble in ether than the iodides, and are less reactive.

In further investigations of this theoretically interesting class of compounds it is proposed, apparently, first to solve the problem of the identity of the halide alkoxides obtained by different paths: (1) the addition, $MgX_2 + Mg(OR)_2$; (2) alcoholysis of a Grignard reagent — it has recently become known that the nearest analogues of ROMgX (the alkylmagnesium halides) are different from the molecular compounds of the type $MgX_2.MgR_2.x(C_2H_5)_2O$, synthesised in the reaction of ethereal solutions of $MgX_2$ and $MgR_2$. [268]

(b) Reactions with the anhydrides of inorganic acids. The reactions of alkoxides with $SO_2$, $CO_2$, $CS_2$, and other anhydrides of inorganic acids are accompanied by addition of the metal and alkoxy-group at a double bond of the anhydride to form salts of alkyl hydrogen sulphites [7,10,191,269], alkyl hydrogen carbonates, [8,191,270–272] and alkyl hydrogen monothiocarbonates [5], thus:

$$MOR + E\begin{matrix}X\\X\end{matrix} \longrightarrow X=E\begin{matrix}M\P\\OR\end{matrix},$$

where E = S or C; X = O or S; and M = Na, K, ½Mg, or ½Ba.

¶ Presumably the authors intended to write the scheme:

$$MOR + E\begin{matrix}X\\X\end{matrix} \rightarrow RO-E\begin{matrix}X^-\\X\end{matrix}\ M^+$$

for $SO_2$ and $CO_2$ at least; however, this would give an xanthate with $CS_2$ (Ed. of Translation).

The reaction of alkali metal alkoxides with carbon monoxide is more complex and the composition of the products is greatly dependent on the temperature and pressure [7]. The reaction of CO with alcohols in the presence of solid NaOR is now used for making formate esters [160,273], or (under different conditions) for the synthesis of salts of the higher carboxylic acids by lengthening of the hydrocarbon chain [5]. In inorganic preparations sodium alkoxides are sometimes used as mild reagents for binding CO molecules. Thus, in the reaction of pentacarbonyliron with NaOR in alcohol solution tris(tetracarbonyliron) $[Fe(CO)_4]_3$ was obtained [274]. The information about the products of the reaction between the alkali metal alkoxides and $S_2O_3$ is contradictory [275].

## 2. Substitution Reactions

(a) Interaction with acids — reaction analogous to neutralisation:

$$MOR + HX \underset{(ROH)}{\rightleftharpoons} MX + ROH. \quad (1)$$

The use of this reaction (usually brought about in alcohol solutions) for preparative purposes has a series of advantages in comparison with the neutralisation of the corresponding bases in aqueous solution. Firstly, the greater volatility of alcohols, and also the lower solubility of the salts formed ensure that equilibrium (1) is displaced to the right. Secondly, under the conditions described anhydrous salts are formed (in the case of fatty acids, soaps) [5].

Of the reactions of alkoxides with inorganic acids, those with hydrogen sulphide which lead to the formation of sulphides or hydrogen sulphides of Li, [62] Na, [276] K, [114] Tl, [85] Ca [194] have been studied most:

$$MOR + H_2S \rightleftharpoons MHS \xrightarrow[(ROH)]{t^\circ} M_2S\downarrow.$$

This reaction is the most convenient method for preparing alkali metal hydrogen sulphides (their salting out from alcohol solutions is effected with ether or benzene [114]).

It is interesting to note that solutions of $H_2S$ in aromatic hydrocarbons or $CHCl_3$ (unlike aqueous solutions) are titrated by alkoxides, despite the almost complete absence of electrical conductivity. This fact served at the time as one of the first proofs of the unsuitability of the Arrhenius "aqueous" theory of acids and bases [260].

Here it is pertinent to refer to the reaction of disubstituted potassium glycerolate with silicic acid — in the form of amorphous silica or the hydrolysis products of $Si(OR)_4$. According to Toropov [204] and Kreshkov [277] this reaction enables calcium silicates soluble in glycerol to be obtained in quantitative yield.

(b) Reaction with water. Products of partial hydrolysis of the alkoxides of Group II metals. Whereas the alkali metal alkoxides with even traces of water undergo hydrolysis in accordance with the equation: $MOR + H_2O \rightleftharpoons MOH + ROH$, the alkoxy-derivatives of bivalent metals (alkaline earth elements and Mg) form intermediate products, hydroxide alkoxides of the type M(OH)(OR) (see also p. 165). In most of the old work on the alkaline earth alkoxides compounds are described (obviously of individual composition) which crystallise from alcohol solutions in those cases where the alkoxides undergo partial hydrolysis or reaction with the corresponding

metal oxide or hydroxide. Even Dumas and Berthelot, and then Forcrand[278] considered them to be oxides with alcohol of crystallisation, MO.$n$ROH. Szarwasy[191] succeeded in isolating the normal basic magnesium methoxides by using the fall in solubility of $Mg(OCH_3)_2$ on raising the temperature (on boiling the alcohol solution, pure magnesium methoxide is precipitated). Szarwasy proposed the formula $Mg(OH)(OCH_3)$ for the partial hydrolysis product on the principle that this compound had considerable thermal stability, with no loss of alcohol on heating (as would have occurred for ROH of crystallisation). Berner[97], as already noted, isolated analogous compounds of Ca and Sr (which in alcoholic solution exist in equilibrium with the normal methoxide and oxide) and showed their individuality by X-ray analysis. Scholder and Kreutz[98] made a systematic investigation of the solid phases existing in equilibrium with solutions of BaO in methanol. Forcrand's results[279] on the overall composition of the compounds formed were confirmed, but from the information on the decomposition of the compounds in a high vacuum at 20° the authors proposed different structural formulae (Table 9). From the results of work[98] on the solubility of various hydrolysis products of $Ba(OCH_3)_2$ in methanol, we attempted to construct an approximate equilibrium diagram for the $Ba(OCH_3)_2 + H_2O \rightleftharpoons CH_3OH + Ba(OH)_2$ reciprocal system (by Jänecke's method). As Fig. 3 shows there are four solid phases in this system at 20°; one of the hydrolysis products is the barium hydroxide alkoxide and the other is a solvate of $Ba(OH)_2$ with the alcohol.

Table 9 lists the compounds of this type mentioned in the literature; we assume that hydroxide alkoxides analogous in composition and method of preparation to the barium compounds[98] possess the same structure.

(c) Reactions with alcohols. These have received detailed consideration above (p. 165). The exchange reactions of alkoxides with β-dicarbonyl or β-hydroxycarbonyl compounds (which obviously react in an enol form) are of definite preparative interest. The products — the β-diketone derivatives of the alkali and alkaline earth metals, Mg and $Tl^I$ — are inner complexes and are therefore not considered in this review. However, it must be noted that there is an important difference between the derivatives of these metals. Whereas all the derivatives of acetoacetic ester (except that of Li) are readily soluble in benzene, resist the action of water, have low melting points, and volatilise easily (that is, they are typical chelates), the analogous Li or sodium compounds of alkylmalonic esters are insoluble in hydrocarbons, decompose without melting, and do not sublime[281]. Hence despite their formal analogy with typical chelates, the latter resemble more closely the alkoxides, a fact which is probably linked with the more polar nature of their molecules and the lower stability of the rings formed.

TABLE 9. Magnesium and alkaline earth metal hydroxide alkoxides.

| ROH | Mg | Ca | Sr | Ba |
|---|---|---|---|---|
| $CH_3OH$ | Mg(OR)(OH)[191] | Ca(OR)(OH)[97] | Sr(OR)(OH)[97] | Ba(OR)(OH)·ROH<br>Ba(OR)(OH)·0.33ROH<br>$Ba(OH)_2 \cdot 2ROH \cdot H_2O$[98,197,279] |
| $C_2H_5OH$ | | Ca(OR)(OH)·0.33ROH[197,198,280]<br>Ca(OR)(OH)[272] | | Ba(OR)(OH)·0.33ROH[197,279] |

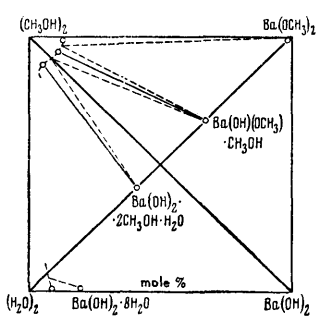

Fig. 3. Approximate solubility diagram for the $Ba(OCH_3)_2$–$CH_3OH$–$H_2O$ system (20°) after Scholder and Kreutz[98].

(d) Reactions with inorganic and organic halides. These play a large part in organic synthesis, where alkoxides are used as alkoxylating agents. The reaction of alkali metal alkoxides with inorganic halides in a medium of organic solvents — or, more correctly, with solvato-acids of the type $H[EX_n(OR)_m]$ is usually the most general method of synthesis of the alkoxy-derivatives of all the elements of the Periodic System: $nMOR + EX_n \rightarrow E(OR)_n + nMX$. This reaction is ionic and, as stated above[226], in many instances titration in alcoholic solution is possible (for example, $HgCl_2$ may be titrated by sodium ethoxide against phenolphthalein)[260]. Whereas the reaction of alkoxides with alkyl halides which are used for the synthesis of ethers (Williamson reaction): $MOR + R'X \rightarrow R'OR + MX$, takes place by an entirely different mechanism (nucleophilic substitution at the carbon atom). But the most ionic Na and K phenoxides generally do not react with alkyl halides, therefore silver phenoxides are used to introduce phenoxy-groups into molecules[282].

In addition to the Na, K, and Li alkoxides, usually used as alkoxylating agents in the Williamson and Schotten–Baumann reactions[283], several authors[24,284] recommend the use of magnesium alkoxides, which sometimes give higher yields of the main reaction product. An unusual application of the Schotten–Baumann reaction appeared recently in the work of Lebl; the reaction of potassium methoxide with acetyl chloride was proposed as a method for obtaining KCl of high purity[285].

(e) Reaction with hydrides. Wiberg and Hartwimmer[69] synthesised borohydrides of the alkaline earth elements directly from alkoxides in tetrahydrofuran:

$$3M(OR)_2 + 4B_2H_6 \xrightarrow[\text{T.H.F.}]{\text{(boiling}} 3M[BH_4]_2 + 2B(OR)_3.$$

Earlier the tetrahydroborates of metals of Groups I and II were made by Schlesinger's method, starting from the corresponding alkoxyborates[69]:

$$M[B(OR)_4] + B_2H_6 \longrightarrow M[BH_4] + 4B(OR)_3.$$

Rossmanith and Macalka[286] carried out an analogous reaction with mixed tetrahydroborates–chlorides of the rare-earth elements. In a solution in tetrahydrofuran, in addition to replacement of chlorine in the molecule of the complex hydride there is replacement of one $[BH_4]$ by a methoxy-group and then also partial alcoholysis of $[BH_4]$:

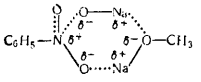
$$NaOCH_3 + LnCl[BH_4]_2 \xrightarrow{-NaBH_4,\ -NaCl} Ln(OCH_3)_2[BH]_4 \longrightarrow Ln(OCH_3)_2[BH_3(OCH_3)],$$

where Ln = Gd, Dy, Y, Sm, Er, etc.

### 3. Oxidation Reactions

The alkali and alkaline earth metal alkoxides are readily oxidised by oxygen in the cold in the solid state, in solution, or as suspensions in organic solvents. The oxidation products of the derivatives of primary alcohols are mainly salts of carboxylic acids, those of secondary alcohols are ketones and metal peroxides [5,287]. In the presence of diphenylmethanol oxygen oxidises sodium and potassium t-butoxides to hydroperoxides MOOH, peroxides, or superoxides, depending upon the reaction conditions (the ratio of the components and the nature of the solvent) [287]. In alcoholic solution in the presence of catalysts (platinum black, $Fe_2O_3$, or $Co_2O_3$) sodium alkoxides are smoothly oxidised to salts of the corresponding acids [5].

The action of chlorine or bromine on NaOR forms a mixture of various oxidation and halogenation products; with $Mg(OC_2H_5)_2$ the main product is acetaldehyde [21]. The reaction of sodium alkoxides with iodine [288] is accompanied by replacement of hydrogen and splitting of the hydrocarbon chain, for example:



$$NaOC_2H_5+3I_2 \longrightarrow CH_2I_2+CHI_3+H_2O+NaI.$$

A detailed summary of work on the oxidation of alkoxides (mainly carried out at the end of the last century), is given in Dermer's review [7].

Aromatic nitro-compounds are reduced by alkali metal alkoxides quantitatively to azoxy-compounds [5,289]:

$$C_6H_5NO_2+CH_3ONa \longrightarrow C_6H_5-\overset{O}{\overset{|}{N}}=NC_6H_5+HCOONa+CH_2O+H_2O.$$

According to Ogata and Mibae [289], the reaction proceeds through a transition state of the type:

(and not through a quinoid structure, as was suggested earlier [290]).

Of all the compounds considered here, only the thallium(I) alkoxides act as oxidants. According to McHatton and Soulal [217], aromatic acyloins reduce TlOR to metallic thallium and are themselves quantitatively oxidised to $\alpha$-diketones:

$$Ar-\underset{\underset{O}{\|}}{C}-\underset{\underset{OH}{|}}{CH}-Ar+2TlOR \longrightarrow Ar-\underset{\underset{O}{\|}}{C}-\underset{\underset{O}{\|}}{C}-Ar+2Tl+2ROH.$$

### 4. Thermal Decomposition of Alkoxides

Despite many investigations of the thermal decomposition of alkoxides, there is not yet a single opinion concerning the mechanism of this process. Tishchenko [1], on the basis of an analysis of the literature on the alkaline earth alkoxides [272] and his own studies of the thermal decomposition of $Al(OR)_3$, proposed the following general scheme for the pyrolysis of alkoxides:

$$M(OR)_n \rightarrow M_2O_n+C_nH_{2n}+ROH \quad (I)$$

$$M_2O_n+ROR \rightarrow (M_2O_n) \quad (II)$$

$$C_nH_{2n+2}+C_nH_{2n}CHO+H_2\ (III) \qquad M(OH)_n+C_nH_{2n}. \quad (IV)$$

The relative amounts of each of the reaction products depend on the decomposition temperature, the stability of the alkoxide group, and mainly on the catalytic properties of the oxide formed. In consequence, reaction (IV) proceeds quantitatively only in the decomposition of alkali and alkaline earth alkoxides (the oxides of which are capable of dehydrating ethers). Hence the primary products of the decomposition, according to Tishchenko, should be ethers or the original alcohols. Actually, when Tropsch and Philippovich [291] heated sodium methoxide to 240° in nitrogen they found dimethyl ether. The thermal decomposition of $Mg(OCH_3)_2$ [25] or of potassium tertiary fluorinated butoxides† [292] is accompanied by the formation of the corresponding alcohols.

The pyrolysis of alkali and alkaline earth metal alkoxides starts at 300–350°. On the basis of many results (given in Tables 1 and 4) it can be suggested that generally the thermal stability of the alkoxides decreases in the homologous series of the alcohols [145] and with increasing branching of the hydrocarbon radical [293]. It is difficult to draw any definite conclusions as to the influence of the metal. Zook et al. [293] gave the following series of decreasing thermal stability: Li > Na > K. An analogous series (including Cs) can also be given for ethoxides (Table 1).

Durand [140], and later Thomas [13] investigated in detail the mechanism of the thermal decomposition of MOR and $M(OR)_2$, and showed that the pyrolysis of the alkali metal methoxides follows a quite special path:

$$6MOCH_3=9H_2+2M_2CO_3+2C+M_2C_2 \quad ; \quad M_2C_2 \rightarrow 2M+2C$$

The second stage, the formation of the free metals, occurs only with K and Cs (sodium acetylide exhibits exceptional thermal stability). Kahlbaum et al. [211] observed the formation of metallic thallium in the decomposition of "thallium ethylate". In the first stage of the thermal dissociation of sodium, potassium, and caesium ethoxides and propoxides, dehydrogenation occurs, with formation of vitreous products of composition $C_nH_{2n-1}OM$, to which Thomas [13] ascribes a vinyl oxide structure: $RCH_2CH_2OM \rightarrow RCH=CHOM + H_2$. The subsequent course of the decomposition, connected with that of the vinyl oxides — and probably of poly(vinyl oxides) — is rather complex and depends on the nature of the radical and metal. For ethoxides, for example, the overall equation is:

$$3\,C_2H_5OM \longrightarrow 4H_2+4C+3MOH+C_2H_4. \ [13,145]$$

In the case of tertiary alkoxides, the gaseous reaction product is almost pure unsaturated hydrocarbon [130] — hence the decomposition proceeds quantitatively according to Eqn. (IV). It is worth noting the thermal decomposition of the "acid" alkoxides of dihydric alcohols [43,101], the first stage of which is symmetrisation by the scheme:

$$2\ \begin{matrix}CH_2OM\\|\\CH_2OH\end{matrix} \xrightarrow{t°<200°} (CH_2OM)_2+(CH_2OH)_2.$$

### 5. Catalytic Action of Alkoxides.

To conclude this review of the chemical properties of alkoxides brief reference must be made to their use as catalysts. This field of application is extremely important, since it is connected with the synthesis of many

† Such as $(CF_3)_2CMeOH$ and $CF_3CMe_2OH$ (Ed. of Translation).

dyestuffs and their intermediates, of pharmaceutical preparations (such as barbituric acid and its derivatives, vitamins B, etc.), perfumes and perfumery materials, and also a series of ketones, aldehydes, esters, and amines which find extensive use in industrial organic syntheses [5,7].

Among the reactions in which alkoxides are used as condensing agents, mention must first be made of the Guerbet reaction. In 1909 Guerbet observed that alcohols (starting with propanol) heated with sodium alkoxides in ampoules double, and sometimes treble, their molecular weight. Subsequently Thomas used potassium alkoxides in this reaction, and in the presence of CsOR was able to condense ethanol also [13]. According to Terent'ev's results [19], magnesium or calcium alkoxides can also act as catalysts for this reaction. Weissmann [13] proposed the following scheme for this reaction:

$$RCH_2CH_2\dot{O}H + H\dot{C}H(R')-CH_2OH \xrightarrow{(-H_2O)} RCH_2CH_2-CH(R')-CH_2OH.$$

In condensations of carbonyl-containing compounds — aldol and crotonaldehyde condensations with malonic or acetoacetic esters, etc. — the formal role of the alkali metal alkoxides is ascribed to dehydration action [4,5,294]. The use of various alkali metal alkoxides in the Claisen condensation is well known (for example, see Ioffe and Nesmeyanov [10], and Berkman and coworkers [294]); recently magnesium ethoxide has been used successfully by Laukkanen [295] for the cyclisation of esters of dibasic acids. It is appropriate here to mention the synthesis of barbituric acid by the condensation of malonic ester with urea using $Mg(OCH_3)_2$. [296]

In the Meerwein–Schmidt–Verley reaction alkoxides are used as reducing agents. To reduce aldehydes to primary alcohols, Meerwein and Schmidt [29] first used $Mg(OC_2H_5)_2$ and $ClMgOC_2H_5$. Simultaneously Verley [297] suggested using sodium alkoxides in this reaction, and Gomberg and Bachmann successfully employed magnesium iodide ethoxide and magnesium bromide ethoxide. The more fundamental nature of the catalysts mentioned is due to some specificity in their action compared with the $Al(OR)_3$ usually employed in this reaction [230,297].

Alkali metal alkoxides are used in the Wolff–Kishner reduction in the second stage only, the catalytic decomposition of hydrazones [294,298].

Information has also been published on the isomerising action of alkali metal alkoxides in relation to the different classes of unsaturated compounds. There is firstly isomerisation of acetylenic hydrocarbons into allenes [294], secondly migration of a triple bond [294], and finally migration of a double bond [156,299].

In the last five years there have been reports of the use of the alkoxides of metals of Groups I–III in processes for the polymerisation of epoxides [152,153,202,300], and of certain types of unsaturated compounds [161,301–304].

As well as the reactions mentioned, alkali metal alkoxides are also used as additions to catalysts. Thus the so-called "Alfin catalysts", which are mixtures of sodium isopropoxide and sodium alkenides, have been used for the polymerisation of dienes [305]. The hydrogenation of furfural diethyl acetal on nickel is much faster in the presence of sodium ethoxide [306].

Of other application of alkoxides we can note the use of NaOR as oil additions to facilitate their drying [5], and of Sr and Ba alkoxides as additives for lubricating oils [75]. Calcium methoxide is a stabiliser for vinyl resins [307], the calcium and magnesium higher alkoxides as additions to anti-knock agents to eliminate the precipitation of lead from them [308]. Vitreous films exhibiting valuable dielectric properties are formed by the heat treatment of barium or strontium alkoxides deposited on a surface by impregnation with alcoholic solutions of $M(OR)_2$. The formation of such films on the surface of fluorine-containing polymers increases their adhesive properties [309]. Thallium "ethylate" had been suggested as a heavy liquid ($d$ = 3.55) for determining the specific gravity of solids [211]. The derivatives of thallium and polyhydric alcohols (like other $Tl^I$ compounds) are used for the stripping of hair from hide [310].

## III. PHENOXIDES OF THE ALKALI AND ALKALINE EARTH METALS, MAGNESIUM, AND THALLIUM(I)

### A. METHODS OF PREPARATION

For the preparation of phenoxides it is possible in principle to use the same methods as for the preparation of alkoxides. Therefore for convenience in Table 10 the same symbols for the preparative methods (Roman numerals) are

TABLE 10. Alkali metal phenoxides.

used as in Tables 1, 4, and 5. The data in Table 10 show that phenoxides are most frequently obtained by the reaction of metal hydroxides with phenols in alcohol, benzene, or aqueous solutions or in the melt (method V). The use of this method in a particular case (unlike alkoxides) is almost without limitation owing to the considerable resistance of phenoxides to the action of water, already referred to.

A special method which can be used only for preparing phenoxides (method IX) consists in fusing aromatic sulphonic acids with alkalis. It is well known that in industry this important method is usually used indirectly for the preparation of phenols. Analogous conversions (usually with formation of disubstituted resorcinolates) also occur under specified conditions with isomeric chlorophenols or benzenedisulphonic acids.

## B. PROPERTIES OF PHENOXIDES

The phenoxides (with the exception of $LiOC_6H_5$), because of their saltlike nature, are insoluble in organic solvents and even in absolute ethanol (they dissolve only on addition of water). However, they are readily soluble in water and the solutions exhibit a strongly alkaline reaction. The dissociation constant of $C_6H_5OH$ ($10^{-10}$) is six orders of magnitude greater than that of water, therefore the equilibrium for the hydrolysis of alkali metal phenoxides is completely shifted to the right only on prolonged heating. However, potassium phenoxide, according to Selivanov's results [311] hydrolyses rather more readily: for example, $Ca(OH)_2$ is formed by the action of benzene or ether on its hydrate, $Ca(OC_6H_5)_2.2H_2O$. Obviously, in this case the hydrolytic equilibrium is displaced to the right by extraction of phenol into the organic phase. In general, naphtholates ($K_{diss}$ of naphthols is $10^{-4}$–$10^{-5}$) do not undergo hydrolytic decomposition.

In contrast with alkyloxides, unsolvated phenoxides are soluble in liquid ammonia [47], they readily crystallise and have a definite melting point, which suggests that their crystal lattice is of a molecular nature. Sodium phenoxides (except for the first member of the series) melt considerably above their potassium analogues (see Table 10). In ammoniacal solutions, phenoxides exhibit appreciable electrical conductivity [164].

According to Fischer's results [312], the pyrolysis of derivatives of $C_6H_5OH$, independently of the nature of the metal, takes place at 450–500°. Under these conditions the aromatic nucleus gives small fragments — $CH_4$, CO, $CO_2$, $H_2$, the formation of which does not enable the mechanism of the thermal decomposition and the nature of the intermediate products to be established.

In 1958 Krüger [313] observed that association is peculiar to the alkali metal phenoxides. For example, $NaOC_6H_5$ exists as dimers in a melt with magnesium sulphate (at 1 M concentration).

Phenoxides crystallise from aqueous solutions as hydrates, and in the presence of phenol as $MOAr.xArOH.yH_2O$. Mixed molecular compounds of this type were observed also in studying solubility in the reciprocal systems $M(OAr)_n$–ArOH–$H_2O$. A detailed investigation was first completed by van Meurs [314] and alkali and alkaline earth metal phenoxides and resorcinolates were dealt with. Lichtenstein and coworkers [320,325] studied the solubility polytherms in systems containing sodium phenoxide or *o*-cresyl oxide, which are of technological importance (in the process for separating phenols in treating lignites). The equilibrium diagram of the $C_6H_5ONa$–$C_6H_5OH$–$H_2O$ system [320] at 25° is shown in Fig. 4. Table 11 lists the solid phases observed in the systems mentioned above.

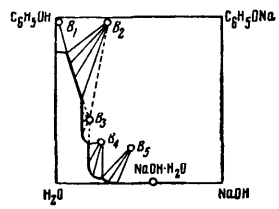

Fig. 4. Equilibrium diagram of the $C_6H_5ONa$–$C_6H_5OH$–$H_2O$ system at 25°. [320]

TABLE 11. Solid phases existing in the $M(OAr)_n$–ArOH–$H_2O$ systems.

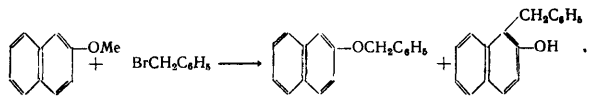
As is evident from the data in Table 11, the formation of molecular compounds with phenols is characteristic only for sodium and potassium phenoxides. The lithium and alkaline earth phenoxides only form hydrates, whose solubility in water falls in the sequences: K > Na > Li; Sr > Ba > Ca. [314]



The "crystal phenolates", $MOAr.nArOH$, are readily soluble in water, alcohol, acetone, and can be recrystallised from hot benzene. They all crystallise well and melt without decomposition.

The problem of the structure of the phenoxide hydrates is interesting. For a long time they, like the products of the partial hydrolysis of alkoxides, were considered to be molecular compounds of hydroxides with phenols [311]. However, Forcrand [341] showed that on careful dehydration of these compounds anhydrous phenoxides could be obtained (and not hydroxides, which are formed in those cases when hydrolysis is carried to the limit).

In comparison with alkoxides, there have been many fewer investigations of the reactions of phenoxides; we will note only the most important of them. The action of $CO_2$ at room temperature on dry sodium phenoxide forms the sodium salt of phenylcarbonic acid (by analogy with alkoxides), and on further heating it isomerises into sodium salicylate [342]. This reaction forms the basis of industrial methods of preparing aromatic hydroxy-acids (Kolbe and Schmidt). In alcoholic solution, evidently a mixture of two acids is formed as a result of partial substitution: phenyl- and ethyl-carbonic [342]. In aqueous solution, according to Meyer [323], the decomposition of phenoxides by carbonic acid sometimes does not go to completion (although $K_{diss}$ of phenol is six orders of magnitude below the first $K_{diss}$ of $H_2CO_3$) owing to the formation of stable "acid phenoxides" (MOAr.ArOH) between unreacted phenoxide and the phenol liberated in the reaction. The equilibrium constant of the reaction: $NaOC_6H_5 + H_2CO_3 \rightleftharpoons C_6H_5OH + NaHCO_3$ is 1.05 at 20°. [343] Wesseley and coworkers [315] found that in the Kolbe reaction of lithium and potassium phenoxides lead mainly to the synthesis of salicylic acid but the potassium and caesium phenoxides to the formation of the *p*-hydroxy--acids.

Sulphur dioxide forms with phenoxides (unlike alkoxides) salts of the phenylsulphinic acid $MSO_2OC_6H_5$ (and not of phenylsulphurous acid) [344].

The reaction of phenoxides with halogen-substituted hydrocarbons, leads, by analogy with other Williamson syntheses, to the formation of ethers. However, owing to conjugation in the system Me–O–C=C–, phenoxides are here characterised by a dual reactivity, due to the formation of not only *O*-derivatives, but also *C*-derivatives. Thus the reaction of 2-naphthyl oxides with benzyl bromide leads according to Zagorevskii's results [218], depending on the nature of the metal, to different proportions of the products of alkoxylation and alkylation:

The maximum yield of esters is reached with silver or tetramethylammonium phenoxide.

The metallation of sodium and potassium phenoxides (by *n*-pentylsodium) leads to the replacement of one or two atoms of hydrogen in the nucleus, which in the case of $NaOC_6H_5$ results in *ortho*-substitution whereas the –OK group proved to be more strongly *meta*-orientating [345].

# CHEMISTRY OF UNSTABLE OXYGEN--CONTAINING RADICALS

L. M. Terman

## INTRODUCTION

In recent years there has been particular interest in unstable free radicals having an unpaired electron on an oxygen atom. A recent review[1] described the production, thermochemistry, and reactions of a large group of alkoxy--radicals, but the four years since its publication have seen a considerable increase of work on these radicals, and this has persuaded us to write the present article.

We shall consider the gas- and liquid-phase reactions most typical of RO· radicals, but not those of stable oxygen-containing radicals such as the substituted phenoxy--radicals, nor heterogeneous reactions involving hydroperoxides.

## REACTIONS OF RO· RADICALS

Oxygen-containing radicals with an unpaired electron on the oxygen atom are produced as unstable intermediates in many chemical processes. We indicate below only the main ones; a detailed list was given in the above review[1].

RO· radicals are produced in the light- and heat-induced decomposition of alkyl and aralkyl

nitrites: $RONO \rightarrow RO\cdot + NO$,

nitrates: $RONO_2 \rightarrow RO\cdot + NO_2$,

hyponitrites: $RONNOR \rightarrow 2RO\cdot + N_2$,

hypochlorites: $ROCl \rightarrow RO\cdot + Cl$,

and peroxides: $ROOR \rightarrow 2RO\cdot$,

and in the decomposition, in solution, of dialkyl and diaralkyl peroxodicarbonates:

$$ROCOOCOR \rightarrow 2ROCO\cdot \rightarrow 2RO\cdot + 2CO_2,$$

dialkyl diperoxocarbonates:

$$ROOCOOR \rightarrow ROOCO\cdot + RO\cdot \rightarrow ROO\cdot + CO_2 + RO,$$

and dialkyl monoperoxocarbonates:

$$ROCOOR \rightarrow ROC\cdot + RO\cdot.$$

The formation of RO· radicals in the photolysis of organic esters and ethers has been described.

The RO· radicals are usually identified by indirect kinetic and analytical methods. Direct mass-spectrometric determination of free RO· radicals has been described only for the phenoxy-radicals produced in the pyrolysis of anisole[2] and the methoxy-radicals produced in the decomposition of methanol and dimethyl ether light-sensitised by mercury[3]. The RO· radicals produced by thermal or photo-decomposition undergo various reactions, the main ones being decomposition, hydrogen abstraction, and disproportionation, depending on the structure of the radicals and the chemical and physical properties of the medium. Moreover, the RO· radicals may isomerise or react with other active particles or radicals present, or with compounds containing double bonds.

Below we list the main reactions of RO· radicals in the gaseous and liquid phases. Since liquid-phase reactions have attracted most attention in recent years, we shall give them more attention here also.

1. Decomposition of RO· radicals. Alkoxy--radicals can decompose by two reactions: with the elimination of a hydrogen atom:

$$RCH_2O\cdot \rightarrow H\cdot + RC\!\!<\!\!\begin{matrix}O\\H\end{matrix},$$

or the alkyl radical:

$$RCH_2O\cdot \rightarrow R\cdot + CH_2O.$$

Of these two the second is more favourable thermodynamically[4] (see Table 1), and experimental observations support this.

The decomposition of methoxy-radicals has been observed in the photolysis of methyl nitrate[6]:

$$CH_3O\cdot \rightarrow CH_2O + H\cdot,$$

and decomposition of ethoxy-radicals at a carbon–hydrogen bond in the pyrolysis[7] and photolysis[8] of ethyl nitrate.

TABLE 1. Enthalpy required for decomposition of radicals.

| Radical | Required enthalpy, kcal mole$^{-1}$ | |
|---|---|---|
| | for elimination of an H-atom | for elimination of an R-radical |
| $CH_3O^{\cdot}$ | 25 | — |
| $C_2H_5O^{\cdot}$ | 21 | 13 |
| n-$C_3H_7O^{\cdot}$ | 19 | 11 |
| n-$C_4H_9O^{\cdot}$ | 23 | 11 |
| $(CH_3)_2CHO^{\cdot}$ | 18 | 6.4 |
| cyclo-$C_6H_{11}O^{\cdot}$ | 16 | 1.1 * (ring opening) |

* A different value has more recently been given[5].

Decomposition of the ethoxy-radical at the carbon–carbon bond with formation of formaldehyde and a methyl radical is much more frequently met with, for example, in the pyrolysis of ethyl nitrite[9,10] or nitrate[11,12]:

$$C_2H_5ONO \rightarrow C_2H_5O^{\cdot} + NO,$$
$$C_2H_5O^{\cdot} \rightarrow CH_3^{\cdot} + CH_2O.$$

Ethane and methane have been found in the decomposition of diethyl peroxide[13–15], ethyl hydroperoxide[14], and ethyl t-butyl peroxide[16], showing that the ethoxy-radicals decompose with the formation of methyl radicals.

The n-propoxy-radicals obtained from di-n-propyl peroxide[14], n-propyl nitrate[17], and n-propyl nitrite[10,18] decompose in this way:

$$CH_3CH_2CH_2O^{\cdot} \rightarrow C_2H_5^{\cdot} + CH_2O.$$

The isopropoxy-radical[10,19] is less stable; even in the presence of cyclohexene, which readily loses an $\alpha$-hydrogen atom, the isopropoxy-radicals are 48% decomposed[16]:

$$\text{iso-}C_3H_7O^{\cdot} \rightarrow CH_3^{\cdot} + CH_3CHO.$$

Under the same conditions, n-butoxy-radicals are 29% decomposed with the formation of formaldehyde and n-propyl radicals:

$$CH_3CH_2CH_2CH_2O^{\cdot} \rightarrow CH_2O + CH_3CH_2CH_2^{\cdot},$$

and in the presence of cyclohexene isobutoxy-radicals are 67% decomposed by the reaction[16]:

$$(CH_3)_2CHCH_2O^{\cdot} \rightarrow (CH_3)_2CH^{\cdot} + CH_2O.$$

The decomposition products of isobutyl nitrite contained formaldehyde and 2-nitrosopropane[10,18].

The s-butoxy-radical decomposes to form acetaldehyde and the ethyl radical[10,18]:

$$CH_3CH_2CH(CH_3)O^{\cdot} \rightarrow CH_3CH_2^{\cdot} + CH_3CHO.$$

Decomposition of the t-butoxy-radical to acetone and the methyl radical has been observed in the pyrolysis of di-t-butyl peroxide[7,20–29], t-butyl nitrite[24,31,32], and t-butyl hydroperoxide[7,30]:

$$(CH_3)_3CO^{\cdot} \rightarrow CH_3^{\cdot} + CH_3COCH_3.$$

The activation energy for the decomposition of the t-butoxy-radical is 11–13 kcal mole$^{-1}$.[33–38] Other t-alkoxy-radicals decompose similarly. At 250°, triethylmethoxyl radicals are 61% decomposed into butane and diethyl ketone[39]:

$$(C_2H_5)_3CO^{\cdot} \rightarrow C_2H_5^{\cdot} + (C_2H_5)_2CO.$$

In the decomposition of mixed t-alkoxy-radicals it is the largest hydrocarbon radical which is the more likely to be produced; for example, the decomposition of the t-pentyloxy-radical is 87–88% by the mechanism producing acetone with elimination of the ethyl radical[22]:

$$CH_3CH_2C(CH_3)_2O^{\cdot} \rightarrow CH_3CH_2^{\cdot} + (CH_3)_2CO.$$

Data obtained in the decomposition of a series of unsymmetrical alkoxy t-butyl peroxides in the presence of cyclohexene have been used to establish the following order of stability for simple alkoxy-radicals[40]:

$$CH_3O^{\cdot} > CH_3CH_2O^{\cdot} > CH_3CH_2CH_2CH_2O^{\cdot} > CH_3CH(CH_3)O^{\cdot} > (CH_3)_2CHCH_2O^{\cdot} > (CH_3)_3CO^{\cdot}.$$

This experimental order is in good agreement with thermochemical data: the alkoxy-radicals which decompose more readily have a lower enthalpy requirement for decomposition[4]. The elimination of a radical with formation of a carbonyl compound in a series of alicyclic oxy-radicals $C_5H_{10}\rangle C\langle^{R}_{O^{\cdot}}$ is thermochemically favourable only with certain substituents, for example, when R is t-butyl, benzyl, or 2-allyl; in most cases the oxy-radical decomposes with ring rupture, which in the case of cyclohexyloxy-radicals requires less energy than loss of a radical[5] (Table 2).

In fact, in the decomposition of cyclohexyl nitrite at 80–225° approximately 40% of the cyclohexyloxy-radicals decompose by ring opening with formation of a new radical. It is probably because of this radical that adipic acid is obtained in the presence of oxygen.

In the liquid phase the decomposition reactions are less characteristic of RO$^{\cdot}$ radicals. The isopropoxy- and cyclohexyloxy-radicals remain undecomposed at 40–70° in certain solvents[41,42], and methoxy-, ethoxy-, n-propoxy-, isopropoxy-, and n-butoxy-radicals generated in various solvents have not decomposed even at 120–155°.[43–45] Tertiary RO$^{\cdot}$ radicals decompose in solvents in which hydrogen abstraction is difficult; the relative yields of products from decomposition of t-butoxy-radicals in more than 30 hydrocarbons have been investigated[18,46], and Table 3 gives the relative rates of reaction of hydrocarbons with t-butoxy-radicals at 135° for 25 h. Decomposition of the t-butoxy-radicals is greatest in benzene and t-butylbenzene, in which hydrogen abstraction is difficult (Table 3).

TABLE 2. Enthalpy required for decomposition of substituted cyclohexyloxy-radicals.

| Aloxy | Group lost | Carbonyl compound | $\Delta H$ required, kcal mole$^{-1}$ |
|---|---|---|---|
| Cyclohexyloxy | H | cyclohexanone | 16 |
| | ring opening | $\cdot CH_2(CH_2)_4CHO$ | 0 |
| 1-Methylcyclohexyloxy | $CH_3$ | cyclohexanone | 4 |
| | ring opening | $\cdot CH_2(CH_2)_4COMe$ | 2 |
| 1-Phenylcyclohexyloxy | $C_6H_5$ | cyclohexanone | 9 |
| | ring opening | $\cdot CH_2(CH_2)_4COC_6H_5$ | 2 |
| 1-Butylcyclohexyloxy | $C_4H_9$ | cyclohexanone | −5 |
| | ring opening | $\cdot CH_2(CH_2)_4COC_4H_9$ | +1.2 |
| Decalyl-9-oxy | 1–9 ring opening | monocyclic radical | −1 |
| | 9–10 ring opening | ditto | 0 |
| 1-Hydroxycyclohexyloxy | OH | cyclohexanone | 20 |
| | ring opening | $\cdot CH_2(CH_2)_3CH{=}CHCHO$ | 1 |
| Tetrahydropyranyl-1-oxy | H | 1-hydroxytetrahydropyran | 16 |
| | ring opening | $\cdot CH_2(CH_2)_3OCHO$ | 0 |
| 1-Ethylcyclohexyl hydroperoxide | H | cyclohex-1-enol | −3 |
| | ring opening | $\cdot CH_2(CH_2)_2CH{=}CHCHO$ | 1 |

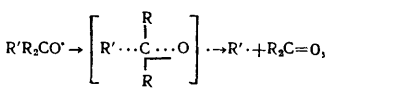

TABLE 3. Relative rates of reaction of t-butoxy-radicals with hydrocarbons.

| Hydrocarbon | Butanol / acetone | Hydrocarbon | Butanol / acetone |
|---|---|---|---|
| Benzene | 0.015 | Cyclohexane | 18 |
| t-Butylbenzene | 0.48 | Ethylbenzene | 4.5 |
| Mesitylene | 7.4 | Tetralin | 24 |
| 1-Methylnaphthalene | 3.2 | 2,3-Dimethylpentane | 4.6 |
| 2-Methylnaphthalene | 1.8 | Decalin | 18 |
| n-Hexadecane | 5.8 | Isopropylbenzene | 3.4 |

It has recently been shown that the isotope effect is fairly large in the decomposition of the t-butoxy-radical[47]; when $^{14}C$ is introduced the rate of decomposition of the radical $(CH_3)_3{}^{14}CO^{\cdot}$ decreases by 7%.

In the decomposition of tertiary alkoxy-radicals the rate of loss of n-alkyl is ten times that for methyl, and the rate for secondary alkyl is 20 times that for ethyl[48].

An important factor in the decomposition of alkoxy--radicals is the nature of the alkyl radical generated, and especially its stability[49]. It is thought that the decomposition includes a transition state, the free energy of activation of which decreases with increasing stability of the radical which is produced:

and in fact the stable benzyl radical is very readily eliminated from the $\alpha\alpha$-dimethylphenethoxy-radical; dimethylbenzylmethanol, produced by abstraction of hydrogen from the solvent by the undecomposed radical, is only formed in small amounts (less than 5%).

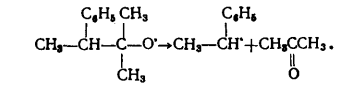
Aralkyloxy-radicals show the same features as the simple oxygen-containing radicals. The first member of this series, the benzyloxy-radical, is exceptionally stable[50-52]. In reactions of benzyl nitrite, dibenzyl hyponitrite, or *p*-nitrobenzyl nitrite in solution, no formaldehyde or phenol derivatives, such as would be formed in decomposition of the benzyloxy-radical:

are observed. The benzyloxy-radicals produced in the thermal decomposition of dibenzyl peroxodicarbonate in benzene, carbon tetrachloride, chloroform, or isopropyl alcohol[41,42,53,54] at 40–70° also do not decompose.

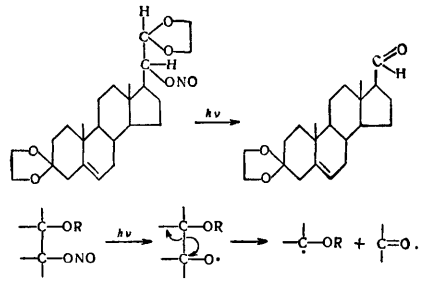
The $\alpha$-phenylethoxy-radical does not decompose at temperatures up to 132°.[55]

The $\alpha$-methylbenzyloxy-radical is somewhat less stable[16]. The phenylmethoxy-radical — from bis(diphenylmethyl) peroxide — decomposes in bromobenzene, isopropylbenzene, or nitrobenzene with the formation of benzophenone. At 210° a phenyl radical is also eliminated (0.03 mole per mole of peroxide)[56,57]. The triphenylmethoxy-radical (from triphenylmethyl nitrate) decomposes with the formation of benzophenone and a phenyl radical[58].

The cumyloxy-radical also decomposes readily[59]:



but no elimination of a phenyl radical is observed. At approximately 160° decomposition of the radical completely suppresses the abstraction of hydrogen from the solvent[60].



The ease of intramolecular fragmentation in $C_6H_5R_2CO^{\cdot}$ radicals thus decreases in the series $CH_3 > C_6H_5 > H$.

The following order of stability of aralkyloxy-radicals in the liquid phase has been suggested, based on experimental results and thermochemical calculations[50] (Table 4).

Decomposition of the *L*-(+)-2-methyl-3-phenylbutoxy--radical has been observed in the thermal decomposition of *L*-(+)-2-methyl-3-phenyl-2-butyl hypochlorite[61] in anhydrous solvents:

An interesting example of decomposition of an alkoxy--radical has been observed in the photolysis of steroidal nitrites[62]. The main photolysis products are carbonyl compounds and acids produced by the scission of oxygen--containing groups adjacent to the active centre, for example:

or[63]

2. Hydrogen abstraction. In all their reactions, particularly in the gas phase, RO$^{\cdot}$ radicals decompose into a carbonyl compound and an alkyl radical, so that in the presence of reagents with an easily broken carbon–hydrogen bond, the hydrogen may be abstracted either by the RO$^{\cdot}$ radical with the formation of an alcohol, or by the R$^{\cdot}$ radical with the formation of the corresponding hydrocarbon RH. We shall consider only reactions involving direct abstraction of hydrogen by RO$^{\cdot}$ radicals.

Gray has estimated the exothermicity of hydrogen abstraction from various hydrocarbons (Table 5).[4] It is seen that hydrogen abstraction should take place least readily from saturated hydrocarbons and most readily from the $\alpha$-methylene group of unsaturated hydrocarbons, and in fact with cyclohexene hydrogen abstraction completely suppresses addition of RO$^{\cdot}$ radicals to the double bond[64].

TABLE 4. Order of stability of aralkyloxy--radicals.

| Radical | Atom or radical lost | Residual carbonyl compound | Increase in enthalpy, kcal mole$^{-1}$ | Stability, decreasing from most (1) to least (6) |
|---|---|---|---|---|
| $C_6H_5CH_2O^{\cdot}$ | $C_6H_5^{\cdot}$ | $CH_2O$ | 16.3 | 1 |
| | $H^{\cdot}$ | $C_6H_5CHO$ | 19.9 | |
| $(C_6H_5)_2CHO^{\cdot}$ | $C_6H_5^{\cdot}$ | $C_6H_5CHO$ | 15.8 | 2 |
| | $H^{\cdot}$ | $(C_6H_5)_2CO$ | 19.4 | |
| $(C_6H_5)_3CO^{\cdot}$ | $C_6H_5^{\cdot}$ | $(C_6H_5)_2CO$ | 11.5 | 3 |
| $C_6H_5CH(CH_3)O^{\cdot}$ | $CH_3^{\cdot}$ | $C_6H_5CHO$ | 6.8 | 4 |
| | $C_6H_5^{\cdot}$ | $CH_3CHO$ | 10.7 | |

In the gas phase hydrogen abstraction depends to a large extent on the stability of the RO$^{\cdot}$ radicals[40]; in the presence of the same hydrocarbon the relative yields of hydrogen abstraction and radical decomposition products differ according to the structure of the radicals.

Methoxy-radicals are the most stable, and in the gas phase they remove hydrogen from cyclohexene [16,40] to produce methanol (76% yield). In the photolysis of methyl acetate[65] the methoxy-radicals abstract hydrogen from acetate molecules; the energy of activation for the abstraction of hydrogen from the acetate by the methoxy-radical (5 kcal mole$^{-1}$) is one-half the energy of activation for hydrogen abstraction by the methyl radical (10 kcal × × mole$^{-1}$) [66,67]. The $CH_3O^{\cdot}$ radicals produced by the thermal decomposition of dimethyl peroxide[68] disproportionate to give methanol and formaldehyde, and the latter then loses hydrogen by reaction with further $CH_3O^{\cdot}$ radicals, so that the final reaction products are methanol and carbon monoxide only. On the other hand, in the decomposition of dimethyl peroxide in methanol[69], the methoxy-radicals abstract hydrogen from the alcohol, and the resulting $^{\cdot}CH_2OH$ radical dimerises to produce ethylene glycol.

The methoxy-radicals produced in the decomposition of dimethyl peroxide[70] and methyl nitrite[70,71] abstract hydrogen from ethane, propane, n-butane, isobutane, neopentane, and cyclopropane.

The ethoxy-radical is somewhat less stable, so that the yield of ethanol by reaction with cyclohexene [16,40] is lower (65%) than the yield of methanol in the corresponding reaction of methoxy-radicals.

In the gas phase the ethoxy-radicals produced in the photolysis of ethyl propionate[71] abstract hydrogen from the parent ester molecule; the energy of activation for this process (5.5 kcal mole$^{-1}$) is in good agreement with the value previously obtained for the methoxy-radical [65-67].

The pyrolysis of ethyl nitrite or nitrate would also be expected to show reaction of ethoxy-radicals with unreacted molecules of the starting material [11,19], but addition of diethyl peroxide to the pyrolysis zone has shown [72,73] that the ethoxy-radicals derived from the peroxide do not abstract hydrogen from ethyl nitrite or nitrate.

The extent of hydrogen abstraction from cyclohexene at 195° by propoxy- and butoxy-radicals [16,40] is shown in Table 6.

TABLE 6. Yield of products from the abstraction of hydrogen from cyclohexene at 195° in the gas phase by RO$^{\cdot}$ radicals obtained by the decomposition of unsymmetrical alkyl t-butyl peroxides.

| RO$^{\cdot}$ | ROH, % | RO$^{\cdot}$ | ROH, % |
|---|---|---|---|
| n-$C_4H_9O^{\cdot}$ | 30 | $(CH_3)_3CO^{\cdot}$ | 8 |
| iso-$C_3H_7O^{\cdot}$ | 19 | | |
| $(CH_3)_2CHCH_2O^{\cdot}$ | 6 | | |

t-Butoxy-radicals are unstable and only rarely abstract hydrogen in gas-phase reactions. Their reaction with aziridine at 129-154° is known [33], and photolysis of di-t-butyl peroxide at 30° has produced a small quantity of t-butyl alcohol [22].

t-Butyl alcohol has been identified in reactions with aldehydes [26,74]. The energy of activation for abstraction of hydrogen from isobutane by t-butoxy-radicals is ~ 4 kcal × × mole$^{-1}$. [38]

Hydrogen abstraction is more typical of RO$^{\cdot}$ radicals in the liquid phase.

In the same solvent under the same temperature conditions, hydrogen abstraction from the solvent by alkyloxy-radicals decreases in the series [43,44]:

$$^{\cdot}OCH_3 > {}^{\cdot}OC_2H_5 > {}^{\cdot}OC_3H_7 > {}^{\cdot}OC_4H_9 > {}^{\cdot}OCH(CH_3)_2.$$

The methoxy-radical abstracts hydrogen from toluene at 155° to give a 100% yield of methanol; the yield of methanol is somewhat lower (70-80%) in diphenylmethane or diphenylethane. The yields of the corresponding alcohols in the reaction of ethoxy- and chloroethoxy-radicals with isopropylbenzene at 125° are of the same order, while n-propoxy- and n-butoxy-radicals give a 60% yield of alcohol and isopropoxy-radicals give only a 50% yield.

Hydrogen abstraction by t-butoxy-radicals has been the most investigated reaction, including abstraction from saturated and alkyl-aromatic hydrocarbons [35,46].

Table 7 shows the relative velocity constants for hydrogen abstraction from various hydrocarbons by $CH_3^{\cdot}$, $CCl_3^{\cdot}$, t-$C_4H_9O^{\cdot}$, and ROO$^{\cdot}$ radicals [75], the rate of abstraction of hydrogen from the methyl group of toluene being taken as the unit.

The decomposition of di-t-butyl peroxide in cyclohexene has produced almost 100% butanol [64]:

TABLE 7. Relative rates of hydrogen abstraction by radicals.

| Substance | ROO$^{\cdot}$ | $^{\cdot}CCl_3$ | Polystyryl | t-Butoxy | $CH_3^{\cdot}$ | |
|---|---|---|---|---|---|---|
| | 90° | 91.5% | 100° | 135° | 80° | 65° |

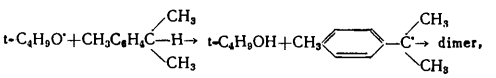
| Diphenylmethane | 16 | 11.9 | 9.5 | — | — | — |

The dimers and trimers of the radicals from the solvent, which are obtained in high yield, retain the initial unsaturation.

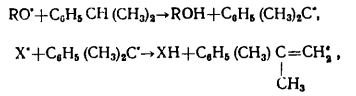
The formation of chlorine-substituted alkenes in the reaction of various alkenes with t-butyl hypochlorite demonstrates that the reaction occurs by hydrogen abstraction from the alkene, and not by addition of a t-butoxy-radical to the double bond[57]; in the light-induced reaction of but-2-ene with t-butyl hypochlorite at 40° the double-bond addition product makes up only 3–4% of the total, 96 ± 3% being chlorobutene isomers.



t-Butoxy-radicals react with substituted cycloalkanes by hydrogen abstraction from a side-chain, without affecting the ring[76], and the reaction with ethylene and propene oxides proceeds analogously: with t-butyl hypochlorite, the corresponding chlorocyclopropanes or chloro-epoxides are produced in high yield. On the other hand, the liquid-phase chlorination of these compounds with chlorine gives large amounts of acyclic chlorinated products. The selectivity of hydrogen abstraction by RO· radicals in this case has provided a convenient preparative procedure.

In alkyl-aromatic solvents t-butoxy-radicals abstract hydrogen from the $\alpha$-carbon atom, producing a stabilised benzyl-type radical, which then dimerises. The hydrogen transfer reaction

does not occur in these reactions[77]. The reaction with isopropylbenzene produces 2,3-dimethyl-2,3-diphenylbutane[20]. Hydrogen abstraction from cumene by t-butoxy-radicals is also observed in the decomposition of di-t-butyl diperoxycarbonate[78], and analogous products are found with ethylbenzene and toluene[64]. t-Butoxy-radicals only abstract hydrogen from the side-chains of alkylbenzenes, unlike the radicals obtained in the decomposition of acetyl or benzoyl peroxide, which can also react with the aromatic nucleus[79].



The reaction of RO· radicals with $p$-chlorotoluene has given 1,2-di-($p$-chlorophenyl)ethane[80], and dehydro-dimers are obtained in the reaction of di-t-butyl peroxide with diphenylmethane; 4-methylbiphenyl; $o$-, $m$-, and $p$-chloro-, $p$-bromo-, and $p$-iodo-toluene; $\beta$- and $\gamma$-picolines; and $p$-methylanisole[81,82]. The hydrogen atom of tertiary groups is readily abstracted[36]; in $p$-methylcumene hydrogen is abstracted from the isopropyl-group, and only one dimer is obtained:

no 1,2-di-($p$-isopropylphenyl)ethane, the dimerisation product of radicals which might be obtained by hydrogen abstraction from the $p$-methyl-group, being found[81,82]. When the peroxide is decomposed in anisole, the dimer, as expected, is not formed.

The reactivity of these alkylbenzenes towards t-butoxy-radicals, measured by the relative rate of formation of the dimer, depends on the substituent groups, and the influence of these is not due solely to their stabilising effect on the benzyl radicals produced by hydrogen abstraction, but also by their polar character, since the results obtained in the decomposition of di-t-butyl peroxide in a series of alkyl-aromatic solvents with various substituents are in accordance with the Hammett $\sigma$ and $\rho$ parameters[83]. For the reaction of t-butoxy-radicals with alkyl-aromatic solvents the value $\sigma$ = -0.5 was found.

In some cases the abstraction of hydrogen from alkyl-aromatic solvents is not accompanied by formation of the corresponding dimers[5]. It is thought that the solvent radicals react with oxy-radicals, giving up hydrogen to them, or combine with other active particles in the system, for example, nitric oxide if the reaction occurs by decomposition of nitrites:

where X· = NO or RO·.

Hydrogen abstraction from benzaldehyde by t-butoxy-radicals produces t-butyl alcohol in 100% yield[84]; the radicals from the solvent give complex association products. Tertiary benzylamines $C_6H_5CH_2NRR'$ are dehydrogenated by t-butoxy-radicals to $C_6H_5\dot{C}HNRR'$ radicals, which then dimerise or disproportionate, depending on R and R'.[85] Analogous reactions are observed with benzyl ethers $C_6H_5CH_2OH$.[86,87]

In dimethylformamide[88] the products of the thermal decomposition of di-t-butyl peroxide are t-butyl alcohol and a mixture which indicates that hydrogen is abstracted both from a methyl and the formyl group of the solvent.

At 140° t-butoxy-radicals abstract an $\alpha$-hydrogen atom from primary and secondary alcohols, forming RR'C·–OH radicals, which then dimerise to a glycol. A mixture of alcohols produces mixed glycols[89].

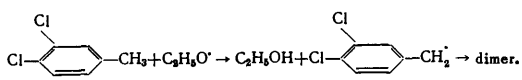
In the decomposition of di-t-butyl peroxide in n-butyric acid at 116° hydrogen is abstracted by the t-butoxy-radicals from the $\alpha$-carbon atom, and the resulting radical dimerises. In the decomposition of the peroxide in ethyl butyrate, hydrogen abstraction from the acid residue of the ester is six times as rapid as from the alcoholic residue, and is ten times as rapid in the $\alpha$-position as in the $\beta$-position[90].

In the decomposition of cyclohexyl or 1-methylcyclohexyl nitrite in cumene[5] the yield of the corresponding alcohol is 0.90–0.97 mole per mole of initial nitrite. In chlorobenzene, as in pyrolysis of the pure nitrites, the yield of alcohol does not exceed 0.6 mole.

The benzyloxy-radical abstracts hydrogen from cumene[91], and the $\alpha$-methylbenzyloxy-radical abstracts hydrogen from benzenethiol, producing 1-phenylethanol in 55% yield[92]; this alcohol is formed in 20–26% yield in the thermal decomposition of phenethyl nitrite[55].

In cumene, the diphenylmethoxy-radical produces 15–24% of 2,2-diphenylethanol[56]. Hydrogen abstraction by the cumenyloxy-radical from cumene decreases rapidly as the temperature is raised from 110° to 160°.[93]

Isopropoxy-, cyclohexyloxy-, and benzyloxy-radicals abstract hydrogen from isopropyl alcohol, dehydrogenating it to acetone[53,94].



The reactions of R· and RO· radicals can be compared by investigating the decomposition of dialkyl peroxodicarbonates and acetyl peroxide in various solvents[43–45]. In solvents whose molecules contain a labile readily removed hydrogen atom, this is abstracted by R· and RO· radicals at approximately the same rate. In solvents without such hydrogen atoms, RO· radicals undergo disproportionation more than they participate in hydrogen abstraction (Table 8).

TABLE 8. Comparison of the reactions of free alkyl and alkoxy--radicals.

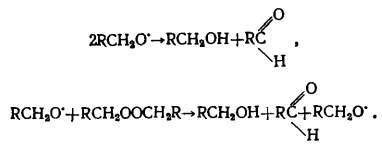
In some cases intramolecular hydrogen abstraction is observed; for example, in the decomposition of bis-(1-methylperoxocarbonatocyclohexyl) peroxide [95] the main products are methanol and the saturated $CH_2(CH_2)_4C(=O)O$ and unsaturated $CH_2(CH_2)_2CH{=}CHC(=O)O$ lactones, the latter being formed when hydrogen abstraction by the RO· radicals from the solvent is difficult. In isopropyl alcohol the yield of unsaturated lactone is 13 mole %, and in cyclohexane and benzene 39–46 mole %, of the total amount of lactones. At the same time there is almost complete absence of reaction between methoxy-radicals and the solvents, which shows that the formation of methanol in solvents with a difficultly removable hydrogen atom proceeds by an intramolecular reaction, the dehydrogenation product being the unsaturated lactone.

Alkoxy-radicals show an interesting selectivity in hydrogen abstraction from the solvent [44,45]: in chloro-substituted aralkyls the position of the chlorine with respect to the supposed point of attack by the alkoxy-radicals has a substantial influence on the course of the reaction. Thus in the reaction of $C_2H_5O\cdot$ radicals with 3,4-dichlorotoluene the dimer 1,2-bis-(3,4-dichlorophenyl)ethane is formed in 61% yield, the disproportionation of the $C_2H_5O\cdot$ radicals in this solvent occurring to no more than 11%:

In 2,6-dichlorotoluene the corresponding dimer, produced from the radicals of the solvent by hydrogen abstraction from the α-position, is formed in only 21% yield, disproportionation of the ethoxy-radicals in this solvent occurring to the extent of 27%; and in benzal chloride there is no attack at the α-position at all, practically no tetrachlorotolane being formed [tolane is diphenylacetylene (Ed. of Translation)].

These results are explained by the so-called "repulsion effect", which is suffered by the approaching alkoxy-radical if chlorine atoms or methoxycarbonyl groups are close to the most probable point of attack. In some cases this effect causes a change in the point of attack. In their reaction with p-isopropylbenzylidene dichloride $(CH_3)_2CHC_6H_4CHCl_2$, ethoxy-radicals abstract only the α-hydrogen of the isopropyl group, giving a symmetrical dimer, while methyl radicals react equally with both α-hydrogen atoms, giving a mixture of isomers of the dimer:



The absence of reaction products of RO· radicals with benzene can apparently be explained in an analogous manner [41,54]. The free electron on the electronegative oxygen atom hinders the formation of the transitional π complex, the existence of which has been clearly demonstrated in the reaction of R· radicals with aromatic compounds:

The selectivity of hydrogen abstraction by the t-butoxy--radical is due to its polar properties, which are equal to those of the chlorine atom [96], but unlike chlorine, t-butoxy--radicals are considerably more sensitive to the strength of the carbon–hydrogen bond; their reactivity towards primary, secondary, and tertiary hydrogen atoms is in the proportion 1 : 8 : 44, as against 1 : 3 : 4.5 for chlorine.

3. Disproportionation. The disproportionation of alkoxy-radicals is considerably more exothermic than hydrogen abstraction. According to Gray [1,4] $\Delta H$ for disproportionation is -70 (-90) kcal mole$^{-1}$.

In many cases it is difficult to distinguish between disproportionation and reaction of the radical with the starting material, since the products are the same:

Clearly, this matter can only be resolved kinetically, by showing the presence or absence of the initiated decomposition.

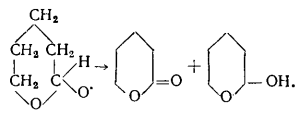
Such special investigations have not been carried out (with certain exceptions [51,53]), so that by the term "disproportionation" is generally understood both reaction between two RO· radicals, and reaction between an RO· radical and the starting material.

Disproportionation in the gas phase is uncommon. For methyl radicals produced in the pyrolysis of dimethyl peroxide [68] disproportionation is observed at 113–143°. The methoxy- and ethoxy-radicals formed in the photolysis of methyl acetate [65] and ethyl propionate [97] and the $CD_3O\cdot$ radicals produced in the photolysis of [$D_3$]methyl acetate [66,67] also disproportionate.

The reaction products obtained in the slow decomposition of di-n-propyl peroxide [14] in the gas phase at 146–175° contain propionaldehyde and propanol, which may be formed by disproportionation of $CH_3CH_2CH_2O\cdot$ radicals; however, initiated decomposition of the peroxide is more probable in this case:

$$CH_3CH_2CH_2O\cdot+(CH_3CH_2CH_2O)_2\rightarrow CH_3CH_2CH_2OH+$$
$$+CH_3CH_2CHO+CH_3CH_2CH_2O\cdot.$$

Disproportionation of $CH_3O^{\cdot}$, $C_2H_5O^{\cdot}$, n-$C_3H_7O^{\cdot}$, iso-$C_3H_7O^{\cdot}$, and n-$C_4H_9O^{\cdot}$ radicals in the liquid phase is observed when they are formed in solvents in which hydrogen abstraction is difficult, for example, in trimethylacetic acid or methyl trimethylacetate [43]. 100% disproportionation of the ethoxy-radicals takes place in dimethyl succinate or dimethyl malonate [44], or 2,6-dichlorotoluene or benzaldehyde [45]. Isopropyloxy-radical disproportionation products have been found in the pyrolysis of diisopropyl peroxocarbonates [98]. With t-butoxy-radicals the reaction is observed to a slight degree, and produces acetone and the t-butyl methyl ether [99]:



$$2\,(CH_3)_3CO^{\cdot} \rightarrow (CH_3)_2C{=}O + CH_3OC\,(CH_3)_3.$$

Disproportionation of benzyloxy- and cyclohexyloxy-radicals occurs in the decomposition of dibenzyl and dicyclohexyl peroxodicarbonates in benzene, carbon tetrachloride, or acetic acid [41,42]. The rate of decomposition of these peroxocarbonates in benzene and carbon tetrachloride is not affected by the presence of 2,2-diphenyl-1-(2,4,6-trinitrophenyl)hydrazino-radicals [53], which shows the absence of initiated decomposition of the peroxides, so that the formation of the corresponding alcohol and ketone in the reaction of the RO$^{\cdot}$ radicals must be due exclusively to their disproportionation.

Disproportionation is also observed when peroxodicarbonates are decomposed in the presence of various metals. Here direct attack of the RO$^{\cdot}$ radicals on the metal with formation of the corresponding alkoxides does not occur [100]. The formation of octanone and (+)-octan-2-ol in the thermal decomposition of optically active (+)-oct-2-yl nitrite [101] is due to disproportionation:

$$2(+)\text{-}C_6H_{13}CH\,(CH_3)\,O^{\cdot} \rightarrow C_6H_{13}COCH_3 + (+)\text{-}C_6H_{13}CH\,(CH_3)\,OH,$$

and similarly for 2-hydroxytetrahydropyran and δ-valerolactone in the thermal decomposition of t-butyl tetrahydropyran-2-yl peroxide [102]:

Disproportionation between two different RO$^{\cdot}$ radicals has been observed in the pyrolysis of allyl t-butyl and t-butyl cyclohexyl peroxides [103]:

$$CH_2{=}CH{-}CH_2O^{\cdot} + t\text{-}C_4H_9O^{\cdot} \rightarrow CH_2{=}CHCHO + t\text{-}C_4H_9OH,$$

The benzyloxy-radicals produced in the decomposition of benzyl nitrite [50] and benzyl hyponitrite [51,104] undergo disproportionation. In the latter case the disproportionation occurs in a "cage" of solvent, since dilution of the hyponitrite solution from 0.1 M to 0.0001 M had practically no effect on the yield of benzaldehyde [104]. The possibility is not excluded of a mechanism whereby two radicals formed in the solvent "cage" first dimerise to dibenzyl peroxide, and then are re-formed by its decomposition and disproportionate. However, dimerisation of two alkoxy-radicals, as will be shown below, is a rare event, and is only found with cumenyloxy-radicals [1]:

$$2C_6H_5C\,(CH_3)_2O^{\cdot} \rightarrow [C_6H_5C\,(CH_3)_2O]_2.$$

Disproportionation has been invoked to explain the formation of 1-phenylethanol in the thermal decomposition of pure 1-phenylethyl nitrite [55].

It is seen from the above that disproportionation is one of the most typical reactions of RO$^{\cdot}$ radicals in the liquid phase. Even in solvents which readily give up hydrogen, in many cases there is parallel formation of disproportionation products [41]. In this connection it is an interesting fact that isopropyloxy-*C* radicals $(CH_3)_2CHOH$ do not disproportionate [53].

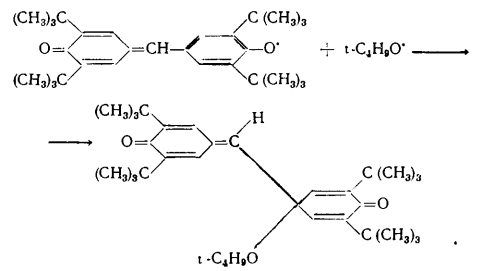
4. Reactions with other radicals. RO$^{\cdot}$ radicals can interact with other radicals present in the system.

The methoxy-radicals produced in the thermal decomposition of methyl t-pentyl peroxide combine with methyl radicals to give a considerable quantity of dimethyl ether [105].

In the photolysis of methyl acetate [106] and [$D_3$]methyl acetate [66,67] the $CH_3O^{\cdot}$ and $CH_3^{\cdot}$ radicals are found to disproportionate and also to recombine, the ratio of the two rates of reaction $K_{dis}/K_{recom}$ being 1.4 and independent of the temperature, indicating the zero energy of activation for the disproportionation.

In the photolysis of ethyl propionate [97] the ratio $K_{dis}/K_{recom}$ for the ethoxy- and ethyl radicals is 2.3. Ethyl methyl ether has been found in the decomposition of t-butyl ethyl peroxide [73].

The formation of 1,2-epoxy-2-methylpropane in the decomposition of di-t-butyl peroxide may be due to the reaction [60]:



$$(CH_3)_3CO^{\cdot} + R^{\cdot} \rightarrow RH + CH_2{-}C\,(CH_3)_2.$$

The reaction between RO$^{\cdot}$ radicals and nitrogen monoxide or dioxide is of this type. Methoxy-radicals can combine with nitrogen monoxide to give methyl nitrite [38], or disproportionation may occur [107]:

$$CH_2O^{\cdot} + NO \rightarrow CH_2O + HNO, \qquad 2HNO \rightarrow H_2O + N_2O.$$

An analogous reaction is known for ethoxy-radicals [31,108]. Such reactions are less characteristic of t-butoxy-radicals. At 160° the rate of combination of nitrogen monoxide with $(CH_3)_3CO^{\cdot}$ is ~0.7 that of decomposition of the radical [34].

The combination of t-butoxy-radicals with the stable galvinoxyl† free radical has been described [109]:

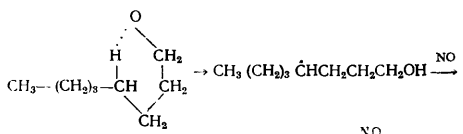
No dimerisation with the formation of oxygen–oxygen bonds occurs, and in general this dimerisation is not a characteristic of RO$^{\cdot}$ radicals; according to approximate calculations [109] the activation barrier for this reaction is fairly high: 5 kcal. Investigation of the thermal decomposition of di-t-butyl monoperoxocarbonate [110] has also shown that there is no recombination of RO$^{\cdot}$ radicals in the solvent "cage".

The products of the reaction of RO$^{\cdot}$ radicals with another stable free radical, the 2,2-diphenyl-1-(2,4,6-trinitrophenyl)hydrazino-radical, have not been described,

† See Ref.109 for a derivation of this name (Ed. of Translation)].

but it is known that the (2,4,6-trinitrophenyl)hydrazino--radical is an active acceptor of RO· radicals, and may be used to study the kinetics of their formation in solution [111].

5. Isomerisation. Gray and Williams [1,4] found that the isomerisation of RO· radicals is thermodynamically favourable (Table 9).



Isomerisation of alkoxy-radicals has been observed in the light-induced reaction of a number of tertiary alkyl hypochlorites [112], a free-radical chain reaction producing the corresponding chlorohydrins:

$$RCH_2(CH_2)_nC(CH_3)_2O \rightarrow R\dot{C}H(CH_2)_nC(CH_3)_2OH \xrightarrow{\text{hypochlorite}}$$
$$\xrightarrow{\text{hypochlorite}} RCHCl(CH_2)_nC(CH_3)_2OH + RCH_2(CH_2)_nC(CH_3)_2O\cdot, \text{ etc.}$$

The yield of the isomerisation product increases with the number of carbon atoms in the t-alkoxy-radical. The intramolecular nature of the hydrogen abstraction step in the rearrangement is demonstrated by the constant yield of isomerisation product as the concentration of hypochlorite in the solution is increased from 1.7 to 6.7 M. No isomerisation of primary or secondary alkoxy-radicals was detected [112], but it was later shown that intramolecular hydrogen abstraction occurs in the light-induced and thermal decomposition of n-butyl hypochlorite, with subsequent formation of the chlorohydrin [113].

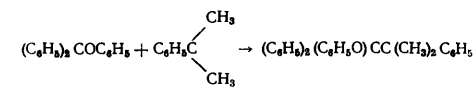
The isomerisation of the alkoxy-radical in the light--induced decomposition of an alkyl nitrite leads to formation of nitroso-alcohol dimers [114]; the isomerisation passes through an intermediate six-membered ring, so that the yield of nitroso-dimer is directly dependent on the structure of the alkoxy-radical.

In the decomposition of n-octyl nitrite the main reaction product is the dimer of 4-nitrosooctan-1-ol:

$$\xrightarrow{NO} CH_3(CH_2)_3CHCH_2CH_2CH_2OH \rightarrow \text{dimer},$$
$$NO$$

but with alkyl nitrites having less than five carbon atoms no intermediate six-membered ring compound can be formed, and the yield of nitroso-dimers is very much less. The same effect is observed with substituted alkylaromatic [115] and cyclohexyloxy-radicals [116]. Cyclohexyl nitrite itself gives a very low yield (4%) of nitroso-dimer, while 2-cyclohexylcyclohexyl nitrite gives a 30% yield of the dimer [116].

No dimer has been detected in the photolysis of benzyl nitrite, but 4-phenylbutyl and 5-phenylpentyl nitrites give up to 35% yields of nitroso-dimer.



There is no evidence for the migration of hydrogen from the benzene nucleus [115]:

Other cases are known of the isomerisation of aryl-substituted alkoxy-radicals. Triphenylmethoxy isomerises into the phenyl ether [117]:

$$(C_6H_5)_2CO\cdot \rightarrow (C_6H_5)_2\dot{C}OC_6H_5 \rightarrow \text{dimer}.$$

In solution in cumene at 120–140° the isomerised triphenylmethoxy-radical combines with the α-cumenyl-radical [91]:

The diphenyl-*p*-tolylmethoxy-radical can isomerise in two ways, with migration of either the *p*-tolyl or a phenyl group [91]:

$$p\text{-}CH_3C_6H_4(C_6H_5)_2CO\cdot \rightarrow (C_6H_5)_2COC_6H_4CH_3 \text{ or } p\text{-}CH_3C_6H_4(C_6H_5)COC_6H_5.$$

The 1-naphthyldiphenylmethoxy- and biphenylylmethoxy--radicals can also isomerise in two ways in solution in cumene, but the rate of migration of the 1-naphthyl or biphenylyl group is six times that of the phenyl [91].

The *p*-nitrophenyldiphenylmethoxy-radical isomerises by migration of the *p*-nitrophenyl group; the resulting radical then decomposes [118]:

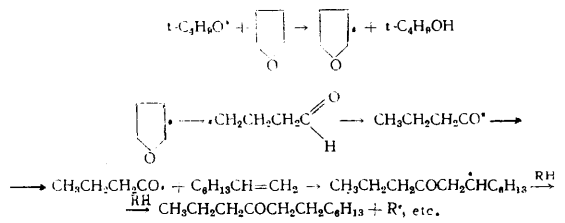
$$p\text{-}NO_2C_6H_4(C_6H_5)_2CO \rightarrow (C_6H_5)_2COC_6H_4NO_2 \rightarrow C_6H_5\cdot + C_6H_5COC_6H_4NO_2.$$

The use of optically active compounds has shown that the 1-phenylethoxy-radical does not isomerise in solution [92], and the absence of isomerisation has been demonstrated for gas-phase reactions of $CH_3O\cdot$ radicals [3] and for reactions of $(CH_3)_2CHO\cdot$ radicals in solvents [94].

6. Addition to a double bond. The addition of RO· radicals to a double bond has been demonstrated in the reaction of di-t-butyl or di-α-cumenyl peroxide with butadiene, isoprene, and chloroprene [119,120]:

$$t\text{-}C_4H_9O\cdot + CH_2{=}CH{-}CH{=}CH_2 \rightarrow t\text{-}C_4H_9OCH_2{-}CH{=}CH{-}CH_2 \rightarrow \text{dimer}.$$

An oxygen-containing polymer is obtained in the decomposition of di-t-butyl peroxide in hex-1-ene, which shows the addition of the RO· radicals to the double bond of the hexene [113]. Benzyloxy-radicals initiate the polymerisation of methyl methacrylate [29].



$^{14}C$-labelled di-t-butyl peroxide has been used to demonstrate that in the polymerisation of styrene the initiation is caused mainly by t-butoxy-radicals [47]. At low concentrations of styrene in the solution and at high temperatures the polymerisation is initiated by the methyl radicals produced in the decomposition of the t-butoxy-radicals.

The complex light-induced decomposition of steroidal nitrites has been explained by the intramolecular reaction of the resulting alkoxy-radical with a double bond [121].

TABLE 9. Thermochemistry of isomerisation of alkoxy--radicals.

| Type of isomerisation | Initial radical | Radical obtained | $\Delta H$, kcal × × mole$^{-1}$ |
|---|---|---|---|
| Migration of a hydrogen atom from carbon | $CH_3O\cdot$ | $\cdot CH_2OH$ | −7.5 |
| | $C_2H_5O\cdot$ | $\cdot CH(CH_3)OH$ | −9.5 |
| | $(CH_3)_2CHO\cdot$ | $\cdot C(CH_3)_2OH$ | −12 |
| | $C_6H_5CH_2O\cdot$ | $\cdot CH(C_6H_5)OH$ | −11 |
| | cyclo-$C_6H_{11}O\cdot$ | cyclo-$\dot{C}_6H_{10}OH$ | −14 |
| Migration of hydrogen atoms from distant $CH_2$--groups | $RCH_2(CH_2)_nO\cdot$ | $RCHCH_2OH$ | −8.5 |
| | $CH_3CH_2O\cdot$ | $\cdot CH_2OCH_3$ | 5 |
| Migration of a methyl group | $(CH_3)_2CHO\cdot$ | $\cdot CH(CH_3)OCH_3$ | 0.5 |
| | $(CH_3)_3CO\cdot$ | $\cdot C(CH_3)_2OCH_3$ | 0.5 |
| | $C_6H_5C(CH_3)_2O\cdot$ | $\cdot CCH_3C_6H_5(OCH_3)$ | −1.5 |
| Ring opening | cyclo-$C_6H_{11}O\cdot$ | — | 4 |
| Migration of an aryl group | $(C_6H_5)_3CO\cdot$ | $\cdot C(C_6H_5)_2OC_6H_5$ | −1.5 |
| | $C_6H_5(CH_3)_2CO\cdot$ | $\cdot C(CH_3)_2OC_6H_5$ | −1.5 |

The products obtained from di-t-butyl peroxide and tetrahydrofuran in the presence of oct-1-ene indicate the following reactions to occur [122]:

In other cases there is no direct evidence of addition of RO· radicals to double bonds. For example, in the polymerisation of styrene in the presence of cyclohexyl hydroperoxide the initiators may be other radicals present in the system [123].

The infrared spectra of the polymer obtained from ethylene in the presence of diethyl peroxodicarbonate exhibit the characteristic carbonate group absorption bands [124], and hence the initiation is due mainly to ROC(=O)O· radicals [125-127]. The polymerisation of other monomers in the presence of peroxocarbonates presumably proceeds analogously.

C-radicals and O-oxyradicals behave differently towards double bonds. By $^{14}C$-labelling, investigation of the decomposition of diisopropyl peroxodicarbonate in isopropyl alcohol in the presence of maleic acid has shown that the isopropyloxy O-radical $(CH_3)_2CHO\cdot$ does not add to the double bond of maleic acid, while the isomeric C-radical $(CH_3)_2C(\cdot)OH$ adds to the maleic acid to give a high yield of terebic acid [94,128] [3-carboxy-4-methylpentan--4-olide (Ed. of Translation)].

The t-butoxy-radical may react with alkenes not by addition at the double bond, but by abstraction of $\alpha$-hydrogen [26,57,129].

2. Synthesis of heterochain block copolymers by polycondensation 207
3. Synthesis of heterochain block copolymers by the combination of polymer blocks containing chemically active terminal groups 207
4. Synthesis of heterochain block copolymers by inter-phase polycondensation 208
5. Method based on inter-chain exchange reactions 208

## I. INTRODUCTION

Until recently, the properties of polymeric materials were varied chiefly by altering the chemical composition and structure of the original monomers, the mean molecular weight of the polymer, the cross-linking of the polymer chain, the molecular-weight distribution, etc. Various methods for modifying macromolecular compounds are now becoming increasingly important. We think that one of the most promising methods, as far as industry is concerned, for modifying polymeric materials involves block and graft copolymerisation.

Block copolymers are macromolecular compounds whose main chain consists of two or more polymer blocks with different chemical composition or spatial configuration, joined to one another either directly or by means of low-molecular bifunctional compounds. The properties of block copolymers are generally determined by the properties of the individual homopolymeric sections in the main chain, but block copolymers also exhibit a number of properties which are not shown by the polymer fragments composing the main chain. An example is the block copolymer, of the diphilic type, consisting of blocks of aliphatic polyester and poly(methacrylic acid). This block copolymer, unlike poly(methacrylic acid), can be melted and is soluble in a mixture of acetone and alcohol, but is insoluble in water. The possibility of using familiar monomers to prepare polymeric materials exhibiting new properties fundamentally different from those of the corresponding homopolymers has led to the recent publication of a large number of papers and reviews [1-29] dealing with the synthesis and study of block copolymers. A classification of block copolymers has now become necessary. We suggest that the most rational basis for a classification of block copolymers is provided by the structural-chemical principle proposed by Korshak[30] for macromolecular compounds. This principle makes it possible to show directly in the name of the block copolymer the chemical character and structural features of its component blocks, their interconnection, and also the position occupied by the given block copolymer in a series of other macromolecular compounds. By analogy with the previously-proposed classification for graft copolymers [31,32], we propose a classification according to which block copolymers can be divided into three types:

1. Homochain block copolymers (main chain consisting of polymeric homochain blocks).
2. Heterochain block copolymers (main chain consisting of polymeric heterochain blocks).
3. Homo-heterochain block copolymers (main chain consisting of polymeric homochain and heterochain blocks).

In the synthesis of block copolymers, the polymer fragments of the main chain may form either highly-ordered (crystalline) or disordered (amorphous) regions in the structure of the block copolymer. To reflect these structural features of block copolymers, the above types of block copolymer can in turn be subdivided into the following three groups: (a) amorphous block copolymers (all polymer fragments of the main chain amorphous); (b) crystalline block copolymers (all polymer fragments of the main chain crystalline); and (c) crystalline-amorphous block copolymers (polymer fragments of the main chain having structures with different degrees of order).

The classification of a block copolymer in a given type and group is independent of whether the polymer blocks making up the block copolymer are joined to one another directly or by means of bifunctional low-molecular compounds.

The proposed classification covers all possible types of block copolymer, including block copolymers consisting of organic and inorganic polymer fragments, natural and synthetic block copolymers, and also the so-called stereo-block copolymers and optically active block copolymers.

Block copolymers are prepared by mechanochemical, radiochemical, and other chemical methods. The first two methods give not only block copolymers but also graft copolymers, and the final product is a mechanical mixture of homopolymers with block and graft copolymers. The separation of this mixture is not always possible. It is

not the aim of the present review to examine in detail the synthesis of block copolymers by all known methods, and we shall restrict ourselves to chemical methods of synthesis.

## II. HOMOCHAIN (CARBOCHAIN) BLOCK COPOLYMERS

The greatest number of papers has been devoted to block copolymers of this type, evidently because of the possibility of synthesising carbochain block copolymers by the usual methods for the homopolymerisation of vinyl monomers. All the methods described for the preparation of carbochain block copolymers are variants of vinyl monomer polymerisation, taking place by a free-radical or ionic mechanism. Irrespective of the nature of the original materials, the block copolymers obtained by the first mechanism are generally amorphous copolymers, whereas those obtained by the second mechanism are crystalline or crystalline-amorphous block copolymers.

### 1. Synthesis of Block Copolymers by Radical Polymerisation

This method has found the widest application in the synthesis of carbochain block copolymers. Since there are many methods for preparing macroradicals capable of initiating carbochain block copolymerisation, this method is extending considerably the range of utilisation of polymerisation for the synthesis of polymers. The production of polymeric radicals and subsequent block copolymerisation can be carried out by a mechanochemical method involving the application of mechanical stress to the polymer chains by means of ultrasonic vibrations[33-36], rolling[37-43], vibration milling[44,45], the electrohydraulic effect[46,47], etc.[48-58] in the presence of a given monomer. Carbochain block copolymers can also be obtained by the action of various forms of high-energy ionising radiation on a polymer chain in the presence of the corresponding monomer[59-68]. The synthesis of carbochain block copolymers by chemical means can be achieved by the addition of "live" macroradicals to the monomer, by the initiation of the block copolymerisation reaction by macroradicals which retain their activity, or by macroradicals formed as a result of the decomposition of peroxide groups in the main chain of the homopolymer. The most complete studies have been made of the method for the synthesis of block copolymers based on the introduction, into the homopolymer block, of terminal groups which, depending on their chemical character, are capable of forming macroradicals and initiating subsequent block copolymerisation.

#### A. Methods based on the presence, in the polymer block, of active terminal groups capable of forming macroradicals initiating the polymerisation of monomers with the formation of block copolymers.

In this method, as in all other methods for the preparation of block copolymers, particular attention is paid, in the synthesis of the block copolymers, to the maximum or complete elimination of the simultaneous formation of graft copolymers and homopolymers. This task is complicated by the fact that the probability of side reactions leading to the formation of undesirable products is much greater under the conditions of synthesis of block copolymers than in homopolymerisation, since the process takes place in two stages.

Depending on the chemical character of the active terminal group introduced into the homopolymer block, the mechanisms of the formation of macroinitiators and the direct formation of block copolymers differ considerably, and it is impossible to give a general scheme for the preparation of block copolymers by this method.

Block copolymerisation initiated by terminal hydroperoxide groups. Homopolymer fragments containing terminal hydroperoxide groups are obtained by polymerising monomers in the presence of dihydroperoxides under conditions ensuring the homolytic decomposition of only one hydroperoxide group, to avoid the formation of an inactive homopolymer[69]. Some patents recommend for this purpose the use of polyfunctional hydroperoxides containing two or more hydroperoxide groups with different reactivities[70]; it is believed that this reduces the formation of homopolymer to a minimum. Most frequently, however, the dihydroperoxides of *p*- and *m*-diisopropylbenzene are used to obtain the polymeric hydroperoxide. To avoid initiation of the homopolymerisation of the primary monomer by the hydroxyl radical, the reaction is carried out in the presence of $Fe^{2+}$ ions[71-73]. It has been suggested[74] that the formation of homopolymer blocks with terminal hydroperoxide groups should be regarded as a series of competing reactions whose kinetics can be examined by the method of Frost and Schwemer[75] with the condition that $[Fe^{2+}]_0 = 2[HOOROOH]_0$.

On the basis of the proposed mechanism for the reaction of the dihydroperoxide, monomer, and $Fe^{2+}$, it was found theoretically that the ratio

$$\frac{\text{Fe}^{2+}\text{ consumed as a result of oxidation by radicals}}{\text{monomer consumed as a result of initiation of polymerisation}} = \frac{[Fe^{2+}]}{[\bar{M}]}\left\{\frac{K_{10}[HOORO^{\cdot}] + K_{20}[\cdot OROM_n^{\cdot}] + K_{30}[\cdot ORO^{-}]}{K_{1i}[HOORO^{\cdot}] + K_{2i}[\cdot OROM_n^{\cdot}] + K_{3i}[\cdot ORO^{-}]}\right\}.$$

An analogous relationship in the form

$$\frac{\Delta Fe^{2+}_{total}\,\Delta^{*}Fe^{2+}}{2\Delta^{*}Fe^{2+} - \Delta Fe^{2+}_{total}} \quad \text{or} \quad \frac{\frac{1}{\Delta Fe^{2+}_{total}}}{\Delta Fe^{2+}_{total} - \Delta^{*}Fe^{2+}} - 2$$

can also be found experimentally, with the condition that the total quantity of $Fe^{2+}$ used up in the course of the reaction ($\Delta Fe^{2+}_{total}$), and the proportion which has reacted with the hydroperoxide ($\Delta^{*}Fe^{2+}$) are known. $[Fe^{2+}]$ is calculated from the experimental data and $[\bar{M}]$ is taken as equal to the concentration of the polymerising monomer.

In the second stage of the synthesis — the synthesis of the actual block copolymer — an effort is made to carry out the reaction under conditions ensuring the minimum possibility of chain-transfer reactions[76]. The method described for the preparation of block copolymers was studied in detail by Molyneux[77] for the case of the block copolymer of styrene with methyl methacrylate. In the first stage of the synthesis, thermal polymerisation of styrene was carried out at 70° in the presence of a dihydroperoxide *m*-diisopropylbenzene to give polystyrene with terminal hydroperoxide groups.

The block copolymer was prepared by suspension polymerisation at 0–25° in the presence of $Fe^{2+}$ ions and sodium pyrophosphate. The reaction products contain polymethyl methacrylate blocks in numbers either equal to or double

the number of original polystyrene blocks. Turbidimetric titration with subsequent extraction showed that the concentration of block copolymers in these products is ~ 10%. This low yield of block copolymers is due to the absence of terminal hydroperoxide groups from a considerable proportion of the polystyrene blocks (~ 25%) and to homopolymerisation of methyl methacrylate. It is assumed that the latter is due to chain transfer to benzene from polymeric radicals, which are localised in the droplets and have a long life time, and also to the reaction of monomer with radicals formed in the organic or aqueous phases of the suspension as a result of the decomposition of hydroperoxide remaining in the polystyrene. The marked non-uniformity of the block copolymer composition (a mixture of block copolymers of two types $A_nB_m$ and $B_mA_nB_m$ is formed) is apparently due to the fact that the original hydroperoxide derivatives of polystyrene contain either one or two hydroperoxide groups.

The chain-transfer reaction can also be used to obtain a homopolymer block with a terminal hydroperoxide group. It has been reported[78] that polymers or statistical copolymers of alkenes, containing terminal hydroperoxide groups, are obtained by polymerising alkenes or their mixtures at 0–35° in an aqueous emulsion containing 0.05–20 wt.% of monomer, in the presence of diisopropylphenyl dihydroperoxide as initiator and a chain-terminating reagent. The polymeric derivatives formed in this way are isolated and used as initiators for block copolymerisation with vinyl monomers. It is recommended that these polymers be stored at a temperature not exceeding 30°, to avoid decomposition of the terminal hydroperoxide groups.

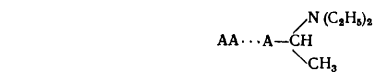
Block copolymerisation initiated by terminal peroxide groups. Terminal peroxide groups are introduced into homopolymer fragments using phthaloyl peroxide[79]. Smets[80] showed that if styrene is kept for 5–6 h at 75° in the presence of 0.5% phthaloyl peroxide, polystyrene containing terminal peroxide groups is formed. This polymeric peroxide, dissolved in a benzene solution of methyl methacrylate, initiates a block copolymerisation reaction at 100°; after treatment for 5 h, the quantity of methyl methacrylate converted amounts to 40%. More detailed study of polymeric derivatives of phthaloyl peroxide[81,82] showed that to obtain a block copolymer in good yield it is necessary to take account of the relative reactivity and ability to undergo chain-transfer reactions shown by the monomeric components taking part in the block copolymer formation. For example, polystyrene containing terminal phthaloyl peroxide groups readily initiates the polymerisation of methyl methacrylate and ethyl $\alpha$-chloroacrylate at 100° but does not initiate the polymerisation of vinyl acetate or vinylpyrrolidone, whereas the analogous peroxide derivative of poly(vinyl acetate) readily initiates the polymerisation of styrene and ethyl $\alpha$-chloroacrylate under the same conditions. The solubility of the block copolymers obtained in this way differed significantly from that of the corresponding homopolymers, and this made it possible to isolate them in pure form. Analysis of the infrared spectra of the block copolymer of styrene with methyl methacrylate showed that the concentration of styrene units in the block copolymer varies from 22% to 30%.

Another method for introducing terminal peroxide groups into homopolymer blocks involves the polymerisation of styrene in the presence of t-butyl hydroperoxide and $Cu^{2+}$ ions[83,84]. The decomposition of t-butyl hydroperoxide in the presence of $Cu^{2+}$ ions evidently leads to the formation of $(CH_3)_3COO^{\cdot}$ and $(CH_3)_3CO^{\cdot}$ radicals, the first of which, probably as a result of recombination with the growing polystyrene macroradical, form active terminal peroxide groups capable of initiating subsequent block copolymerisation.

$$(CH_3)_3COO^{\cdot}+\dot{C}H(C_6H_5)CH_2CH(C_6H_5)CH_2-\cdots\longrightarrow$$

$$\longrightarrow(CH_3)_3COOCH(C_6H_5)CH_2-CH(C_6H_5)CH_2-\cdots.$$

An interesting property of this polymeric peroxide is its relatively high thermal stability; it does not decompose below 60°, even when exposed to ultraviolet light.



Study of the kinetics of formation of these macroperoxides[85,86] showed that the order of the reaction involved in the initiation of the primary monomers by t-butoxy- and t-butylperoxy-radicals decreases with increase in their concentration, since the primary radicals take part in a chain-termination reaction. In the block copolymerisation of these macroradicals with methyl methacrylate and vinyl acetate, it was observed that increase in the viscosity of the reaction medium decreased the yield of block copolymer.

The use of 2–8 mole % $(CH_3)_3COOOC(CH_2)_4COOOC(CH_3)_3$ has been recommended for the initiation of the polymerisation of the primary monomer in the synthesis of analogous polymeric peroxide derivatives[87]. The polymerisation is carried out homogeneously or heterogeneously at 70–90°. This method has been used to prepare homopolymer blocks of styrene, vinyl chloride, methyl methacrylate, and vinyl acetate, containing one terminal peroxide group. The absence of macromolecules containing no terminal peroxide groups is apparently due to the extremely low initiating power of the $(CH_3)_3CO^{\cdot}$ formed in the decomposition of the initiator

$$(CH_3)_3COOOC(CH_2)_4COOOC(CH_3)_3\longrightarrow(CH_3)_3COOOC(CH_2)_4^{\cdot}+CO_2+{}^{\cdot}OC(CH_3)_3.$$

Satisfactory results were obtained in the block copolymerisation of polystyrene with acrylonitrile, of poly(vinyl acetate) with styrene, and of poly(vinyl chloride) with styrene, although the block copolymers obtained had a low polymerisation coefficient. Block copolymers with vinyl chloride could not be obtained, because of the high rate constant of the chain-transfer reaction via the monomer.

Block copolymerisation initiated by terminal amino-groups. In the synthesis of carbochain block copolymers by chain-transfer reactions[88], the use of terminal amino-groups in homopolymer blocks as macromolecular chain-transfer reagent has been proposed[89]. The rate constants for chain transfer were determined for the radical polymerisation of styrene and vinyl acetate in the presence of primary, secondary, and tertiary amines[90]. The highest values of the rate constant for chain transfer were observed for the polymerisation of acrylonitrile and methyl methacrylate in the presence of triethylamine[91]; this is attributed to the formation of ionic structures in the transition state. Bamford and coworkers[92] showed that to obtain block copolymers of the type $A_nB_m$ it is best to carry out the homopolymerisation of the monomer A in the presence of triethylamine; chain transfer takes place through the latter with the formation of a compound of the type

This polymeric product was used as macromolecular chain-transfer agent in the homopolymerisation of the monomer

under conditions ensuring a high degree of chain transfer by the growing radical.

To reduce the formation of homopolymer to a minimum, it is recommended that the second stage of the synthesis of the block copolymer be carried out using monomers for which the life time of the kinetic chain during polymerisation is appreciable. A series of equations for calculating kinetics of block copolymerisation were proposed for the case of the block copolymer of methyl methacrylate with acrylonitrile. In the derivation of the equation, which makes it possible to determine the number of transfer acts (n.t.) through each polymeric molecule formed, it was postulated that chain transfer takes place only through the polymer chain. The equation is

$$\text{n.t.} = (k_3'[S_A] + k_3''[E])\{k_3'[S_A] + k_3''[E] + (Ik_4)^{1/2}\}^{-1},$$

where $[S_A]$ is the concentration of poly(methyl methacrylate), $[E]$ the concentration of terminal groups, $I$ the rate of initiation, $k_3'$ and $k_3''$ the rate constants for the chain-transfer reaction through the elementary units of the polymer chain and through the terminal amino-groups respectively, and $k_4$ the mean rate constant for the chain-termination reaction resulting from disproportionation.

The weight-average concentration of poly(methyl methacrylate) fragments ($m$) is calculated from the equation

$$m = a(k_3'[S_A] + k_3''[E])\{k_3'[S_A] + k_3''[E] + (Ik_4)^{1/2}\}^{-1},$$

where $a$ is the polymerisation coefficient for poly(methyl methacrylate) with terminal amino-groups.

The following equation was proposed for the number-average polymerisation coefficient of polyacrylonitrile $\bar{P}$ for a low degree of conversion

$$\bar{P} = k_2[B]\{k_3'[S_A] + k_3''[E] + (Ik_4)^{1/2}\}^{-1},$$

where $k_2$ is the rate constant for the reaction of chain growth and $[B]$ the acrylonitrile concentration.

Bamford and White [93] found that the dependence of the concentration of block copolymer molecules of the type $A_nB_m$, containing $a$ units of monomer A and $b$ units of monomer B, $[P_{ab}]$, on the quantities $a$ and $b$ is given by the equation

$$[P_{ab}] = [S_B]\alpha^{a-1}(1-\alpha)^2\beta^b(1-\beta)k_3'[S_A]/k_2[B],$$

where $[S_A]$ and $[S_B]$ are the concentrations of the homopolymer blocks $A_n$ and $B_m$ respectively, $\alpha$ and $\beta$ the probability factors for growth of the homopolymer chains of monomers A and B, $[B]$ is the concentration of monomer B, and $k_3'$ and $k_2$ are the rate constants for the reactions of chain transfer and chain growth respectively. These equations were used to find the block copolymer distribution with respect to chain length ($r = a + b$) for a given composition ($a/b = c$) and the distribution with respect to composition for a given chain length. It was shown that the quantity of graft copolymer formed as side product is $[k'/k''(1 - \alpha)]$ times the concentration of block copolymers, where $k'$ and $k''$ are the rate constants for the reactions of chain transfer by any unit of the polymer chain and by the terminal amino-group of the polymer formed by the polymerisation of monomer A. From this it follows that with increase in the polymerisation coefficient of the original monomer, equal to $1/(1 - \alpha)$, the concentration of impurity increases, although this is also accompanied by the formation of a block copolymer with greater molecular weight. Since the block copolymer synthesised by means of terminal amino-groups is non-uniform with respect to composition and dimensions of the homopolymer fragments, it was considered advisable either to fractionate the macromolecular chain-transfer agent thoroughly before the synthesis of the actual block copolymer or to extract the low-molecular fractions from it with a suitable solvent.

A polymer containing a terminal aromatic amino-group is obtained by a polymerisation reaction initiated by a diazonium salt and an aromatic acid containing a free amino-group or a group from which a free aromatic amino-group can be prepared by subsequent reactions. This reaction was used to obtain an acrylonitrile homopolymer with a terminal amino-group, and after diazotisation this was used as macromolecular initiator for block copolymerisation with acrylonitrile and 2-methyl-5-vinylpyridine [94,95].

Block copolymerisation initiated by terminal groups containing halogen. Homopolymeric blocks with terminal halogen atoms absorb light with wavelength 2880–3500 Å, are raised to an excited state, and dissociate into free reactive polymeric radicals which are used as macromolecular initiators in block copolymerisation. The macromolecular halides are usually prepared by the thermal or photolytic polymerisation of styrene [96,97] or methyl methacrylate [98] in the presence of $CBr_4$ or $CBrCl_3$ which terminate the chain by a chain-transfer reaction.

In the second stage of the synthesis of the block copolymer, the macrohalide obtained is irradiated with ultraviolet light in the presence of a vinyl monomer, for example, methyl methacrylate, styrene, acrylonitrile, etc. The macroradical formed as a result of irradiation initiates the secondary polymerisation with the formation of the block copolymer, which can be isolated by fractionation on a column using the method developed by Baker and Williams [99].

The centres initiating block copolymerisation are formed only by decomposition of the C–Br group, since $CCl_3$ groups do not undergo photolytic decomposition under the conditions of the synthesis, whereas $CBr_3$ groups undergo further photolysis and are converted into centres initiating block copolymerisation. Chlorine-containing block copolymers are obtained in analogous fashion [100]. Hydrophilic block copolymers are obtained by polymerising acrylic acid in the presence of organic bromine-containing compounds with three or four carbon atoms and three bromine atoms. The resulting bromine-containing acrylic acid homopolymer is dissolved in an inert aqueous medium with another vinyl monomer, for example acrylamide, and the mixture is irradiated with ultraviolet light to give the block copolymer [101,102].

Block copolymerisation initiated by terminal groups containing sulphur. In the polymerisation of vinyl monomers in the presence of organic compounds containing sulphur atoms, it was found that the latter take part in chain-transfer reactions with the formation of homopolymeric blocks containing terminal SH groups [98,103]. These polymers are capable of undergoing photolytic decomposition at the terminal group, so that they may initiate block copolymerisation when irradiated with ultraviolet light in the presence of vinyl monomers. An analogous ability to undergo chain-transfer reactions is shown by various organic disulphides [104], and disulphides such as tetraethylthiuram disulphide† are used

† Bis(diethylthiocarbamoyl) disulphide (Ed. of Translation).

simultaneously to initiate the polymerisation of the primary monomer.

The polymerisation of styrene using tetraethylthiuram disulphide as initiator leads to the formation of polymer blocks with terminal sulphur-containing groups capable of undergoing photolysis with the formation of macroradicals which initiate block copolymerisation. A block copolymer of styrene with methyl methacrylate was prepared in this way [105]. Analysis showed that the product of this block copolymerisation consisted of 40% pure block copolymer, 30% styrene homopolymer, and 30% methyl methacrylate homopolymer [106]. Block copolymers of styrene with vinyl acetate were synthesised in analogous fashion in yields of more than 70%. [107] These block copolymers are soluble in most hydrocarbons and ketones, and are insoluble in methanol. The poly(vinyl acetate) block of this block copolymer can then be hydrolysed with a methanol solution of alkali to give the block copolymer of styrene with vinyl alcohol [108]. This block copolymer is insoluble in benzene, methanol, and water, and merely swells in these solvents; it is partly soluble in phenol and cresol. Another method of using sulphur-containing organic compounds in the synthesis of block copolymers involves the polymerisation of styrene (initiator diisopropylphenyl monohydroperoxide) in the presence of cumenethiol as chain-transfer agent. Chain transfer leads to the formation of polystyrene with molecular weight 28 000 (compared with 83 000 for control specimens of polystyrene), from which it is concluded that about 25% of the polystyrene blocks contain terminal isopropyl groups. These terminal groups are readily oxidised to hydroperoxide groups to give polystyrene blocks with terminal hydroperoxide groups which are capable, in the presence of $Fe^{3+}$ ions, of initiating the block copolymerisation of polystyrene with various vinyl monomers [109].

Block copolymerisation initiated by terminal groups consisting of acid hydrazides. Acrylonitrile is capable of undergoing polymerisation in the presence of the redox system consisting of acid hydrazides and $Fe^{3+}$ ions. The initial rate of polymerisation of acrylonitrile in 1 *N* acetic acid solution at 40° is almost linearly dependent on the concentration product $[\text{acid hydrazide}]^{1/2}[Fe^{3+}]^{1/2}$. The polymerisation of acrylonitrile can be initiated in analogous fashion by using, instead of the monomeric acid hydrazides, polymeric blocks containing acid hydrazides as terminal groups. This method has been used to prepare block copolymers of polyaminotriazole with polyacrolein, exhibiting a high affinity for acid dyes [110].

B. Methods based on the presence, in the main chain of the polymeric block, of active groups capable of forming macroradicals which initiate the polymerisation of monomers with the formation of block copolymers.

Block copolymerisation initiated by dye molecules present in the leuco-form in the main chain of the polymeric block. On the basis of spectroscopic data obtained by Oster's method [111] in studies of the products of the photopolymerisation of vinyl compounds, in the presence of dyes (eosin, safranine, Acridine Orange), reducing agents (ascorbic acid, thiourea), and oxygen, it has been established that the dye molecules are incorporated in the polymer molecule in the leuco-form. The photosensitising effect of the dyes present in the polymer molecule can be used for the initiation of block copolymerisation [112]. The irradiation, with visible light, of ω-*N*-(aminoeosin)-poly(methyl methacrylate) containing 1 eosin group for every 48 methyl methacrylate groups, in acetic acid in the presence of thiourea and acrylamide gave a block copolymer of methyl methacrylate and acrylamide, with a concentration of second monomer residues equal to 40%. A block copolymer of methyl methacrylate with styrene was obtained in analogous fashion but in higher yield (concentration of second monomer 79%); hydrolysis of this block copolymer showed that the homopolymer blocks are joined to one another by leuco-groups.

Block copolymerisation initiated by peroxide groups present in the main chain of the polymer block. Peroxides formed in the polymer during storage are capable of decomposing to form macroradicals which initiate block copolymerisation [113]. To obtain block copolymers using these polymeric peroxides, specimens of poly(methyl methacrylate), polystyrene, and poly(vinyl acetate) are kept in the vapours of styrene, acrylonitrile, vinylidene chloride, vinyl acetate, and methyl methacrylate [114]. Despite the heterogeneity of the process, which decreases considerably the rate of the block copolymerisation, analysis of the product showed an appreciable concentration of block copolymers. In the bulk copolymerisation of methyl methacrylate, styrene, and vinyl acetate in the presence of oxygen, peroxide bonds are formed in the main chain of the polymer [115]. If this polymeric peroxide is swollen in monomer and then heated, the macroradicals formed in the thermal decomposition of the peroxide groups begin to initiate polymerisation of the monomer adsorbed on the particles of polymeric peroxide, with the formation of a block copolymer.

Peroxide groups can also be introduced into the main chain of a polymer by a variety of chemical methods. For example, the partial dehydrochlorination of poly(vinyl chloride) gives a polymer with a main chain containing double bonds, ozonisation of which gives peroxide groups capable of initiating the block copolymerisation of vinyl monomers [116].

C. Methods based on the presence, in the main chain of the polymeric block, of side branches capable of undergoing photolytic degradation with the formation of macroradicals which initiate the polymerisation of monomers with the formation of block copolymers.

Block copolymerisation initiated by macroradicals formed by the photolytic degradation of keto-groups present in the polymer in the form of side branches. Irradiation of poly(vinyl methyl ketone) with ultraviolet light of wavelength 3130 Å leads to decomposition of the polymer by photolytic degradation according to a scheme analogous to that for the decomposition of monomeric aliphatic ketones under identical conditions [117-119]. The resulting macroradicals are capable of initiating the homopolymerisation and block or graft copolymerisation of monomers such as methyl methacrylate and vinyl acetate. As in the case of simple radical polymerisation, the rate of the block or graft copolymerisation depends on the concentration of keto-groups and is proportional to the square root of the intensity of irradiation.

D. Methods based on the introduction, into the monomer, of a mixture of polymer-homologues containing free active radicals capable of initiating the polymerisation of monomers with the formation of block copolymers.

Block copolymerisation initiated by radicals which have not lost their activity. In a study of the photopolymerisation of methyl methacrylate, Melville [120] observed that growth of the polymer chains continues after irradiation has stopped, and that this "growing polymer" may initiate the polymerisation of chloroprene without irradiation. Thomas [121] suggested that polymeric chains capable of growth may be preserved in a solid polymer. These macroradicals may initiate block copolymerisation when brought into contact with vinyl monomers. In the block polymerisation of acrylonitrile or acrylamide, the polymer formed is insoluble in the original monomer and is precipitated; this precipitate retains a large quantity of free macroradicals capable of further growth. With increase in temperature or the addition of solvents, the radicals occluded in the polymer are liberated due to the unwinding of the coiled polymer molecules, and may become centres for the initiation of the polymerisation of a second monomer [122]. The yield of block copolymers in this block copolymerisation is generally low — less than 5% in the case of poly(acrylonitrile) and less than 8% in the case of poly(acrylamide). This low yield of block copolymer is due to the incomplete liberation of the radicals during the block copolymerisation; this was confirmed by electron paramagnetic resonance studies. A block copolymer of methyl methacrylate with styrene was synthesised in analogous fashion [123].

The products of the emulsion polymerisation of styrene and methyl methacrylate, under the conditions of micro-gel formation, also contain radicals capable of initiating block copolymerisation. It has been established by electron microscopy [124] that the block copolymerisation is accompanied by an increase in the dimensions of the particles of the micro-gel; no new particles are formed. It is not clear whether the block copolymerisation centres are situated inside the micro-gel particles or on their surface. No homopolymer is formed under these conditions. These radicals can be used to prepare the block copolymer of vinyl acetate with methyl methacrylate [35]. For this purpose vinyl acetate is emulsion polymerised under the influence of $\gamma$-radiation; the macroradicals thus formed initiate the polymerisation of the second monomer.

Block copolymerisation initiated by long-lived macroradicals. In the suspension polymerisation of a water-insoluble monomer in the presence of an aqueous solution of another monomer, the macroradicals formed may diffuse through the phase boundary and initiate the polymerisation of the second monomer with the formation of a block copolymer. Block copolymers of methacrylic acid with styrene and vinyl acetate were prepared in this way [125-127]. Because of the complex mutual solubility of the monomers in one phase, however, the resulting block copolymer has an extremely indefinite composition and is formed in low yield. Block copolymers of *N*-vinylpyrrolidone with styrene [128] and vinyl chloride [129] are obtained in analogous fashion. A slightly different method was proposed for the preparation of block copolymers soluble in water and capable of being used as settling agents and filter aids [130]. One or several vinyl compounds forming water-soluble polymers (for example, acrylic or methacrylic acids or their salts or amides) are polymerised in aqueous solution and a further 0.5–30 wt.% of a vinyl monomer containing sulphonic or phosphoric acid residues in the molecule is added to polymerise with the still active primary monomer, which is not removed from the polymerisation medium.

Another example of block copolymerisation initiated by macroradicals with relatively long lifetime is the so-called "dynamic" method of block copolymer synthesis proposed by Hicks and Melville [131-134]. The essential features of the method are as follows. Monomer A, containing a photosensitiser, passes through a capillary, a small section of which is irradiated with a powerful quartz mercury lamp, into a reservoir containing monomer B. Decomposition of the sensitiser in the irradiated section produces free radicals (up to $10^{-4}$ mole) which react with the molecules of monomer A and form polymeric radicals of the type AA... A$^{\cdot}$. When they enter the reservoir containing monomer B, these radicals continue to grow, with the attachment of molecules of monomer B. The polymer molecules formed in this way have the structure ...AAABBB... or ...AAABBBBBAAA..., depending on the mechanism of the chain-termination reaction. Calculation shows that at an appropriate rate of flow of monomer A through the capillary, the main bulk of the free radicals formed during the irradiation are not deactivated in the time taken for the reaction mixture to pass through the capillary and enter the reservoir containing monomer B. The results of the theoretical calculations are confirmed by direct determination of the quantity of polymer formed only in the capillary and the quantity of polymer formed in the reservoir containing monomer B. This method has been used to synthesise block copolymers of butyl acrylate and acrylonitrile (monomers A) with styrene, using as sensitiser the dinitrile of azocyclohexanecarboxylic acid. The structure of the polymers obtained was studied by ultraviolet spectroscopy. Block copolymers of n-butyl acrylate with 2-vinylpyridine were synthesised in analogous fashion [135]; study of these block copolymers showed that their molecules consist of a poly(vinyl pyridine) block and a block of a statistical copolymer of both monomers used for the synthesis, situated between blocks consisting of units of the first monomer. This structure in the products obtained is due to the presence of both monomers in the second stage of the synthesis of the block copolymer.

E. Methods based on inter-chain exchange reactions during radical polymerisation, leading to the formation of block copolymers.

In the radical polymerisation of vinyl monomers to appreciable degree of conversion, secondary processes take place [136] involving reaction between the macroradicals formed. These reactions are of two types: (1) inter-chain exchange — a process of repeated degradation and recombination of macroradicals, and (2) the cross-linking of chain macromolecules without the formation of a gel. As a model system for the synthesis of a block copolymer, in which inter-chain reactions might take place in more or less "pure" form, use has been made of mixed solutions of polymers, in which thermal decomposition of the initiators — the sources of the primary free radicals — was carried out. The formation of block copolymers, confirmed by ultraviolet spectroscopy, was observed in mixed solutions

of polystyrene and polyisobutene in toluene in the presence of benzoyl peroxide and methylphenyltriazole. A method based on sedimentation in a density gradient was used for the quantitative analysis of the products obtained.

As mentioned above, the properties of block copolymers show not only the properties of their component homopolymers but also, as a rule, new properties differing sharply from those of the homopolymer. Some block copolymers exhibit properties which are so unique that the isolation of the pure block copolymers and the study of their properties is of considerable practical and theoretical interest. A number of reviews have been devoted to methods of studying block copolymers [137,138]. In our opinion, the most promising qualitative methods for the identification of block copolymers are nephelometric [139] and turbidimetric [140] titration. An apparatus has been described [141] for automatic turbidimetric titration, which makes it possible to determine the presence of a block copolymer in its mixtures with homopolymers.

The applicability of X-ray structural analysis to the study of block copolymers was confirmed for the block copolymer of methyl methacrylate with acrylonitrile [142]. The X-ray diffraction patterns for the block copolymers are similar to those for a mechanical mixture of the homopolymers, but there are certain differences in the scattering of X-rays by the block copolymers. The weight-average molecular weight of the block copolymers can be determined by light-scattering methods. The applicability of Stockmayer's equation

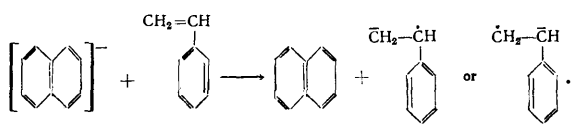
$$(I_0/k'c)_{c\to 0} = (dn/dc)_0^2\,\overline{M}\omega + 2b\,(dn/dc)_0\,\{M\Delta x\} + b^2\{M\,(\Delta x)^2\},$$

to the determination of the weight-average molecular weight of block copolymers from the values of the reduced intensity of the scattering of light in three different solvents has been studied experimentally for the block copolymer of styrene with methyl methacrylate. The parameters for the polydispersity of composition $M\Delta x$ and $M(\Delta x)^2$ show satisfactory agreement with one another when any three measurements in different solvents are chosen [143].

The thermodynamic equations for solutions of homopolymers have been used to calculate the Hildebrand solubility parameters for statistical, block, and graft copolymers $\delta_i = \sqrt{(\Lambda_i - RT)/V_i}$, where $\Lambda_i$ is the molar heat of volatilisation and $V_i$ the molar volume of the $i$th component of the mixture. Using the subscripts A and B to denote the values of $\delta$ for the corresponding homopolymers, and the subscript 0 for the solvent, and taking $(\delta_A - \delta_B) = p$ (with the condition that $\delta_A > \delta_B$), $|\delta_0 - \delta_A| = \Delta\delta_A$, $RT$ = = 600 cal, and $V_0 = 100$ cm$^3$, the authors obtained the following condition for the solubility of the statistical copolymers:

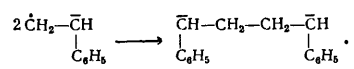
$$\Delta\delta_A + p(1-\beta) \leqslant {}^1/_6, \qquad (1)$$

where the solubility parameter $\delta_p = \delta_A\beta + \delta_B(1-\beta)$. This result was obtained from an analysis of the systems by the Flory–Huggins method. The derivation of this equation was based on the fact that the entropy ($S$) of the statistical copolymer is the same as the entropy of the homopolymer with the same polymerisation coefficient, whereas the heat of mixing $\Delta H$ depends on the interaction of the solvent with the main units of A and B. In the case of the block copolymers, it is necessary, in the calculation of the entropy, to make allowance for the fact that the volumes of the statistical segments are different for the homopolymers A and B. In the calculation of $\Delta H$ for the block copolymers, in the case of comparable homopolymers, the solubility condition is described by Eqn. (1), whereas for non-comparable homopolymers the solubility condition is described by the quadratic relation $(\Delta\delta_A)^2 - 2p(1-\beta)\Delta\delta_A + p^2(1-\beta) \leqslant (2^{-1} - z^{-1})RT/V_0$, where $z$ is the coordination number of the Flory–Huggins quasi-lattice and $\beta$ the volume fraction of monomer A in the statistical copolymer [144].



In the study of solutions of block copolymers of styrene with methyl methacrylate, containing 50–74% styrene, it was shown [145] that the dependence of the main thermodynamic properties of solutions, in toluene and ethyl methyl ketone, of fractionated specimens of these block copolymers, on the composition of the fractions, passes through a maximum at a styrene concentration of ~60%. In particular, the entropy of dissolution, heat of dilution, molecular dimensions, and the unperturbed length of the molecules of the block copolymers, calculated from viscosimetric data, have maximum values for the specimens containing 60% styrene. This phenomenon was related to the limiting intramolecular "separation into layers" of the homopolymeric sections of the block copolymer molecule as a result of their low compatibility in the given proportions. At the same time the values of the second virial coefficient and the Huggins constant are unaffected by change in the composition of the block copolymer, and this in turn can be attributed to the mutually cancelling influence of the two homopolymeric blocks of the same block copolymer molecule. The apparent dissociation constants of the block copolymers of acrylic acid with acrylamide were determined by electrometric titration [146] in 0.1 $N$ carbonate-free sodium chloride solution, with 0.1 $N$ sodium hydroxide solution. It was found that the acidity of this block copolymer is the same as that of polyacrylic acid.

In the study of the viscosity and light scattering of solutions of block copolymers of acrylonitrile and methyl methacrylate in mixed solvents [147], it was found that when benzene is added to a solution of the block copolymer in dimethylformamide there is a sharp decrease in viscosity and an increase in turbidity, continuing over a definite time interval. An analogous effect is produced by the addition of other precipitants to this solution. The critical concentration increases in the order $H_2O < CH_3COOH <$ $< C_2H_5OH < C_6H_6 < CCl_4 < (CH_3)_2CO$. The subsequent addition of dimethylformamide restores the viscosity of the system and decreases the turbidity, with considerable hysteresis. This change in the properties of the block copolymer solutions is due to the repeated formation of aggregates as a result of electrostatic interaction between the acrylonitrile units in the block copolymer chains. The use of the viscosity and light scattering of solutions of block copolymers in mixed solvents has been proposed for the determination of the composition and structure of block copolymers. The addition of acetonitrile to a benzene solution of the block copolymer of styrene with methyl methacrylate gives stable colloidal dispersions of the polymer as a result of the partial displacement of the chains of the polystyrene block while the chains of the polymethyl methacrylate block remain as it were dissolved in the solvent–precipitant mixture. Analogous dispersions can be obtained by peptising dry block copolymer; in this case it is found that the dimensions of the particles in the dispersion are related to the molecular weight of the block copolymer. A model has been proposed [148] relating the dimensions of the particles, the mean-square distance between the ends of the chains, and the molecular weight of the block copolymer.



In a study of the vitrification temperature of block copolymers of acrylonitrile with methyl methacrylate [149], it was found that the value is intermediate between the vitrification temperatures of poly(acrylonitrile) and poly(methyl methacrylate), and depends to a marked extent on the structural arrangement of the monomer units in the polymer chain. This confirms the general hypothesis that the vitrification temperature of polymers is sensitive to the degree of structural order. The results of the studies showed that in this block copolymer the poly(acrylonitrile) block has a much greater influence on the properties of the block copolymer than the poly(methyl methacrylate) block.

## 2. Synthesis of Block Copolymers by Anionic Polymerisation

The simplest carbochain block copolymers can be synthesised by the "live" chain method proposed by Szwarc [150,151] and others [152]. In the case of styrene, anionic polymerisation can be carried out in the presence of the products of the addition of alkali metals to aromatic compounds in tetrahydrofuran. The resulting polymer molecule remains "live" during polymerisation until all the monomer is used up, as a result of which the "live" end may undergo polymerisation with new units of another monomer, added to the polymerisation system. Champetier [153] proposed the following mechanism for this block copolymerisation: naphthalene reacts with sodium or lithium to form a compound with component ratio close to 1. In tetrahydrofuran, capture of the electron of the sodium by naphthalene leads to dissociation of this compound to the $Na^+$ cation and the naphthalene radical-anion. In the presence of styrene, this radical-anion can act as an agent for the transfer of the negative charge to the styrene, with the formation of the styrene radical-carbanion.

Theoretically, there are two possible ways in which the polymerisation of styrene may begin under the influence of the styrene radical-carbanion — radical and anionic. Since in a medium of tetrahydrofuran the rate of anion polymerisation is much greater than that of radical polymerisation, however, and the styrene radical-carbanions have a tendency to combine at low temperatures by means of their radical ends with the formation of doubly-charged carbanions, in practice only anionic polymerisation takes place.

In the same paper Champetier states that the initiation of the polymerisation of the first monomer A by initiator is possible when the reduction potential of the initiator is higher or only slightly lower than the reduction potential of the monomer, since an equilibrium reaction of the type

takes place.

Initiation does not take place if the reduction potential of the initiator is appreciably lower than the reduction potential of the monomer. This also applies to the second stage of the synthesis of the block copolymer, that is, in order to obtain a block copolymer, it is necessary that the reduction potential of the polymer block be greater or only slightly less than the reduction potential of the second monomer. The block copolymers obtained with this condition usually consist of a central homopolymeric block (AAA), bounded on both sides by two different polymer blocks (BBB). If, however, the two monomers have fairly similar reduction potentials, it is possible to obtain a block copolymer whose main chain consists of several successive alternating homopolymer blocks AAA and BBB. A block copolymer with this structure was synthesised from styrene and isoprene [154] in tetrahydrofuran in the presence of the sodium naphthalenide as catalyst. Two series of block copolymers were obtained, with molecular weights 15 800 and 158 000 and the same molar ratio of homopolymeric blocks of styrene (A) to homopolymeric blocks of isoprene (B), but with different numbers and lengths of alternating blocks (A... AB... BA... AB... B). It was found that when the first (original) monomer is isoprene, the polydispersity of the block copolymers is greater, evidently due to the fact that the life of the polyisoprene chain is longer than that of the polystyrene chain.

Block copolymers of styrene with methyl methacrylate [155-157], containing about 46% styrene and 54% methyl methacrylate, are obtained by initiating the polymerisation of methyl methacrylate with "live" polystyrene at -70° in solution in tetrahydrofuran. To determine the molecular weight of the polystyrene blocks in these block copolymers, the growth of the "live" polystyrene chain in control experiments was terminated before the addition of methyl methacrylate and the light scattering of benzene solutions of the block copolymer was compared with that of solutions of the control specimen of homopolystyrene [158]. A combination of these methods and chemical analysis showed that the molecular weight of the polystyrene blocks is the same as that of the control homopolystyrene. When block copolymerisation was complete, no homopoly(methyl methacrylate) was detected, although about 50% of the polystyrene does not react; this is evidently due to the influence of deactivating impurities. Block copolymers of styrene and acrylonitrile were synthesised in analogous fashion [156,159]. Here it was found that acrylonitrile cannot form either a "live" polymer or a homopolymer. The solubility of these block copolymers in dimethylformamide increases with increase in their styrene content.

In the presence of sodium-naphthalene or sodium–biphenylide in tetrahydrofuran, "live" polymers may also be formed by 1,2-dihydronaphthalene and 2-vinylpyridine, and block copolymers of these compounds with styrene [160], containing up to five segments of homopolymer blocks, have been prepared. The viscosity of the resulting block copolymers is anomalously low, evidently due to the mutual incompatibility of the segments.

On the basis of the electron affinity of the monomers, Franta [161] studied the ability of monomers to form block copolymers under the influence of phenylisopropylpotassium of the "live" disodium tetramer of $\alpha$-methyl-styrene in tetrahydrofuran in an atmosphere of argon at -80°. The monomers studied were arranged in the following order of increasing carbanion stability and ability to initiate the polymerisation of all subsequent monomers, with the formation of block copolymers: $\alpha$-methylstyrene (1), styrene (2), isoprene (3), 2-vinylpyridine (4), 4-vinylpyridine (5), $\alpha$-vinylnaphthalene (6), $p$-bromostyrene (7), methyl methacrylate (8), methacrylonitrile (9), methyl acrylate (10), acrylonitrile (11), and ethylene oxide (12). Block copolymers are formed in good yield by the reaction of "live"

polymers of (2) with (3)–(9) and (12), (3) with (12), (5) with (8), and (7) with (8). The polymerisation of styrene is not initiated by the carbanions of (7), (8), and (9), and the polymerisation of 4-vinylpyridine is not initiated by the carbanions of (8).

Other catalysts which are often used in anion polymerisation to obtain carbochain block copolymers are the alkyllithiums: methyllithium, ethyllithium, n-propyllithium, n-butyllithium, n-pentyllithium, and their mixtures[162], and also compounds of lithium with alicyclic or aromatic radicals[163]. These have been used to prepare block copolymers of styrene with methacrylonitrile and of styrene with acrylonitrile. Block copolymers of butadiene or piperylene [penta-1,3-diene (Ed. of Translation)] with styrene, or of piperylene with isoprene, were prepared in analogous fashion[164]. Of the block copolymers obtained in the presence of alkyllithiums, the block copolymer of styrene with isoprene has been studied in most details[165]. Comparison of the curves for the nephelometric titration of the block copolymer and a mechanical mixture of the homopolymers of styrene and isoprene, with the same composition as the block copolymer, together with comparison of their ultraviolet spectra, showed that the copolymer is a block copolymer. The quantitative composition of the block copolymer was studied by measuring the partial specific volumes, by measuring the refractive indices of films of the block copolymer, and by ultraviolet spectroscopy. The equilibrium sedimentation of the block copolymer in a density gradient was also studied[166]; for this purpose a solution of the block copolymer in a mixture of butyl chloride and dichloroethane was placed in the centrifugal field of an ultracentrifuge. When equilibrium was established, the traces of homopolymers were concentrated at the foot of the cell and at the meniscus, and the block copolymer, which has an intermediate density, collected in a narrow band at a certain distance $x$ from the axis of rotation. The integral block copolymer concentration distribution close to $x$ has the form of a gaussian curve, whose width is determined by diffusion and the polydispersity of the composition.

Anionic block copolymerisation can also be carried out in the presence of metallic lithium[167,168]. The reaction is carried out in tetrahydrofuran. An interesting feature is that the reaction appears to take place as a result of instantaneous growth of the radical-ion. Metallic sodium can also be used as catalyst for this polymerisation[169,170]. A method has been described[171] for preparing block copolymers using metallic sodium; a film of sodium is treated successively with the vapours of styrene and $\alpha$-methylstyrene. The latter polymerises at the anionic end of the polystyrene with the formation of a live block copolymer radical. By repeating this operation it is possible to obtain a block copolymer with the required number of blocks. The softening temperature of the block copolymers is intermediate between that of a mixture of the homopolymers and that of a statistical copolymer of the same components, and decreases with increase in the number of blocks.

A method has been described[172] for preparing a block copolymer of ethylene with propene in the presence of a catalytic metal–Lewis acid ($TiCl_4$, $VOCl_3$) system. In this case also, polymerisation takes place by an anionic mechanism.

Stereospecific Ziegler–Natta catalysts[173] have also found extensive application in anionic block copolymerisation. For the most part these catalysts are used to obtain block copolymers of alkenes and their $\alpha$-substituted derivatives. The preparation of block copolymers of ethylene with propene with an unlimited number of homopolymer blocks of both monomers has been described[174]. To obtain these blocks of given length, it is recommended that each monomer be introduced into the polymerisation system alternately or after strictly defined time intervals[175] or until the vapour pressure of a given monomer decreases during polymerisation to a definite required value[176]. Another method for preparing these block copolymers[177] is based on the fact that the catalyst at the end of the growing chain does not lose its activity. In this method, as the polymerisation of ethylene is nearing completion, propene is added to the polymerisation system to undergo block copolymerisation with the polyethylene. This process may be repeated indefinitely to give block copolymers with a predetermined number of homopolymer blocks of both monomers. Increase in the total duration of the reaction gives block copolymers with a high characteristic viscosity, and increase in the propene content gives a polymer with higher density.

It has been shown possible[178] to apply rheological analysis to block copolymers of this type. Analogous methods may be used to obtain block copolymers of pent-1-ene, oct-1-ene, cyclohexene, butadiene, or isoprene with allyl bromide or chloride, methallyl chloride, isoprene, butadiene, styrene, but-1-ene, oct-1-ene, and chloroprene[179], and of ethylene with but-2-ene.[180] Infrared spectroscopy and X-ray diffraction showed[181] that block copolymers of acrylonitrile with vinyl acetate, methyl methacrylate, or styrene have a lower crystallinity than the homopolymers of these monomers, obtained under analogous conditions. A number of published facts[182] indicate that when certain catalytic systems such as $TiCl_4 + LiAlR_4$ or $VOCl_3 + AlR_2Cl$ are used, growth of the macromolecules continues for several days. These "long-lived" macromolecules were used for the synthesis of block copolymers of ethylene with propene and of ethylene with but-1-ene, with different types of distribution of the monomer units in the blocks. By varying the method of preparing the block copolymers, it was possible to obtain polymers with different structures, from crystalline to amorphous. The molecular conformation of the polymer and its hydrodynamic and mechanical properties were studied[183] for the case of the block copolymer of styrene with isoprene in the ratio 4 : 5. The molecular configuration of this block copolymer was investigated in the course of a study of the characteristic viscosity, diffusion, and sedimentation of the polymer in benzene, which is an effective solvent for both homopolymeric blocks, and also in ethyl methyl ketone and octane, which are selective solvents for the polystyrene and polyisoprene blocks respectively. It was shown that in the selective solvents, the insoluble blocks form globules but are retained in solution by the blocks which are "soluble" in the given solvent. This leads to a departure from the relationship connecting $\langle r^2 \rangle^{1/2}$ with $[\eta]$ and $D$, derived by Flory for flexible chain macromolecules, whereas this relationship is satisfied completely for the same block copolymer in benzene. Study of films of block copolymers obtained from selective solvents showed that the globular structure of the "insoluble" blocks is preserved completely after removal of the selective solvent, so that the film of block copolymer, obtained from solution in octane, behaves like rubber with a chemically bound filler, and the film obtained from solution in ethyl methyl ketone behaves like plasticised polystyrene.

The polymerisation of diazo-compounds in the presence of boron trifluoride or its derivatives takes place by a mechanism identical with that of the polymerisation of alkenes in the presence of Ziegler–Natta catalysts.

The macromolecules of the type $X_2B-(CHR)_n-X$ formed as a result of polymerisation are able in turn to initiate the polymerisation of freshly prepared diazo-compounds with the formation of block copolymers of the type $X_2B-(CHR)_n-(CHR')_m-X$. A polymerisation mechanism has been proposed[184], similar to that of the polymerisation of ethylene in the presence of alkylaluminiums, involving coordination of the diazoalkanes with the boron catalyst and subsequent migration of the groups initially bound to the boron atom. Analogous derivatives containing boron were observed in the reactions of diboranes with dialdehydes and ketones. Alkylene oxides can also react with diborane with the formation of products of the type $H_2B(OCH_2CHR)_nH$ and $HB\begin{smallmatrix}(OCH_2CHR)_xH\\(OCH_2CHR)_yH\end{smallmatrix}$. These reactions, as noted above, are similar to the polymerisation of alkenes, catalysed by alkylaluminiums, since both reactions include the stepwise anionic growth of the metal–alkyl chain. Since the diazoalkane has much higher nucleophilic activity than ethylene, it can, unlike ethylene, react with alkylborons. Alkylaluminiums in turn have a higher electrophilic activity than the corresponding alkylborons, so that it is to be expected that diazo-compounds will undergo block copolymerisation when initiated with alkylaluminiums more readily than the corresponding alkenes.

An ionic mechanism involving anionic and cationic polymerisation stages was proposed[185] for the preparation of block copolymers of $\alpha$-methylstyrene and isobutene with acrylonitrile and with acrylates. The $\alpha$-methylstyrene or isobutene is polymerised by a cationic mechanism with the formation of positive ions at the ends of the growing chains. Acrylonitrile or acrylates in turn polymerise by an anionic mechanism to give macromolecules containing terminal negative ions. The reaction of these growing macromolecules with ions of opposite sign at the ends of the chains gives the corresponding block copolymers.

Anionic polymerisation is also used to prepare the so-called stereo-block copolymers, consisting of polymeric molecules containing alternating, relatively long polymeric fragments with different spatial configurations, formed from the same monomer. These macromolecules may consist of isotactic and atactic segments, or of isotactic segments alone, with different spatial configurations. The mechanism of their formation was examined by Natta[186] on the basis of the assumption that two processes take place simultaneously — chain growth and a process in which inversion of configuration takes place. In practice, amorphous polymers, regarded as atactic, may contain very short stereo-blocks[187], which have not yet been isolated in pure form. The stereo-block copolymers of $\alpha$-alkenes, with relatively long segments with definite spatial configurations, are usually isolated from a mixture of the amorphous and crystalline polymers by extraction with selective solvents[188,189] with increasing solvent power for the given polymer. In this way it is possible to separate the amorphous polymer and stereo-block copolymers with different crystallinities[190-193]. Natta[194] showed, however, that the fractionation method is not always applicable to the separation of stereo-block copolymers of propene, since the solubility of the polymer usually depends not only on the degree of crystallinity but also on its molecular weight and structure. The separation of stereo-block copolymers differing only in their degree of crystallinity can be carried out successfully on a chromatographic column with a substrate of isotactic polypropene. In a study of the mechanical properties of the stereo-block copolymer of propene[195], it was found that at a high degree of isotactic character, when the macromolecule contains very small atactic segments, the fibres obtained from a melt of the block copolymer have a high strength.

A stereo-block copolymer of methyl methacrylate, consisting of alternating isotactic and atactic or syndiotactic and atactic polymeric blocks is obtained by the radical and anionic polymerisation of methyl methacrylate at low temperatures[196-198]. The isotactic-syndiotactic stereo-block copolymer of methyl methacrylate is obtained by polymerising methyl methacrylate in the presence of 9-fluorenyllithium at -70° in a medium of toluene[199]. This type of stereo-block copolymer crystallises readily[200,201] from pentyl acetate, heptan-4-one, and octan-3-one. The stereo-block copolymer of styrene can be isolated by extracting polystyrene synthesised in the presence of titanium-containing organometallic catalysts and washed beforehand with dry diethyl ether[202]. A method has been described for preparing linear stereo-block copolymers of propene, but-1-ene, and pent-1-ene, with macromolecules containing isotactic crystallising sections with asymmetric carbon atoms with the same spatial configuration, and also non-isotactic non-crystallising sections[203,204]. In the isolation of these stereo-block copolymers, the resulting mixture of polymers is separated by extraction with selective solvents, which dissolve first the non-isotactic polymers and then the stereo-block copolymers with gradually-increasing degrees of crystallinity. It has been reported that stereo-block copolymers can also be obtained from the dialkenes butadiene and isoprene[205]. It was suggested[206] that under the conditions of the stereospecific polymerisation of isobutyl vinyl ether[207,208], a stereo-block copolymer whose macromolecule consists of *d*- and *l*-isotactic segments and several atactic segments, distributed along the polymer chain, is also formed.

In the study of stereo-block copolymers, the proportion of isotactic and syndiotactic fragments can be determined by infrared spectrocopy[209,210] and the three-dimensional structure as a whole can be determined by measuring the heats of fusion[211,212] or by nuclear magnetic resonance studied on instruments with a high resolving power[213,214]. The three-dimensional structure of the stereo-block copolymer of styrene can also be determined from the difference in the rates of hydrolysis of the benzanilides of the atactic and isotactic segments of the polymer[215], which are readily obtainable from polystyrene and consist of the polyvinyl benzanilides with the corresponding spatial configurations.

### 3. Synthesis of Carbochain Block Copolymers by the Combination of Polymer Blocks, Containing Chemically Active Terminal Groups, by Means of Low-Molecular Bifunctional Compounds

To obtain homochain polymer blocks containing chemically active terminal groups, Bamford and Jenkins[216] proposed that the polymerisation of the original monomer be initiated using organic compounds containing two azo-groups and a functional group capable of reacting with hydroxyl or carboxyl groups. By initiating the polymerisation of styrene, acrylonitrile, and methyl methacrylate with $\gamma,\gamma'$-azo-$\gamma$-cyanovaleric acid or $\delta,\delta$-azo-$\delta$-cyano-n-pentanol, they prepared[217] homopolymeric blocks of styrene, acrylonitrile, and methyl methacrylate containing carboxyl or hydroxyl groups. To obtain macromolecules with a relatively low molecular weight and relatively high concentration of active terminal groups in the mixture of poly-

mer homologues, they suggested the use of an apparatus which makes it possible to carry out this process continuously. Block copolymers can be synthesised from the macromolecules with active terminal groups prepared in this way, by two methods: (1) by direct combination of two macromolecules, or (2) by the combination of two macromolecules by means of low-molecular bifunctional compounds such as decamethylene glycol.

In a study of the resulting block copolymers, Bamford and Jenkins[218] found that the molecular-weight distribution of these block copolymers is a function of the molecular-weight distribution of the original homopolymer blocks, the duration of the reaction, and the chemical properties of the reactive terminal groups. Using the method of Laplace transformations, they derived a general equation which makes it possible to use the measured characteristic viscosity to reach conclusions regarding the ratio of the final and initial mean polymerisation coefficients.

## III. CARBO-HETEROCHAIN BLOCK COPOLYMERS

Carbo-heterochain block copolymers, like carbochain block copolymers, can be obtained by various mechanochemical methods. The degradation of the polymer chains for the formation of reactive macroradicals is achieved using various grinding assemblies[219-222], by means of the electrohydraulic effect[46,47,223], and also by the freezing and subsequent melting of aqueous solutions of the polymers[224-226].

Carbo-heterochain block copolymers can also be obtained by anionic or radical polymerisation, by polycondensation, and by combining carbochain blocks with heterochain homopolymeric blocks.

### 1. Synthesis of Carbo-Heterochain Block Copolymers by Ionic Polymerisation

By analogy with the synthesis of carbochain block copolymers, carbo-heterochain block copolymers can be synthesised by Szwarc's "live" chain method. This method has been used to synthesise block copolymers of isoprene with ethylene oxide[161], of styrene with ethylene oxide, and of styrene with propene oxide[227]. This gives block copolymers of two types: polystyrene–poly(alkylene oxide) and poly(alkylene oxide)–polystyrene–poly(alkylene oxide). The polymeric products formed in the reaction always contain the alkylene oxide homopolymer in quantities corresponding to 46.4–73.6% of the total poly(alkylene oxide) content[228], probable due to the presence, in the polymerisation system, of traces of moisture, alkali, or oxygen, which terminate the growth of the block copolymer chain. In a study of the block copolymer of the second type in the block copolymer–water–ethylbenzene system[229], it was found that in these systems the block copolymers form mesomorphic gels resembling the nematic structures in the systems formed by water with low-molecular soaps. Study of the resulting birefringent structures by means of X-rays and the polarisation microscope showed that the hydrophobic polystyrene blocks, in the mixture with ethylbenzene, are localised with the formation of a hexagonal liquid-crystalline lattice in cylindrical regions with parallel orientation; the space between these regions is filled with a mixture of the hydrophilic poly(ethylene oxide) blocks and water. Each of the separate homopolymer blocks of the block copolymer has the configuration of a statistical coil. The equilibrium diagram shows clearly an immiscibility zone in which the gel is present in equilibrium with the isotropic liquid. At low concentrations of block copolymer, separation of the phases also takes place, and the aqueous and ethylbenzene layers can be separated by centrifuging. Mesomorphic gels are also formed in binary systems if the solvent is an effective solvent for the poly(alkylene oxide) blocks and an ineffective solvent for the polystyrene blocks, or vice versa. The gels may be nematic or smectic, depending on the nature of the solvent, but in both cases they are extremely stable.

The influence of the nature of the solvent on the structure of the mesomorphic gels of the block copolymers of styrene with ethylene oxide have also been studied by the method involving the scattering of X-rays at small angles in nitromethane, which is a solvent for the poly(ethylene oxide) and a precipitant for polystyrene, and in butyl phthalate, which is a solvent for polystyrene and a precipitant for poly(ethylene oxide)[230]. Mesomorphic gels of the block copolymer of styrene with ethylene oxide are formed in solutions in acrylic acid, which is a solvent for poly(ethylene oxide) and a precipitant for polystyrene, and in methyl methacrylate, which is a solvent for polystyrene and a precipitant for poly(ethylene oxide). When these systems are iradiated with ultraviolet light[231], the monomer present in the system polymerises in the presence of the mesomorphic phase, ensuring the production of a solid protective mesomorphic gel structure and forming a copolymer with an ordered structure. The irradiation of the "block copolymer of styrene with ethylene oxide–acrylic acid" system gives a copolymer of acrylic acid, whose gel has a cylindrical structure up to a concentration of block copolymer in the system equal to 90%, and a lamellar structure at other concentrations. The "block copolymer of styrene with ethylene oxide–methyl methacrylate" system under analogous conditions forms only a lamellar structure. The cylindrical structures were evidently formed by the aggregation of "cylinders" of polystyrene blocks surrounded by a solution of the poly(ethylene oxide) blocks, and the lamellar structure by a combination of alternating layers of "crystalline" poly(ethylene oxide) blocks and a polystyrene blocks in solution respectively.

Anion polymerisation can also be used to prepare carbo-heterochain block copolymers with general formula:

$$CH_3(C_2H_4)_n C(R')(R'')O[CH_2CH(R''')O]_m CH_2CH(R''')OH,$$

where R′ and R″ are alkyl groups with 1–4 carbon atoms, R‴ = H, $CH_3$, or $C_6H_5$, $n$ = 30–250, and $m$ = 1–70. These block copolymers are obtained by the reaction of polyethylene telomers, modified by monohydrie aliphatic alcohols or dialkyl ketones, with alkylene oxides in the presence of Na, Ce, Li, K, $NaOCH_3$, NaOH, or KOH in the molten state at 110–200° or in aqueous emulsion[232]. The block copolymer of acrylonitrile with ethylene oxide is obtained by polymerising acrylonitrile under the influence of the sodium salt of polyethylene glycol[233]. The composition of this block copolymer can be studied by infrared spectroscopy.

### 2. Synthesis of Carbo-Heterochain Block Copolymers by the Combination of Polymer Blocks, Containing Chemically Active Terminal Groups, by Means of Low-Molecular Bifunctional Compounds

Carbo-heterochain block copolymers of the polystyrene–poly(ethylene oxide)–polystyrene and polystyrene–poly(ethylene oxide) types are prepared by the combination of

polyhydroxyéthylene glycol with polystyrene containing one or two terminal acid chloride groups and prepared by the reaction of "live" polystyrene with phosgene[228].

It is also possible to synthesise carbo-heterochain block copolymers based on 2,2-di-(4-hydroxyphenyl)propane polycarbonate. These are prepared by linking polystyrene with low-molecular 2,2-di-(4-hydroxyphenyl)propane polycarbonate containing terminal hydroxyl groups[234]. Polycarbonate blocks with low molecular weight, controllable within narrow limits, are obtained by varying the concentration of the original substances and the reaction temperature, and polystyrene blocks with terminal hydroxyl groups are prepared by hydrolysing a polymer obtained in the presence of benzoyl peroxide and containing terminal benzoxy-groups. The presence of flexible blocks in the block copolymer chain facilitates ordering of the polycarbonate, which forms flexible polymers with a high melting point. It was found[235] that during the bulk polymerisation of a mixture of styrene with $\beta$-propiolactone in the presence of an initiator of the radical type, the product is a copolymer, hydrolysis of which, followed by treatment with poly(ethylene oxide), gives a carbo-heterochain block copolymer.

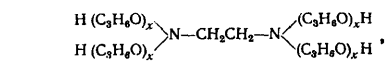
### 3. Synthesis of Carbo-Heterochain Block Copolymers by Radical Polymerisation

A method was recently developed for preparing polymeric peroxide initiators[236], making it possible to carry out carbo-heterochain block copolymerisation by the radical-polymerisation method. These initiators are prepared by polymer-analogue transformations from aliphatic or aromatic polyesters containing terminal carboxyl or acid chloride groups at the surface of separation between the two phases. On thermal decomposition, these initiators form macroradicals capable of initiating the block copolymerisation of vinyl monomers, which polymerise by a radical mechanism. This method has been used to synthesise a block copolymer of a polyester of hydroxyheptanoic acid with poly(methacrylic acid). Unlike poly(methacrylic acid), the resulting block copolymer is fusible, soluble in a mixture of acetone and methanol, and insoluble in water.

An extremely promising method for the production of fibres involves the use of carbo-heterochain block copolymers which may be partly or completely crystalline according to the crystallising ability of the homopolymer fragments which alternate regularly in the main chain of the block copolymer. The carbo-heterochain block copolymer of acrylonitrile with 10–40% of compounds such as poly(vinyl alcohol), poly(ethylene oxide), starch, cellulose, and poly(acrylic acid) can be used[237] to prepare readily dyed fibres using ordinary shaping methods.

## IV. HETEROCHAIN BLOCK COPOLYMERS

Heterochain block copolymers were first found in natural macromolecular compounds. In a study of silk fibroin, consisting of a polypeptide chain[238], it was found that the amino-acids are arranged in the chain in an ordered fashion. X-Ray diffraction study of the same silk fibroin[239] established that its molecule, with molecular weight ~30 000, consists of three segments of an ordered structure with molecular weight ~7000, separated by amorphous segments with molecular weight ~5000. This indicated that silk fibroin is a natural heterochain stereo-block copolymer. A number of block copolymers of cellulose were prepared by synthesis[240]. It was found[241] that substitution in cellulose under heterogeneous conditions in most cases gives heterochain block copolymers containing large segments of unchanged glucose residues, located chiefly in crystalline regions. The glucose residues in the amorphous regions are very sensitive to the action of substituents. X-Ray structural analysis shows that up to a degree of substituion in the cellulose equal to 25–35%, no changes are observed in the crystalline regions. The resulting block copolymer combines the properties of rigidity and strength, associated with the crystalline regions, with elasticity and flexibility, asociated with the substitution in the amorphous regions.



Synthetic heterochain block copolymers can be obtained by ionic polymerisation, polycondensation, the combination of heterochain polymeric blocks containing chemically active terminal groups, inter-phase polycondensation, and exchange reactions.

### 1. Synthesis of Heterochain Block Copolymers by Ionic Polymerisation

This method has been used to prepare heterochain block copolymers of formaldehyde with various polymeric blocks containing active terminal hydroxyl, sulphydryl, carboxyl, or primary amino-groups[242]. For example, the polymerisation of 99% pure formaldehyde in the presence of dimethyldialkylammonium hydroxide and poly(tetramethylene glycol) with molecular weight ~7000 gives a block copolymer containing 73% poly(methylene oxide) units. This block copolymer is less crystalline but has a higher impact strength than the formaldehyde homopolymer[243]. The preparation of block copolymers of diisocyanates or bisepoxy compounds with linear polyesters containing terminal hydroxyl groups has been described[244]. X-Ray structural analysis of these block copolymers indicates the presence of crystalline regions with structures identical with that of the crystallites of the homopolymers. Some block copolymers with low glass points and low degrees of crystallinity, such as poly(ethylene terephthalate)–poly(ethylene adipate), are rubberlike materials with high strength. The block copolymers of ethylene oxide with propene oxide[245] have found extensive application as non-ionic detergents. A poly(propene oxide) block containing a terminal hydroxyl group is used as the original hydrophobic fragment of the block copolymer chain[246–248]. When ethylene oxide is added to this macromolecular glycol, its terminal groups initiate block copolymerisation with the formation of a block copolymer with general formula:

$$HO-(CH_2CH_2O)_x-(C_3H_6O)_y-(CH_2CH_2O)_xH.$$

The physical properties of these block copolymers may be varied over a wide range to give mobile liquids (40% ethylene oxide), waxy products (50% ethylene oxide), and hard solids (70% ethylene oxide). Analogous methods can be used to prepare block copolymers of propene oxide and ethylene oxide with ethylenediamine[249], since the reaction of propene oxide with ethylenediamine gives a macromolecular compound with general formula

whose terminal groups are able to initiate the polymerisation of ethylene oxide with the formation of a block copolymer.

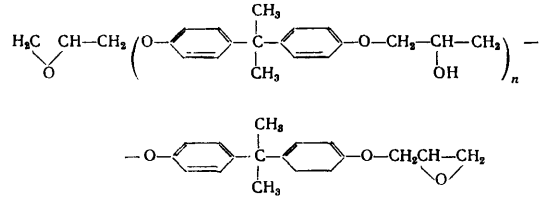
Block copolymers of alkene 1,2-oxides, with general formula $R''(RCHRCHO)_n-(R'CHR'CHO)_mH$, where R and R' represent the H atom or a hydrocarbon radical, and R'' the radical in the catalyst molecule, are obtained in two stages[250]. In the first stage, the polymerisation of the alkylene oxide $\overrightarrow{RCHRCRO}$ is initiated by organometallic catalysts, and in the second stage the polymerisation of the other alkene oxide $R'\overrightarrow{CHR'CHO}$ is initiated by the primary polymer block containing active terminal groups. When alkaline or acidic catalysts are used in the first stage of the block copolymerisation, it is possible in analogous fashion to obtain block copolymers of alkyl glycidyl esters with ethylene oxide. Block copolymers of this type have found application as surface-active agents[251]. It was found that the surface-active properties of these block copolymers deteriorate sharply with increase in the length of the lateral groups.

In a study of block copolymers of the poly(ethylene oxide)–poly(propene oxide)–poly(ethylene oxide) type[252], it was found that in benzene solution these copolymers form inclusion compounds with urea and thiourea. Viscosimetric determination of the molecular weights of these inclusion compounds showed that there is an appreciable fractionating effect.

The ion polymerisation method was also used to prepare heterochain stereo-block copolymers[253]. For example, the polymerisation of acetaldehyde in the presence of partly hydrolysed aluminium alkoxide gave a stereo-block copolymer of acetaldehyde, whose structure was confirmed by solubility data, infrared spectroscopy, and X-ray structural analysis. This stereo-block copolymer is less elastic than atactic amorphous polyacetaldehyde. Its solubility is intermediate between the solubilities of the crystalline and amorphous polymers[254].

### 2. Synthesis of Heterochain Block Copolymers by Polycondensation

This method for preparing the heterochain block copolymers has been very little studied, and is used chiefly for modifying the properties of polyesters used in the production of synthetic fibres. It has been used to prepare block copolymers of ethylene terephthalate with poly(ethylene oxide) by heating a mixture of dimethyl terephthalate, ethylene glycol, and poly(ethylene oxide) at 200–275°, in the presence of PbO. Study of the properties of this block copolymer[255] showed that the introduction of poly(ethylene oxide) blocks with molecular weight 1000–6000 into the polymer increases the hydrophilic character of the polymer, its flexibility, and the ease with which it can be dyed. The degree of crystallinity, strength, and ductility shown by this block copolymer, are almost the same as those for polyethylene terephthalate, but the stability to the action of ultraviolet light is much lower. At concentrations of poly(ethylene oxide) in the block copolymer up to 20%, the mechanical properties deteriorate[256] due to the decreased concentration of crystalline fraction in the fibre.



### 3. Synthesis of Heterochain Block Copolymers by the Combination of Polymer Blocks Containing Chemically Active Terminal Groups

This method, involving the introduction of flexible and elastic blocks of one polymer into the main chain of another polymer with a rigid structure, can be used to modify macromolecular compounds such as polycarbonates[257]. As a result of the presence of these blocks, which alternate regularly in the main chain of the block copolymer, the final product is also elastic. For example, the block copolymer formed by the combination of polycarbonate blocks with poly(tetramethylene oxide) is an elastomer[234]. More frequently, however, the polymeric blocks are joined by means of low-molecular bifunctional compounds such as diisocyanates, with the formation of heterochain polyester–urethane block copolymers[258,261].

The methods for preparing these block copolymers are varied. For example, a polyester with a molecular weight of several thousand, obtained by the polycondensation of adipic acid with ethylene glycol, is treated with an excess of diisocyanate to join the polyester blocks. The isocyanate groups formed at the ends of the chain are in turn capable of reacting with water, glycols, or diamines, with the formation of substituted ureas[262]. Analogous methods are used to prepare block copolymers of poly(ethylene terephthalate) with poly(ethylene succinate), poly(ethylene adipate), poly(ethylene azelaate), poly(ethylene sebacate), poly(ethylene phthalate), poly(ethylene isophthalate), and poly(diethylene adipate)[263]. Tetramethylene diisocyanate is used as linking agent. The properties of these block copolymers differ considerably, depending on the chemical nature of the original polyester blocks. The degree of crystallinity of the reactants and products can be determined by X-ray structural analysis and from the temperature of the second-order transformation.

It is possible to obtain a rubberlike elastic heterochain block copolymer suitable for the production of fibres and films[264] by using as the original polymer blocks, polyesters prepared by the polycondensation of glycol with an aliphatic dicarboxylic acid or with an asymmetric aromatic dicarboxylic acid and poly(ethylene terephthalate), and by using tetramethylene diisocyanate as linking agent. The preparation of block copolymers by the combination of statistically mixed polyesters using diisocyanates has also been described[262]. These block copolymers have a lower strength than the analogous block copolymers consisting of two components, evidently because of the irregularity of the polyester chain, resulting from the introduction of a third component into the polyester block[265]. The use[266] of symmetrical aromatic diisocyanates as linking agents instead of aliphatic diisocyanates improves the physical properties of the resulting block copolymer. With increase in the "diisocyanate : polyester" ratio, the molecular weight of the heterochain block copolymer increases, with a corresponding increase in the viscosity of the dilute solutions, the Mooney plasticity, and the softening temperature. It was found[267] that in order to obtain polyester-urethane block copolymers with increased elasticity it is best to link the original polyester blocks by means of diisocyanates with three alkyl substituents. The physical properties of these block copolymers are also influenced to a marked extent by the crystallinity of the original polyester blocks[268]. For example, polyethylene terephthalate and polyethylene adipate are crystalline, and the physical properties of block copolymers based on these compounds are almost identical with those of the homopolymers. If, however, the crystallinity of one of these blocks is broken down, for example, by the introduction of a non-crystalline segment such as poly(propene adipate), the impact strength of the block copolymer increases, but all the other mechanical properties deteriorate, in almost direct proportion to the concentration of added polymer block, which acts as an internal

plasticiser. Heterochain block copolymers can also be obtained from epoxide resins of the type

(synthesised by the usual methods and containing active terminal epoxy-groups[269]) by the reaction with phenol–formaldehyde and urea–formaldehyde resins, polyamides, etc. Block copolymers of this type, prepared by the reaction of ED-5 and ED-6 with dimethylresorcinol resin, are used to impregnate glass fibres for the production of glass-fibre-reinforced plastics. Lacquer from this block copolymer, and glass fabric impregnated with it, remain stable for 2–2.5 months[270]. The fusion of phenol–formaldehyde and other polycondensation resins with polyesters, and also the treatment of Novolaks first with a polyhydric alcohol and then with a polybasic acid, was used by Petrov to obtain a number of heterochain block copolymers, which he called joint resins[271].

### 4. Synthesis of Heterochain Block Copolymers by Inter-Phase Polycondensation

Study of inter-phase polycondensation showed that this method can be used to prepare macromolecular compounds for the synthesis of heterochain block copolymers[272].

The block copolymers are prepared by the reaction of polymeric blocks containing terminal acid chloride and hydroxyl groups[273] at the phase boundary between two immiscible solvents[274]. The preparation of analogous block copolymers by the reaction of polyester blocks containing terminal hydroxyl groups with a mixture of the acid chlorides of dicarboxylic acids and diphenols has been described[275]. Similar block copolyesters[276] can be prepared by the joint condensation of two polyesters, for example, poly(ethylene terephthalate) and poly(ethylene isophthalate)[277].

### 5. Method Based on Inter-Chain Exchange Reactions

When two homopolyesters are fused together, a statistical copolymer is obtained[278]. In a study of the inter-chain reaction between polyester macromolecules, Korshak and coworkers[279] established that the process involves degradation and intermolecular exchange, as a result of which block copolymers are formed as intermediate products. This work enabled a number of authors to prepare various block copolymers by exchange reactions[280]. The use of CaO as catalyst for the reaction was proposed[281]. In analogous fashion, Flori[273] prepared block copolyesters using macromolecules containing terminal acid chloride and hydroxyl groups as original homopolyester blocks. In this case the formation of the block copolyesters most probably takes place both by the interaction of the active terminal groups of the polyesters and by the inter-chain exchange reaction. To increase the ease with which the fibres based on poly(ethylene terephthalate) can be dyed, Kresse[282] used exchange reactions to synthesise a number of block copolyesters of poly(ethylene terephthalate). In a study of the reaction conditions, he found that one of the decisive factors influencing the rate of redistribution is the viscosity of the components of the block copolycondensation Beginning with the formation of macromolecules of definite magnitude, the exchange reactions proceed predominantly by an intermolecular exchange mechanism; the block copolyester formed at the start of the reaction is converted into a mixed polyester in the subsequent stages of the reaction. The formation of block copolyesters in the poly(ethylene terephthalate) macromolecule was proved by extracting the products of the joint polycondensation. A fibre capable of undergoing subsequent orientation was formed from the resulting block copolyesters.

Mixed polyamides have been prepared in analogous fashion by fusing two polyamides together[283]. It is possible that when two different polyamides are fused together, exchange reactions take place, and the formation of the mixed polymers passes through a stage involving the formation of block copolymers[284]. Experimental confirmation of this suggestion was found in work by Ayers[285]. In a study of the formation of the statistical copolyamide based on nylon-6,6 and nylon-6,10 by distribution chromatography on paper, Ayers showed that formation of the block copolymers begins approximately half an hour after the start of the reaction, and that in the subsequent reaction these block copolymers are completely converted into the mixed polyamide. More detailed study of this reaction[286] showed that as the mixture of polyamides is heated there is a decrease in the temperature of flow and an increase in the solubility and tensile strength. The block copolymers formed in the reaction have a comparatively short life, of the order of 3–5 h. Analogous results were obtained in a study of inter-chain reaction for the case of the preparation of a mixed polyamide from poly(hexamethylene adipamide) and poly(hexamethylene sebacamide)[287]. The rate of the inter-chain reaction is increased considerably by the addition of small quantities of hexamethylenediammonium adipate, which catalyses side reactions. This catalyst also accelerates the subsequent conversion of the intermediate block copolymer into the mixed polyamide[288]. Inter-chain reaction has also been used to prepare heterochain block copolymers of polyamides with various thermosetting resins[289]; for this purpose the mixture of polyamide and epoxide resin is heated at 240–290° in the presence of t-butyl peroxide. When poly(aminotriazole) blocks are heated[290], only very stable block copolymers are formed, and on subsequent heating these are converted into a mixed polymer. The authors attribute this to the fact that in this polymeric system there is no inter-chain exchange reaction and the block copolymers are formed only by the reaction of the terminal groups of the homopolymers. Inter-chain reaction was recently used[291] to give a new type of heterochain block copolymer, consisting of mixed polyamido-esters. Polymeric products of this type are of considerable practical interest, since they open up the possibility of preparing polymers with a new combination of properties, based on previously prepared polymers. The formation of these mixed polymers in the first stage of the process, as in the case of mixed polyamides, is said to pass through a stage involving the formation of block copolymers, which apparently can be isolated in pure form under suitable conditions.

Modern methods of organic synthesis are making it possible to extend considerably the number of block copolymers. In addition to the synthesis of new block copolymers, it is necessary to pay particular attention to the

study of the dependence of the properties of block copolymers on their composition, the magnitude and number of the blocks, the sequence of the blocks, etc. The elucidation of this dependence will make it possible to achieve deliberate control of the synthesis of block copolymes and to obtain polymers with a desired range of properties.

5. Reactions of carbodiimides with isocyanates 216
6. Applications of carbodiimides 216

## 1. INTRODUCTION

The carbodiimides form a class of organic compounds the membership of which is determined by the presence of the carbodiimide grouping $-N=C=N-$. The general formula of the carbodiimides may be represented as follows:

$$R-N=C=N-R',$$

where R and R′ are alkyl or aryl groups.

Carbodiimides may be regarded as alkyl (aryl) derivatives of the simplest representative of the class HN=C=NH, which exists mainly as the tautomeric form of cyanamide, $H_2N-C\equiv N$.[1] Carbodiimides form one of several classes of organic compounds with cumulative double bonds (isocyanates, ketens, allenes, ketenimines). Although some aromatic carbodiimides were first synthesised 80 years ago, it is only in recent years that interest in them has been aroused[1]. Recently polymeric carbodiimides $(-R-N=C=N-)_x$ with fibre- and film-forming and other valuable practical properties have been obtained.

In Russian literature there are only references of the most general kind to the carbodiimides[2].

## 2. PREPARATION OF CARBODIIMIDES

Up to recently the method of synthesising carbodiimides by eliminating hydrogen sulphide from disubstituted thioureas had the most importance preparatively[3].

$$RNHCSNHR' \xrightarrow{-H_2S} RN=C=NR'.$$

The starting thioureas are obtained from amines or disulphides. Aliphatic amines first form the salt of a substituted dithiocarbamic acid:

$$RNHCS\overline{S}R'\overset{+}{N}H_3 \xrightarrow{t^\circ} RNHCSNHR'+H_2S.$$

The thioureas are treated with mercury(II) oxide, lead(II) oxide, or sodium hypochlorite, and carbodiimides are formed. A large number of aliphatic, aromatic, and mixed carbodiimides have been synthesised in this way. When thioureas are treated with mercury(II) oxide or sodium hypochlorite the yield of carbodiimides is fairly high: with dicyclohexylcarbodiimide the yield reaches 90%.[4-10]

In an original method of preparing dicyclohexylcarbodiimide developed by Amiard, water is eliminated from *NN'*-dicyclohexylurea with the aid of *p*-toluenesulphonyl chloride and pyridine[11]. The starting symmetrical dicyclohexylurea is obtained in good yield by heating urea with cyclohexylamine:

$$2C_6H_{11}NH_2 + NH_2CONH_2 \rightarrow C_6H_{11}NHCONHC_6H_{11} + 2NH_3,$$

$$C_6H_{11}NHCONHC_6H_{11} + 2p\text{-}CH_3C_6H_4SO_2Cl \longrightarrow$$

$$\longrightarrow C_6H_{11}N=C=NC_6H_{11} + (p\text{-}CH_3C_6H_4SO_2)_2O + 2HCl.$$

Diethylcarbodiimide was first synthesised by the interaction of ethyl isocyanate and tetraethylphosphine imide; the latter can be obtained from triethylphosphine and ethyl azide[12]:

$$(C_2H_5)_3P+C_2H_5N_3 \rightarrow (C_2H_5)_3P=NC_2H_5+N_2,$$

$$(C_2H_5)_3PNC_2H_5+C_2H_5NCO \rightarrow C_2H_5N=C=NC_2H_5+(C_2H_5)_3PO.$$

Some aromatic carbodiimides were first prepared by the prolonged heating of isocyanates. For example, diphenylcarbodiimide is prepared by heating phenylisocyanate for 24 h at 180° in the absence of air[13]:

$$2C_6H_5NCO \longrightarrow C_6H_5N=C=NC_6H_5+CO_2.$$

Prolonged heating converts diisocyanates into polycarbodiimides. Thus, when methylenebis-(4-phenylisocyanate) was heated at 220° in the absence of air, the content of isocyanate groups fell from 33.5 to 25.8% in 11 h and to 22.8% in 24 h and methylenediphenyl-4,4'-poly(carbodiimide) was formed. An empirical formula relating the degree of conversion of isocyanates into carbodiimides with the temperature and duration of the reaction has been derived from a study of the kinetics of the thermal conversion of a number of isocyanates into carbodiimides[14]:

$$g = 100 - at^2,$$

where $g$ is the amount of unreacted isocyanate groups expressed as a percentage of the initial quantity, $t$ the time of heating in hours, and $a$ an empirical temperature coefficient (at 220° this varies from 0.1 to 0.6, and at 180° it varies from 0.01 to 0.06).

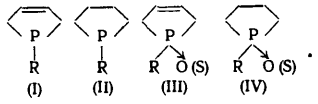
It has been demonstrated that the thermal conversion of isocyanates into carbodiimides is autocatalytic.

The conversion of isocyanates into carbodiimides on heating presumably proceeds through intermediate unsymmetrical cyclic dimers. The decarboxylation of such dimers is greatly facilitated by the non-uniform distribution and displacement of electron density in the ring[15]:

The method of preparing carbodiimides by heating isocyanates has not been widely used because a large amount of by-products is formed in the reaction.

The method of preparing carbodiimides by the catalytic decarboxylation of isocyanates, which has been developed in recent years, is in practice the most important method[16-23]. Carbodiimides are prepared by this method by adding a decarboxylation catalyst to isocyanates, in the pure state or in an inert solvent; heating for several hours produces a vigorous evolution of carbon dioxide and carbodiimides are formed in high yield

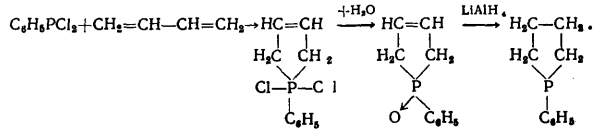
$$2RNCO \xrightarrow[\text{catalyst}]{t^\circ} RN=C=NR+CO_2.$$



The following examples illustrate the method. *p*-Nitrophenylisocyanate is heated with catalyst (1-ethyl-3-methyl--3-phospholine-1-oxide) and there is a vigorous evolution of carbon dioxide; after 1–2 min the reaction mass solidifies and, after removal of the residual carbon dioxide, 4,4'-dinitrophenylcarbodiimide is obtained in 100% yield[19].

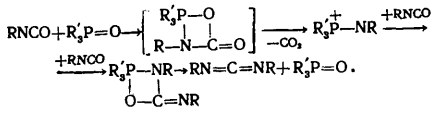
Aliphatic carbodiimides are formed in low yield by this method, but the yield of product can be increased, however, by selecting suitable conditions. Thus, when 50 g of butylisocyanate was boiled with 0.7 g of 3-methyl-1--phenylphospholen 1-oxide for 15 h only 6.2 g (15.5% yield) of dibutylcarbodiimide was obtained; when, however, the same amount of butyl isocyanate was heated in decahydronaphthalene with double the amount of catalyst, 24 g (60% yield) of dibutylcarbodiimide was obtained 15 min after the beginning of the reaction[20]. Diethylcarbodiimide has been obtained in 50% yield by heating a solution of ethyl isocyanate in toluene (1 : 1 by volume) in the presence of 3-methyl--1-phenylphospholen 1-oxide (3% of the weight of isocyanate) for 6 h at 100–105°.[17]

Polycarbodiimides are obtained from diisocyanates by the same method. The reaction is, as a rule, carried out in a solvent (light petroleum, benzene, toluene, xylene) in the presence of 2–3% of decarboxylation catalyst.



A great many compounds have been used as catalysts for the decarboxylation of isocyanates. However, the greatest catalytic activity is shown by substituted phosphocyclopentenes, phospholens (I), and their saturated analogues, the

phospholans (II), and also by the oxides and sulphides of the phospholens (III) and phospholans (IV):[24]



(I) (II) (III) (IV)

These organophosphorus catalysts are obtained by fairly simple methods, for example, by the reaction of alkyl- or aryl-dichlorophosphines with isoprene or butadiene, or in other ways[18,20,25]:

In addition to the phospholens, trialkylphosphine oxides have been proposed as catalysts for the decarboxylation of isocyanates. The mechanism of formation of carbodiimides when these catalysts are used is represented as follows[21-23]:

A number of other organophosphorus, and also organoarsenic, compounds, with a strongly polarised P=O or As=O bond have fairly high catalytic activity; examples are, the phosphates $(RO)_3PO$, the phosphonates $(RO)_2P(O)R'$, triarylarsine oxides $Ar_3AsO$, etc.[21,26] The activities of different catalysts have been compared by studying the kinetics of the decarboxylation of isocyanates[15,22].

## 3. PHYSICAL PROPERTIES OF CARBODIIMIDES

Aliphatic carbodiimides are colourless or slightly coloured distillable liquids with a characteristic odour. The aromatic carbodiimides are generally crystalline compounds that decompose or become partly polymerised on long storage or on being heated. For example, dicyclohexylcarbodiimide, which is widely used in laboratory practice, is a crystalline compound with m.p. 35–36° under normal conditions. It is fairly stable and can be kept for several months; it is readily soluble in inert organic solvents and in alcohol, with which it virtually does not react even on being heated; in this it differs from other carbodiimides. The stability of carbodiimides increases with increasing chain length and branch of side-chains.[27,28] For example, diethylcarbodiimide polymerises after a few days, but diisopropyl- or dicyclohexyl-carbodiimides are stable when stored for several months[12,28]. Unsaturated dialkenecarbodiimides with an unbranched chain (diallyl- and allylbromo-carbodiimides) are stable as monomers only when a polymerisation inhibitor has been added[29].

The aromatic carbodiimides differ considerably in their stability[10]. For example, di-*p*-iodophenylcarbodiimide polymerises very readily. The freshly prepared unsubstituted diphenylcarbodiimide is a mobile liquid, but after a few days it is converted to a solid pasty mass. Di-*p*-tolylcarbodiimide is a solid crystalline compound that remains stable for several months. Bis-(*p*-dimethylaminophenyl)-carbodiimide is stable for three years. Alcoholic solutions of aromatic carbodiimides are more sensitive to heat than solutions of aliphatic carbodiimides.

TABLE. Carbodiimides prepared by decarboxylation of isocyanates.

| Carbodiimide | B.p., °C/mmHg | Literature reference |
|---|---|---|
| Dipropyl | 56—58/11 | 18 |
| Diisopropyl | 36—37/10 | 33 |
| Diallyl | 58—60/10 | 18 |
| Diisopropenyl | 73/43 | |
| Diphenyl | 171/12 | 18 |
| Dicyclohexyl | 154/12 | 22 |
| 4,4′-Dinitrophenyl | m.p. 164—166 | 19 |

The decomposition and polymerisation products of carbodiimides are basic, but their composition and structure have not been sufficiently studied. The dimers and trimers of diphenyl- and di-*p*-tolyl-carbodiimides have been most studied[10].

The physical properties and stability of the poly(carbodiimides) depend on the methods by which they are prepared and the degree of polymerisation. Poly(carbodiimides) may be obtained as elastic vulcanisates, glasslike blocks, moulding powders, film, and fibres. They are soluble in organic solvents. The poly(carbodiimide) obtained from toluene-2,4-diisocyanate melts at 113–115°; the poly-(carbodiimide) of methylenebis-(4-phenylisocyanate), which melts at 250°, is similar to Nylon-6.[16]

An intense absorption band characteristic of the –N=C=N– group occurs in the 2100–2130 $cm^{-1}$ region of the infrared spectrum of carbodiimides[15,16,19]. It is interesting that allenes have a characteristic absorption band in the 1875–2000 $cm^{-1}$ region[25,30]; isocyanates have a band in the 2180–2270 $cm^{-1}$ region[31], and ketimines a band at about 2000 $cm^{-1}$.[32] Table 1 shows some carbodiimides obtained by the decarboxylation of isocyanates.

## 4. CHEMICAL PROPERTIES OF CARBODIIMIDES

The chemical properties of the carbodiimides are determined primarily by their unsaturation, and therefore by their tendency to enter into addition reactions. This refers in particular to reactions with compounds having an active hydrogen atom.

a. Reactions with weak acids. Carbodiimides combine with hydrogen sulphide to form *sym*-dialkyl(aryl)-thioureas[5,34]:

$$RN{=}C{=}NR + H_2S \rightarrow RNHCSNHR.$$

With hydrogen selenide the carbodiimides form the corresponding selenoureas[35]:

$$RN{=}C{=}NR + H_2Se \rightarrow RNHCSeNHR.$$

Carbodiimides react with hydrogen cyanide to form α-cyano-*NN′*-dialkyl(aryl)formamidines[36,37]:

$$RN{=}C{=}NR + HCN \rightarrow RNHC(=NR)CN.$$

b. Reactions with phenols. When carbodiimides are heated with phenols, crystalline ethers of pseudoureas are formed[3]:

$$RN{=}C{=}NR + ArOH \rightarrow RNHC(=NR)OAr.$$

c. Reactions with carboxylic acids. Carbodiimides react with carboxylic acids to form acyl ureas or

acid anhydrides and ureas, according to the reaction conditions [27,34]:

$$RN{=}C{=}NR + R'COOH \begin{cases} \rightarrow RNHCONHR + (R'CO)_2O \\ \rightarrow R'CONRCONHR \end{cases}.$$

Carbodiimides react analogously with dicarboxylic acids [38,39]. Oxalic acid forms disubstituted ureas with carbodiimides [10]. This reaction is used for the identification of carbodiimides. Carbodiimides are quantitatively determined in the following manner [40]. A known amount of oxalic acid dissolved in dioxan is added to the carbodiimide sample, the mixture is heated under reflux, and the solution is titrated against sodium methoxide dissolved in a mixture of benzene and methanol in the presence of Thymol Blue indicator.

The use of the reactions of carbodiimides with carboxylic acids is considered in greater detail below, in the Section dealing with applications of carbodiimides. This also applies to the reactions of carbodiimides with phosphoric acids.

d. Reactions with phosphoric acid. Carbodiimides react vigorously with esters of phosphoric acid to give esters of pyrophosphoric acid in quantitative yield [41]:

$$2(RO)_2POOH + RN{=}C{=}NR \longrightarrow R\overset{+}{N}H{=}\overset{\cdot}{C}{-}\overset{\cdot}{N}HR + \bar{O}P(OR)_2 \longrightarrow$$

$$\longrightarrow (RO)_2P(O)-O-P(O)(OR)_2 + RNHCONHR$$

The reaction with alkylsulphonic acids occurs in a similar manner with the formation of acid anhydrides and ureas [10]:

$$2R'SO_3OH + RN{=}C{=}NR \rightarrow R'SO_2{-}O{-}SO_2R' + RNHCONHR.$$

e. Reactions with alcohols. On being heated, alcohols combine with carbodiimides to form substituted ureas. The reaction goes best in the presence of acid catalysts [42,43]:

$$RN{=}C{=}NR \xrightarrow{H^+} R\overset{+}{N}H{=}C{=}NR \xrightarrow{+R'OH} RNHC(=NR)OR' + H^+.$$

f. Other addition reactions. In the presence of catalytic quantities of their sodium derivatives, malonic ester, acetoacetic ester, and acetylacetone form substituted amidines with carbodiimides [44], for example:

$$RN{=}C{=}NR + CH_2(COOC_2H_5)_2 \rightarrow RNHC(=NR)CH(COOC_2H_5)_2.$$

Substituted amidines are also formed by the reaction of carbodiimides with Grignard reagents [45]:

$$RN{=}C{=}NR + R'MgBr \rightarrow RNCR'{=}NRMgBr \xrightarrow{H_2O} RNHCR'{=}NR + MgOHBr.$$

Ammonia combines with carbodiimides to give disubstituted guanidines [5]:

$$RN{=}C{=}NR + NH_3 \rightarrow RNHC(=NR)NH_2.$$

Carbodiimides react with amines to form trisubstituted guanidines [5,6]:

$$RN{=}C{=}NR + R'NH_2 \rightarrow RNHC(=NR)NHR'.$$

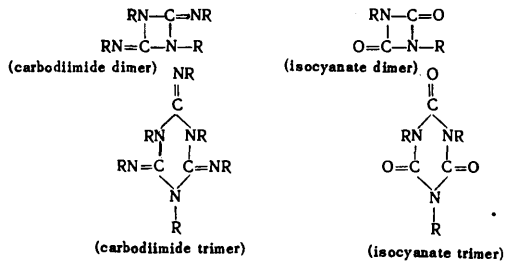
With cyanamide they form disubstituted cyanoguanidines [46]:

$$RN{=}C{=}NR + H_2NC{\equiv}N \rightarrow RNHC(=NR)NHCN.$$

Aliphatic carbodiimides react with cyanamide in the presence of sodium ethoxide.

Diazomethane combines with aromatic carbodiimides to form triazole derivatives [47,48]:

$$ArN{=}C{=}NAr + CH_2N_2 \rightarrow ArNHC(=CH{-}N{=}N){-}NAr.$$



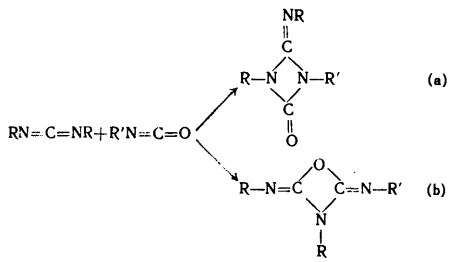
Derivatives of tetrazole are formed by the addition of hydrazoic acid to carbodiimides [49,50]:

$$ArN{=}C{=}NAr + HN_3 \rightarrow ArN{=}C(N_3){-}NHAr \rightarrow ArN{-}C(=N{-}N{=}N){-}NHAr.$$

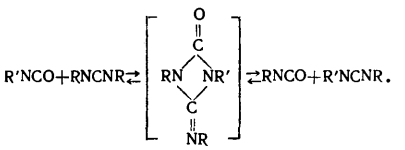
Dry hydrogen chloride reacts vigorously with diphenylcarbodiimide [10]. The reaction proceeds with appreciable evolution of heat and leads to the addition of one or two molecules of hydrogen chloride, depending on the proportions of the reagents. In the presence of water this reaction leads to the formation of *sym*-diphenylurea

$$C_6H_5N{=}C{=}NC_6H_5 \begin{cases} \xrightarrow{HCl} C_6H_5NH{-}CCl{=}NC_6H_5 \\ \xrightarrow{2HCl} C_6H_5NH{-}CCl_2NHC_6H_5 \\ \xrightarrow[HCl]{H_2O} C_6H_5NHCONHC_6H_5 \end{cases}.$$

g. Formation of dimers and trimers. The carbodiimides form dimers and trimers similar in structure to isocyanate dimers and trimers [3,51]:



The chemical properties of the carbodiimides given above show that these are similar to those of other classes of compounds with cumulative double bonds, in particular to those of the isocyanates. However, under ordinary conditions the carbodiimides react less vigorously than the isocyanates with acids, alcohols, and amines [51]. The aliphatic carbodiimides are less reactive than the aromatic [15].



The chemical properties of the polycarbodiimides have been little studied up to now. Some of them, for example the polycarbodiimide obtained by decarboxylation of methylene-bis-(4-phenylisocyanate) react slowly with acids, alkalis, and amines, even on heating [15]. In contrast, the polycarbodiimide obtained from toluylenediisocyanate readily reacts with alcohols and ammonia [17,18].

## 5. REACTIONS OF CARBODIIMIDES WITH ISOCYANATES

Several years ago it was shown that carbodiimides react with isocyanates to form thermally unstable adducts [15]:

Compound with structure (a) was identified by infrared spectroscopy as the main product of the reaction. Compounds of this type are called uretonimines by analogy with uretdiones, the dimerisation products of isocyanates [15]. When heated, uretonimines decompose into the starting materials and products in which the radicals are completely or partially exchanged:

It is possible to exchange completely or partly the radicals of carbodiimides and isocyanates by suitable choice of reagents and reaction conditions.

Uretonimines are obtained from carbodiimides and isocyanates by heating them in the absence of air and moisture to 100–160°. Copper and copser salts are used as catalysts. Uretonimines are high-boiling liquids or solid compounds. For example, the uretonimine obtained from diisopropylcarbodiimide and phenyl isocyanate is a yellowish crystalline compound under ordinary conditions [52].

Diisocyanates react with carbodiimides to form two types of end-products [15]:

$$RNCNR+OCNR'NCO\rightarrow RNCNR'NCO+RNCO,$$
$$\text{(a)}\ RNCNR'NCO+RNCNR\rightarrow RNCNR'NCNR+RNCO,$$
$$\text{(b)}\ RNCNR'NCO+OCNR'NCO\rightarrow OCNR'NCNR'NCO+RNCO,$$

where $R = C_6H_{11}$; $R' = (CH_2)_6$.

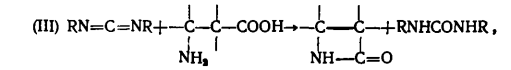
In the last stage of the reaction, polymers of different chain length and with different end-groups can be obtained; the product depends on the proportions of the reagents used. Thus, if dicyclohexylcarbodiimide is added to an excess of hexamethylenediisocyanate, a poly(carbodiimide) of the following structure is obtained:

$$C_6H_{11}-[-(CH_2)_6-N=C=N-]_x-C_6H_{11}$$
$$(x=1, 2, 3).$$

If the diisocyanate is used in excess, the poly(carbodiimide) will have the isocyanate end-groupings:

$$O=C=N-(CH_2)_6-[-N=C=N-(CH_2)_6-]_x-N=C=O$$
$$(x=1, 2, 3).$$

In both cases, products of more branched structure are obtained along with these compounds. These products are formed by the direct reaction of carbodiimides with isocyanate groups according to the scheme given above for the formation of uretonimines [15].



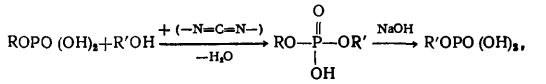
## 6. APPLICATIONS OF CARBODIIMIDES

As already mentioned, until a method of preparing carbodiimides by the catalytic decarboxylation of isocyanates was developed, they had no industrial applications and were used in laboratory synthesis and analysis for characterising carboxylic acids, identifying amino-acids in peptides, etc. [2]

Carbodiimides are also used as dehydrating agents for the production of ester (I), amide (II), lactam (III), and peptide (IV) bonds:

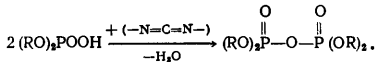
(I) $RN=C=NR+R'OH+R''COOH\rightarrow R''COOR'+RNHCONHR,$

(II) $RN=C=NR+R'NH_2+R''COOH\rightarrow R''CONHR'+RNHCONHR,$



(III) 

(IV) $RN=C=NR+R'CHNH_2COOH+R''COOH\rightarrow R''CONHCHR'COOH+RNHCONHR.$

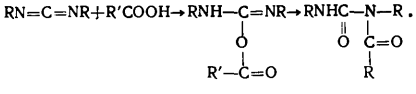


These reactions are quantitative with dicyclohexylcarbodiimide [2].

The β-lactam ring in penicillinoic acid was first closed to form penicillin by means of carbodiimides [2].

Other examples of the use of carbodiimides in dehydrating reactions are known in addition to the cases given above. Thus, carbodiimides have been used for phosphorylation reactions [2]:

and also for the preparation of pyrophosphoric acids:



Peptides can be selectively degraded by means of carbodiimides:

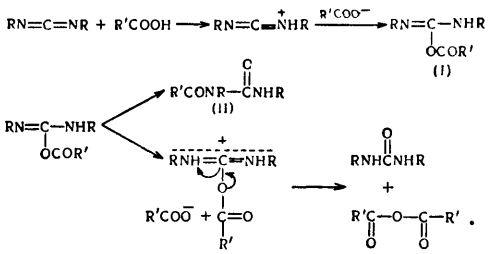
$$CH_3CONHCH_2CONHCH_2COOH+RN=C=NR\rightarrow$$
$$\rightarrow CH_3CONHCH_2CONRCONHR \xrightarrow{NaOH} CH_3CONHCH_2COOH+NH_2CH_2CONRCONHR.$$

Carbodiimides have been successfully used in the synthesis of nucleotides, polynucleotides, coenzymes, etc. [43]

Polycarbodiimides have not yet found wide practical applications. But studies of the properties of polycarbodiimides give grounds for regarding them as promising polymer materials with film-forming and fibre-forming capabilities. Poly(carbodiimides) are outstandingly stable to heat and to the action of corrosive liquids [15,18,19,23].

The tendency of carbodiimides to form acylated substituted ureas by reaction with carboxylic acids has been utilised in employing them as anti-aging additives to polyurethanes. In these cases, the reaction of carbodiimides with acids goes according to the following scheme:

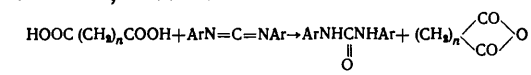
It is well known that when plastics containing ester groupings age, carboxylic compounds are formed that accelerate the reaction autocatalytically. It has been shown that poly-(carbodiimides) are effective inhibitors of this process. They are very compatible with plastics, stable on storage, non-volatile, etc.[15,53]



Carbodiimides can be used as anti-shrink additives in the treatment of textiles[54].

Some carbodiimides are physiologically active[54]. The toxicity of dicyclohexylcarbodiimide for the rat ($LD_{50}$) is 2.6 g $kg^{-1}$. Carbodiimides have herbicidal and fungicidal activity[55].

The use of carbodiimides in acylation reactions. The ability of carbodiimides to combine with carboxylic acids with the formation of *NN'*-diaryl- or *NN'*-dialkyl-ureides has been used for the identification of these acids[56]. The same reaction has been used for the detection of traces of acids in animal and vegetable oils[57]. In this reaction the best results are obtained with dicyclohexylcarbodiimide.



The nature of the end-products in this reaction depends on the structure of the carbodiimide and on the type of solvent. Ureides are the main products formed from diarylcarbodiimides; in those cases where dicyclohexylcarbodiimide was used, acid anhydrides and dicyclohexylurea were obtained as the main products. Zetzsche, using dicyclohexylcarbodiimide, obtained the anhydrides of butyric and stearic acids in 90% yield[56]. Ether, benzene, acetone, cyclohexane, and light petroleum were used as solvents in these reactions. Ureides of *NN'*-dicyclohexylurea were obtained in pyridine or alcohol solution.

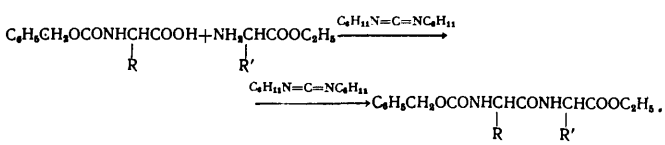
According to Khorana[43], the mechanism of formation of acid anhydrides together with ureides may be represented as follows:

In accordance with the proposed scheme, a molecule of acid combines with one of the double bonds of carbodiimide to form an intermediate compound (I), which either rearranges to a more stable form with the formation of a ureide (II) or reacts with a second molecule of acid, if this is present in excess, to give an acid anhydride and a substituted urea. In alcoholic solution, compound (I) reacts with the alcohol to form an acid ester.

Khorana, who analysed the different directions the reactions of carbodiimides with carboxylic acids may take, has made the following observations[10]. With aromatic acids the reaction goes mainly in the direction of forming alkylureas. Ether, benzene, dioxan, and pyridine may be used as solvents; the use of alcohols is undesirable as they form polymeric by-products. Under very mild conditions an acyl urea is formed quantitatively. Since acylureas crystallise very well, this reaction may be used to characterise carboxylic acids. The most suitable carbodiimide for this purpose is *sym*-bis-(*p*-dimethylaminophenyl)carbodiimide. Malonic, succinic, and glutaric acids mainly form disubstituted ureas and cyclic anhydrides. Evidently, cyclisation occurs after 1,2-addition:

where $n$ = 1, 2, 3.

Similarly, phthalic acid and maleic acid form cyclic anhydrides, but fumaric acid gives the normal adduct:



Adipic acid forms the monoacyl- and diacyl-ureas. The higher acids give normal derivatives, and each carboxylic group reacts independently.

Aliphatic carbodiimides, as a rule, form disubstituted ureas and anhydrides with carboxylic acids. However, by controlling the reaction an acylurea can be obtained. For example, when the reaction is carried out in hot pyridine and the carboxylic acid is added in portions to dicyclohexylcarbodiimide, the acylurea is obtained in satisfactory yield. Dicyclohexylurea is formed when dicyclohexylcarbodiimide reacts with an aqueous solution of acetic acid. To obtain diisopropylurea, the reaction between diisopropylcarbodiimide and acetic acid is carried out in acetone[58].

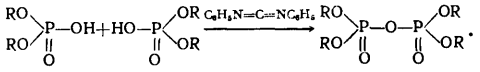
Methyl benzoate has been obtained from methanol and benzoic acid in the presence of dicyclohexylcarbodiimide[59]. A patent has also been obtained for the preparation of esters by the reaction of chloroacetic, phenoxyacetic, and salicyclic acids with methanol and 2-chloroethanol in the presence of dicyclohexylcarbodiimide. The desired products were obtained in 72–100% yield[60]. Butyranilide has been obtained by the reaction of butyric acid with aniline in the presence of dicyclohexylcarbodiimide[59]. This interesting observation was further applied in carrying out syntheses, with the use of amino-acids and carbodiimides. Like ordinary organic acids, in this reaction amino-acids form ureides, many of which have been prepared by Khorana[41].

Khorana noted that when the reaction was carried out with dicyclohexylcarbodiimide in pyridine solution cleavage of the ureide occurred[41]. When alcohol was used as a solvent, a certain amount of urea was formed in addition to the ureides. This suggests that in the course of the reaction dehydration of two molecules of amino-acid occurred with the possible formation of a peptide.

A new method of synthesising peptides has been developed[61], consisting in a reaction between a benzyloxycarbonylamino-acid, or a phthaloylamino-acid, and the ethyl ester of another amino-acid in the presence of dicyclohexylcarbodiimide:

In this way the ethyl ester of benzyloxycarbonylglycyl--*L*-phenylalanylglycine, benzyloxycarbonyl-*L*-serylglycine, phthaloyl-*L*-phenylalanylglycine, and phthaloyl-*L*--phenylalanyl-*L*-leucine have been obtained; the yield of peptide in these reactions was 70–90%.

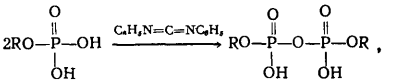
Peptides were also obtained by Khorana, but in lower yield (20–50%)[62]. In addition to peptides, he isolated ureides



of *NN'*-dicyclohexylurea of the type $C_6H_{11}NHCONRC_6H_{11}$, where R = *N*-(*p*-toluenesulphonyl)-*DL*-phenylalanyl or *NN'*-phthaloyl-*DL*-phenylalanyl.

Using these methods, Amiard obtained a number of dipeptides of methionine, protecting the amino-groups with trityl groups $C(C_6H_5)_3$ and then condensing the protected methionine with esters of glycine and leucine[63]. The reaction was carried out in methyl chloride; the yield was 80–90%. Using the same method, Amiard[64] synthesised $\alpha$- and $\gamma$-glutamylpeptides, and Sheehan[65] synthesised di- and tri-peptides containing hydroxyamino-acids (serine and threonine).

The use of carbodiimides for the synthesis of peptides is of great preparative value. Previous methods were based on the activation of the carboxyl group taking part in the reaction, after which derivatives were obtained, for example acyl chlorides, azides, etc.[66] The use of cyclohexylcarbodiimide eliminated the necessity of using these derivatives, since in the presence of carbodiimides, peptides are formed directly as a result of the reaction of the free carboxyl group of one amino-acid molecule with the free amino-group of another molecule. The use of carbodiimides in the synthesis of peptides is dealt with in a number of original papers[67-70].



The use of carbodiimides in the synthesis of phosphorus-containing compounds. We have already noted that carbodiimides react with esters of phosphoric acid to form derivatives of pyrophosphoric acid[41]. In this way various esters and anhydrides of phosphoric acid can be obtained together with other compounds such as nucleotides, oligonucleotides, some coenzymes, etc.[66] Depending on the properties of the reagents, the phosphorylation reaction in the cold in aqueous pyridine solution, in anhydrous pyridine, or in dimethylformamide may take from several minutes to several hours[66].

*sym*-Tetrabenzyl-, tetraphenyl-, and tetra-*p*-nitrophenyl-pyrophosphate esters are obtained by condensing diesters of phosphoric acid[71]:

Adenosine diphosphate and adenosine triphosphate[72] and also a series of other important biochemical products[73-76] are obtained by the interaction of orthophosphoric acid with adenosine-5′ phosphoric acid in the presence of dicyclohexylcarbodiimide.

A symmetrical diester of pyrophosphoric acid is obtained by condensing two molecules of adenosine-5′ phosphoric acid in the presence of dicyclohexylcarbodiimide[77]:

where R is adenosine.

Todd and coworkers have synthesised nicotinamide–adenine dinucleotide in this way[78]. Another important coenzyme, flavin–adenine dinucleotide, was obtained in a similar way, but di-*p*-tolylcarbodiimide was used as a dehydrating and condensing agent[79]. Cytidine diphosphate choline and cytidine diphosphate ethanolamine were obtained with the aid of the same carbodiimide[80].

The use of carbodiimides in the synthesis of mixed acid anhydrides. Mixed acid anhydrides formed by the reaction of an amino-acid with adenosine-5′ phosphoric acid participate in the synthesis of protein, and interest in the synthesis of this type of compound is understandable[81]. The methods previously used for the synthesis of mixed acid anhydrides[82,83], for example the reaction of an acid chloride with the silver salt of adenosine-5′ phosphoric acid, or the action of amino-acid esters on the sodium salt of adenosine-5′ phosphoric acid, gave low yields.

The use of carbodiimides has enabled great progress to be made in this important field of synthesis. Berg[84] obtained derivatives of the anhydrides of *L*-serine, *L*-phenylalanine, *L*-tryptophan, and *D*-methionine by reaction of amino-acids with adenosine-5′ phosphoric acid in the presence of dicyclohexylcarbodiimide. Other important mixed anhydrides have been obtained with the aid of carbodiimides[84-86]. A mixed anhydride of adenylic and sulphuric acid (adenosine-5′ phosphosulphate), which is of biochemical interest, has been obtained in 40–50% yield by the action of concentrated sulphuric acid on adenosine-5′ phosphoric acid in the presence of dicyclohexylcarbodiimide in aqueous pyridine solution[87].

---o0o---

In conclusion, it should be noted that the cases of the use of carbodiimides which we have considered are of great preparative value and primarily lead to a reduction in the number of intermediate stages and to an increased yield of the desired products compared with other methods. When carbodiimides are used, complicated multi-stage syntheses are reduced to one or two steps in the majority of cases. Another important advantage of syntheses with the use of carbodiimides is the simplicity of these compounds as condensing and water-removing agents. Reactions in which carbodiimides are used are usually carried out under mild conditions at room temperature, or at a slightly higher temperature, with the use of such accessible solvents as ether, pyridine, or dimethylformamide. Dicyclohexylurea, which is formed as a result of these reactions, is poorly soluble in these solvents, and this facilitates the purification and separation of the reaction products. Moreover, the course of the reaction can be followed by observing the amount of substituted urea precipitated. These reactions, as a rule, do not take more than a few hours.

Because of the development of new methods of synthesising carbodiimides by the catalytic decarboxylation of isocyanates, they have become more accessible and the range available has been extended. On the whole, the outlook for the wide use of carbodiimides and poly(carbodiimides) is very promising.

2. Electromigration of impurities in alkali metals 229
3. Electromigration in various solvents (semiquantitative data) 230
4. Electromigration in dilute solutions based on Cd, In, Sn, Pb, Bi, Ag, Fe, Ni, etc. 231
5. Electromigration in binary liquid alloys 234
6. Relationship between electrical conductivity and electromigration in liquid metals 235
7. Study of the electrodiffusion potential in liquid metallic solutions 235

## I. INTRODUCTION

The concept of electromigration (or electrodiffusion, electrolytic migration, etc.) covers a range of phenomena associated with the directed displacement of the components of a solution when an electric current is passed through the solution. Since a real substance, even when chemically pure, in general consists of a solution either of different isotopes or of defects of different types in a matrix (vacancies, displaced atoms, etc.) and, moreover, contains activated complexes in a transition state, the phenomenon of electromigration may be and is observed even in pure substances.

The magnitude of the electromigration effect depends on various factors: the nature of the solution, the magnitude of the electric field, concentration, temperature, and other parameters. Since the directed displacement (migration) during electromigration (e.m.) takes place due to and by means of the random diffusion movements of individual particles, the direct relation between the elementary acts of diffusion and e.m. is obvious. If the external electric field applied to the system is weak compared with the atomic field, the role of the external field is merely a certain ordering of the individual elementary acts of diffusion but does not lead to a change in the mechanism of the acts themselves. This feature is related to the fact that a weak external field may be regarded as a perturbation which alters the number of particles undergoing migration with the field and against the field but does not influence the frequency of these displacements. The frequency of the displacements may depend on the external field when the change in potential energy associated with the displacement of a charged particle and its environment in the external field becomes comparable with the activation energy of the diffusion process. For this it is necessary to use a field with an intensity of $10^7$–$10^8$ V $cm^{-1}$, which is hardly possible.

The elementary act of diffusion is a fairly complex process, particularly in metals. A charge introduced into a metal should be screened by the conduction electrons. These screening electrons are usually not localised close to the central charge (impurity ion) and they cannot be regarded as moving behind the central charge like the rigid sheath of an ion. Thus the elementary act of diffusion in a metal involves not only the displacement of the charged impurity ion but also the redistribution of the conduction electrons in space, leading to more or less complete screening of the ion throughout the whole path of the displacement. In the case of electromigration, these processes take place together with the passage of current through the metal, so that the interaction of the ion itself and the screening charge with the stream of conduction electrons becomes significant. As a result of all these features, the electromigration effects characterise not only the charge of the ions of the components of the solution but also the state of the conduction electrons and the interaction of the former with the latter. Thus the study of electromigration makes it possible to investigate not only the electrical properties of the diffusing particles but also the mechanism and characteristic features of the elementary act of diffusion itself.

The phenomenon of e.m. has recently become one of the most widespread means of studying ionic crystals and semiconductors. In the case of ionic crystals this is due chiefly to the fact that in these crystals the e.m. (ionic conduction) is responsible for the electrical conductivity of the substance and is a property which is extremely sensitive to the formation of charged complexes, defects, etc., in the crystal. The study of e.m. in salts is facilitated by the possibility of producing intense electric fields ($10^4$–$10^5$ V $cm^{-1}$). The study of e.m. in semiconductors makes it possible to establish the sign and magnitude of the charge on the impurity, which determines its action as an alloying additive (donor or acceptor behaviour). In view of the importance of impurities in metallurgy and in semiconductor physics, the study of e.m. in these materials is being widely developed.

Unfortunately, insufficient attention is as yet being paid to the study of e.m. in metallic systems. This is due partly to the fact that the magnitude of e.m. in metals is relatively low (the transport numbers of ions in metallic solutions, in the most favourable case, amount to $10^{-4}$–$10^{-5}$ mole × × $faraday^{-1}$). In addition, the lack of a satisfactory theory of e.m. is hindering considerably the development of experimental work in this field. Only in recent years has interest in the study of e.m. increased, chiefly in connection with the discovery that it is possible to separate isotopes by means of e.m. in liquid metals. Work has also begun on the study of e.m in solid metallic solutions and pure metals, chiefly in the USSR. A characteristic feature is the effort to advance from qualitative on semi-quantitative studies to a precise quantitative characterisation of e.m. It should be noted, however, that until recently the interpretation of the results of e.m. measurements were oversimplified. Einstein's relationship between mobility and diffusion coefficient makes it possible to use the rate of movement of an impurity in an electric field to determine a certain characteristic with the dimensions of charge — "the effective charge" — whose magnitude is determined not only by the charge of the diffusing ion but also by all the interactions between this ion and the surrounding system of ions and electrons. In earlier work, however, this effective charge was identified with the "true charge" of the ion, and on this basis far-reaching conclusions were made regarding the nature of the interaction in solutions, etc. The position has recently changed somewhat. In the study of e.m., allowance is now being made for the so-called "electron wind", that is, the interaction of the stream of electrons (the electric current) with the impurity ions. These and other features complicate considerably the picture of diffusion migration in an electric field and make the interpretation of experimental data difficult. In particular, there is as yet no reliable method for calculating the "true charge" of an ion from the magnitude of the effective charge during electromigration in solid solutions.

In the study of e.m. in liquid metallic solutions, the position is even less satisfactory. Despite much work carried

out in this direction, there are very few trustworthy experimental data. This is due to the unreliability of the procedures used. The chief factor leading to incorrect results is apparently convection produced by the high current densities, heating of the alloy, and the influence of density gradients produced during electromigration.

Generally speaking, liquid solutions provide a simpler object for study than solid solutions. Since the activation energy of diffusion in liquid metals is smaller by about one order of magnitude than that in solid solutions and is close to the energy of the thermal movement of the atoms, the difference between the ground state and the transition state for a liquid is apparently of little significance. It is then possible, as a first approximation, to neglect the discontinuous nature of diffusion migrations and to take as a basis a model of electromigration according to which the impurity ion drifts at a constant velocity in a viscous liquid under the influence of an electric force. This treatment avoids the difficulties associated with a detailed examination of the immediate environment of the diffusing ion and facilitates the interpretation of experimental results.

Experimental work has revealed a fairly distinct boundary between e.m. in liquid and solid metals. This boundary apparently does not indicate any fundamental difference in their behaviour, but certain qualitative differences are evident. The main reasons for these differences may be assumed to be the absence of a rigid lattice in the crystals and, as already noted, the appreciable difference in the activation energies of diffusion. A position has thus arisen, in which studies in each of the two fields are carried out by different methods, and different results are obtained. The investigation of the reasons for the differences should lead to a better understanding of the mechanism of diffusion in both cases.

The present review deals with the results of the study of e.m. in liquid metallic solutions.

## II. PHENOMENOLOGICAL DESCRIPTION OF ELECTROMIGRATION IN LIQUID METALS

The first attempts to give a quantitative description of e.m. for the particular case of extremely dilute binary metallic solutions were made by Wagner[1] and Schwarz[2]. Wagner introduced the mobilities of the solvent and impurity $u_1$ and $u_2$, the coefficients of self-diffusion of the solvent $D_1$ and diffusion of the impurity $D_2$, the charges of the ions of the solvent $z_1 e$ and impurity $z_2 e$, where $e$ is the charge of the electron. The velocities of the ions in a field with intensity 1 V cm$^{-1}$ are

$$v_1 = \frac{z_1 e u_1}{300}; \quad v_2 = \frac{z_2 e u_2}{300}. \tag{1}$$

Wagner introduced the transport number of the impurity $t_2$ as the increase in the mole fraction of impurity at the cathode, related to a constant number of moles of the mixture at the cathode and divided by the number of equivalents of charge passed. Using Einstein's relationship

$$u_i = \frac{D_i}{kT}, \tag{2}$$

Wagner obtained[1,3]

$$\frac{t_2}{N_2} = \frac{96\,500}{300} \frac{z_2 D_2 - z_1 D_1}{\varkappa} \frac{Ned_1}{RTA_1}, \tag{3}$$

where $N_2$ is the mole fraction of the impurity, $\varkappa$ the conductivity of the solution in $\Omega^{-1}$ cm$^{-1}$, $N$ Avogadro's number, $d_1$ the density of the solvent, $A_1$ its atomic weight, $R$ the gas constant, and $T$ the absolute temperature. Wagner used formula (3) to calculate the values of $t$ for a number of amalgams, taking $z_1$ and $z_2$ equal to the chemical valencies.

Wagner's treatment of e.m. in liquid solutions cannot be regarded as satisfactory, for the following reasons.

1. If diffusion processes take place in a liquid, in most cases it is rational to select a system of taking readings which is related not to the liquid but to the vessel containing it. The total volume flow (the flow of particles multiplied by their volume) due to the diffusion of each component should then be equal to zero. In this case the kinetics of the process would be determined not by the two diffusion coefficients $D_1$ and $D_2$ but merely by a single hetero-diffusion coefficient $D = D_1 N_2 + D_2 N_1$ (see, for example, Belashchenko[5] and Wagner[6]).

2. The ions in the solution are influenced not only by the force of the field $Ff = eEz$, where $E$ is the field intensity, but also by other forces. In actual fact, in the presence of only field forces, all the ions of the solution or pure metal as a whole would be influenced by a force not equal to zero. Because of the electrical neutrality of the conductor, however, the passage of current through it should not lead to the production of a resultant force. It is therefore necessary to take account of other forces in addition to the field forces, and these should not be internal forces (of the type exemplified by Stokes' frictional forces), since the resultant of internal forces is equal to zero. These additional forces are produced by the interaction between the ion subsystems and the conductivity electrons. Moreover, it is necessary to take account of the interaction between different types of ion subsystem.

Schwarz[2] examined the problem of e.m. from a different viewpoint, making use of the analogy between the behaviour of charges in an electric field and that of particles of different mass in a gravitational field. A mass immersed in a liquid is acted upon by a displacing force. By analogy, when current is passed through a metallic solution, each impurity ion is acted upon by an "electrohydrostatic force" proportional to its volume and the solvent charge density. The charge densities of each component are

$$\alpha_1 = \frac{ez_1}{\bar{v}_1}; \quad \alpha_2 = \frac{ez_2}{\bar{v}_2}, \tag{4}$$

where $\bar{v}_1$ and $\bar{v}_2$ are the partial volumes of the solvent and impurity ions. Since the electrohydrostatic force opposes the field force (otherwise the components would not accumulate at the electrodes during e.m. but would be deposited on them), it should be directed towards the anode. Thus the impurity ion is acted upon by two forces: the field force $F_f = eEz_2$ and the electrohydrostatic force

$$F_{eh} = \bar{v}_2 \alpha_1 E, \tag{5}$$

which can be calculated from Archimides' law. The resultant force is

$$F_2 = F_f - F_{eh} = E\bar{v}_2(\alpha_2 - \alpha_1). \tag{6}$$

By using Einsten's relationship and taking the solvent as the fixed system of coordinates, Schwarz obtained

$$\frac{t_2}{N_2} = \frac{96\,500}{300} \frac{ND_2 d_1 e}{RTA_1 \varkappa} \left(\frac{z_2}{\bar{v}_2} - \frac{z_1}{\bar{v}_1}\right)\bar{v}_2. \tag{7}$$

The values of $z$ in Schwarz' treatment are arbitrary and are not equal to the ordinary chemical valencies.

Schwarz' treatment is also unsatisfactory, although it is better than Wagner's method. Schwarz does in fact take account of the existence of a force acting in a direction opposite to that of the field force, but he arbitrarily assumes that it is proportional to the volume of the ion. With this assumption, the total force acting on all the ions of the solution is again not equal to zero, and the condition of mechanical equilibrium between the current and the conductor is broken down.

Wagner[6] showed that Schwarz' introduction of the "electrohydrostatic force" is equivalent to the statement that in the solution the quantities of equal magnitude are not the transport numbers of each of the two components, as in Wagner's work[1], but the volume streams of the ions of each type, and this provides a more satisfactory description of the properties of the liquid. Wagner[6] also pointed out that no method has yet been found for determining the charges of the ions $z_1$ and $z_2$ (that is, for taking account of the interaction between the ions and the stream of electrons) and that formulae (3) and (7) are only approximate.

Drakin[7] calculated the stationary state in a concentrated binary solution on the basis of classical thermodynamics. In the virtual transfer of one mole of the first component from the origin of coordinates to the point $l$, the work of transfer is

$$A_1 = RT \ln \frac{a_0'}{a_l'}, \tag{8}$$

where $a_0'$ and $a_l'$ are the activities of the first component at the origin of coordinates and at the point $l$. At equilibrium, this work should be equal to the electrical work, so that

$$RT \ln \frac{a_0'}{a_l'} = \Delta U z_1 F, \tag{9}$$

where $\Delta U$ is the potential drop on the given section, and $F$ is the Faraday. Similarly, for the transfer of one mole of the second component in the opposite direction,

$$RT \ln \frac{a_l''}{a_0''} = -\Delta U z_2 F. \tag{10}$$

Combining (9) and (10), Drakin obtained the stationary-state equation

$$\ln \frac{a_0'}{a_0''} - \ln \frac{a_l'}{a_l''} = \frac{\Delta U F (z_1 - z_2)}{RT}. \tag{11}$$

The transport number $t_i$ in dilute solution is given by

$$\frac{t_i}{N_i} = \frac{D (z_1 - z_2) F^2}{\varkappa RT}. \tag{12}$$

The method used by Drakin to calculate the stationary state in e.m. was criticised by Baranowski[8], who pointed out that since the solution–current system is not an equilibrium system but merely a stationary system, it is necessary to apply to it the methods of not classical thermodynamics but the thermodynamics of irreversible processes. This criticism also applies to the theories of Schwarz and Wagner.

Baranowski[9,10] examined e.m. using Onsager's method. Let us use the symbols $I_k$ to denote the streams of the ions of the components, and $I_e$ to denote the stream of electrons. We then have

$$I_k = \sum_1^n L_{ki} X_i + L_{ke} X_e,$$
$$I_e = \sum_1^n L_{ei} X_i + L_{ee} X_e, \tag{13}$$

where $L_{ps}$ represents the kinetic coefficients ($L_{ps} = L_{sp}$), $n$ the number of components, and $X$ the thermodynamic forces

$$X_i = -\operatorname{grad} \mu_i - e_i \operatorname{grad} \varphi,$$
$$X_e = -\operatorname{grad} \mu_e + F \operatorname{grad} \varphi, \tag{14}$$

where $\mu_i$ is the molar chemical potential of the $i$th component, $e_i$ its molar charge, $\mu_e$ the molar chemical potential of the electron, and $\varphi$ the electric potential. Allowance is then made for the electrical-neutrality condition

$$\sum_1^n e_i c_i - F c_e = 0, \tag{15}$$

where $c$ is the concentration, and for the relationship between the flows of the components

$$\sum_1^n I_i \bar{v}_i = 0, \tag{16}$$

where $\bar{v}_i$ represents the partial volumes of the components, and the quantities $e_i'$ are introduced from the formulae

$$L_{ke} = \sum_{i=1}^{n-1} L_{ki} e_i'. \tag{17}$$

We then have[10]

$$I_k = \sum_{i=1}^{n-1} L_{ki} \left( X_i - \frac{\bar{v}_i}{\bar{v}_n} X_n + e_i' X_e \right),$$
$$I_e = \sum_{k=1}^{n-1} \sum_{i=1}^{n-1} L_{ki} e_i' \left( X_k - \frac{\bar{v}_k}{\bar{v}_n} X_n \right) + L_{ee} X_e. \tag{18}$$

The case of an extremely dilute binary solution is then taken. In this case

$$X_1 = -\operatorname{grad} \mu_1 - e_1 \operatorname{grad} \varphi,$$
$$X_2 = -e_2 \operatorname{grad} \varphi,$$
$$X_e = F \operatorname{grad} \varphi. \tag{19}$$

Introducing the symbol

$$e_1 - \frac{\bar{v}_1}{\bar{v}_2} e_2 - e_1' F = E^*, \tag{20}$$

Baranowski obtains for the stationary state ($I_1 = I_2 = 0$) the condition

$$\frac{\operatorname{grad} \mu_1}{\operatorname{grad} \varphi} = -E^*, \tag{21}$$

where the subscript "1" refers to the impurity.

In diffusion in a metallic solution, an electrodiffusion potential is produced

$$\frac{\operatorname{grad} \varphi}{\operatorname{grad} \mu_1} = \frac{t_1}{F}, \tag{22}$$

where $t_1$ is the transport number of the impurity, equal to $I_1/I_e$ when $\operatorname{grad} \mu_1 = 0$.

The relationship between the diffusion coefficient, $t_1$, and $E^*$ is given by

$$D = \frac{\varkappa t_1 RT [1 + \partial \ln f_1 / \partial \ln c_1]}{c_1 E^* F}, \tag{23}$$

where $f_1$ is the activity coefficient.

According to Baranowski[9,10], the quantity $E^*$ is the characteristic transport charge and has the significance of the "effective charge" of the impurity ions, calculated for 1 g-ion.

When $e_1' = 0$ and $\bar{v}_1 = \bar{v}_2$, Eqn. (21) becomes Drakin's formula (11). In the case of solid alloys, where the condition for the relationship between the streams of ions can

be neglected, the quantity $E^*$ becomes equal to $e_1 - e'_1F$ — see (20).

The quantities $\mu_i$ in (14) have the significance of the chemical potentials of the ions. The final result — Eqns. (21) and (22) — however, should contain the chemical potential of the "neutral" component, whose relation to the concentration of the solution is known from thermodynamic data. Let us denote the chemical potential of the first component (not the ion!) by the symbol $\mu_1^*$. We then have

$$\mu_1^* = \mu_1 + \frac{e_1}{F}\mu_e, \tag{24}$$

since in solution we have the equilibrium

$$i\text{th atom} \rightleftarrows i\text{th ion} + \frac{e_1}{F}(\text{electron}).$$

Thus

$$\operatorname{grad}\mu_1^* = \operatorname{grad}\mu_1 + \frac{e_1}{F}\operatorname{grad}\mu_e. \tag{25}$$

For a very dilute solution, however, $\operatorname{grad}\mu_e = 0$, so that $\operatorname{grad}\mu_1^* = \operatorname{grad}\mu_1$ and in Eqns. (21) and (22) it is possible to replace $\mu_1$ by $\mu_1^*$.

An examination of e.m. in a two-component metallic solution with any concentration at constant temperature was made by Belashchenko and Zhukhovitskii [11] for the particular case where $\bar{v}_1 = \bar{v}_2$, i.e. $I_1 + I_2 = 0$. Onsager's equations were written in the form

$$I_i = L_{ik}X_k (i, k = 1, 2, 3), \tag{26}$$

where $I_1$ and $I_2$ are the streams of ions of the first and second components, and $I_3$ the stream of electrons (summation with respect to $k$). The forces $X_i$ are

$$X_1 = -\frac{\partial\mu_1}{\partial x} - e_1\frac{\partial\varphi}{\partial x},$$
$$X_2 = -\frac{\partial\mu_2}{\partial x} - e_2\frac{\partial\varphi}{\partial x},$$
$$X_3 = -\frac{\partial\mu_3}{\partial x} - e_3\frac{\partial\varphi}{\partial x}, \tag{27}$$

where $\mu_1$, $\mu_2$, and $\mu_3$ are the chemical potentials of the individual ions (not the atoms of the components!) of the first and second types and of the electrons, $e_1$, $e_2$, and $e_3$ their charges (in cgs units), $x$ the coordinate of the length of the specimen, and $\varphi$ the electric potential. The electrical-neutrality condition is of the form

$$\sum_{i=1}^{3} e_i I_i = I, \tag{28}$$

where $I$ is the density of the external current passing through the system. From the condition $I_1 + I_2 = 0$, it follows [11] that

$$L_{11} = -L_{12} = L_{22},$$
$$L_{13} = -L_{23}. \tag{29}$$

The chemical potentials of the atoms $\mu^*$ (which can be measured in a thermodynamic experiment) were then introduced [11]:

$$\mu_1^* = \mu_1 - \frac{e_1}{e_3}\mu_3,$$
$$\mu_2^* = \mu_2 - \frac{e_2}{e_3}\mu_3. \tag{30}$$

Eqns. (30) are equivalent to Eqns. (24). Solution of systems (26)–(27) with allowance for (28)–(30) and the Gibbs–Duhem equation gives the result [11]

$$I_1 = c_1u_1E - D\frac{\partial c_1}{\partial x}, \tag{31}$$

where $\mu_1$ is the mobility of the first component, $E$ the field intensity due to the external current, and $E = I/\varkappa$, where $\varkappa$ is the conductivity. In e.m. the gradients of the chemical potentials of the ion and electron are combined in such a way that the diffusion (or electrodiffusion) stream depends, in the final analysis, only on the gradient of the chemical potential of the neutral atoms. This feature confirms the familiar view that the measurement of the potential jump at a phase boundary, not only by equilibrium measurements but also by kinetic measurements, is impossible.

Belashchenko and Zhukhovitskii [11] defined the "effective charge of the ion" $e_i^*$ by the relationship

$$u_i = \frac{D}{kT}e_i^*\frac{\partial\ln c_i}{\partial\ln a_i}, \tag{32}$$

where $a_i$ is the thermodynamic activity of the $i$th component. This charge has a simple physical significance: if a total moving force $F_i$ acts upon the $i$th ion in solution, we have

$$e_i^* = \frac{F_i}{E}, \tag{33}$$

where $E$ is the field intensity due to the external current. Thus the effective charge of the ion $e^*$ takes account of the ordinary field force, the interaction of the ion with the stream of electrons, the interaction of ion subsystems of different type, etc. The factor $d\ln c_i/d\ln a_i$ in (32) indicates, as usual, the deviations of the properties of the solution from ideal behaviour.

In the stationary state, $I_1 = 0$ and [11]

$$\frac{\partial\ln a_1}{\partial x} = \frac{e_1^*E}{kT}. \tag{34}$$

An analogous equation is applicable for the second component. The effective charges are related to one another by the condition that the total force acting on the whole of the solution is equal to zero (the condition of mechanical equilibrium)

$$c_1e_1^* + c_2e_2^* = 0. \tag{35}$$

It was shown [12] that Baranowski's formula (21) for the stationary state in the case of an infinitely dilute solution is equivalent to (34). In this case $E^*$ from (20) is equal to $Ne_1^*$, where $N$ is Avogadro's number.

In the case of diffusion in a non-uniform open specimen we should observe an effect which is the opposite of electromigration — the production of an electrodiffusion potential (e.d.p.). The suggestion that an e.d.p. exists in metals was first made by Lewis and coworkers [13]. For the value of the e.d.p. in the diffusion of an impurity from a very dilute solution into pure solvent, Schwarz [14] obtained the expression

$$t_1 = \frac{\Delta UF}{RT}, \tag{36}$$

where $t_1$ is the transport number of the impurity and $\Delta U$ the voltage between the solution and the solvent.

For the electric field in ordinary diffusion, the following expression was obtained [11]

$$\frac{\partial\varphi}{\partial x} = -\frac{1}{e_3}\frac{\partial\mu_3}{\partial x} - e_1^*\frac{D}{\varkappa}\frac{\partial c_1}{\partial x}\left(1 + \frac{c_1}{c_3}\right). \tag{37}$$

The first term on the right-hand side is the ordinary "internal" contact potential difference, that is, the contact potential difference when the jumps at the metal–vacuum interface are independent of composition; the second term

is the e.d.p. gradient. It can readily be shown that in the case considered by Schwarz, (36) and (37) are equivalent.

An interesting feature is that the e.d.p. gradient has a form which resembles Ohm's law. In actual fact, the factor $-D\frac{\partial c_1}{\partial x}$ in Eqn. (37) is equal to the flow of ions of the first component; the factor $-D\frac{\partial c_1}{\partial x}e_1^*\left(1+\frac{c_1}{c_2}\right)$ then describes a certain effective current density produced by the movement of the ions, and division of the current density by the conductivity $\varkappa$ gives the corresponding field intensity.

The heat of transport was also examined by Thompson's method [11]. It was shown that the heat of transport consists of two parts: a term related to the transport of the electronic charge $e_1 - e_2$ (compensating the transport of the ionic charges) from a point with one value for the chemical potential of the electron to a point with another value, and a term which describes the work of transport of ions with definite effective charges in the field of the external current $E$.

In this case the field and the electron stream perform work $(e_1^* - e_2^*)Edx$, where $dx$ is the path.

The results of this work [11] were generalised [15] for the case of an arbitrary $n$-component alloy. The calculations showed that the stationary distribution of each component in any case is determined only by the effective charge of the corresponding ion:

$$\frac{\partial \ln a_i}{\partial x} = \frac{e_i^* E}{kT}. \qquad (38)$$

The effective charges of the ions of different components are related to one another by the expression [see (35)]:

$$\sum_{i=1}^{n} c_i e_i^* = 0. \qquad (39)$$

Another approach to the problem of e.m. for the particular case of the separation of isotopes in an electric field was given by Klemm [16,17]. If $z_i$ is the valency, $\zeta_i$ the degree of ionisation, $N_i$ the mole fractions, $r_{ik}$ the "coefficients of friction" between particles of the $i$th and $k$th types and $v_{ik} = v_i - v_k$ the relative velocity of particles of the $i$th and $k$th types, the conditions for equality of the electric forces and the forces of friction for each type of particle can be written in the form:

$$\begin{aligned} -\zeta_1 z_1 F \operatorname{grad}\varphi &= r_{12}N_2 v_{12} + r_{1n}N_n v_{1n}, \\ -\zeta_2 z_2 F \operatorname{grad}\varphi &= r_{21}N_1 v_{21} + r_{2n}N_n v_{2n}, \\ \zeta_n z_n F \operatorname{grad}\varphi &= r_{n1}N_1 v_{n1} + r_{n2}N_2 v_{n2}, \end{aligned} \qquad (40)$$

where the subscript 1 refers to the light isotope, the subscript 2 to the heavy isotope, and the subscript $n$ to the electrons. It is assumed that $r_{ik} = r_{ki}$ and $z_1 = z_2 = z$. We also have

$$N_1 + N_2 = N_p,\ N_p + N_n = 1,\ N_n = zN_p,$$

$$\zeta_p = (N_1\zeta_1 + N_2\zeta_2)/N_p. \qquad (41)$$

The solution of system (40) has the form

$$\frac{v_{12}}{v_{pn}} = \left(\frac{\zeta_1 - \zeta_2}{\zeta_p} - \frac{r_{1n} - r_{2n}}{r_{pn}}\right) \Big/ \left(1 + \frac{r_{12}}{zr_{pn}}\right). \qquad (42)$$

The subscript $p$ is written where the difference between 1 and 2 is insignificant.

It was shown [16] that

$$z\zeta_p\left(1 + \frac{r_{12}}{zr_{pn}}\right) = \frac{RT\varkappa}{F^2 cD}, \qquad (43)$$

where $c$ is the concentration of the substance in g-equiv. $cm^{-3}$.

Klemm considers that this model cannot explain the experimentally observed movement of the light isotope towards the anode during electromigration and suggests that the ions of each type may exist in two states — mobile (activated) and immobile. It is then necessary, instead of the three equations (40), to write four equations: for the mobile ions of the light isotope, the mobile ions of the heavy isotope, the immobile ions, and the electrons. Using the subscript $b$ to denote the mobile ions and the subscript $u$ to denote the immobile ions, Klemm [17] obtained

$$\frac{v_{12}}{v_{pn}} = \frac{N_b}{N_p}\frac{v_{bn}}{v_{pn}}\frac{r_{2bu} - r_{1bu}}{r_{bn}} \Big/ \left(1 + \frac{N_b}{N_n}\frac{r_{1bab}}{r_{bn}}\right). \qquad (44)$$

The available experimental data on e.m. and diffusion in liquid metallic solutions do not, however, give sufficient grounds for accepting the hypothesis that the properties of ions in the ground state and transition state differ significantly. On the contrary, it has been shown [18,19] that diffusion in liquid metals is described satisfactorily by a theory which differs from the Frenkel'–Eyring theory and does not introduce the activation energy. Thus the question of the extent to which it is necessary to allow for the differences in the properties of the same ion at different moments of time (that is, at different points in its path) remains open. Nevertheless, the fact that the Stokes–Einstein relationship

$$D = \frac{kT}{4\pi\eta r}, \qquad (45)$$

applies satisfactorily to metallic solutions (see, for example, Ma and Swalin [19] and Sobol' [20]) indicates that the drift model is quite satisfactory. If this is the case, the differences in the properties of the ions at different points in its path can as a first approximation be assumed to be insignificant. It is possible that this is not the case for the effect of isotope separation by the e.m. method in liquid metals. Unique features may also be produced in liquid systems with strong interaction between the components (with the formation of intermetallic compounds), particularly at points close to the corresponding maxima on the liquidus curves. This question requires further study.

In the transfer of ions in electrolyte solutions it is necessary to take account of the relaxation and cataphoretic effects. Effects analogous to these may be produced in molten metals. In particular, the "electron wind" may be regarded as essentially an electronic cataphoretic effect. The relaxation effect, proportional to the rate of drift of the ions, is apparently negligibly small in metals, since in this case the fields which can be produced are weak. We may also, however, have an ionic cataphoretic effect, that is, entrainment of an ion during e.m. by the surrounding ions. This effect was examined [22] by the Debye–Fal'kenhagen method, with the assumption that each ion entrains its first coordination sphere, which moves as a single unit.

In a completely disordered solution there is no ionic cataphoretic effect, since the force acting on the first coordination sphere is equal to zero. When a statistical correlation exists, the second approximation of the theory of solutions [22] gives

$$e_i^{**} = e_i^*\left(1 + \frac{\Delta H}{2\pi\eta r_c N D}\right), \qquad (46)$$

where $e_i^{**}$ is the apparent effective charge, $e_i^*$ the effective charge taking account of only the "true charge" and the interaction with the conductivity electrons, $\Delta H$ the enthalpy of mixing of the given solution, $\eta$ its dynamic viscosity, $r_c$ the radius of the first coordination sphere, $N$ Avogadro's

number, and $D$ the diffusion coefficient. Formula (46) is applicable for $|\Delta H| \ll RT$, when the quasichemical method of the theory of solutions is applicable. Substituting $D$ from (45) and assuming that $r/r_c \simeq 1/3$, we obtain[22]

$$e_i^{**} \simeq e_i^{*}\left(1 + \frac{2}{3}\frac{\Delta H}{RT}\right). \quad (47)$$

Thus positive deviation from ideal behaviour should lead to the inequality $|e_i^{**}| > |e_i^{*}|$, and negative deviation should lead to the opposite inequality.

In the case where $|\Delta H| > RT$, it is fairly difficult to take account of the interaction of ions of different type during e.m. In this case, however, interesting effects are observed, particularly the inversion of the direction of e.m. at definite concentrations of the solution[23]. A solution of the problem of the influence of the strong interaction of ions in alloys on e.m. would be extremely useful.

## III. METHODS OF STUDYING ELECTROMIGRATION IN LIQUID METALS

The most common method involves the study of the stationary distribution of the components of the solution in a capillary. The liquid alloy is poured into the capillary and direct current is passed through it until a stationary state is established. The alloy is then cooled and analysed, graphs giving the distribution of the components along the capillary are constructed, and the electromigration characteristics are calculated.

Studies have shown[24,25] that the position and shape of the capillary have a very marked influence on the results of the experiment. In particular, the straight horizontal capillary used by Kremann and coworkers is unsuitable for the study of e.m. During e.m., a density gradient is produced along the capillary, leading to longitudinal convection; the heavier layers of metal flow under the lighter layers. Increase in the capillary diameter facilitates this process. Thus the results obtained in horizontal capillaries of appreciable diameter (1.5–3 mm) may be regarded as only qualitative.

Zigzag and spiral capillaries have been used[24,26-29] to reduce convection. This precaution is inadequate, since in the bends in the capillary, where the heavier component should migrate upwards, an unfavourable density gradient is created and convection is produced.

It is possible to estimate the part played by convection from the time required for the stationary state to become established. The order of magnitude of this time interval is

$$\tau \sim l^2/D, \quad (48)$$

where $l$ is half of the length of the capillary. For example, for a capillary with length 40–50 cm and $D \sim 10^{-5}$ cm$^2$ s$^{-1}$, the value of $\tau$ is ~ 300–400 d. The observed values, however, are $\tau_{obs} \simeq 20$ h,[23] $\tau_{obs} \simeq 300$–400 h,[27] and $\tau_{obs} \simeq 2000$ h,[24] that is, $\tau_{obs} \ll \tau$. Thus convection takes place in spiral and zigzag capillaries, so that the effective diffusion coefficient $D_{eff} \gg D$.

Straight vertical capillaries have also been used to study e.m.[25,30-34]. A vertical temperature gradient of ~ 0.5–1 deg cm$^{-1}$ was produced with a heater, and the direction of the current in the specimen was chosen in such a way that the lighter component migrated upwards. These precautions ensured a decrease in density from below upwards, and this favours suppression of convection. Under these conditions $\tau_{obs} \simeq \tau$.[35,36] For example, for a 40 mm column of metal, $\tau_{obs} \simeq 2$ d.

The influence of free convection and surface phenomena on diffusion was verified[25] in studies which showed that with change in the capillary diameter from 0.64 mm to 2.09 mm the diffusion coefficient of $^{113-123}$Sn in Pb at 350° changes insignificantly. Thus under these conditions (small) vertical temperature gradient, concentration of light component decreasing from above downwards) free convection can be suppressed. The same result was obtained in a study of the effect of the e.m. of $^{110m}$Ag in liquid Pb and Sn in capillaries with different diameters[25].

An extremely important factor in the capillary method is the current density. In work by Kremann and coworkers[23,37-47], a "saturation" effect was observed: at high current densities (10–20 A mm$^{-2}$ and above), the e.m. became independent of current density; this was attributed to the turbulent nature of the movement of the melt in the capillaries. At low current densities (~ 1 A mm$^{-2}$ and below) the e.m. effect is proportional to the current density[24,25].

It was established[48] that the scattering of electrons at the boundary between the molten metal and the walls of the capillary should produce electroconvection, in which the metal moves in the same direction as the electrons along the axis of the capillary, and in the opposite direction at the walls of the capillary. In this case the apparent effective charge will be less than the actual value. Let us introduce the symbol $z^*$ to denote the effective charge, expressed in units of the charge of the electron $e$, that is, $z^* = e^*/e$. It was shown[25] that

$$\frac{z^*}{z^*_{app}} = 1 + \frac{10^{-4}}{0.48 D_0 D}(1-\varepsilon)^2\left(\frac{end\lambda^2}{\eta}\right)^2 E^2, \quad (49)$$

where $D_0$ is the coefficient of self-diffusion of the solvent, $\epsilon$ a coefficient defining the proportion of electrons undergoing mirror reflection from the boundary, $d$ the diameter of the capillary, $n$ the concentration of free electrons, $\lambda$ the mean free path, $\eta$ the viscosity, and $E$ the field intensity.

It was found[22] that for the case of the e.m. of $^{60}$Co in liquid Sn at 350° the dependence of $z^*/z^*_{app}$ on $E^2$ is in fact linear up to a current density of 5.3 A mm$^{-2}$. The mean free path of the electrons, calculated from the slope of this straight line, is $2.2 \times 10^{-7}$ cm (with the assumption that $\epsilon = 0$), which is of the same order of magnitude as the value of $\lambda$ calculated from the electrical conductivity of tin ($0.92 \times 10^{-7}$ cm). The optimal current density in metals of the type Sn, Pb, and Bi, at which electroconvection can still be neglected, is 1–1.5 A mm$^{-2}$.

In this connection it should be noted that work on the separation of isotopes during e.m. in metals (the Haeffner effect)[49-52] is usually carried out at high current densities (10–20 A mm$^{-2}$ and above). This should lead to the development of electroconvection, so that the results obtained in this work can hardly be regarded as quantitative. The marked influence of electroconvection is indicated by the fact that the values of the effective diffusion coefficient in liquid Rb, K, and In [52] varied from $2.5 \times 10^{-4}$ cm$^2$ s$^{-1}$ to $10^{-3}$ cm$^2$ s$^{-1}$, that is, they are greater by 1–2 orders of magnitude than the real values. To obtain accurate results, it is necessary to carry out e.m. experiments at low current densities.

Another possible mechanism of the influence of current density on the e.m. effect was considered[35]: excitation of laminar convection as a result of the heating of the metal in a vertical capillary by the direct current. Since the temperature at the axis is slightly higher than that at the walls

of the capillary, the metal begins to rise along the axis and to descend at the walls, leading to convective agitation. It was found[35] that

$$\frac{z^*}{z^*_{app}} = 1 + 2.26 \times 10^{-7} \frac{R^{10}}{D^3} \left( \frac{g\beta\rho j^2}{\nu\gamma} \right)^3, \quad (50)$$

where $R$ is the capillary radius, $g$ the acceleration due to gravity, $\beta$ the coefficient of volume expansion, $\rho$ the resistivity, $j$ the current density, $\nu$ the kinematic viscosity, and $\gamma$ the thermal conductivity.

The convection effect is extremely sensitive to the radius of the capillary. It follows from formulae (49) and (50) that for a radius of 1 mm and current densities less than 10 A mm$^{-2}$, the effect of electroconvection should be more marked than that of thermal convection. At a radius of 2 mm and $j$ = 10 A mm$^{-2}$, however, the decisive role should be played by thermal convection (for common metals). In this case the ratio $z^*/z^*_{app}$ should be proportional to $j^4$ and not $j^2$. It is necessary, however, to take account of the fact that the presence of rough areas on the walls of the capillary or the existence of an immobile surface layer of liquid should suppress electroconvection.

Other reasons for the convective agitation of melts in capillaries during the passage of direct current have been discussed[53]: these include electroosmosis[54] and magnetic movement resulting from conicity of the capillaries. It was shown that convection and hence increased effective diffusion coefficients may be produced by a magnetohydrodynamic effect at conicities of the order of 0.01 cm$^{-1}$; the effect is proportional to the current density to the fourth power and the capillary radius to the tenth power. Unlike thermal convection — formula (50) — which develops in vertical capillaries, magnetohydrodynamic convection should be observed for any position of the specimen.

When the stationary state has been reached and fixed by cooling, the specimens are divided into sections and analysed, and a curve is constructed giving the dependence of the logarithm of the thermodynamic activity of a given component on the length along the axis of the specimen. The effective charge $z^* = e^*/e$ can be found from Eqn. (38)[31,32]. The authors of the works cited restricted themselves to the determination of the difference between the concentrations at the ends of the specimens or the calculation of various e.m. characteristics (for example, a constant[27-29] for which the name "electrodiffusion coefficient" was proposed), whose relationship to the effective charge can be established.

An interesting feature is that the e.m. effect depends little on temperature. Experimental work[24,25,27,47] has shown that change in temperature over a range of 100 deg has no influence on $z^*$ (there are grounds for expecting $z^*$ to show this behaviour, see below). The study of e.m. over a wide temperature range would be extremely valuable, however. Unique features in the behaviour of $z^*$ might possibly be observed at temperatures close to the melting point.

A direct determination of the rate of migration of an impurity in an electric field has been carried out[55,56]. Two identical capillaries, placed vertically and filled with mercury, were used. Contacts were sealed to the upper ends, and the lower ends were immersed in a dish containing mercury. If current is passed through the specimens in series, the two capillaries are heated to the same extent, and a differential thermocouple with junctions fixed at corresponding points in the capillaries will show no readings. If the mercury in one of the dishes is replaced by an amalgam, the impurity begins to migrate along the capillary and alters the resistance of the mercury. The temperature at different points in the capillary will then change as a result of the change in power. At the moment when the diffusion front reaches one of the thermocouple junctions, it will begin to give readings. From a knowledge of the time required for the diffusion front to move from the end of the capillary to the point where the junction was situated, Schwarz calculated the mobility of the impurities in mercury.

A feature of this method is that in the simultaneous e.m. of several impurities, the latter move at different rates and are separated in space, as in chromatography.

The mobilities of various impurities in mercury were studied[14] by measuring the electrodiffusion potential. To increase the effect, Schwarz connected ten cells in series, since the e.d.p. of a single cell amounted to $10^{-7}$–$10^{-8}$ V. The transport numbers of the impurities were determined from formula (36). The e.d.p. effect in liquid alloys of tin, lead, bismuth, tellurium, etc. has also been studied[57,58].

A method was recently proposed for studying e.m. in crossed electric and magnetic fields[59,60]. A gold amalgam was placed in a 10 cm × 1 cm × 0.025 mm vacuum-tight vessel. The electric current was passed in a direction parallel to the 1 cm edge and a magnetic field with induction 5500 G was applied in a direction perpendicular to the 10 cm × 1 cm face. After passage of a current of 15 A for 6 days, the amalgam at one end of the long edge showed threefold enrichment relative to that at the other end. The effect was assumed to be due to the fact that the velocities of the electrons directed at right angles to the electric and magnetic fields were not equal to zero (in a second approximation)[60]; the Hall field was assumed to be insignificant.

The force acting on the ion in crossed fields was calculated[61]. According to this calculation,

$$F_i = E_x e \bar{v}_i \left( \frac{z_i}{\bar{v}_i} - \frac{z_0}{\bar{v}_0} \right), \quad (51)$$

where $z_i$ and $z_0$ are the true charges of the impurity and solvent ions, $\bar{v}_i$ and $\bar{v}_0$ their volumes, and $E_x$ the intensity of the Hall field. Application of formula (51) to Knof's results[59] gives an absurd result for $z$ for gold (of the order of $10^4$ units of electronic charge[35]). Calculations made by Knof[60] also give a value for the effect which is smaller by two orders of magnitude than that observed in earlier work[59]. Further studies are required to find the reasons for this discrepancy. It is possible that in the earlier work[59] a characteristic multiplication effect operated, analogous to that in thermal-diffusion columns.

## IV. DETERMINATION OF THE EFFECTIVE CHARGES OF IONS IN METALLIC SOLUTIONS

As pointed out above, in order to establish the significance of the effective charge it is necessary to examine all the forces acting on the ion of a given type. According to Mangelsdorf[62], it is necessary to take account of the following forces: (1) the ordinary field force; (2) a force due to polarisation of the non-localised electrons by the field; (3) a force due to polarisation of the electrons by the current (the conductivity electrons are scattered on the ions and should "push" the charge cloud screening the ion in the direction of their movement; (4) a force due to polarisation of the surrounding ions by the field; and (5) a force related to the polarisation of the surrounding ions by the current.

Finally, if chemical forces operate between the impurity ion and the surrounding solvent, an important factor, according to Mangelsdorf[62], is the ratio of the radius of influence of these forces to the mean free path of the electrons, that is, the number of collisions with ions undergone by an electron scattered by the impurity in the sphere of action of the chemical forces. Mangelsdorf[62] did not give an analysis of the relative part played by these factors.

If the interaction between the ions of the components is not significant (energy of mixing $\Delta\epsilon = \epsilon_{12} - \frac{\epsilon_{11} + \epsilon_{22}}{2} \ll kT$, where $\epsilon_{ik}$ is the energy of interaction of pairs of ions which are nearest neighbours), the chief forces acting on an ion in a metal during e.m. are the field force and the "force of the electron wind" (forces 1 and 3 according to Mangelsdorf[62]). The first of these is determined by the so-called "true charge" of the ion and the second by the intensity of the interaction of the ion with the current. To describe the interaction it is more convenient to use not the coefficients of friction $r_{ik}$ introduced by Klemm[16,17] but the cross-section for the scattering of electrons on the ions[63].

Calculation of the interaction force of the electrons with the current, carried out by Fiks[64] for a free-electron model (degenerate gas), leads to the expression

$$F_e = -eEnl\sigma, \qquad (52)$$

where $e$ is the charge on the electron, $E$ the field intensity, $n$ the concentration of free electrons, $l$ the mean free path on the Fermi level, and $\sigma$ the cross-section of scattering of the electron on the impurity ion. In the case of a pure metal, $nl\sigma = z$, where $z$ is the valency of the ion, so that the force $F_e$ is equal to the field force $zeE$ with the opposite sign; this satisfies the condition for mechanical equilibrium of the specimen.

Fiks[64], like Klemm[17], assumed that it is necessary to take account of the differences in the properties of the ions in the ground state and transition state for e.m. in liquid metals, at least for the case of the separation of isotopes. For the total force acting on the $i$th ion in the transition state ("activated ion"), Fiks[64] obtained

$$F_i = eE\left(z_{ti} - \bar{z}\frac{\sigma_i^*}{\bar{\sigma}}\right), \qquad (53)$$

where $z_{ti}$ is the "true charge" of the $i$th ion in the transition state, $\sigma_i^*$ the corresponding cross-section of scattering, $\bar{z}$ and $\bar{\sigma}$ the mean values of $z$ and $\sigma$ for all the components of the solution. Thus for the effective charge the following expression is applicable

$$e_i^* = ez_i^* = \frac{F_i}{E} = e\left(z_{ti} - \bar{z}\frac{\sigma_i^*}{\bar{\sigma}}\right), \qquad (54)$$

that is,

$$z_i^* = z_{ti} - \bar{z}\frac{\sigma_i^*}{\bar{\sigma}}. \qquad (55)$$

It was shown[31] that relationship (55) can be obtained directly from the condition for mechanical equilibrium of the specimen (39). Here it was assumed that the difference in the electrical properties ($z$ and $\sigma$) of different ions of the same component is insignificant for e.m. in liquid metallic solutions. Thus for a two-component solution the following expressions are applicable[31]:

$$z_1^* = \frac{N_2(\sigma_2 z_1 - \sigma_1 z_2)}{\sigma_1 N_1 + \sigma_2 N_2},$$

$$z_2^* = \frac{N_1(\sigma_1 z_2 - \sigma_2 z_1)}{\sigma N_1 + \sigma_2 N_2}, \qquad (56)$$

where $z_i$, $\sigma_i$, and $N_i$ are the "true charge" of the $i$th ion, the cross-section of scattering of the conductivity electrons on the $i$th ion, and the mole fraction of the $i$th component respectively. For a very dilute solution ($N_2 \to 0$):

$$z_1^* \simeq 0, z_2^* = z_2 - z_1\frac{\sigma_2}{\sigma_1}. \qquad (57)$$

Determination of the values of the true charges on the ions of the components in different solutions would give information on the type of bond and the distribution of electrons close to the impurity atom, and would undoubtedly be extremely valuable for the theory of the metallic state. On the other hand, a knowledge of the cross-section of scattering is of interest for the theory of electrical conductivity, the thermal conductivity of metals, etc. It can be seen from (57)–(59) that it is impossible to calculate unambiguously all the values of $z$ and $\sigma$ for the ions of the components of the solution merely from e.m. data. It has been shown[30,31,33,34], however, that fairly reliable data on $z$ and $\sigma$ can be obtained by studying e.m. in a series of suitably selected solutions, for example, with a common solvent or a common impurity.

To estimate the cross-section for scattering of the electrons on the impurity ion $\sigma$ it is possible to use the relationship between $\sigma$ and the influence of the impurity on the electrical resistance of the solvent[65,66]

$$\Delta\rho_i = \frac{mv_0}{e^2} N_i\sigma_i, \qquad (58)$$

where $mv_0$ is the impulse of the electron on the Fermi level, $e$ its charge, $N_i$ the atomic fraction of the impurity, and $\Delta\rho_i$ the residual resistance due to the impurity. In the case of liquid alloys, however, Eqn. (58) appears to be unsuitable. According to (58), $\Delta\rho_i$ should always be positive. For solid solutions this is almost always the case. In the case of liquid alloys, however, positive values of $\Delta\rho$ are encountered no more frequently than negative values. This is due to the fact that in systems with low affinity of the components (for example, in simple eutectic systems) a tendency towards additivity of the resistivity of the alloys is observed. The applicability of Eqn. (58) to liquid alloys is thus doubtful.

Mott[65,66] examined a solution of a multivalent impurity in a univalent metal and used, to calculate $\sigma$, the ordinary theory of scattering of electrons by a force centre with spherically symmetrical field[63]. The form of the force field was obtained by the Thomas–Fermi method as a screened coulombic potential

$$\varphi = \frac{\Delta ze}{r}e^{-\beta r}, \qquad (59)$$

where $\Delta z$ is the difference in the valencies of the impurity and solvent, $\beta$ a screening constant, and $r$ the distance from the ion. Thus for the value of $\sigma$ we have[65]

$$\sigma = \frac{\pi}{2}\frac{e^4(\Delta z)^2}{\epsilon_0^2}\left\{\ln\left(1+\frac{1}{y}\right) - \frac{1}{1+y}\right\}, \qquad (60)$$

and

$$\frac{1}{y} = \frac{(2mv_0)^2}{\beta^2\hbar^2}. \qquad (61)$$

where $\epsilon_0$ is the Fermi energy and $\hbar$ Planck's constant divided by $2\pi$. Substitution of the value of $\beta$ gives for $1/y$ the expression

$$1/y = 5.1 \times 10^{-8} n^{1/3} z^{1/3}, \qquad (61a)$$

where $n$ is the concentration of free electrons and $z$ the charge of the ion.

It was also pointed out[65], however, that in metals the electron density is insufficiently high for the Thomas–Fermi method to be completely applicable. Kun[67] calculated the residual resistance for a solution of gold in silver; the electron density was found by the Thomas–Fermi method. and also by exact solution of the Schrödinger equation. The two methods gave similar values for $\Delta\rho$ (0.16 $\mu\Omega^{-1}$ per 1 at.% Au), which showed poor agreement with the experimental value (0.38 $\mu\Omega$ $cm^{-1}$ per 1 at.% Au). According to Kun[67], the discrepancy is due to the fact that the free-electron model is not completely applicable to the phenomenon of electrical conductivity. The results given by formula (60) are therefore only of the correct order of magnitude.

The cross-sections of scattering for impurities in multivalent-metal solvents have apparently not been calculated.

## V. RESULTS OF STUDIES OF ELECTROMIGRATION IN LIQUID METALLIC SOLUTIONS

### 1. Electromigration in Amalgams

A number of studies have been made of the phenomenon of e.m. in amalgams[13,14,23,24,43,46,55,56,68-72]. Some of these studies[13,14,24,55,56,72] produced more accurate results than the others, in which inadequate procedures made it impossible to obtain reliable results.

Lewis and coworkers[13] found that traces of sodium and potassium in dilute amalgams move towards the anode during e.m., that is, exhibit a negative effective charge. They therefore suggested[13] that the alkali metal atoms undergo chemical reaction with mercury, forming more or less stable complexes which are the actual diffusion units. These investigators noted[13] a relationship between the magnitude of the e.m. effect and the influence of the impurity on the electrical resistance of mercury. This correlation led them to the conclusion[13] that e.m. in amalgams is due to "friction" between the complexes and the stream of conductivity electrons.

The existence of "friction" between complexes and the stream of conductivity electrons was suggested even earlier by Skaupy[73,74], in whose opinion these complexes should also influence the viscosity, the conductivity being smaller, the greater the increase in viscosity of mercury when the impurity is added. If the impurity decreases the resistance of mercury, it should move to the cathode during e.m.

Results obtained[24] for amalgams of Na, Ba, Li, and Ca confirmed this viewpoint (see Table 1). The movement of complexes towards the cathode can be understood, however, only if account is taken of the action of the ordinary field force on the positive charge.

The results obtained by Schwarz by different methods are summarised in his monograph[14] and are given in Table 2. The second column gives the values of the transport numbers at 25°, divided by the atomic fraction of the impurity. The third column gives the values of the velocity of migration $V$ (cm $h^{-1}$) for a field intensity of 1 V $cm^{-1}$. The positive sign denotes that the impurity migrates towards the cathode. An interesting feature is that the values of the mobilities of the impurities in mercury, obtained by three different methods (establishment of the stationary state in a capillary, direct measurement of the velocity of migration, and measurement of the e.d.p.) show satisfactory agreement with one another[14], apparently indicating that in Schwarz's measurements convection played little part.

The fourth column of Table 2 gives the values of the diffusion coefficients $D$ for impurities in mercury at 25°, measured by Schwarz[76]. We used this data and the relationship

$$V(\text{cm h}^{-1}) = \frac{3600ez^*D}{300\,kT}, \qquad (62)$$

to calculate the effective charges $z^*$ of the impurities in mercury (fifth column in Table 2). The sixth column gives the values of the increments in the resistivity per 1 at.% of impurity[75].

It can be seen that for most impurities a relationship is observed between the signs of $z^*$ and $\Delta\rho$: a positive value of $z^*$ corresponds to a negative $\Delta\rho$, and vice versa. This correlation is not observed for Tl, Pb, and Bi; the first two undergo almost no migration in the field, and bismuth moves on the "wrong" direction. The suggestion that there exists friction between complexes and the stream of electrons evidently does not make it possible to explain all the phenomena of e.m. in amalgams.

The dependence of $z^*$ on $\Delta\rho/c$ (Fig. 1) constructed from the data in Table 2, shows that most impurities can be divided into groups, within which the relationship between $z^*$ and $\Delta\rho/c$ is approximately linear. However, if we construct the dependence of $\Delta\rho/c$ on the relative change in volume on the dissolution of impurities in mercury, we find that Zn, Cd, Tl, Sn. Pb, and Bi lie satisfactorily on the

TABLE 1. Electromigration of impurities in mercury[13] and their influence on the resistivity of mercury[75].

| Impurity | Composition, at.% | Current density $j$, A $mm^{-2}$ | Specific e.m. effect, $\Delta/j$ | Increment in resistance $\Delta\rho/c$, $\mu\Omega$ cm (at.%)$^{-1}$ | Direction of movement |
|---|---|---|---|---|---|

| Ga | 52 | 2.9 | — | ~1 | — |

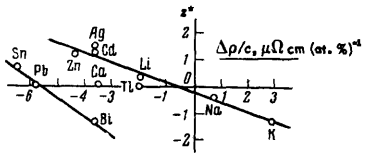

Fig. 1. Dependence of the effective charges of impurities in mercury on the increments in the electrical resistance.

same straight line[62]. The point corresponding to the changes in volume and resistivity during the crystallisation of mercury lies on the same straight line. This gave grounds for the suggestion[62] that the influence on the resistivity of mercury shown by those impurities which lower the resistance is that which would be expected if a certain volume of mercury "crystallised" around the impurity atom. This process leads to a decrease in resistance.

A noteworthy feature is that traces of Sn, Pb, and Bi in mercury form a separate group in Fig. 1. The displacement of the effective charges for these impurities towards more negative values compared with the other impurities may be due to the fact that, in addition to the above-mentioned complexes formed close to the impurity atoms, other factors also have an influence in this case, for example, the true charge $z$. It is significant that Sn, Pb, and Bi are multivalent, whereas the other metals given in Fig. 1 are univalent or bivalent (the properties of thallium resemble those of a univalent metal). The large excess of charge on the Sn, Pb, and Bi ions should lead to increased scattering of electrons on the impurity ions and should therefore displace $z^*$ towards more negative values.

The interesting phenomenon of inversion of e.m. was observed in amalgams of Na, K, and Ba.[23,43] The experiments were carried out in 20–80 cm capillaries with internal diameter 0.4–1.6 mm, at 240° and current density 3–7 A mm$^{-2}$. The duration of the experiment was 70 h. It was found that at impurity concentrations less than 15 at.% Na, 11 at.% K, and 3.9 at.% Ba, the impurities move towards the anode, whereas at higher concentrations they move towards the cathode.

In these systems the interionic interaction apparently has a significant influence on e.m. In the solid state a whole series of intermetallic compounds is formed ($BaHg_{11}$, $KHg_3$, $KHg_2$, KHg, $NaHg_4$, $NaHg_2$, etc.)[77], so that the short-range order in liquid amalgams should show corresponding characteristic features. There may be a change (even in the sign) of the "true charge" of each ion. Moreover, in systems with appreciable interionic interaction, the ionic cataphoretic effect discussed above may play an important part.

## 2. Electromigration of Impurities in Alkali Metals

From the viewpoint of the theory of the e.m. of impurities in alkali metals, an extremely interesting feature is that these metals are the simplest materials for study, and it is possible to carry out quantitative calculations for them; a number of studies have been made of e.m. in alkali metals[27–29,35,78–80]. Drakin and Mal'tsev[27] studied e.m. in the sodium–potassium system at 100° in bent capillaries and found that in this case inversion of the e.m. takes place; at concentrations less than 48 wt.%, sodium migrates towards the anode, and at higher concentrations it migrates towards the cathode. Study of the e.m. of traces of mercury (0.4 at.%) and lead (0.6 at.%) in liquid potassium at 100°[28] showed that in both cases the impurity migrates towards the anode, the e.m. effect being much greater than that in the liquid systems previously studied.

The e.m. of traces of thallium in potassium (0.19 at.%), mercury in sodium (0.6 at.% and 1.1 at.%), lead in sodium (0.45 at.%), and cadmium in sodium (0.21 at.%) was studied at 110° in a 15 cm capillary with internal diameter 2 mm.[29] The capillary was bent to form a spiral, and ten platinum leads were sealed into the walls of the capillary at equal intervals to measure the electrical resistance. It was possible to measure the e.m. effect with sufficient accuracy only for solutions of mercury in sodium and of thallium in potassium. More precise data for Pb and Cd in Na, and for Hg in K, were obtained later[78].

The effective charges $z^*$ of impurities in sodium and potassium, calculated from electrodiffusion coefficients[28,29,78] had the following values:

| Solvent | Na | Na | Na | K | K | K |
|---|---|---|---|---|---|---|
| Impurity | Hg | Pb | Cd | Tl | Hg | Pb |
| $z^*$ | −18 | −27.2 | −7.3 | −20 | −12.6 | −22 |

It was suggested[29] that the reason for such high negative values of $z^*$ for impurities in sodium and potassium is the entrainment of the particles of impurity by the stream of electrons ("electron wind").

The e.m. of $^{115m}$Cd and $^{204}$Tl in liquid sodium at 120° (impurity concentration 0.5 wt.%) was studied[35] in straight vertical capillaries with a 50 mm column of metal and internal diameter 1 mm. Electrodiffusion annealing was continued for 20 days with the passage of a current with strength 1.5 A through the specimens. The values found for the effective charges of Cd and Tl in sodium at 120° were -70 units and -55 units (accuracy ±15%). These charges were calculated for specimens with favourable direction of migration of the impurity (from above downwards).

The e.m. in a ternary K–Na–Hg system containing 46 wt.% Na, 50 wt.% K, and the rest Hg for different annealing times at 30° was studied[79] in a 77 mm vertical capillary with internal diameter 1.67 mm. Ten sealed-in platinum leads were used to follow the change in the concentration of the solution during e.m. It was assumed that in a melt with the above composition, potassium and sodium do not take part in e.m. (without allowance for the mercury, the composition coincides with that for which inversion of e.m. was observed[27]). The kinetic e.m. curves gave for the diffusion coefficient of mercury the value $1.16 \times 10^{-5}$ cm$^2$ s$^{-1}$ and for the "electrodiffusion constant" the value $1.82 \times 10^5$ deg V$^{-1}$. This value corresponds to an effective charge $z^* = -15$. This value is approximately equal to the mean of the values of $z^*$ for mercury in sodium and potassium.

The results of the measurement of the e.m. of impurities in alkali metals can be compared with their influence on the resistance of the solvent. Since the absolute value of $z^*$ for the impurities is high in all cases, it may be assumed that $|z| \ll |z^*|$. It then follows from (52) that

$$z_i^* \simeq -nl\sigma_i. \qquad (63)$$

From (63) and (58) we obtain

$$z_i^* \simeq -\frac{\Delta\rho_i}{N_i\rho_0}, \qquad (64)$$

where $\Delta\rho_i$ is the change in the electrical resistance of the solvent when the impurity is introduced, $N_i$ its mole fraction, and $\rho_0 = mv_0/(e^2nl)$ the electrical resistivity of the pure solvent.

Values were obtained for $\Delta\rho$ for a number of impurities in liquid sodium[81]. These can be used to calculate $z_i^*$(calc.). These values of $z^*$ are given in Table 3, together with published values[28,29,35].

The values of $z^*$ obtained experimentally in spiral capillaries[28,29] (Table 3) are much lower than the values obtained in vertical capillaries[35] and the values calculated from formula (64). On the other hand, the results obtained in vertical capillaries[35] show satisfactory agreement with the values of $z^*$ calculated from Eqn. (64). It may thus be assumed that Eqn. (58) is applicable to dilute solutions based on liquid sodium.

It is possible to verify the applicability of the Thomas–Fermi model for the case of solutions of impurities in sodium. The cross-section of scattering $\sigma$ for impurities with different ion charges in Na and K at 100° was calculated from Eqn. (60)[35] and the effective charges $z^*$ were calculated from the formula[61]:

$$z^* = z - nl\sigma \qquad (65)$$

(see Table 4). It can be seen from Table 4 that the calculated values of $z^*$ for impurities with an ion charge $z \leqslant 2$ have a reasonable order of magnitude, but that for $z = 3$ the calculation gives values of $z^*$ which are not observed experimentally.

The use of the Thomas–Fermi method in this case is hardly valid, since there is a fairly strong interaction between the atoms of the impurities Cd, Pb, Hg, etc. and the solvent. In the solid state, the alkali metals react with heavy metals to form intermetallic compounds of the type $NaCd_2$, $K_2Pb$, KTl, etc.[77] This interaction leads to ordering of the solvent close to the impurity atom: the bond becomes covalent or even partly heteropolar. The valency electrons of the impurity will therefore not become non-localised in the usual sense.

TABLE 4. Effective charges of impurities in alkali metals at 100°, found by Thomas–Fermi method.

| $z$ for impurity | $\Delta z = z - 1$ | In potassium | | In sodium | |
|---|---|---|---|---|---|
| | | $10^{16}\sigma_i$, cm$^2$ | $z^*$ | $10^{16}\sigma_i$, cm$^2$ | $z^*$ |
| 1 | 0 | 0 | 1 | 0 | 1 |
| 2 | 1 | 2.27 | —42 | 1.34 | —49 |
| 3 | 2 | 10.7 | —207 | 6.16 | —235 |
| 4 | 3 | 25.8 | — | 15.3 | — |

TABLE 5. Effective charge of the spherical nonconducting complexes (radius = $r$) in potassium and sodium at 100°.[35]

| $10^8 r$, cm | Effective charge | |
|---|---|---|
| | in potassium | in sodium |
| 1 | —24 | —48 |
| 2 | —97 | —192 |
| 3 | —219 | —435 |

It was shown[22] that when the bonding is strong, it is possible to use a model according to which the impurity atom forms a stable complex with the solvent which behaves during e.m. as a non-conducting sphere of radius $r$. In this case[63]

$$\sigma = 4\pi r^2, \qquad (65a)$$

from which, in accordance with (63),

$$z^* = -4\pi nlr^2. \qquad (66)$$

The calculated values of $z^*$ for impurities in K and Na (Table 5) show that the non-conducting sphere model gives reasonable values of $z^*$ when the radii of the complexes have the values 1–2 Å. The real radius should be about twice this value. Thus the non-conducting sphere model gives values of $z^*$ which are too high by a factor of $\sim 2$–4. A possible reason is that the region inside the complex is not completely inaccessible to the conduction electrons, so that the non-conducting sphere model is not applicable in these cases.

The e.m. of oxygen in liquid sodium at 300° was studied[80] in U-shaped Pyrex capillaries with broadened sections at the ends. Extensive migration of oxygen towards the anode was observed, amounting to several tenths of a milligramme of oxygen for every 3600 C of electricity passed, at an average oxygen concentration of $\sim 5 \times 10^{-2}$ wt.%. Calculation using formula (62) shows that the value of $z^*$ for oxygen in liquid sodium has an order of magnitude of $-10^4$. If these results are reliable, they may be explained by means of the non-conducting sphere model. According to (66), the value of $z^*$ is $-10^4$ for $r \simeq 15$ Å, that is, the complex should contain 100–150 atoms of oxygen and sodium.

### 3. Electromigration in Various Solvents (Semiquantitative Data)

Here we shall deal chiefly with the results of Kremann and coworkers, but also some data obtained by others[26,82,83]. Kremann characterised the e.m. effect by the difference ($\Delta$) in the weight percentages of each component at the ends of the specimens. The results which he obtained can be regarded as only qualitative, because of the unsatisfactory features of the procedure used.

Drakin[26] made a special study of e.m. in eutectic tin–bismuth and cadmium–bismuth alloys close to the eutectic

point. If the initial state of the alloy is given by a point close to the eutectic on the equilibrium diagram, the portions of the alloy at the ends of the specimen during e.m. may fall in two-phase regions of the diagram, as a result of enrichment in one of the components. The corresponding solid solutions or pure metals begin to separate from the melt. It was shown[26] that the e.m. method makes possible the fairly satisfactory separation of the original eutectic alloy into almost pure components, particularly if the solid components have a higher resistivity than the liquid.

The results obtained by Kremann and coworkers and by other workers[26,82,83] are given in Table 6. The sixth column gives the components migrating towards the cathode, the fifth column gives the current density $j$, and the seventh column gives the e.m. effect $\Delta$.

Kremann[84] tried to explain his results on the basis of Skaupy's ideas[73] regarding dissociation in metallic solutions. According to Kremann, the more positive component in the solution should be the one with the lower ionisation energy; this component will also migrate to the cathode during e.m. Kremann[84] arranged the substances which he studied in the following order:

$$\text{Br Sb Hg Pb Sn Zn Cd Cu Ag Al Na K}. \qquad (67)$$

A solution component lying to the right in series (67) should migrate to the cathode during e.m.

Let us write in the same order the first ionisation potentials of the atoms of series (67) (in eV):

$$7.25 \quad 8.35 \quad 10.41 \quad 7.37 \quad 7.54 \quad 9.37 \quad 8.94 \quad 7.67 \quad 7.58 \quad 5.94 \quad 5.09 \quad 4.32. \qquad (68)$$

TABLE 6. Electromigration in liquid metallic alloys[26,82,83,14].

| System | Temperature, °C | Concentration, wt. % | Duration of annealing, h | Current density, A mm$^{-2}$ | Component moving to cathode | Effect $\Delta$, wt. % | Refs. |

* Summarised results[14].

No appreciable tendency towards a monotonic change in ionisation potential is observed in series (68), so that the sequence (67) proposed by Kremann is purely empirical. Series (67) cannot explain all the observed e.m. data. For example, Na and K in amalgams migrate to the cathode only in sufficiently concentrated solutions. Sometimes series (67) predicts incorrectly the direction of migration, so that it may be assumed that the description of the direction of e.m. in different systems by a simple analogy with the potential series is hardly possible.

## 4. Electromigration in Dilute Solutions Based on Cd, In, Sn, Pb, Bi, Ag, Fe, Ni, etc.

The e.m. of traces of the radioactive isotopes $^{65}$Zn, $^{113-123}$Zn, $^{115m}$Cd, $^{72}$Ga, $^{210}$Bi, $^{75}$Se, $^{45}$Ca, and $^{110m}$Ag was studied in liquid lead, cadmium, bismuth, and tin[30,85], in 40 mm capillaries with internal diameter $\sim 1$ mm, at a current strength of 1.5 A, with duration of electrodiffusion annealing equal to 15 days. An interesting feature is that in most cases the value obtained for the effective charge was slightly higher when the light component migrated upwards. This means that the slight changes in density during e.m. in dilute solutions are still able to produce weak convection currents in the capillary. It can be seen from Table 7 that the direction of e.m. in the systems studied agrees with that found earlier by Kremann — see the "potential" series (67).

A semi-empirical relationship which makes it possible to explain the values of $z^*$ for the solutions studied was obtained[30]. An attempt was made to calculate the effective charges of the impurities in various solvents making the following assumptions: (1) the cross-section of scattering is proportional to the square of the "true charge" of the ion (of both impurity and solvent); and (2) the "true charge" of the ion is equal to the number of its group $\bar{z}$ in Mendeleev's Periodic System. Thus from (57) we have

$$z_2^* = z_2 - \bar{z}_1\left(\frac{\bar{z}_2}{\bar{z}_1}\right)^2 = \bar{z}_2 - \frac{\bar{z}_2^2}{\bar{z}_1}. \qquad (69)$$

The values of $z_2^*$ calculated from formula (69) are given in the sixth and last columns of Table 7. The good agreement between experiment and formula (69) is noteworthy. Deviations from the calculated values are observed only for silver and calcium. These results indicate that Belashchenko's suggestions[30] regarding $z$ and $\sigma$ for metallic solutions are apparently correct.

From this it follows, in particular, that the model assuming incoherent scattering of the conductivity electrons on the force centres is applicable to the case of liquid alloys

TABLE 7. Effective charges of impurities in various solvents[30,85].

| Solvent | Impurity: element | Impurity: wt. % | Temperature, °C | $z_2^*$ (mean) | $\bar{z}_2 - \frac{\bar{z}_2^2}{\bar{z}_1}$ | Solvent | Impurity: element | Impurity: wt. % | Temperature, °C | $z_2^*$ (mean) | $\bar{z}_2 - \frac{\bar{z}_2^2}{\bar{z}_1}$ |
|---|---|---|---|---|---|---|---|---|---|---|---|

* Taken from Belashchenko[35].

not only for the impurities but also for the solvent. Thus the resistance of a pure liquid metal can be described not by the approximation assuming scattering of the electrons on phonons but by the approximation assuming incoherent scattering on individual atoms. This conclusion agrees with the almost linear behaviour of the electrical-resistance isotherms in a number of simple binary eutectic systems. When the electrical-resistance isotherm has a clearly--defined parabolic form, similar to that for solid solutions, this may mean either that the coherence of the scattering is largely preserved, or that the cross-section of scattering for the components depends on the composition, or that the scattering of the electrons by the ions is related not only to the charge on the ion but also to other properties of the ion. In the last case the cross-section may depend, for example, on the difference in the volumes of the atoms of solvent and impurity. In this case we would hardly expect that the cross-section of scattering would be related in simple fashion to the position of the components in Mendeleev's Periodic System.

The behaviour of the noble metals silver and gold in various solvents is of considerable interest, in view of their increased electron affinity. The results of a preliminary study of the e.m. of silver (Table 7) showed that $z^*$ for silver differs significantly from that calculated from formula (69). The effective charges of the isotopes $^{110m}$Ag and $^{198}$Au in liquid Cd, In, Tl, Sn, Pb, and Bi at 350° were determined[25] in vertical capillaries with diameter 1 mm and length of metal column 40 mm, at a current strength of 1.5 A. The results are given in Table 8 and Fig. 2 (the values of $z^*$ for gold and silver in mercury at 25° are taken from Table 2).

TABLE 8. Effective and "true" charges of noble metals in various solvents[25].

| Solvent | Period V | | | Period VI | | | |
|---|---|---|---|---|---|---|---|
| | Cd | In | Sn | Hg* | Tl | Pb | Bi |
| $z^*$ for silver | —1.25 | —0.74 | —1.07 | 1.43 | 0.64 | 0.48** | 0.14 |
| $z^*$ for gold | —2.2 | — | —2.0 | 1.47 | —0.28 | —0.10 | —0.18 |
| $z$ for silver | —0.87 | —0.6 | —0.9 | ? | 0.9 | 0.56 | 0.14 |

* Data from Table 2.

** More accurate value than that given in Table 7.

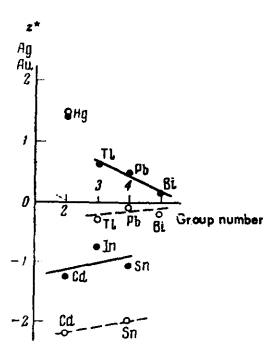

Fig. 2. Effective charges of traces of gold and silver in various solvents. ● — $z^*$ for silver, ○ — $z^*$ for gold.

To find the "true charge" of the Ag and Au ions in the solution[25], it was assumed, as in other work[30], that the cross-section of scattering is proportional to the square of the true charge. Eqn. (57) is then written in the form

$$z_3^* = z_3 - \frac{z_3^2}{\bar{z}_1}, \qquad (70)$$

where $\bar{z}_1$ is the Group number of the solvent.

It can be seen from Fig. 2 that the charges $z^*$ and $z$ for silver and gold change fairly regularly with change in the Group number of the solvent within a given period of Mendeleev's Periodic System. On going from solvents of the Fifth Period (Cd, In, and Sn) to solvents of the Sixth Period (Hg, Tl, Pb, and Bi), the charges of silver and gold change significantly, becoming more positive in the solvents of the Sixth Period. This change in $z^*$ is approximately the same for silver and gold and amounts to 1.5–2 electronic charges.

The simple zone model, which assumes that the valency electrons are free, does not explain this result. According to Friedel[86], a local bound-electron level may be produced in metals close to an impurity atom if the ionisation energy of the impurity atom is greater than the depth of the potential well for an electron in the solvent. The production of local levels should lead to the formation of neutral impurity atoms or even negative ions. Since Pb has a greater atomic volume, that is, a lower concentration of valency electrons, than Sn, the Fermi energy in Pb is smaller. If we assume that the work functions for Pb and Sn are about equal, we find that the bottom of the potential well in Pb is higher than that in Sn. Thus according to Friedel[86], the formation of local states is more probable in Pb than in Sn, that is, an impurity should be more negative in Pb than in Sn.

The data in Table 8 do not agree with this conclusion. Since the above discussion is applicable not only to Sn and Pb, the reasons for the deviation from Friedel's theory[86] should be general for all the solutions studied. Either this theory is inapplicable to multivalent solvents, or the interaction of the impurity ion with the surrounding ions of the solvent produces a significant displacement of local levels, not taken into account by this theory.

The marked influence of the nature of the interaction between the impurity and solvent is revealed by examining the equilibrium diagrams for the systems formed by silver and gold with the metals of Periods V and VI.[77] With metals of Period V (Cd, In, and Sn), silver and gold form exclusively diagrams with electron compounds and intermetallic compounds, but with metals of Period VI (Tl, Pb, and Bi) they form chiefly eutectic systems. Eutectic character in a system A–B is usually associated with a positive value for the energy of mixing

$$\varepsilon = \varepsilon_{AB} - \frac{1}{2}(\varepsilon_{AA} + \varepsilon_{BB}), \qquad (71)$$

where $\epsilon_{ik}$ is the potential energy of the pairing interaction. In systems with appreciable affinity of the components, the energy of mixing is usually negative. Thus the increase in the negative character of the charges of silver and gold on going from solvents of Period VI to solvents of Period V should be associated with a decrease in the energy of mixing (on going from positive values of $\epsilon$ to negative values) or should even be responsible for this decrease. The extremely incomplete data on heats of dissolution[87] suggest that these heats decrease on going from silver to gold and from solvents of Period VI to solvents of Period V; in the last case the sign of the heat of dissolution changes from negative to positive.

It can be seen from Table 8 that for the Ag–Sn, Au–Bi, and Au–Pb systems the direction of e.m. is opposite to those given in Table 4. This is apparently due to the inadequacy of Kremann's procedures.

The e.m. of traces of $^{204}Tl$ in liquid Cd, In, Sn, Pb, and Bi was studied at 350°.[32] The values of $z^*$ for thallium are given in Table 9. The dependence of $z^*$ for thallium on the position of the solvent in Mendeleev's Periodic System is the same as that for the noble metals silver and gold. Change in the Group number of the solvent again leads to a small change in $z^*$ for thallium, and change from solvents of Period VI to solvents of Period V is accompanied by a decrease in $z^*$ by 1.5–2 units. In the case of thallium, however, there is no sharp boundary between the types of equilibrium diagram which it forms with the metals of Periods V and VI.

The fact that for e.m. in dilute solutions thallium behaves like silver and gold is apparently related to the similarity between the structures of the electron clouds of the Ag, Au, and Tl atoms. The inner levels of these atoms have identical structures. The differences lie in the number of valency electrons ($5s^1$ for silver, $6s^1$ for gold, and $6s^26p^1$ for thallium). The similarity between Ag, Au, and Tl apparently indicates that the dissolution of thallium in a metal is accompanied by an appreciable displacement of the $6s^2$ level, so that the corresponding electrons remain bound.

The influence of incomplete filling of the 3*d* level on e.m. was studied[32,34] for the case of solutions of $^{60}Co$ and $^{63}Ni$ in Cd, In, Sn, Pb, and Bi at 350° in straight vertical capillaries with diameter ~ 1 mm at a current strength of ~ 2 A. The length of the metal columns was 40 mm. The results[32,34] (Table 10) show that $z^*$ for the transition-metal impurity depends to a marked extent on the Group number of the solvent. It was suggested[32] that the "true charge" of the transition metal is the same in all solvents and that, as before, the "true charge" of the solvent $z_1$ is equal to its Group number $\bar{z}_1$ in Mendeleev's Periodic Table, and $\sigma_1 \simeq k\bar{z}_1^2$. Eqn. (57) then acquires the form

$$z_2^* = z_2 - \frac{a}{z_1}. \qquad (72)$$

where $z_2$ and $a$ are constants which depend on the nature of the impurity but not on the nature of the solvent. The plot of $z^*$ for the impurity against $1/\bar{z}_1$ should be given by straight lines. Fig. 3 shows that this relationship is satisfied fairly well. The equations for the graphs in Fig. 3 are

$$z^*(\mathrm{Co}) = 10 - \frac{64}{\bar{z}_1}, \qquad (73)$$

$$z^*(\mathrm{Ni}) = 3 - \frac{22.8}{\bar{z}_1}. \qquad (74)$$

In all the solutions the predominant part in e.m. is played by the "electron wind".

Two explanations for the unique features of the e.m. of transition-metal impurities were put forward[32,34]. The first is based on Friedel's concept[88,89], according to which the 3*d* states of the impurity electrons are raised into the conductivity zone of the solvent and take part in resonance with the valency states, so that the 3*d* cloud of the transition-metal impurity is "smeared out". To explain the high value of the "true charge" of traces of Co and Ni — 10 and 3 according to formulae (73) and (74) — it was suggested[32] that the 3*d* electrons taking part in the resonance behave during e.m. in the same way as the valency electrons of non-transition elements. This is also responsible for the high values of the cross-sections of the scattering of electrons on transition-metal impurities.

Another reason for the high negative values of $z^*$ may be the scattering of the conductivity electrons on unfilled states of the 3*d* level[34]. In this case the e.m. effect should increase with increase in the number of unfilled 3*d* states[90]. It is suggested that an analogous mechanism is responsible, in particular, for the increased electrical resistance of pure transition metals[90].

It can be seen from Table 10 that the cross-section of scattering is approximately proportional to the square of the number of unfilled states in the free Co and Ni atoms. If we assume that the "true charges" of Co and Ni are small and positive, we find from Table 10 that $z^*_{Co}/z^*_{Ni} \simeq \sigma_{Co}/\sigma_{Ni} = 2.5$ (for solutions in Cd and In). The ratio of the numbers of unfilled 3*d* states in Co and Ni is 3:2, however. It is possible that the two mechanisms described are of equal importance in the e.m. of transition-metal impurities.

The electromigration of impurities in liquid transition metals (Fe and Ni) was studied[91] at 1500–1600° with wire specimens in quartz capillaries. A liquid zone of length 12–15 mm was produced by heating a section of the capillary with the wire in a molybdenum spiral. The results (Table 11) show that $z^*$ for impurities lying to the left of

TABLE 9. Electromigration of thallium in various solvents at 350°.[32]

| Solvent | Period V | | | Period VI | |

1) $z^*$ for cobalt; 2) $z^*$ for nickel.

TABLE 11. Electromigration of impurities in liquid iron (~1600°) and nickel (~1500°).[91]

| Solvent | Impurity | At. fraction of impurity | $z^*$ |
|---|---|---|---|
| Fe | Mn | 0.005 | 5 |
| Fe | Ni | 0.08 | —4 |
| Ni | Mn | 0.10 | 56—76 |
| Ni | Fe | 0.02 | 15 |
| Fe | C | 0.016 | 11 |

the solvent in the Periodic System are positive, the values being greater, the further the impurity from the solvent. The high positive values of $z^*$ for the impurities were attributed[91] to the influence of the "hole wind", that is, to the scattering of holes in the 3*d* zone of the alloy on unfilled states of the 3*d* level of the impurity or on the ions of non-transition impurities (C in Fe).

The e.m. of traces of Cu, Ni, Mg, Zr, Pd, and U in liquid bismuth was studied[92] at 500°. The method involved the measurement of the quantity of impurity passing under the influence of current from a large volume of solution into a capillary with one end immersed in the solution (or in the opposite direction). The concentration of impurity amounted to 0.05–0.5 wt.%. The mobilities of the impurities (in the order given above) had the following values ($cm^2\ s^{-1}\ V^{-1}$): $-1.95 \times 10^{-4}$, $5.0 \times 10^{-4}$, $-5.97 \times 10^{-4}$, $2.61 \times 10^{-4}$, $3.05 \times 10^{-4}$, and $2.57 \times 10^{-4}$ (the results for nickel contradict those in Table 10). It was assumed[92] that the e.m. method can be used to separate the components of the solution.

Studies were made[93,94] of the e.m. of traces of sulphur in molten cast iron (1340°, duration of heating 11–29 h), length of specimens 35–40 mm, average composition 0.07–0.11 wt.% sulphur, cast iron saturated with carbon) and silver (1080°, duration of heating 12 h, length of specimens 35 mm, average composition 0.1% sulphur). The values found for the effective charges $z^*$ were 1.5–2.4 for sulphur in cast iron and -5.5–10.8 for sulphur in silver. These results indicate that the electron wind plays a significant part in e.m. in liquid silver, whereas in the case of cast iron the forces of the field, the electron wind, and the hole wind almost balance. The determination of the "true charge" of sulphur in cast iron and silver on the basis of the data obtained is difficult.

## 5. Electromigration in Binary Liquid Alloys

It was shown[30] that e.m. in the simplest cases is described satisfactorily by formula (69), that is, it agrees with the suggestion that the "true charge" $z$ is equal to the Group number of the element $\bar{z}$ and with the proportionality $\sigma \simeq k\bar{z}^2$. The applicability of these assumptions for concentrated solutions was verified[31,33] for the Cd–Sn, Cd–Bi, Cd–Pb, and Bi–Sn systems. Formula (56) can be written in the form

$$z_1^* = \frac{N_2\left(\frac{\sigma_2}{\sigma_1}Z_1 - Z_2\right)}{1-\left(1-\frac{\sigma_2}{\sigma_1}\right)N_2}. \qquad (75)$$

If $z_1$, $z_2$, and $\sigma_2/\sigma_1$ are constant within a given binary system, we have

$$z_1^* = \frac{aN_2}{1-bN_2}. \qquad (76)$$

It was found[31,33] that e.m. in the systems studied is described satisfactorily by equations of type (76):

in the cadmium–tin system

$$z_{Sn}^* = -\frac{1.01N_{Cd}}{1-0.813N_{Cd}}, \qquad (77)$$

in the bismuth–cadmium system

$$z_{Bi}^* = -\frac{1.87N_{Cd}}{1-0.886N_{Cd}}, \qquad (78)$$

in the bismuth–tin system

$$z_{Sn}^* = \frac{2.5N_{Bi}}{1+0.552N_{Bi}}, \qquad (79)$$

in the cadmium–lead system

$$z_{Pb}^* = -\frac{1.06N_{Cd}}{1-0.78N_{Cd}}. \qquad (80)$$

These equations were used to find the ratios $\sigma_i/\sigma_{Bi}$:

$$\frac{\sigma_{Cd}}{\sigma_{Bi}} = 0.114;\quad \frac{\sigma_{Sn}}{\sigma_{Bi}} = 0.644;\quad \frac{\sigma_{Pb}}{\sigma_{Bi}} = 0.519. \qquad (81)$$

It was shown[31] that

$$\sigma_i \sim (\bar{z}_i)^{2.36}, \qquad (82)$$

that is, the proportionality $\sigma \simeq k\bar{z}^2$ is satisfied approximately, but not rigorously.

The experimental values of $z^*$ for lead and tin in the cadmium–lead and cadmium–tin systems at 300°[31,33] are given in Fig. 4, together with a curve calculated from Eqn. (75) on the assumption that $z_1 = 4$, $z_2 = 2$, and $\sigma_2/\sigma_1 = \left(\frac{2}{4}\right)^{2.36}$ [in accordance with (82)]:

$$z_{Pb,Sn}^* = -\frac{1.222N_{Cd}}{1-0.805N_{Cd}}. \qquad (83)$$

It can be seen from Fig. 4 that as a first approximation, the agreement between calculation and experiment is satisfactory. The discrepancy amounts to ~10%. The discrepancy is slightly greater (40%) in the Cd–Bi and Bi–Sn systems[31]. Thus the assumptions that the true charge is

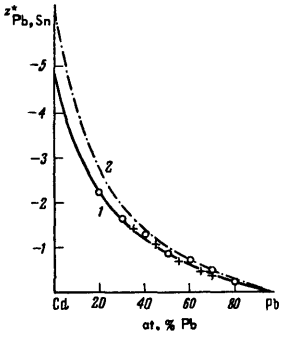

Fig. 4. Effective charges of tin and lead in the cadmium–tin and cadmium–lead systems. + — $z^*$ for tin, ○ — $z^*$ for lead. 1) Plot of $z^*_{Pb} = -\frac{1.06N_{Cd}}{1-0.78N_{Cd}}$, 2) plot of $z^*_{Pb,Sn} = -\frac{1.222N_{Cd}}{1-0.805N_{Cd}}$.

equal to the Group number and that $\sigma$ is approximately proportional to the square of the charge apply fairly satisfactorily to simple eutectic systems.

On going to more complex systems, however, the hyperbolic relationship (76) no longer applies. For example, in the Au–Sn system at 450°,[33] $z^*$ for gold shows a maximum in the range 20–30 at.% Au, but with further increase in the gold concentration, $z^*$ decreases. In the Cd–Tl system[35] the value of $\sigma$ for thallium is anomalously high (3 times the calculated value). It is as yet difficult to discuss the results of e.m. in these systems, because of the lack of experimental material.

## 6. Relationship Between Electrical Conductivity and Electromigration in Liquid Metals

The relationship between the scattering cross-sections responsible for e.m. and electrical resistance has been examined[33]. If it is assumed that these cross-sections are equal, it is possible to use the e.m. data and a knowledge of $\sigma_2/\sigma_1$ to calculate the ratio of the electrical resistivities of the corresponding pure liquid metals. The results[33] are given in Table 12. In the absence of e.m. data, the $\sigma_2/\sigma_1$ values were calculated from formula (82). Table 12 shows that the discrepancy between $\rho_{exp}$ and $\rho_{calc}$ is small for Pb, Bi, Sb, Ag, Cu, and Na. An appreciable difference is observed for Sn, Hg, and Al. The last two metals also show anomalous behaviour in the jump in the values of $\rho$ on fusion[95].

The results obtained indicate that the ratios of the cross-sections of scattering $\sigma_2/\sigma_1$ for the phenomena of e.m. and electrical conductivity are fairly close. The electrical resistivity of a liquid metal can evidently be regarded, as a first approximation, as due to incoherent scattering on ions.

It was shown[33], however, that constant values of $\sigma_2/\sigma_1$ within a given binary system should not be observed if the $\rho$ isotherms show a maximum. An example of this is the potassium–sodium system. It was observed[29] that the concentration dependence of the e.m. effect (with inversion) is similar to the function $\frac{\partial}{\partial N_2}(V_{mean}/\rho)$, where $N_2$ is the atom fraction of potassium, $V_{mean}$ the mean atomic volume of the alloy, and $\rho$ its electrical resistivity. The relationship between e.m. and $\rho$ for K–Na alloys was also examined by Belashchenko[33]. It was found that in systems with a maximum value of $\rho$ it is more convenient, as in the case of solid solutions, to consider the individual components of the electrical resistance: the additive component and the residual resistance, and also the corresponding components of the cross-section of scattering $\sigma$. Simultaneous examination of the data for e.m. and $\rho$ made it possible to determine the fraction $f$ of the residual resistance corresponding to all the sodium atoms in the solution[33]:

$$f \simeq 0.1 + 0.9 N_{Na}. \qquad (84)$$

TABLE 12. Calculation of the electrical resistivity $\rho$ of liquid metals from e.m. data[33].

| Metal | z | Temp., °C | $\rho_{exp}/\rho_{calc}$ | Metal | z | Temp., °C | $\rho_{exp}/\rho_{calc}$ |
|---|---|---|---|---|---|---|---|
| Cd | 2 | 321 | 1.00 | Hg | 2 | 0 | 2.81 |
| Sn | 4 | 232 | 0.45 | Al | 3 | 658 | 0.35 |
| Pb | 4 | 327 | 1.09 | Ag | 1 | 1000 | 1.52 |
| Bi | 5 | 269 | 0.77 | Cu | 1 | 1100 | 1.56 |
| Sb | 5 | 631 | 0.79 | Na | 1 | 100 | 1.11 |

The inversion of e.m. in the K–Na system is attributed[33] quantitatively to the fact that the potassium ion (diameter 4.76 Å) dissolved in sodium (diameter 3.82 Å) distorts the arrangement of the ions in several coordination spheres, whereas the sodium ion dissolved in potassium influences only its first coordination sphere.

## 7. Study of the Electrodiffusion Potential in Liquid Metallic Solutions

The first studies of electrodiffusion potential (e.d.p.) in amalgams were made by Schwarz[14]. The mobilities of the impurities, calculated from the results of e.d.p. measurements, showed good agreement with the e.m. data and are given in Table 2.

The e.d.p. effect was studied[35,57,58] in liquid alloys of the Pb–Sn, Bi–Sn, Bi–Cd, Bi–Te, and Na–Tl systems. In the last two systems, marked deviations from ideal behaviour were observed. In the solid state the components form intermetallic compounds $Na_2Tl$, NaTl, and $Bi_2Te_3$.

Since the magnitude of the e.d.p. is of the order of $10^{-6}$–$10^{-5}$ V, special precautions were necessary to eliminate the Seebeck effect. The experiments were carried out in glass capillaries of internal diameter 1 mm. The denser component was poured into the capillary first, followed by the second metal. The total length of the specimen was 20–40 mm. The heating was carried out in an oil thermostat at temperatures up to 350°, or in a vacuum furnace; the specimens were kept in a copper thermostat block. In the measurement of the e.d.p., molybdenum leads sealed to the ends of the capillary were connected to a galvanometer.

The initial values of the e.d.p. (after rapid heating to the required temperature) were $1.5 \times 10^{-6}$ V in the Bi–Sn system at 280°, $5 \times 10^{-6}$ V in the Pb–Sn system at 375°, $5 \times 10^{-5}$ V in the Bi–Cd system at 330°, $8 \times 10^{-5}$ V in the Na–Tl system at 310°, and $5 \times 10^{-5}$ V in the Bi–Te system at 590°. During the heating of the specimens, a sudden decrease in e.d.p. was observed at the melting points of the intermetallic compounds NaTl and $Bi_2Te_3$. During isothermal treatment the value of the e.d.p. decreased smoothly to zero as a result of the equalisation of the composition.

The results of e.d.p. measurements[57,58] were used to calculate the effective charges of the components. By integrating Eqn. (37) with allowance for (76), we obtain[35,58]

$$\epsilon \simeq -\frac{\bar{D}}{\bar{\varkappa}} e \left(\frac{\bar{N}}{\bar{V}}\right) z_{10}^{*} \frac{(1-b)\ln(1-b)}{b}, \qquad (85)$$

where the bar above the symbols denotes that the quantity is averaged with respect to composition within the binary system, $V$ is the volume of 1 g-atom of the alloy, and $z_{10}^*$ is the value of $z_1^*$ as $\bar{N}_1 \to 0$. If we assume that $\sigma_2/\sigma_1 = (\bar{z}_2/\bar{z}_1)^2$, where $\bar{z}$ is the Group number of the component, we can use the value of the e.d.p. $\epsilon$ to calculate $z_{10}^*$ and compare these results with the e.d.p. results. Since the averaging process is not sufficiently rigorous, the calculated values of $z_{10}^*$ are only approximate. Nevertheless, these values of $z^*$ show satisfactory agreement with those found from e.m., with respect to both sign and magnitude[96]. The calculation of $z^*$ for systems with intermetallic compounds was not carried out, since in these cases the values of $D$, $V$, and $\varkappa$ should depend to a marked extent on composition. The sign of the e.d.p. in these cases is given by the rule according to which $z^*$ for the component with the smaller Group number is positive — see Eqn. (69). The high values of the e.d.p. in these systems indicate, however,

that when there is a specific interaction between the ions of the components, formula (69) may give marked deviations from reality.

It was shown[57] that the temperature dependence of the e.d.p. is due chiefly to the change in the diffusion coefficient; this makes it possible to determine the activation energy of diffusion $Q$ in liquid alloys. For the Pb–Sn system, the mean value of $Q$ was found[57] to be 7 kcal mole$^{-1}$ with an accuracy of ~ 20%.

---o0o---

The results of the study of e.m. in liquid alloys of metals of the type Cd, Sn, Pb, Bi, etc. make it possible to assume that the "true charge" $z$ is approximately equal to the Group number of the given element in the Periodic System. In other words, despite the small screening radii in metals (less than $10^{-8}$ cm), the valency electrons of these elements are almost completely delocalised for e.m. (and electrical conductivity). This is evidently related directly to the familiar Hume–Rothery rule. In the case of transition--metal impurities, the concept of "true charge" is more complicated. Data on the migration of traces of Co and Ni do not agree with the assumption that their 3$d$ levels are filled by the conductivity electrons of the solvent (so-called donor–acceptor interaction).

In the simplest cases, $\sigma$ depends on the Group number of the element and is approximately proportional to the square of the Group number. For systems with linear electrical-resistivity isotherms, the scattering on the ions of the components is found to be for the most part not a collective act but a separate act. The presence of unfilled $d$ levels leads to an increased scattering of electrons. From this it follows that the e.m. method is convenient for the study of interaction in systems containing transition metals. Filling of the sublevels should lead to a decrease in the contribution made to $z^*$ by the scattering of the charge carriers. Moreover, $z^*$ is extremely sensitive to specific interionic interaction. The limiting case of a strong bond is apparently exemplified by solutions of cadmium, etc. in alkali metals, where it is possible to use the spherical--complex model. In these systems inversion of e.m. may be expected.

In view of the similarity in the energetic properties of liquid and solid metallic alloys, it may be assumed that the "true charges" of the ions are similar in the two cases. However, the mechanisms of the scattering of conductivity electrons on the ions of the impurity and solvent are not the same. Moreover, the values of $\sigma$ for ions in the ground state and transition state also differ[16,17,64]. Thus other relationships are to be expected for e.m. in solid solutions.

## NOTE ADDED IN PROOF

It has been shown[97] that traces of Tl, In, and Ba in liquid Na move during e.m. to the positive electrode; however, traces of Sr and Ag, which do not form compounds with Na, take almost no part in e.m. These results provide evidence in support of the model according to which the complex is entrained by the electron wind. It has been proposed[98] that the characteristic features of interatomic bonding in solutions be studied by a "probe" method, in which the e.m. of an impurity with a known true charge in the solution being studied is determined. The method was applied to the Cd–Bi system; a trace of $^{113-123}$Sn was used as probe.

## I. GENERAL REMARKS

Among the organic compounds which form cations and are used in analytical chemistry, the many derivatives of pyrazolone have recently found extensive application — antipyrine, pyramidone, and compounds obtained by condensing antipyrine with various aldehydes and ketones (we shall subsequently refer to these compounds, including pyramidone, as antipyrine derivatives)†. Of the latter, the following are used for the determination of many elements: diantipyrinylmethane, diantipyrinylmethylmethane, diantipyrinylpropylmethane, diantipyrinylphenylmethane, diantipyrinyl-*o*-hydroxyphenylmethane, diantipyrinyl-*p*-hydroxyphenylmethane, diantipyrinyl-*o*-nitrophenylmethane, diantipyrinyl-*p*-dimethylaminophenylmethane, diantipyrinyl-*p*-tolylmethane, diantipyrinylfurylmethane, diantipyrinyl-*p*-hydroxy-*m*-methoxyphenylmethane, antipyrinylbis-(*p*-methylaminophenyl)methane, and antipyrinylbis-(*p*-dimethylaminophenyl)methane. All these compounds in acid solutions are able to form complex organic cations

$$R + H^+ \rightleftarrows RH^+.$$

In the form of these cations they give compounds with many anions, particularly complex ions containing a metal

$$[M^{m+}X_n]^{(m-n)-} + (m-n)\,RH^+ \rightleftarrows (RH^+)_{(m-n)}\,[M^{m+}X_n]^{(m-n)-},$$

where M is a metal, X an electronegative ligand, and R the organic cation.

In neutral or almost neutral media, in which the equilibrium $R + H^+ \rightleftharpoons RH^+$ is displaced to the left, however, antipyrine and its derivatives are able to form compounds of the ammine type:

$$[M^{m+}X_n]^{(m-n)-} + pR \rightleftarrows [M^{m+}R_p]\,X_m + X^-_{(n-m)}.$$

Compounds of this type have been prepared for many metals with antipyrine, pyramidone, and diantipyrinylmethane[1-21]. In the case of the other antipyrine derivatives, the formation of such compounds is evidently hindered by the large size of the amine molecule; this is observed even for the case of complex formation with diantipyrinylmethane[19].

The formation of the various compounds in an R–M–X system depends on the acidity of the medium, the strength of the M–X, M–R, and R–H bonds, and the geometric dimensions of the molecule of the organic cation.

The resulting complexes of both types in a number of cases exhibit valuable properties — low solubility (which ensures a high sensitivity for the reaction), characteristic colour, extractability by organic solvents immiscible with water, etc. This has made it possible to develop gravimetric, titrimetric, photometric, and other methods of determination, and also methods for the separation of many elements.

† We shall not deal with picrolonic acid, 3-methyl-1-phenylpyrazol-5-one, etc., which are not strictly speaking antipyrine derivatives, nor with isopropylantipyrine, antipyrinylmethylenes, etc., which have not yet found extensive applications in analytical chemistry.

Several dyes with antipyrine nuclei have been proposed as analytical reagents: antipyrinylbis-(*p*-methylaminophenyl)methanol, antipyrinylbis-(*p*-dimethylaminophenyl)methanol, and antipyrinylbis-(*p*-benzylmethylaminophenyl)methanol.

In acid solutions they give large organic cations with an intense red colour. Many complex anions containing a metal react with them to form sparingly soluble precipitates. A characteristic feature of these reactions is the change in the colour of the solution during complex formation: the red characteristic of the reagent changes to bright blue, followed by the separation of a blue-violet precipitate and decolorisation of the solution. This colour effect has been used to develop titrimetric methods for the determination of elements forming sparingly soluble compounds with the dyes.

In a number of cases the compounds formed are readily extracted by benzene, ether, and toluene. The colour of the extracts is suitable for spectrophotometric determination. The method has a high sensitivity and in some cases a high selectivity.

Antipyrine and its derivatives listed above (including the dyes with antipyrine nuclei) have been used for the determination or separation of K, Cu, Ag, Au, Ca, Zn, Cd, Hg, Sn, Pb, Ga, In, Tl, the lanthanides, Si, Ti, P, V, As, Sb, Te, Bi, W, U, Re, F, Cl, Br, I, Fe, Co, Ni, Pd, Os, Ir, and Pt. In most cases the methods of determination and separation are based on the formation of onium compounds.

The essential features and possible applications of the proposed methods are examined briefly below.

## II. ELEMENTS OF GROUP I OF THE PERIODIC SYSTEM (K, Cu, Ag, Au)

### Potassium

Only an indirect method has been described for the determination of K using antipyrine, based on the formation of the green nitrosoantipyrine[22]. Potassium is first separated as $NaK_2[Co(NO_2)_6]$, the precipitate is dissolved, and antipyrine is added to the solution. The potassium content is found from the intensity of the resulting colour. The formation of nitrosoantipyrine is used for the determination of antipyrine and nitrites[23-34].

### Copper

In acid solutions in the presence of $Cl^-$, $Br^-$, $I^-$, $SCN^-$, and $CN^-$ ions, copper reacts with antipyrine and its derivatives to give compounds of the ammonium salt type, of which the compounds with antipyrine and pyramidone have been isolated and analysed[35]. A method has been proposed for the detection of Cu from the formation of the sparingly soluble yellow precipitate with antipyrine or pyramidone in the presence of KI.[36,37]

In acid medium, Cu reacts with antipyrine in the presence of $SCN^-$ ions to form a compound which can be extracted with chloroform to give a violet to brownish violet extract. The reaction is highly sensitive and selective and has been recommended for the detection of Cu.[38]

An analogous reaction is given by pyramidone[38]. Kolthoff and Hamer[39] found that pyramidone reacts with Cu salts in the presence of $SCN^-$ ions to give a grey-blue to violet precipitate. The detectable minimum corresponds to 1 $\mu g\ ml^{-1}\ Cu^{2+}$. At low Cu concentrations the solution is violet[40-43] (oxidation of pyramidone takes place).

It is possible to determine Cu by precipitation and weighing as $(C_{13}H_{17}ON_3.H)[Cu(SCN)_2]$.[35] Compounds of Cu with antipyrine and pyramidone, of the ammine type, have also been prepared[3,4,6,7,9,44], but they have not found analytical application.

### Silver

$AgNO_3$ oxidises pyramidone with the formation of the violet colour characteristic of the product of the oxidation of pyramidone and the separation of a grey-black precipitate of metallic silver[30-33]. The reaction can be used for the detection of Ag or pyramidone.

### Gold

A method has been described for the detection of small quantities (0.01 mg) of Au in the form of the sparingly soluble chloroaurate of antipyrine[45]. The chloroaurate of diantipyrinylmethane has been isolated from acid solutions in the form of red-brown crystals[46].

## III. ELEMENTS OF GROUP II OF THE PERIODIC SYSTEM (Ca, Zn, Cd, Hg)

Antipyrine and its derivatives have not been used for the determination of Mg, Sr, and Ba, although compounds of the ammine type formed by these elements with antipyrine and pyramidone are known[4,6-8].

### Calcium

An indirect method for the determination of calcium using antipyrine, based on the formation of nitrosoantipyrine, has been described[47]. Ca is first separated as $K_2CaNi(NO_2)_6$. The nitrite in the resulting precipitate is determined photometrically with antipyrine.

### Zinc

In acid solutions in the presence of $SCN^-$ ions, zinc reacts with antipyrine and its derivatives to form sparingly soluble compounds of the type $(RH)_2[Zn(SCN)_4]$. The compound with antipyrine has been proposed for the qualitative detection of Zn.[39,48,49] The precipitate can be detected at a concentration of 100 $\mu g\ ml^{-1}$ Zn. Precipitation with pyramidone makes it possible to detect 6-7 $\mu g\ ml^{-1}$ Zn in the presence of Ba, Ca, Mg, Sr, Al, Mn, As, and Cd, if the reaction is carried out in acetic acid[50-52].

Zhivopistsev[53] established that the compound of $Zn^{II}$ with pyramidone, $(C_{13}H_{17}ON_3.H)_2[Zn(SCN)_4]$, is isomorphous with the analogous cobalt compound $(C_{13}H_{17}ON_3.H)_2.[Co(SCN)_4]$. In the presence of Co, the Zn precipitate is coloured blue by the Co, which undergoes isomorphous coprecipitation. In this case it is possible to detect 0.2 $\mu g$ Zn.

The compound of Zn with pyramidone is readily obtained in the pure form, has a constant composition, and had been used to standardise solutions of Complexone III‡.[54]

The precipitation of Zn with pyramidone has also been used for the micro-crystalloscopic detection of pyramidone[55]. Diantipyrinylmethane has been used to purify Ni, Mn, Al, and Cr salts from Zn.[56]

The compound formed by Zn with diantipyrinylmethane is readily soluble in chloroform. This feature has been used for the determination of Zn in highly pure nickel, after preliminary extraction with chloroform (Ni remains in the aqueous phase)[57].

Gusev and Bitovt[58-61] found that the compound of Zn with diantipyrinylmethylmethane at pH 2-2.5 forms a stable white turbidity which makes possible the nephelometric determination of 0.12-2 $\mu g$ of Zn in the presence of the cations of analytical groups I and II, and also Al, Mn, $Fe^{III}$, Cu, Ni, and Co respectively. The method has been used to determine Zn in industrial atmospheres, alloys, foodstuffs, blood, and other materials.

Zhivopistsev[62] proposed that the precipitation of $Zn(SCN)_4^{2-}$ ions with antipyrinylbis-(*p*-dimethylaminophenyl)methane be used for the detection of small quantities (0.1-0.28 $\mu g \times \times ml^{-1}$) of Zn.

Sparingly soluble bright blue precipitates $(RH)_2[Zn(SCN)_4]$ are formed by Zn in acid solutions with antipyrinylbis-(*p*-methylaminophenyl)methanol and antipyrinylbis-(*p*-dimethylaminophenyl)methanol (the detectable minimum corresponds to 0.2-0.3 $\mu g$ and 2-3 $\mu g$ of Zn respectively)[63,64]. It has been shown possible to determine Zn gravimetrically as $(C_{29}H_{32}O_2N_4)_2[Zn(SCN)_4]$. The error in the determination of 5-20 mg of Zn does not exceed 3-4%.[65] The determination of Zn can be completed photometrically after dissolving the precipitate in 1 *N* HCl. The error in the determination is 2-4%.[66] A titrimetric method has been developed for the determination of Zn using antipyrinylbis-(*p*-dimethylaminophenyl)methanol[67]. The error in the determination of 0.001-0.03 g of Zn amounts to 2-3%. In neutral or almost neutral solutions Zn forms a compound of the ammine type, $Zn(R)_2(SCN)_2$.

Zhivopistsev[68] has developed a titrimetric method for the determination of Zn using pyramidone. The method has been used to determine Zn in alloys of the "Elektron" type [Mg-base alloys (Ed. of Translation)].

### Cadmium

In acid solutions, cadmium gives sparingly soluble compounds $(RH)_2[CdX_4]$ with antipyrine§ and its derivatives, not only in the presence of $SCN^-$ ions as in the case of Zn, but also in the presence of $Br^-$ and $I^-$ ions.

Precipitation by antipyrine in the presence of $Br^-$ and $I^-$ ions has been proposed for the detection of Cd and antipyrine[36,37,69,70]. When the reaction is carried out in the presence of bromides, it is possible to detect 50 $\mu g\ ml^{-1}$ Cd. Gusev[70] developed a gravimetric method for the determination of Cd as $(C_{11}H_{12}ON_2.H)_2[CdBr_4].2C_{11}H_{12}ON_2$. Korenman and coworkers[71,72] studied the completeness of

‡ Sodium salt of EDTA (Ed. of Translation).

§ In the case of antipyrine, the compound $(C_{11}H_{12}ON_2H)_2.[CdBr_4].2C_{11}H_{12}ON_2$ is formed.

precipitation of Cd as antipyrine tetrabromocadmate¶ and the possible coprecipitation of $Fe^{3+}$, $Zn^{2+}$, and $Hg^{2+}$ ions with the Cd precipitate, and established that the precipitation of Cd is not quantitative and that $Fe^{3+}$, $Zn^{2+}$, and $Hg^{2+}$ are coprecipitated.

The determination of Cd can be completed not only by weighing the precipitate but also iodometrically or by titration with alkali and Methyl Orange after dissolving the antipyrine tetrabromocadmate precipitate[73]. The iodometric method is based on the formation of iodopyrine. The excess of iodine is titrated with thiosulphate.

The compound of Cd with pyramidone $(C_{13}H_{17}ON_3 \cdot H)_2 \cdot [CdI_4]$ has been recommended for the detection of Cd ($> 3.64$ μg ml$^{-1}$) and pyramidone (the detectable minimum corresponds to 5 μg of pyramidone in one drop of solution)[51,55]. The precipitate is also suitable for the gravimetric determination of Cd in the presence of small quantities of Zn.[35] Diantipyrinylmethane precipitates Cd quantitatively from 0.5–2.0 $N$ $H_2SO_4$ solutions as $(C_{23}H_{24}O_2N_4 \cdot H)_2 \cdot [CdBr_4]$. The formation of diantipyrinylmethane tetrabromocadmate has been made the basis of gravimetric[74-77], potentiometric[78], and amperometric[79] methods for the determination of Cd.

In the presence of iodides, an even less soluble compound of Cd with diantipyrinylmethane is formed; this has been used for the determination of small quantities (0.002–0.0001%) of Cd in highly pure nickel[80].

Diantipyrinyl-*o*-hydroxyphenylmethane also precipitates Cd quantitatively as $(C_{29}H_{26}O_3N_4 \cdot H)_2[CdBr_4]$. The precipitate has a definite composition and is suitable for the gravimetric determination of Cd[81].

The dyestuffs antipyrinylbis-(*p*-methylaminophenyl)-methanol and antipyrinylbis-(*p*-dimethylaminophenyl)-methanol react with Cd in acid medium in the presence of $SCN^-$ or $I^-$ ions to form sparingly soluble compounds which, as in the case of Zn, are suitable for the qualitative and quantitative determination of Cd.[64,67].

A method has been developed for the detection of Cd in the presence of Cu and also Al, Mn, Cr, Ni, Co, Fe, As, and the alkali and alkaline earth metals, using antipyrinylbis-(*p*-benzylmethylaminophenyl)methanol, which reacts with Cd in acid medium to give a precipitate of $(C_{40}H_{39}ON_4)_2 \cdot [CdBr_4]$.[82] The drop method makes it possible to detect 0.01 μg of Cd.

Compounds of the ammine type have also been used for the determination of Cd. A method has been developed for the gravimetric determination of Cd by precipitation and weighing as $[Cd(C_{13}H_{17}ON_3)_2](SCN)_2$.[83]

Popel'[79] obtained good results in the amperometric titration of Cd with $(NH_4)_2[Hg(SCN)_4]$ solution in the presence of antipyrine or pyramidone.

A method has been proposed for the amperometric determination of Cd, based on the formation of a sparingly soluble precipitate of $(C_{13}H_{17}ON_3)_2[CdI_2]$† at pH 2–5 in the presence of an excess of pyramidone. The titration is carried out with KI solution from the cathodic Cd current.

The successive determination of Bi (titration in 4.5–6 $N$ $H_2SO_4$) and Cd (titration at pH 2–5) has been shown to be possible. The method was tested on alloys containing Cd and Bi, together with Zn, Al, and Mn.[84]

### Mercury

Antipyrine, pyramidone, antipyrinylbis-(*p*-methylaminophenyl)methanol, antipyrinylbis-(*p*-dimethylaminophenyl)methanol have been used for the qualitative and quantitative determination of Hg.

Antipyrine and pyramidone form compounds with $Hg^I$ and $Hg^{II}$ in the presence of $Cl^-$, $Br^-$, $I^-$, $CN^-$, $NO_3^-$, and $SCN^-$ ions[85-92]. Mercury is precipitated by antipyrine from acidic solutions in the presence of KI as $(C_{11}H_{12}ON_2 \cdot H)_2[HgI_4]$ (sensitivity 4 μg ml$^{-1}$ Hg,[93] limiting dilution 1 : 200 000 [36,37]).

In dilute solutions, a stable turbidity suitable for the nephelometric determination of Hg is formed[93].

Antipyrine tetraiodomercurate is readily extracted by chloroform from 0.3–1.3 $N$ $H_2SO_4$, HCl, or $HNO_3$ solutions. The colour of the extracts can be used for the spectrophotometric determination of 1–80 μg of Hg in 5 ml of solution at $\lambda = 330$ mμm.[94]

In the presence of bromides, the compound $(C_{11}H_{12}ON_2 \cdot H)_2[HgBr_4] \cdot 2C_{11}H_{12}ON_2$ is formed. Cd, Zn, and $Fe^{III}$ are coprecipitated, but in a number of cases the coprecipitation is slight and cannot influence the accuracy of the gravimetric determination of Hg as antipyrine tetrabromomercurate[72,95].

The coprecipitation of Cd with the Hg precipitate can be used for the separation of small quantities (20–70 μg) of Cd from solutions of Zn and Cu salts[96].

Sudo[97] showed that the antipyrine–thiocyanato-complex of Hg is extracted quantitatively from weakly acidic (pH 1.8–2.3) solutions by a 3 : 1 mixture of pentanol and ethyl acetate. The optical density of the extracts ($\lambda = 325$ mμm) is proportional to the Hg concentration in the range 5–40 μg ml$^{-1}$.

Zhivopistsev[98] developed a titrimetric method for the determination of Hg using antipyrinylbis-(*p*-dimethylaminodiphenyl)methanol, based on the precipitation of $[HgI_4]^{2-}$ by the dyestuff from 0.7–1.5 $N$ HCl solutions. The method can be used to determine 0.0003–0.06 g of Hg with an error of 3–4%.

Hg can also be determined with antipyrinylbis-(*p*-methylaminophenyl)methanol, which forms an even less soluble compound with $[HgI_4]^{2-}$ (the detectable minimum corresponds to 0.6 μg Hg).[64]

A method for the detection of Hg using pyramidone is based on the oxidation of pyramidone by mercury(II) (the blue-violet product of the oxidation of pyramidone is formed). The detectable minimum corresponds to 20 μg Hg.[99] The reaction can be used to distinguish the $Hg_2^{2+}$ cation from the $Hg^{2+}$ cation.

## IV. ELEMENTS OF GROUP III OF THE PERIODIC SYSTEM (Ga, In, Tl, lanthanides)

### Gallium

Gallium is precipitated from acidic solutions in the presence of $Cl^-$, $Br^-$, and $I^-$ ions by diantipyrinylmethane,

¶ We shall use this terminology, since it is widespread in the literature, although it would be more correct to refer to these as "antipyrinium" salts.

† This is presumably a compound of the ammine type (Ed. of Translation).

diantipyrinylpropylmethane, and diantipyrinylphenylmethane. A gravimetric method has been developed for the determination of Ga as $(C_{26}H_{30}O_2N_4.H)[GaCl_4]$.[100]

The compound of Ga with diantipyrinylphenylmethane is extracted quantitatively by chloroform and this has been used for the separation of Ga from Al, Zn, Cd, Pb, Bi, As, Fe, Cu, In, and Ge by extraction[101].

Ga reacts with the dyestuffs to form the compounds $RHGaCl_4$, which are readily extracted by toluene and chloroform[102]. The use of antipyrinylbis-(*p*-benzylmethylaminophenyl)methanol has been proposed for the spectrophotometric determination of Ga. Ga is extracted from 6 *N* HCl to the extent of 90%. The sensitivity corresponds to 0.2 $\mu g\ ml^{-1}$ Ga. The method is applicable to the determination of Ga in bauxites, alumina, and copper–zinc ores.

### Indium

In sulphuric acid solutions (~0.5 *N*) in the presence of $SCN^-$ ions, indium reacts with antipyrine, pyramidone, and diantipyrinylmethane to form sparingly soluble compounds $[In_2(R)_3](SCN)_6$.[103] The compound with antipyrine has the composition $[In(C_{11}H_{12}ON_2)_3](SCN)_3$. The least soluble compound is that formed with diantipyrinylmethane. It has been shown possible to determine In gravimetrically as $[In_2(C_{23}H_{24}O_2N_4)_3](SCN)_6$.

A nephelometric method has been developed for the determination of microgramme quantities (0.5–1.0 $\mu g\ ml^{-1}$) of In.

### Thallium

Tervalent thallium in acid medium in the presence of $Cl^-$, $Br^-$, and $I^-$ ions reacts with antipyrine and its derivatives to form sparingly soluble compounds $(RH)[TlX_4]$. The compound of $TlBr_4^-$ with antipyrine has the composition $(C_{11}H_{12}ON_2.H)[TlBr_4].C_{11}H_{12}ON_2$.

The compound with antipyrinylmethane $(C_{23}H_{24}O_2N_4.H).[TlBr_4]$ has been used for the gravimetric determination of $Tl^{III}$ in the presence of Cu, Zn, $PO_4^{3-}$, $AsO_4^{3-}$, and also Fe, Bi (after their conversion into the complexonates) and Sb (converted beforehand into the tartrato-complex)[104]. The method has been used to determine $Tl^{III}$ in its alloys with Sb, As, or P.[105]

The determination of $Tl^{III}$ as $(C_{23}H_{24}O_2N_4.H)[TlBr_4]$ can be finished titrimetrically[105]. Diantipyrinylpropylmethane has been recommended for the precipitation of $Tl^{III}$ from hydrochloric acid (1–6 *N*) solutions[106]. The precipitate has a definite composition corresponding to the formula $(C_{26}H_{30}O_2N_4.H)[TlCl_4]$, is sparingly soluble ($5.6 \times 10^{-5}$ M), and is suitable for the gravimetric determination of $Tl^{III}$. The method has been used to determine $Tl^{III}$ in cadmium.

Diantipyrinyl- and diantipyrinylpropyl-methane tetraiodothallates are readily extracted by benzene with the formation of yellow extracts ($\lambda$ = 400–405 m$\mu$m, $\epsilon$ = 12 000)[107]. The extraction-photometric determination of $Tl^{III}$ is possible in the presence of Fe, Bi, Cu, Zn, Cd, Pb, Ga, and In. The minimum detectable quantity corresponds to 0.3 $\mu g \times \times ml^{-1}$ Tl.

An extraction-photometric method for the determination of $Tl^{III}$ using antipyrinylbis-(*p*-dimethylaminophenyl)methanol has also been proposed[108]. The method is based on the formation of a compound by $TlCl_4^-$ and the dyestuff, readily extracted by a 2 : 3 mixture of benzene and $CCl_4$.

In weakly acidic solutions $Tl^{III}$ oxidises pyramidone with the formation of a blue-violet compound. After 30 min the solution (pH 3.5–4.5) becomes red ($\lambda$ = 510 m$\mu$m) and this colour is preserved for 50–100 min. Kamemoto[109] has used this for the colorimetric determination of $Tl^{III}$. The method makes it possible to determine 0.5–4.5 mg Tl in 50 ml solution.

### The Lanthanides

These react with antipyrine and pyramidone to form compounds of the ammine type[5,10,11]. The solubilities and rates of formation of the compounds differ. Marsh[110,111] has used this feature to separate the lanthanides by fractional crystallisation; he showed that in the form of the compounds $[M(C_{11}H_{12}ON_2)_6]I_3$, Lu and Tu, Lu and Er, Lu and Yb, and Y and Ho are readily separated; Ho, Dy, and Tb are less readily separated; and Pr and Nd are not separated.

## V. ELEMENTS OF GROUP IV OF THE PERIODIC SYSTEM (Ti, Si, Ge, Sn, Pb)

### Titanium

In hydrochloric acid (0.5–6 *N*) or sulphuric acid solutions, titanium reacts with diantipyrinylmethane to form a yellow compound ($\lambda$ = 385 m$\mu$m, $\epsilon$ = 15 000). The molar ratio of Ti to diantipyrinylmethane in the complex is 1 : 3.[112] The compound is an ammine‡. Thus in 0.01–2 *N* HCl solutions the complex $[Ti(C_{23}H_{24}O_2N_4)_3]^{4+}$ exists[114].

The solutions obey Beer's law in the range 1–3 $\mu g\ ml^{-1}$ Ti. Ti can be determined spectrophotometrically in the presence of $Fe^{II}$, Al, Cd, Hg, Zn, and the alkali and alkaline earth metals; fluorides and phosphates do not interfere[115]. The method is 20 times more sensitive than the peroxide method and has the advantage over the chromotropic acid method that it does not require strict observation of the reaction conditions (pH, etc.). The method has been used to determine small quantities of Ti (0.0001–0.00005%) in aluminium and magnesium[116], and also to determine Ti in the presence of V in heat-resistant nickel- and iron-base alloys[117].

In the presence of thiocyanates, Ti reacts with diantipyrinylmethane to give a complex which is readily extracted from hydrochloric acid solutions by chloroform. On this basis a method has been developed for separating Ti from Al and Fe with subsequent determination as $TiO_2$.[118]

The composition of the complex formed in an excess of $SCN^-$ ions corresponds to the formula $[Ti(C_{23}H_{24}O_2N_4).(SCN)_4]$.[114,119] The chloroform extracts ($\lambda$ = 420 m$\mu$m, $\epsilon$ = 60 000) are suitable for the spectrophotometric determination of 2–20 $\mu g$ Ti in 25 ml extract[120].

---

‡ Compounds of the ammonium salt type have been isolated from chloroform solutions and analysed: $(C_{23}H_{24}O_2N_4.H)_2[TiCl_6]$ and $(RH)_2[Ti(SCN)_6]$. The compounds $(RH)[TiO(SCN)_3]$, where R = diantipyrinylpropyl-, diantipyrinylisobutyl-, and diantipyrinylphenyl-methane[113], have been isolated from aqueous alcohol solutions.

In hydrochloric acid or sulphuric acid solutions, $Ti^{III}$ and $Ti^{IV}$ react with diantipyrinyl-*o*-hydroxyphenylmethane to give readily soluble inner-complex compounds. The $Ti^{III}$ compound has an intense yellow colour. The solutions are suitable for the qualitative and quantitative determination of Ti.[121] The minimum detectable quantity corresponds to 0.35 $\mu$g ml$^{-1}$ Ti. The spectrophotometric method can be used to determine 2–30 $\mu$g ml$^{-1}$ Ti.

The salts of the diantipyrinyl-*o*-hydroxyphenylmethane complex of $Ti^{IV}$ with $NO_3^-$, $ClO_3^-$, $SCN^-$, and $ClO_4^-$ ions are sparingly soluble and separate as characteristic crystalline precipitates suitable for the qualitative detection of Ti.[122-124]

Antipyrine has also been used to precipitate the tannin complex of Ti. The antipyrine-tannin method has been used to determine small quantities (0.1–0.01 g) of Ti in the presence of Fe, Al, and Cr.[125] The reaction has been proposed for the detection of Ti by the spot method[126].

## Silicon

Silicon in the form of molybdosilicic and tungstosilicic acids is precipitated from acid solutions by antipyrine and pyramidone in the form of the sparingly soluble compounds $(C_{13}H_{17}ON_3)_3H_8Si(Mo_2O_7)_6.6H_2O$,[127,128] $4C_{11}H_{12}ON.SiO_2.12WO_3$, and $3C_{13}H_{17}ON_3.SiO_2.12WO_3$.[129] A method has been developed for the gravimetric determination of Si as pyramidone molybdosilicate[128]. The other compounds have been used for the amperometric[129-132] and titrimetric[133] determination of antipyrine and pyramidone. The methods developed can probably be used no less successfully for the determination of Si or W.

## Germanium

Germanium is precipitated from acid solutions as the sparingly soluble antipyrine or pyramidone molybdogermanates[134]. It has been shown possible to determine Ge gravimetrically as the antipyrine compound. Pyramidone molybdogermanate can be used to develop a vanadometric method for the determination of Ge by titration of the excess of pyramidone after separation of the precipitate. The vanadometric method for the determination of pyramidone makes it possible to determine 0.004–0.02 g of pyramidone with an error of ±3%.[135]

## Tin and Lead

Tin and lead react with antipyrine and its derivatives to give sparingly soluble compounds[36,37,52,56,57,62,136-140]. The compound formed by Sn with antipyrine in the presence of KI has been used to detect Sn after separation from interfering elements as the sulphide[141].

# VI. ELEMENTS OF GROUP V OF THE PERIODIC SYSTEM (P, V, As, Sb, Bi)

## Phosphorus

Molybdophosphoric or tungstophosphoric acids are precipitated by antipyrine and pyramidone from acid solutions. The compounds have been used for the spectrophotometric[142-144] and amperometric[130,131] determination of antipyrine and pyramidone and also for the detection of phosphoric acid[145].

Gusev[146] proposed a nephelometric method for the determination of phosphates, based on the formation of a stable turbidity when ammonium molybdate and antipyrine are added to a nitric acid (~ 2 *N*) solution of the phosphates. The method can be used to determine 0.05 $\mu$g ml$^{-1}$ P with an error of ±10%.

## Vanadium

Vanadium has been determined using diantipyrinylphenylmethane by precipitation and weighing as $(C_{28}H_{28}O_2N_4)_2H_4V_6O_{17}$ (or as $V_2O_5$ after ignition of the precipitate)[147].

Sokolova[148] has proposed a spectrophotometric method for the determination of V using pyramidone. The method is based on the formation of a blue solution by the reaction of pyramidone with V and tungstophosphoric acid in $Na_2CO_3$ solution. The detectable minimum corresponds to 0.3 $\mu$g ml$^{-1}$ V. Beer's law is observed in the range 0.6–30 $\mu$g ml$^{-1}$.

## Arsenic

Arsenic(V) in nitric acid solutions in the presence of ammonium molybdate reacts with antipyrine to form a stable turbidity, which is suitable for the nephelometric determination of As.[149] The method makes it possible to determine 0.1–2 $\mu$g ml$^{-1}$ As with an error of ±10%.

## Antimony

Antimony(III) reacts with antipyrine in acid solution in the presence of KI to give a yellow precipitate[141,150-153]. The sensitivity corresponds to 25 $\mu$g ml$^{-1}$ Sb and the limiting dilution is 1 : 20 000 (according to Korenman 1 : 40 000[36,37]). In dilute solutions (0.2 *N* with respect to HCl) a stable turbidity is formed, shown by Gusev[154] to be suitable for the nephelometric determination of 2.5 $\mu$g ml$^{-1}$ Sb in the presence of 75 $\mu$g ml$^{-1}$ $Sn^{2+}$. The error in the determination does not exceed ±5–6%.

The complex of Sb with antipyrine is readily extracted by chloroform. The coloured extracts ($\lambda$ = 345 m$\mu$m) can be used for the spectrophotometric determination of 1–100 $\mu$g Sb.[155]

Diantipyrinylmethane precipitates Sb quantitatively even at low concentrations of KI in the solution (0.1 M); from very dilute solutions antimony is coprecipitated quantitatively with the sparingly soluble diantipyrinylmethane iodide. This has been used for the separation and subsequent polarographic determination of microgramme quantities ($5 \times 10^{-9}$ g litre$^{-1}$) of Sb.[156]

## Bismuth

In acid solutions in the presence of $Cl^-$, $Br^-$, $I^-$, and $SCN^-$ ions, bismuth(III) reacts with antipyrine and its derivatives to form the compounds $(RH)[BiX_4]$, sparingly soluble in water. The reaction is highly sensitive. Thus precipitation of $BiI_4^-$ makes it possible to detect Bi at a dilution of 1 : 2 000 000 using antipyrine, or 1 : 48 000 using pyramidone[36,37,157,158].

The formation of pyramidone tetraiodobismuthate has been made the basis of nephelometric [159], amperometric [160], and heterometric (by Bobtelsky and Cohen) [161,162] methods for the determination of Bi and also for the titrimetric determination of pyramidone [163].

The nephelometric method based on the formation of a stable turbidity in dilute nitric acid solutions makes it possible to determine 0.5 μg $ml^{-1}$ Bi in the presence of 0.1 mg $ml^{-1}$ Sb, 0.015 mg $ml^{-1}$ Pb, and 10 mg $ml^{-1}$ Sn with an error of ±3–7%.

The amperometric determination is carried out by titrating sulphuric acid (2.5 M $H_2SO_4$) solutions of the Bi salt with potassium iodide in the presence of pyramidone, from the cathodic Bi current at a dropping mercury electrode.

The heterometric titration of nitric acid (~ 0.5 $N$) solutions of $Bi(NO_3)_3$ with pyramidone solution (in the presence of KI) or with KI solution (in the presence of pyramidone) can be used to determine ~ 1 mg Bi.

The titrimetric determination of pyramidone using potassium iodobismuthate involves the precipitation of pyramidone with standard $KBiI_4$ solution with subsequent titration of the excess of Bi with Complexone III until the disappearance of the yellow of the potassium iodobismuthate solution. The formation of the sparingly soluble compound with diantipyrinylmethane $(C_{23}H_{24}O_2N_4.H)[BiI_4]$ was used by Zhivopistsev and Parkacheva [164] to develop a titrimetric method for the determination of Bi. The method can be used to determine 80–50 mg Bi with an error of 2–3%.

A gravimetric method for the determination of Bi using diantipyrinylmethane by precipitation and weighing as $(C_{23}H_{24}O_2N_4.H)[BiCl_4]$ has been proposed [165]. The precipitation is carried out from hydrochloric acid (0.5–2.0 $N$) solutions; the error in the determination is 2–3%.

The compounds of Bi with antipyrine and diantipyrinylmethane are readily extracted by various organic solvents with the formation of coloured extracts suitable for the spectrophotometric determination of Bi.

Sudo [94,155] developed an extraction-photometric method for the determination of Bi using antipyrine in the presence of $SCN^-$ or $I^-$ ions. In the first case, Bi is extracted from weakly acidic solution (pH 1.8–2.3) by a 1 : 4 mixture of pentanol and ethyl acetate. The optical density of the extracts is measured at 325 mμm. The method makes it possible to determine 1–100 μg Bi in 5 ml solution.

In the second case (in the presence of KI) the extraction is carried out with chloroform. Measurement of the optical density of the extracts at 500 mμm makes it possible to determine 1–50 μg Bi in 5 ml solution.

In the presence of diantipyrinylmethane, $BiI_4^-$ ions are readily extracted by chloroform over a wide range of acidity (up to 3 $N$ with respect to HCl or $H_2SO_4$) of the original solution [166]. The colour of the extracts can be used for the photometric determination of 20–30 μg Bi in 25 ml.

## VII. ELEMENTS OF GROUP VI OF THE PERIODIC SYSTEM (Te, W, U)

Antipyrine and its derivatives have not yet been used for the determination of Cr and Mo. Compounds of $Cr^{III}$ with antipyrine [6,7] and of $Cr^{VI}$ (as $Cr_2O_7^{2-}$) with diantipyrinylphenylmethane [167] have been prepared. The addition of pyramidone solution to potassium dichromate solution produces a dark green which changes to wine red [168,169].

### Tellurium

In acid solutions tellurium(IV) reacts with the antipyrine derivatives diantipyrinylmethane, diantipyrinylpropylmethane, and diantipyrinylphenylmethane to give compounds of the type $(RH)_2[TeCl_6]$ and $(RH)_2[TeBr_6]$, which are readily extracted by dichloroethane to give coloured extracts [170]. On this basis, a method has been developed for the extraction-photometric determination of tellurium. The method makes it possible to determine 10–100 μg $ml^{-1}$ Te.

$Se^{IV}$, unlike $Te^{IV}$, is not extracted from hydrochloric acid solutions by dichloroethane in the presence of diantipyrinylpropylmethane. This has been used for the separation of Se and Te by extraction. A single extraction gives almost complete separation of 0.05–2 mg of Se and Te. [171]

### Tungsten

In acid solutions, tungsten forms sparingly soluble compounds with antipyrine [172–176], pyramidone [177–180], diantipyrinylphenylmethane [181], diantipyrinyl-*o*-hydroxyphenylmethane [182], and various other antipyrine derivatives. These reagents have been used for the gravimetric determination of W. In all cases the determination is finished by igniting the precipitates and weighing the resulting $WO_3$. The accuracy of the proposed methods is no less than the classical cinchonine method, but is more rapid and uses more readily available reagents.

### Uranium

In sulphuric acid solutions in the presence of $SCN^-$ ions, uranium in the form of uranyl nitrate reacts with antipyrine and some of its derivatives to form sparingly soluble compounds with variable composition [183]. At low U concentrations the compound with diantipyrinyl-*p*-dimethylphenylmethane gives a stable turbidity which is suitable for the nephelometric determination of U. The method makes it possible to determine 0.5–5 μg $UO_2^{2+}$ in the presence of 2.5 mg $La^{3+}$.

In the presence of bromides, uranyl nitrate reacts with diantipyrinyl-*p*-hydroxy-*m*-methoxyphenylmethane with the formation of yellow compound. Maximum development of the colour is observed at pH 2–3. The extraction-photometric method makes it possible to determine 5–60 μg × × $ml^{-1}$ $UO_2^{2+}$ in the presence of appreciable quantities of $Th^{4+}$, $Ni^{2+}$, $Mn^{2+}$, $Mg^{2+}$, and $Cu^{2+}$. The error in the determination amounts to ±3.5%. The method is suitable for the determination of uranium in various minerals (samarskite, aeschynite, sooty uranite, etc.).

## VIII. ELEMENTS OF GROUP VII OF THE PERIODIC SYSTEM (Mn, Re, F, Cl, Br, I)

### Manganese

Compounds of $Mn^{II}$ with antipyrine, of the ammine type, have been prepared [6] but these have not been used for the determination of Mn.

Rhenium

Re in the form of perrhenate and chlororhenate forms sparingly soluble compounds with antipyrine [184].

Fluorine

Čelechovsky and Holer [185] developed a photometric method for the determination of fluorides, based on the decolorisation of the red solution of the $Fe^{III}$–antipyrine complex in the presence of fluorides. The method makes it possible to determine 35–300 μg F in 25 ml solution. The error in the determination is 3.1–4%.

Chlorine, Bromine, and Iodine

These oxidise pyramidone with the formation of a blue-violet colour [186]. The reaction with I has been recommended for the detection of pyramidone [186].

In the presence of $I^-$ ions and also $Br^-$, $SCN^-$, and $S_2O_3^{2-}$ ions, the copper–pyramidone complex is decomposed with the formation of the salt of Cu with the corresponding anion; the solution is coloured violet by the product of the oxidation of pyramidone [43]. The reaction has been recommended for the detection of iodides. The sensitivity corresponds to 3.2 μg $ml^{-1}$ $I^-$ (limiting dilution 1 : 12 500).

Antipyrine has also been used to combine with the iodine liberated in the determination of iodides using iodate [187].

IX. ELEMENTS OF GROUP VIII OF THE PERIODIC SYSTEM (Fe, Co, Ni, Pd, Os, Ir, Pt)

Iron

In hydrochloric acid, sulphuric acid, acetic acid, and neutral solutions, iron(III) reacts with antipyrine to form a red compound readily soluble in water. This was observed at an early date by Knorr [23], who was the first to prepare antipyrine. The reaction is fairly sensitive (according to Knorr the limiting dilution is 1 : 100 000) and suitable for the qualitative and quantitative determination of Fe and antipyrine [24,26,28,30–33,188,189]. The complex formed is of the ammine type. The compound $(C_{11}H_{12}ON_2)_3.FeCl_3$ has been prepared in the crystalline state [190]. The addition of $K_4[Fe(CN)_6]$ solution to a solution containing $Fe^{3+}$ and antipyrine gives an immediate dark red precipitate of $[Fe(C_{11}H_{12}ON_2)_3][Fe(CN)_6].3H_2O$. Analogous compounds have been obtained with other complex anions: $[Fe(CN)_5.(NH_3)]^{2-}$, $[Co(CN)_6]^{3-}$, and $[Fe(CN)_5(NO_2)]^{2-}$. [191,192]. This indicates that in solution $Fe^{III}$ reacts with antipyrine to form the complex cation $[Fe(C_{11}H_{12}ON_2)_3]^{3+}$.

Other authors [189] report the formation of the cation $[Fe_2(C_{11}H_{12}ON_2)_3]^{6+}$. Compounds confirming the possible formation of this cation have been prepared in the crystalline state: $[Fe_2(C_{11}H_{12}ON_2)_3][Fe(CN)_5(NO_2)]_3$ [191] and $(C_{11}H_{12}.ON_2)_3.2FeCl_3$. [32,33,193,194]

In the presence of $SCN^-$ ions the red sparingly-soluble compound $[Fe(C_{11}H_{12}ON_2)_3](SCN)_3$ is formed [191,194,195].

Sudo [196] established that the complex of $Fe^{III}$ with antipyrine is readily extracted from weakly acidic solutions (pH 2.5) in the presence of $SCN^-$ ions by certain organic solvents. The best of these is a 4 : 1 mixture of ethyl acetate and isobutanol. The red extracts are suitable for the spectrophotometric determination of Fe. The method has been used to determine small quantities (0.0002%) of Fe in the metals aluminium, magnesium, zinc, and lead. The error in the determination is < 5%. [197]

Dick [198] found that from acetic acid solutions containing an excess of thiocyanate ions, $Fe^{III}$ is precipitated quantitatively as $[Fe(C_{11}H_{12}ON_2)_3](SCN)_3$. The sensitivity of the reaction corresponds to 0.2 μg Fe.

In acid medium, antipyrine forms with $K_4[Fe(CN)_6]$ the sparingly soluble compound $(C_{11}H_{12}ON_2)_2H_4[Fe(CN)_6]$. [190,199,200] Hexacyanoferrate(III) does not form a compound of this type and this has been used to identify $[Fe(CN)_6]^{4-}$ in the presence of $[Fe(CN)_6]^{3-}$. [201]

The reaction of $K_4[Fe(CN)_6]$ with antipyrine was used by Gusev [51] for the titrimetric determination of antipyrine involving titration of the excess of $K_4[Fe(CN)_6]$ with $KMnO_4$ solution after separation of the precipitate.

Diantipyrinylmethane, like antipyrine, reacts with $Fe^{III}$ in hydrochloric acid solutions to form a red complex. The number of diantipyrinylmethane molecules entering the resulting compound depends on the acidity of the medium [202]. Thus at pH 1–2 the complex $Fe(C_{23}H_{24}O_2N_4)_2^{3+}$ is formed. In 1 *N* HCl solutions the cation $Fe(C_{23}H_{24}O_2N_4)^{3+}$ predominates. The solutions of the complex (λ = 440–460 mμm), formed at pH 2.2–2.5, are suitable for the spectrophotometric determination of Fe. [203] The sensitivity of the reaction corresponds to 0.08 μg $ml^{-1}$ Fe.

Zhivopistsev and Chelnokova [204] found that $Fe^{III}$ is extracted quantitatively from strongly acidic (5–7 *N* HCl) solutions by chloroform in the presence of diantipyrinylmethane. In this case a compound of $Fe^{III}$ with diantipyrinylmethane, of the ammonium salt type, is probably formed. A method was developed [204] for the quantitative separation and subsequent determination (from the colour of the extracts in the case of small quantities, or as $Fe_2O_3$ after re-extraction with water in the case of large quantities) of Fe from Ti, Cr, Ni, Al, Mn, and Mg, using diantipyrinylmethane and chloroform.

In the presence of $SCN^-$ ions, coloured compounds $Fe(C_{23}H_{24}O_2N_4)_3(SCN)_3$ ( pH 2, λ = 455 mμm, ε = 10 000) and $(C_{23}H_{24}O_2N_4.H)_3[Fe(SCN)_6]$ (1 *N* HCl, λ = 475 mμm, ε = 35 000), readily extracted by chloroform, are formed [202]. This forms the basis of a method proposed by Zhivopistsev [205] for the extraction-photometric determination of Fe. The detectable minimum corresponds to 0.04–0.05 μg Fe. In the presence of Co the determination of Fe can be finished using *o*-phenanthroline after re-extraction with acetate buffer solution (pH 5.37). [206]

Iron is coprecipitated quantitatively in the form of the diantipyrinylmethane–thiocyanato-complex with diantipyrinylmethane thiocyanate. This has been used to purify Ni, Mn, Al, and Cr salts from Fe. [56] Thus after the precipitation, nickel contains < 0.0002% Fe.

Diantipyrinylphenylmethane, unlike antipyrine, precipitates $[Fe(CN)_6]^{3-}$ ions from sulphuric acid solution and gives no precipitate with $[Fe(CN)_6]^{4-}$. The precipitate has a definite composition corresponding to the formula $(C_{29}H_{28}O_2N_4.H)_3[Fe(CN)_6]$ and is suitable for the gravimetric determination of cyanoferrate(III) in the presence of cyanoferrate(II), and also for the determination of cyanoferrate(II) after oxidation to $[Fe(CN)_6]^{3-}$. [167]

In acid medium in the presence of $SCN^-$ ions, antipyrinylbis-(*p*-dimethylaminodiphenyl)methane reacts with

$Fe^{III}$ to form a sparingly soluble compound[62]. The reaction is extremely sensitive (0.02–0.03 μg $ml^{-1}$ Fe).

Diantipyrinylfurylmethane in acid medium reacts with $Fe(SCN)_3$ to give a red compound which is sparingly soluble in water and readily soluble in acetone. The acetone solutions are suitable for the spectrophotometric determination of 0.3–1 μg $ml^{-1}$ Fe.[207]

It is also possible to determine Fe using pyramidone. The proposed methods are based on the oxidation of pyramidone by $Fe^{III}$ with the formation of an intense blue-violet colour. The detectable minimum corresponds to 0.1 μg $ml^{-1}$ Fe.[188,208] In the acidity range 0.1–0.2 *N* HCl the colour of the solution depends little on the acidity, and the spectrophotometric determination of 0.5–3.0 μg $ml^{-1}$ Fe is possible[209].

The reaction has also been used to identify $[Fe(CN)_6]^{3-}$ in the presence of $[Fe(CN)_6]^{4-}$ [210,211] and for the determination of pyramidone[30-33,47,212].

## Cobalt

In acid solutions in the presence of $SCN^-$ ions, cobalt(II) reacts with antipyrine§ and its derivatives to form blue compounds $(RH)_2[Co(SCN)_4]$ which are sparingly soluble in water but readily soluble in certain organic solvents. The compound with antipyrine has the composition $(C_{11}H_{12}ON_2.H)_2[Co(SCN)_4].2C_{11}H_{12}ON_2$.[215]

The formation of antipyrine tetrathiocyanatocobaltate has been recommended as a sensitive and selective reaction for the detection of Co.[38,48,215,216]

Antipyrine tetrathiocyanatocobaltate is readily extracted from weakly acidic solutions (pH 1.8–2.2) by a 5:1 mixture of ethyl acetate and benzene[217]. The coloured extracts ($\lambda$ = 630 mμm, $\epsilon$ = 3156) can be used for the spectrophotometric determination of 1–100 μg of Co in 5 ml.

The formation of pyramidone tetrathiocyanatocobaltate is highly sensitive (the detectable minimum corresponds to 1 μg Co) and has been used for the detection of Co in nickel[218,219] and for the identification of pyramidone[55]. Zhivopistsev[220] has suggested that the reaction be carried out in the presence of $Zn^{2+}$ ions, which react with pyramidone to give the compound $(C_{13}H_{17}ON_3.H)_2[Zn(SCN)_4]$, isomorphous with the compound $(C_{13}H_{17}ON_3.H)_2[Co(SCN)_4]$. In this case the Co compound does not form supersaturated solutions (which is the case at low $Co^{2+}$ contents) and the sensitivity of detection increases: the white Zn precipitate is coloured blue in the presence of as little as 0.4 μg Co.[2]

The compound of Co with diantipyrinylmethane $(C_{23}H_{24}O_2N_4.H)_2[Co(SCN)_4]$ has been recommended by Zhivopistsev for the detection[74] and quantitative determination[221] of Co. The spot test method has been used to detect 0.06 μg Co in the presence of Cr, Ni, $Fe^{II}$, Mn, Al, Zn, and the alkali and alkaline earth metals. The complex is readily extracted by chloroform with the formation of a blue extract. The colour of the extracts can be used for the spectrophotometric determination of Co in the presence of the elements indicated above. The error in the determination is 1 μg at a Co content less than 10 μg $ml^{-1}$, and 2 μg at a Co content of 10–50 μg $ml^{-1}$. The method has been used to determine small quantities (0.1–1.25%) of Co in steels containing up to 20% Ni.[222]

In the presence of Fe or Cd, which are also readily extracted in the form of compounds with diantipyrinylmethane, the determination of Co can be finished using nitroso-R-salt after re-extraction with acetate buffer solution. This method has been used to determine 0.0007% Co in pure nickel[206]. Ikramov[223] has made a comparative study of the diantipyrinylmethane and nitroso-R-salt methods for the determination of Co.

Diantipyrinylmethane has also been used for the detection of $SCN^-$ ions (the detectable minimum corresponds to 0.13 mg $ml^{-1}$).[224]

Equally sensitive reactions with Co in the presence of $SCN^-$ ions are given by diantipyrinylmethylmethane, diantipyrinylpropylmethane, diantipyrinyl-*o*-hydroxyphenylmethane, and diantipyrinyl-*p*-hydroxyphenylmethane (sensitivity 7.5 μg Co in 2 ml); less sensitive reactions are given by diantipyrinyl-*p*-tolylmethane (10 μg Co), diantipyrinyl-*o*-nitrophenylmethane (15.0 μg Co), and diantipyrinyl-*p*-dimethylaminophenylmethane (20.0 μg Co)[225]. All these reagents, like diantipyrinylmethane, are suitable for the photometric determination of cobalt from the blue colour of the benzene extract. The optimum acidity corresponds to 0.02 *N* $H_2SO_4$. The error in the determination of 0.06–0.1 mg Co in 2–5 ml of extract does not exceed ±10%. The method has been used for the determination of Co in bronze and cast iron.

A titrimetric method has been proposed for the determination of Co using pyramidone, based on the formation, at pH 5–6, of the complex $Co(C_{13}H_{14}ON_3)_2(SCN)_2$, which is sparingly soluble in water[226].

## Nickel

From acetic acid solutions in the presence of pyramidone and $NH_4SCN$, nickel is precipitated as $[Ni(C_{13}H_{17}ON_3)_2].(SCN)_2$. The precipitate is almost insoluble in solution containing an excess[227] of the reagents and is suitable for the gravimetric determination of Ni and pyramidone[228,229]. The sensitivity corresponds to 10 μg $ml^{-1}$ Ni.

## Palladium

In acid solutions, palladium(II) reacts with antipyrine and diantipyrinylmethane to form complexes which are readily extracted by chloroform with the formation of coloured extracts. On this basis, Sudo[94] developed a spectrophotometric method for the determination of Pd using antipyrine. The optimum acidity of the solution corresponds to 0.3–1.5 *N* HCl or $H_2SO_4$, or 0.3–1.0 *N* $HNO_3$. The method can be used to determine 1–20 μg Pd in 5 ml of extract.

Kreimer and coworkers[230] proposed the use of antipyrinylmethane instead of antipyrine. The optical density of the extracts was measured at 450 mμm. The sensitivity corresponds to 0.43 μg $ml^{-1}$ Pd. The method was used for the determination of 0.01–0.05% Pd in the products of nickel manufacture, containing up to 40% Ni, 20% Cu, and 5% Fe.

§ A spot test for the detection of $Co^{2+}$ using antipyrine has been described, based on the formation of a blue-green or pale green (depending on the Co content) colour, developed by drying a strip of filter paper moistened first with $Co^{2+}$ solution and then with 20–30% antipyrine solution[213,214].

Palladium is readily extracted from hydrochloric acid (0.5–5 *N* HCl) solutions with dichloroethane in the presence of diantipyrinylpropylmethane (with a sixfold excess of the reagent the degree of extraction of Pd is >99%). This has been used to remove traces of Pd from Rh.[231,232]

Compounds of Pd with antipyrine and pyramidone have also been prepared: $(C_{11}H_{12}ON_2.H)_2[Pd(CN)_4]$, $(C_{13}H_{17}ON_3.H_2)_2[Pd(SCN)_4]$, and $(C_{11}H_{12}ON_2.H)_2[PdCl_4].2H_2O$.[233–235] No practical use has been made of these compounds, however,

## Osmium

In acid solutions, osmium in the form of $OsCl_6^{2-}$ or $OsBr_6^{2-}$ reacts with antipyrine, diantipyrinylmethane, diantipyrinylpropylmethane, and diantipyrinylphenylmethane to form the compounds $(RH)_2[OsCl_6]$ and $(RH)_2[OsBr_6]$.[236] A method has been proposed for the gravimetric determination of osmium by precipitation and weighing as $(C_{23}H_{24}O_2N_4.H)_2.[OsBr_6]$ and $(C_{26}H_{30}O_2N_4.H)_2[OsCl_6]$.[237] The method can be used to determine 5–13 mg Os with an error of ±3%.

$Os^{IV}$ is readily extracted by dichloroethane, with the formation of coloured extracts, from hydrochloric and hydrobromic acid solutions (0.5–5 *N*) containing diantipyrinylmethane, diantipyrinylpropylmethane, and diantipyrinylphenylmethane. On this basis a method has been developed for the extraction-photometric determination of Os using diantipyrinylpropylmethane[238,239].

$Os^{IV}$ is extracted from hydrochloric acid (0.5–5 *N*) solutions with a 0.1% solution of the reagent in dichloroethane. The optical density of the extracts ($\lambda$ = 346 mμ, $\epsilon$ = 10 500; $\lambda$ = 378 mμ, $\epsilon$ = 8000) is measured relative to a solution of the reagent saturated with 1 *N* HCl. The method can be used to determine 2–20 μg ml$^{-1}$ Os in the presence of 40 mg Ru with an error of ±10%.

## Iridium

In acid solutions, iridium in the form of $IrCl_6^{2-}$ and $IrBr_6^{2-}$ reacts with antipyrine, diantipyrinylmethane, diantipyrinylpropylmethane, and diantipyrinylphenylmethane to give the compounds $(RH)_2[IrCl_6]$ and $(RH)_2[IrBr_6]$.[240]

The compound formed by iridium with diantipyrinylpropylmethane is sparingly soluble in water (the solubility in 0.5 *N* HCl amounts to $3.8 \times 10^{-5}$ M) and has been used for the gravimetric determination of iridium by precipitation and weighing as $(C_{26}H_{30}O_2N_4.H)_2[IrCl_6]$. The error in the determination of 5–13 mg Ir amounts to ±3%.

The complex of $Ir^{IV}$ with diantipyrinylpropylmethane is readily extracted by dichloroethane with the formation of a coloured extract (the degree of extraction for a tenfold excess of the reagent amounts to 98.5%). On this basis a method has been developed for the extraction-photometric determination of 4–40 μg ml$^{-1}$ Ir using diantipyrinylpropylmethane[231,232].

## Platinum

Platinum(IV) is readily extracted by dichloroethane from hydrochloric acid (0.5–6 *N*) solutions in the presence of diantipyrinylpropylmethane (the degree of extraction with a sixfold excess of the reagent is greater than 99%).[231,232] This has been used for the separation of traces of Pt from Rh by extraction.

Compounds of Pt with antipyrine, pyramidone, and diantipyrinylmethane have also been prepared: $(C_{11}H_{12}ON_2.H)_2[PtCl_6]$,[199] $(C_{11}H_{12}ON_2.H)_2[PtCl_4]$, $(C_{11}H_{12}ON_2.H)_2[Pt(CN)_4]$,[234,235] $(C_{13}H_{17}ON_3.H)_2[PtCl_6]$,[239] and $(C_{23}H_{24}O_2N_4)H_2[PtCl_6]$.[46] These compounds have not, however, found application in analysis.

## INTRODUCTION

The ability to form organometallic compounds has for long been regarded as a characteristic property of metals. D. I. Mendeleev, describing the then undiscovered elements eka-boron and eka-silicon, stated that they should form organometallic compounds. The many attempts to prepare organic derivatives of metals of the transition periods were until recently always unsuccessful. The only exceptions were the polyphenyl derivatives of chromium discovered in the 1920's by Hein. Later, however, it was established that these have the peculiar sandwich structure characteristic of a variety of transition elements.

The lack of experimental success was attributed to the impossibility of existence of this type of compound. In the most complete monograph published at that time, Krause and von Grosse [1] provided theoretical justification for the assumption that the covalent bond between a transition metal and an organic radical is unstable. As an example, they examined the possibility of the existence of organometallic compounds of titanium. In their opinion, the bivalent titanium derivatives, formed by means of the valency *s* electrons, should be more stable than the quadrivalent titanium derivatives, whose formation should involve the valency *s* and *d* electrons of the transition metal.

Nesmeyanov [2] divided all the elements of the Periodic System into two classes, depending on the possibility of formation of stable alkyls and aryls. For transition metals, which have incomplete lower *d* levels in addition to valency *s* and *p* electrons, sandwich or diarene derivatives are more characteristic. Several excellent reviews and monographs dealing with the latter have recently been published.

In the last 10–12 years, increasing experimental evidence has appeared for the formation of $\sigma$ bonds between transition metals and carbon. A number of truly covalent compounds of transition metals have been prepared, and these have attracted greater attention from research workers.

Alkyl and aryl derivatives of transition elements have been the subject of a review by Cotton [3], covering material up to 1955, and a section of a monograph by Zeiss [4], including some material up to 1960. This field of chemistry is making rapid progress, and it seemed to us useful to review briefly recent work on the organometallic compounds of the transition metals. The review deals with compounds containing a metal–carbon $\sigma$ bond. The only $\pi$-cyclopentadienyl derivatives dealt with are those which, in addition to the $\pi$-cyclopentadienyl group, contain an organic radical covalently bound to the element.

In this review the alkyls and aryls of the transition metals are examined according to the groups of the Periodic System, starting with Group IV (titanium, zirconium, and hafnium). The compounds of vanadium, niobium, and

tantalum in Group V, chromium, molybdenum, and tungsten in Group VI, and manganese and rhenium in Group VII are characterised. In the case of Group VIII, only the compounds of iron, cobalt, and nickel are included. The review does not deal with the peculiar organometallic derivatives of the first "b" subgroup — copper, silver, and gold — or with the platinum subgroup.

## GROUP IV

### Titanium

Of the organometallic compounds of the transition metals of Group IV, the titanium derivatives have been most extensively studied. This has been due largely to the industrial use of catalysts of the Ziegler–Natta type for the polymerisation of alk-1-enes. The complex polymerisation catalysts of this type contain alkyl compounds of zinc, aluminium, and sodium together with halides of transition metals, chiefly titanium. Reaction between the components leads to halogen–alkyl exchange on the titanium atom and is accompanied by the reduction of quadrivalent titanium to lower-valency compounds.

The large number of papers on the study of various catalytic systems of this type served as the starting point for the development of the chemistry of organotitanium compounds, whose existence, up to 1952, had been regarded as impossible. Since the catalytic systems contained alkyl components, chiefly of aluminium, preparative work in the chemistry of organometallic compounds of titanium had a distinct bias towards aliphatic derivatives.

At the present time, the known alkyl compounds of titanium include products of the type $R_nTiX_{4-n}$ (where $n$ = 1, 2, 3, or 4, R = methyl, ethyl, or butyl, and X = Cl, Br, or I) obtained by alkylation of a quadrivalent titanium halide with the corresponding derivatives of lithium, zinc, aluminium, lead, and other metals.

The mono- and di-alkyl compounds have been most extensively studied. The exchange reaction between a titanium halide and an organoaluminium derivative of general formula $R_nAlX_{3-n}$ is carried out in an inert atmosphere in solution in organic solvents (hexane, benzene, methylene chloride, etc.) at temperatures from -80° to 0°. To obtain the monoalkyl product, the reaction is carried out in an excess of $TiX_4$. Dialkyltitanium dihalides are obtained at a ratio of $TiX_4 : R_nAlX_{3-n}$ = 1 : 2. When the reaction is complete, the resulting organoaluminium compound $R_{n-1}AlX_{3-(n+1)}$ is converted into the insoluble or non-volatile state by the action of alkali or alkaline earth metal halides, and also higher ethers, phosphines, etc.[5,6]. The titanium mono- and di-alkyls are isolated by vacuum distillation of the reaction mixture. Thus methyltitanium trichloride is obtained by the exchange reaction of trimethylaluminium or of dimethylaluminium chloride with titanium tetrachloride in hexane solution[7]. The aluminium compound is added slowly to an excess of $TiX_4$ at room temperature

$$(CH_3)_2AlCl + TiCl_4 \rightleftarrows CH_3AlCl_2 + CH_3TiCl_3.$$

Sodium chloride is added to the reaction mixture to bind the organoaluminium compound in the complex $Na[AlCl_3(CH_3)]$, and the mixture is vacuum-distilled to give methyltitanium chloride in the form of dark violet crystals with m.p. 28.5° and b.p. 37° at 1 mmHg. Methyltitanium trichloride melts to form a yellow liquid, and is soluble in many organic solvents — hexane, benzene, and halogeno--derivatives — to give yellow solutions. Methyltitanium trichloride is monomolecular in benzene solution[5]. Dimethylzinc can be used instead of dimethylaluminium chloride and in this case the yield of product is 75% of the theoretical[7].

The monoethyl derivative was prepared in analogous fashion by the alkylation of an excess of $TiCl_4$ with tetraethyllead at -80°; the product has a lower thermal stability than the methyl derivative[8]. At 20° the ethyl derivative is a reddish liquid which decomposes in 24 h; iso-$C_4H_9TiCl_3$ is obtained by a method analogous to that for the methyl derivative but at a lower temperature[5].

Dimethyltitanium dichloride can be obtained from the monomethyl derivative by further methylation. Thus the action of trimethylaluminium on a hexane solution of $CH_3TiCl_3$ cooled to -80° gave almost black crystalline $(CH_3)_2TiCl_2$:

$$CH_3TiCl_3 + Al(CH_3)_3 \rightarrow (CH_3)_2TiCl_2 + (CH_3)_2AlCl.$$

Solutions of the latter in hexane are also pale yellow. Dimethyltitanium dichloride can be obtained by the disproportionation of methyltitanium trichloride with dicyclopentadienyldimethyltitanium at temperatures from -80° to 0° and a molar ratio of 1 : 2, and also by the reaction of dicyclopentadienyldimethyltitanium with titanium tetrachloride in hydrocarbon solutions[9]:

$$2(C_5H_5)_2Ti(CH_3)_2 + TiCl_4 \rightarrow 2(C_5H_5)_2Ti(CH_3)Cl + (CH_3)_2TiCl_2.$$

At a component ratio of 1 : 1 the reaction is

$$(C_5H_5)_2Ti(CH_3)_2 + TiCl_4 \rightarrow (C_5H_5)_2TiCl_2 + (CH_3)_2TiCl_2.$$

The dialkyl derivatives are less stable than the monoalkyl derivatives[10-13].

Tri- and tetra-methyltitanium can be obtained by the successive replacement of all the halogen atoms in a titanium halide by alkyl groups. Tetramethyltitanium is obtained in 50–70% yield from the ether addition compound in ethereal solution by the action of methyllithium or methylmagnesium chloride at temperatures from -50° to -80°.[14,15] It is obtained as glistening yellow crystals which distil with ether *in vacuo* at a temperature not exceeding 0°, and are stable at -78°.

$$TiCl_4 + 4CH_3Li \rightarrow (CH_3)_4Ti + 4LiCl.$$

Tetramethyltitanium was isolated in crystalline form from hexane solutions. After removal of ether, the hexane solution at temperatures between -30° and -50° gave glistening yellow needles of tetramethyltitanium, which forms methane on hydrolysis. Analysis of the product[16] gave the ratio $Ti : CH_4$ = 1 : 4.

Trimethyltitanium iodide $(CH_3)_3TiI$ is obtained by the exchange reaction of tetramethyltitanium in 2 : 1 ether — hexane solution with gaseous $CF_3I$ at reduced temperature (-78°).[17] Methyl iodide is a side-product of the exchange reaction. When the temperature is raised to -50°, the solution becomes brown and does not give a positive Gilman reaction. Trimethyltitanium iodide is obtained as yellow needles by removal of the solvent. The compound is stable in the absence of oxygen at low temperatures. On hydrolysis of the product, the ratio of liberated methane to hydrogen iodide is 2.95 : 1.

In ether, titanium trichloride does not react appreciably with methyllithium, but the pale blue suspension of $TiCl_3$ in tetrahydrofuran or its pale brown suspension in dimethoxyethane react rapidly at temperatures between -50°

and -80° with an ethereal solution of methyllithium, to form lithium chloride and a dark green solution, evidently containing trimethyltitanium [14]. The possibility of formation of the bivalent and tervalent titanium compounds RTiX and $RTiX_2$ has also been reported briefly [13,18].

The interesting observation that organomagnesium compounds undergo isomerisation in the presence of small quantities of $TiCl_4$ is attributed to the intermediate formation of organotitanium compounds according to the scheme

$$(CH_3)_2CHMgBr + TiCl_4 \rightarrow (CH_3)_2CHTiCl_3 + MgClBr,$$
$$(CH_3)_2CHTiCl_3 \rightarrow CH_3CH{=}CH_2 + TiCl_3H,$$
$$CH_3CH{=}CH_2 + TiCl_3H \rightleftarrows CH_3CH_2CH_2TiCl_3,$$
$$CH_3CH_2CH_2TiCl_3 + RMgBr \rightleftarrows CH_3CH_2CH_2MgBr + RTiCl_3.$$

This is confirmed by the displacement of propene by the addition of other alkenes [19]

$$RCH{=}CH_2 + CH_3CH_2CH_2MgBr \xrightarrow{TiCl_4} RCH_2CH_2MgBr + CH_3CH{=}CH_2.$$

Repeated attempts to prepare aryl derivatives of titanium were unsuccessful for almost a century. The reactions of titanium tetrachloride with diphenylmercury, phenylsodium, and an aryl Grignard reagent, with heating of the components to 200°, always led to the formation of biphenyl and titanium trichloride [20]. The reaction of titanium tetrachloride with diphenylmercury took place according to the equation

$$TiCl_4 + (C_6H_5)_2Hg \rightarrow C_6H_5HgCl + TiCl_3 + {}^1/_2(C_6H_5)_2.$$

The formation of titanium trichloride and biphenyl might indicate decomposition of an unstable organotitanium compound formed initially.

The first aryl organotitanium compound isolated in pure form was phenyltitanium triisopropoxide, obtained by the reaction of titanium tetraisopropoxide with phenyllithium [21]

$$Ti(OC_3^iH_7)_4 + C_6H_5Li \rightarrow C_6H_5Ti(OC_3^iH_7)_3 + LiOC_3^iH_7.$$

This was the first compound to be prepared containing a carbon–titanium σ bond. The complex $C_6H_5Ti(OC_3^iH_7)_3 \cdot LiOC_3^iH_7 \cdot LiBr \cdot (C_2H_5)_2O$ is first formed, and this is decomposed by a slight excess of titanium tetrachloride:

$$C_6H_5Ti(OC_3^iH_7)_3 \cdot LiOC_3^iH_7 \cdot LiBr \cdot (C_2H_5)_2O + {}^1/_4TiCl_4 \rightarrow$$
$$\rightarrow C_6H_5Ti(OC_3^iH_7)_3 + LiCl + LiBr + (C_2H_5)_2O + {}^1/_4Ti(OC_3^iH_7)_4.$$

Unlike the alkyl derivatives, phenyltitanium triisopropoxide is an almost colourless compound with m.p.88–90°, stable in an inert atmosphere in the absence of moisture. It can be obtained in almost quantitative yield by the reaction of phenyllithium with $TiCl(OC_3^iH_7)_3$ in ether solution [22].

With change in the ratio of titanium tetraisopropoxide and phenyllithium from 1 : 1 to 1 : 2 and 1 : 4, the thermal stability of the resulting organotitanium compounds decreases considerably. It was concluded that, in compounds of general formula $RnTiX_{4-n}$, the stability is determined chiefly by the value of $n$, but also depends on the electronegativity of R and X. It was found that stable compounds are formed only when $n \leqslant 2$ and X is sufficiently electronegative [23]. It was suggested that tetraphenyltitanium is extremely unstable, but yellow-orange crystals of this compound, fairly stable at low temperature, have recently been obtained by reaction of the ether addition compound of titanium tetrachloride with phenyllithium

$$TiCl_4 + 4C_6H_5Li \rightarrow (C_6H_5)_4Ti + 4LiCl.$$

The formation of phenyltitanium chlorides $(C_6H_5)_nTiX_{4-n}$ (where $n$ = 1–2) as intermediate products was observed in the reaction of diphenylmercury with $TiCl_4$ in solutions of various organic solvents at ~ 90°. [24] The presence of the phenyl–titanium bond was proved by the reaction with mercuric chloride, leading to the formation of phenylmercury chloride, and also by oxidation to phenol and biphenyl. The possible disproportionation of the monophenyl derivative to the disubstituted product, and also its decomposition to biphenyl and titanium dichloride, were noted

$$2C_6H_5TiCl_3 \rightarrow (C_6H_5)_2TiCl_2 + TiCl_4,$$
$$(C_6H_5)_2TiCl_2 \rightarrow (C_6H_5)_2 + TiCl_2.$$

The replacement of all the chlorine atoms in $TiCl_4$ by phenyl groups, on reaction with phenyllithium in ether solution at -80°, gives glistening orange-yellow leaflets of tetraphenyltitanium. The formation of tetraphenyltitanium is proved by the reaction with mercuric chloride, leading to the quantitative separation of phenylmercury chloride. The reaction with cyclopentadiene leads to the replacement of two phenyl groups by cyclopentadienyl groups, with the formation of dicyclopentadienyldiphenyltitanium [25]

$$(C_6H_5)_4Ti + 2C_5H_6 \rightarrow (C_6H_5)_2Ti(C_6H_5)_2 + 2C_6H_6.$$

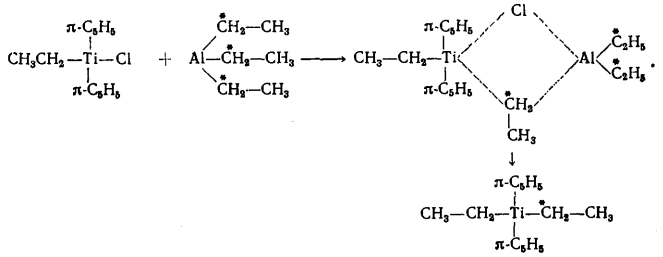
Tetraphenyltitanium, as predicted [23], is thermally unstable; with increase in temperature to -30° it decomposes with the formation of biphenyl and diphenyltitanium

$$(C_6H_5)_4Ti \rightarrow (C_6H_5)_2 + (C_6H_5)_2Ti.$$

The latter is a black pyrophoric substance, soluble in tetrahydrofuran and benzene. Its thermal stability is greater than that of its quadrivalent analogue.

A covalent titanium–radical bond is found in dicyclopentadienyl derivatives of the type $\pi\text{-}(C_5H_5)_2TiR_2$, where $\pi\text{-}C_5H_5$ is the cyclopentadienyl group or a monosubstituted cyclopentadienyl group joined to titanium in a $\pi\text{-}(C_5H_5)_2Ti$ sandwich, and R = $CH_3$, $C_2H_5$, or $C_6H_4X$. In these mixed organometallic compounds the electronic energy levels of the transition metal are filled by the π electrons of the sandwich group, leading to an increase in the stability of the compound as a whole and of the metal–carbon σ bonds in particular. The alkyl and aryl compounds were prepared by the action of the alkyls of Li, Mg, Zn, and Al on dicyclopentadienyltitanium dichloride. The dibromo-, diiodo-, dicyano-, dithiocyanato-, or dialkoxy-derivatives can be used instead of the dichloride.

$$\pi\text{-}(C_5H_5)_2TiCl_2 + RLi \rightarrow \pi\text{-}(C_5H_5)_2Ti(R)Cl + LiCl,$$
$$\pi\text{-}(C_5H_5)_2TiCl_2 + 2RLi \rightarrow \pi\text{-}(C_5H_5)_2TiR_2 + 2LiCl.$$



Products of complete and partial substitution $(C_5H_5)_2TiR_2$ and $(C_5H_5)_2Ti(R)X$ were obtained in this way [11,26–28]. Brief mention may be made of individual representatives of this type. The monomethyl derivative $\pi\text{-}(C_5H_5)_2Ti(CH_3)Cl$ forms red-orange crystals with m.p. 168–169°, soluble in water in the cold without decomposition. The first value given for the yield of this product was 1%; [26] the compound was later prepared in 90% yield [11,27]. The action of direct sunlight produces a rapid irreversible change in the compound. The monopropyl compound $(C_5H_5)_2Ti(C_3H_7)Cl$ begins to decompose at 160°; it is prepared from dicyclopentadienyltitanium dichloride and propyllithium.

Dicyclopentadienyldimethyltitanium $(C_5H_5)_2Ti(CH_3)_2$ forms orange needles with a characteristic odour and is prepared in analogous fashion in 95% yield [27]. It is stable to the action of water and oxygen, but darkens and decomposes rapidly on exposure to light.

The compound $(CH_3C_5H_4)_2Ti(CH_3)_2$ is obtained in 65% yield in the form of yellow crystals which are stable in air and in water but decompose on strong illumination or heating.

All these compounds can be used as catalysts for the polymerisation of alkenes, particularly in conjunction with organoaluminium compounds.

The reaction of ethyldicyclopentadienyltitanium chloride with $^{14}C$-labelled triethylaluminium leads to further exchange of ethyl groups by the titanium and aluminium atoms

The resulting diethyl derivative decomposes at 40°, as indicated by the isolation of the labelled decomposition products — ethane and ethylene[20].

Diaryl derivatives of dicyclopentadienyltitanium $\pi$-$(C_5H_5)_2TiR_2$ were prepared with R = $C_6H_5$, $m$-$CH_3C_6H_4$, $p$-$CH_3C_6H_4$, and $p$-$(CH_3)_2NC_6H_4$. These compounds form yellow-orange crystals which melt with decomposition[29,30]. The most stable is $\pi$-$(C_5H_5)_2Ti(C_6H_5)_2$, which melts at 146–148° and is monomolecular in benzene solutions. All these compounds are readily soluble in organic solvents. Their thermal stability depends to a marked extent on the nature of the aryl group. Thus dicyclopentadienyldiphenyltitanium can be kept for several days at room temperature, whereas the $p$-dimethylaminophenyl derivative could not be isolated in pure form. With an excess of phenyllithium, the formation of dark-coloured complexes $Li[Ti(C_5H_5)_2(C_6H_5)_3]$ and $Li_2[Ti(C_5H_5)_2(C_6H_5)_4]$ is observed; hydrolysis of ethereal solutions of these compounds leads to regeneration of the original product.

$$(C_5H_5)_2Ti(C_6H_5)_2 + C_6H_5Li \rightarrow Li[Ti(C_5H_5)_2(C_6H_5)_3] \xrightarrow{H_2O} \xrightarrow{H_2O} (C_5H_5)_2Ti(C_6H_5)_2 + C_6H_6 + LiOH.$$

In addition to the dicyclopentadienyl compounds, monocyclopentadienyl derivatives of quadrivalent titanium, of the type $\pi$-$C_5H_5TiR_3$, with a titanium–radical bond, are known. These compounds are obtained by an exchange reaction, analogous to that described above, between monocyclopentadienyltitanium trichloride and alkali-metal alkyls or aryls. Thus the reaction of $C_5H_5TiCl_3$ with methyllithium gave the trimethyl compound $C_5H_5Ti(CH_3)_3$, which is stable at -70° and can be distilled at -20° and 0.5 mmHg.[31] At -80° the compound can be isolated from pentane solution in the form of lemon yellow crystals which are pyrophoric in air at room temperature[27].

The phenyl analogue $C_5H_5Ti(C_6H_5)_3$ is obtained in solution in analogous fashion by the use of phenyllithium. It is a yellow compound, stable in solution at -70°. With increase in temperature to room temperature it decomposes with formation of the bivalent titanium compound $C_5H_5TiC_6H_5$; the products of the decomposition carried out in ethereal solution contain also biphenyl and benzene[32]. The presence of phenyl–titanium bonds in these compounds was proved by the reaction with mercuric chloride. In the case of $C_5H_5Ti(C_6H_5)_3$, the quantity of phenylmercury chloride formed corresponds to three phenyl–titanium bonds, and in the case of the monophenyl compound, the yield of phenylmercury chloride amounts to 1 mole per mole of $C_5H_5TiC_6H_5$ taken. In both cases the cyclopentadienyl–titanium bond is unaffected, as indicated by the formation of cyclopentadienyltitanium trichloride in the products of the reaction with mercuric chloride. $C_5H_5TiC_6H_5$ is a black compound which is oxidised extremely readily in air and is soluble in benzene and tetrahydrofuran. It reacts at low temperatures with halogen-containing organic solvents ($CHCl_3$ and $CCl_4$).

Thermal stability. A distinctive feature of organotitanium compounds is their extremely low thermal stability. In the series of alkyl or aryl derivatives of the type $RnTiX_{4-n}$, compounds with a smaller number of organic groups and with more strongly electronegative groups X are the more stable[23]. Thus methyltitanium trichloride is stable at 20° for several days in the absence of air and moisture. The yellow dioxan addition compounds of $R_2TiX_2$ are stable at 20° for 24 h. Tetramethyltitanium is stable at -70°. The decomposition of methyltitanium trichloride has been studied in more detail. At about 100° the compound decomposes with the formation of $TiCl_3$, methane, and polymethylene. The $TiCl_3$ produced catalyses the decomposition, which takes place more readily in ether and hydrocarbons. The rate of decomposition of methyltitanium trichloride increases on irradiation or treatment with $BF_3$.[5] In a mixture of $CCl_4$ and ether, considerable quantities of methyl chloride are formed, as a result of the disproportionation of methyltitanium trichloride[7]. In a recent paper[33], the reactions of $CH_3TiCl_3$ with carbon tetrachloride in the presence of metallic mercury are interpreted as free-radical reactions. Evidence for this is provided by the formation of methylmercury chloride, hexachloroethane, and other products of the free-radical reaction.

With increase in temperature to room temperature, tetramethyltitanium decomposes spontaneously with the formation of a black precipitate and a metallic mirror[16]. The decomposition products are pyrophoric and possibly contain derivatives of bivalent titanium.

The same is observed in the case of the phenyl derivatives. The thermal decomposition of tetraphenyltitanium gives diphenyltitanium and biphenyl[24]. The thermal stability of diphenyltitanium is much greater than that of tetraphenyltitanium. The former decomposes at 200–250° *in vacuo* with the formation of biphenyl and metallic titanium.

The thermal stability of organotitanium compounds of the above types decreases sharply when one or two cyclopentadienyl groups, joined to the metal in a sandwich, are introduced into the molecule:

$$R_4Ti > R_3TiC_5H_5 > R_2Ti(C_5H_5)_2.$$

The monocyclopentadienyl derivatives of quadrivalent titanium $C_5H_5Ti(CH_3)_3$ and $C_5H_5Ti(C_6H_5)_3$ darken and decompose when warmed to room temperature in the light. Cyclopentadienyltriphenyltitanium decomposes in ethereal solution with the loss of two phenyl groups in the form of benzene and biphenyl:

$$C_5H_5Ti(C_6H_5)_3 \xrightarrow{ether} C_5H_5TiC_6H_5 + C_6H_6 + (C_6H_5)_2.$$

A bivalent titanium derivative is formed. The presence of the cyclopentadienyl and phenyl groups in this compound was proved by the reaction with mercuric chloride

$$C_6H_5TiC_6H_5 + HgCl_2 \rightarrow [C_6H_5TiCl] + C_6H_5HgCl,$$
$$[C_6H_5TiCl] + HgCl_2 \rightarrow C_6H_5TiCl_3 + Hg,$$
$$[C_6H_5TiCl] + 2HgCl_2 \rightarrow C_6H_5TiCl_3 + 2HgCl.$$

In the thermal decomposition of mixed dicyclopentadienyl derivatives of titanium under mild conditions, the titanium–radical σ bond is broken first[34]. When dicyclopentadienyldiphenyltitanium is heated in solution at ~90°, the two phenyl groups are removed successively in the form of free radicals:

$$(C_5H_5)_2Ti^{4+}(C_6H_5)_2 \rightarrow (C_5H_5)_2Ti^{3+}C_6H_5 + C_6H_5^{\cdot},$$
$$(C_5H_5)_2Ti^{3+}C_6H_5 \rightarrow (C_5H_5)_2Ti^{2+} + C_6H_5^{\cdot}.$$

A derivative of tervalent titanium is produced in the first stage of the process. The two cyclopentadienyl–titanium bonds are unaffected, as indicated by the conversion of the dark-coloured product of the thermal decomposition to the stable dichloride $(C_5H_5)_2TiCl_2$ by the action of halogen-containing compounds ($CCl_4$, $HgCl_2$, benzyl chloride, etc.)[35,36].

The low thermal stability of organotitanium compounds results from the electron-unsaturation of the structure of the central titanium atom. Stabilisation results when the *d* electron level is filled by donor atoms and the electronic structure shows maximum approach to that of the nearest inert gas (krypton). The least stable tetramethyltitanium has a deficit of ten electrons, whereas the more stable $(C_5H_5)_2TiR_2$ has a deficit of only four electrons. Filling of the *d* level of titanium may also be brought about by electron donors such as amines, phosphines, and ethers. Complexes obtained with the above ligands are more stable, Thus methyltitanium trichloride forms a tetrahydrofuran derivative which is soluble in organic solvents and very sensitive to oxygen and moisture, but which has a higher thermal stability (m.p.107–108°). It reacts with metallic mercury in $CCl_4$ medium by a free-radical mechanism to give methylmercury chloride[37]. Insoluble complexes of methyltitanium trichloride with triphenylphosphine and dioxan are known[5]. Dimethyltitanium dichloride also forms a dioxan derivative. An ammine of diphenyltitanium which is readily oxidised in air and is hydrolysed with the liberation of ammonia has been described[25]. Diphenyltitanium reacts with tetrahydrofuran to give a tetrahydrofuran derivative. The latter is a black substance which is readily oxidised with the formation of biphenyl and phenol. Its reaction with mercury derivatives is similar to that of diphenyltitanium.

Action of water, acids, and alcohols. The Ti–R σ bond is generally broken by the action of water, alcohols, and other hydroxyl-containing compounds. In the case of the simplest alkyl derivatives $CH_3TiCl_3$, $(CH_3)_2TiCl_2$, $(CH_3)_4Ti$, etc., the reaction takes place with the quantitative liberation of methane. The compounds $(C_5H_5)_2Ti(CH_3)X$, $(C_5H_5)_2Ti(CH_3)_2$, and $C_5H_5Ti(CH_3)_3$ are stable towards water but are decomposed quantitatively by dilute acids[27]. The phenyl derivatives react with water, aqueous acids, or alcohols, with the formation of benzene. The products of the hydrolysis of $C_6H_5Ti(OC_3^iH_7)_3$ contain isopropanol and benzene[23]. Diphenyltitanium reacts with dilute hydrochloric acid with the formation of hydrogen, benzene, and $TiCl_3$:

$$(C_6H_5)_2Ti + 2HCl \rightarrow 2C_6H_6 + TiCl_2,$$
$$TiCl_2 + HCl \rightarrow {}^1/_2H_2 + TiCl_3.$$

The reaction of $(C_6H_5)_2Ti$ with isopropanol gives benzene as the main product[24]. Cyclopentadienyltriphenyltitanium reacts with isopropanol to give benzene in quantities corresponding to three phenyl groups, the cyclopentadienyl–titanium bond being unaffected. Small quantities of acetone are also detected[32].

Dicyclopentadienyldiphenyltitanium is stable to water. Dilute inorganic acids at room temperature lead to quantitative rupture of the $Ti–C_6H_5$ bonds but do not affect the $(C_5H_5)_2Ti$ group. The action of hydrochloric acid gives benzene and dicyclopentadienyltitanium dichloride:

$$(C_5H_5)_2Ti(C_6H_5)_2 + 2HCl \rightarrow 2C_6H_6 + (C_5H_5)_2TiCl_2.$$

The reaction with alcohols takes place at elevated temperatures with the formation of benzene, acetone, and, apparently, a dicyclopentadienyltitanium dialkoxide[35].

Action of halogens and halogeno-derivatives. The reaction with halogen provides an analytical test for an alkyl–titanium σ bond. Quantitative formation of alkyl iodides has been observed with $CH_3TiCl_3$, $(CH_3)_4Ti$, and $(CH_3)_2Ti(C_5H_5)_2$:

$$(CH_3)_4Ti + 4I_2 \rightarrow 4CH_3I + TiI_4,$$
$$(C_6H_5)_2Ti(CH_3)_2 + 2I_2 \rightarrow (C_6H_5)_2TiI_2 + 2CH_3I.$$

In the case of the phenyl derivatives this reaction is incomplete. Thus the reaction of a benzene solution of diphenyltitanium with iodine at room temperature leads to the formation of 20% of iodobenzene and $TiI_4$.

The phenyl–titanium bonds in diphenyltitanium are readily broken by the action of chloroform or carbon tetrachloride. The reaction with chloroform takes place at room temperature, as indicated by a change in colour from black to yellowish brown. The reaction products are benzene, biphenyl, and titanium tetrachloride; derivatives of bivalent or tervalent titanium were not observed[25].

Cyclopentadienyltriphenyltitanium is decomposed by chloroform between -70° and -50° with the formation of almost the theoretical quantity of benzene and dicyclopentadienyltitanium dichloride[32].

The thermochemical and photochemical reactions of dicyclopentadienyldiphenyltitanium in chloroform solution give benzene and dicyclopentadienyltitanium dichloride in analogous fashion. With carbon tetrachloride, chlorobenzene is formed[35,36].

It was noted above that the reactions of methyltitanium trichloride with carbon tetrachloride gave appreciable quantities of methyl chloride[7,33,37].

The reaction of tetramethyltitanium with $CF_3I$ gives methyl iodide in addition to trimethyltitanium iodide, but the mechanism of the reaction is not clear[17].

Action of metal halides. Metal halides react with the R–Ti bond. The action of the halides of tin, titanium, mercury, and other metals on a variety of organotitanium compounds has been noted. The action of $SnCl_4$

on methyltitanium trichloride leads to the formation of titanium tetrachloride and the methyl derivative of tin:

$$4CH_3TiCl_3 + SnCl_4 \rightarrow 4TiCl_4 + Sn(CH_3)_4.$$

The catalytic action of $TiCl_3$ on the decomposition of methyl derivatives of titanium was noted above. An analogous influence is shown by titanium dichloride. Titanium tetrachloride decomposes methyltitanium trichloride [7] and tetramethyltitanium [14]:

$$CH_3TiCl_3 + TiCl_4 \rightarrow 2TiCl_3 + CH_3Cl,$$
$$(CH_3)_4Ti + 3TiCl_4 \rightarrow [4CH_3TiCl_3] \rightarrow 4TiCl_3 + 4\dot{C}H_3.$$

Phenyltitanium triisopropoxide reacts with mercuric chloride to give heterolytic exchange of phenyl for halogen with the formation of phenylmercury chloride. Addition of titanium tetrachloride to the isopropoxide gave a catalyst for the intensive polymerisation of propene [38]. The reaction with $TiCl_4$ was studied in more detail in hexane or benzene medium at room temperature. Biphenyl, isopropoxytitanium trichloride, and a tervalent titanium compound were isolated from the reaction mixture:

$$C_6H_5Ti(OC_3H_7)_3 + 2TiCl_4 \longrightarrow \begin{matrix} C_6H_5TiCl_2(OC_3H_7) \\ \swarrow \qquad \searrow \\ 1/2(C_6H_5)_2 \quad + \quad C_3H_7OTiCl_2 \end{matrix} + 2C_3H_7OTiCl_3.$$

The biphenyl isolated from the products of the reaction carried out in labelled benzene was almost inactive.

To prove the presence of a C–Ti $\sigma$ bond, extensive use is made of the reaction with mercuric chloride, leading to formation of an unsymmetrical organomercury compound and titanium halides. Thus methyltitanium trichloride gives the methyl derivative of mercury [33]; phenylmercury chloride is the chief product of the reaction of phenyl compounds of titanium [24,32,34,35].

Oxidation. Oxidation is a characteristic reaction for the Ti–R bond. The oxidation of lower-valency titanium derivatives takes place very vigorously, often with spontaneous ignition. Thus diphenyltitanium, particularly in the finely divided state, ignites in air [24]. The oxidation of diphenyltitanium in benzene solution is complete in 1–2 h at room temperature; phenol and biphenyl are found among the reaction products. Special experiments on oxidation in labelled benzene medium showed that the products contained no tracer atoms from the solvent [25]. The products of the decomposition of tetramethyltitanium are pyrophoric [16], and cyclopentadienylphenyltitanium is vigorously oxidised [32].

In a series of quadrivalent derivatives, the stability to the action of oxygen increases with the introduction of cyclopentadienyl groups into the molecule. Methyltitanium trichloride reacts rapidly with the absorption of $\frac{1}{2}O_2$ per mole, the solution giving a precipitate which is coloured pale brown by impurities:

$$CH_3TiCl_3 + 1/2O_2 \rightarrow CH_3OTiCl_3.$$

This is followed by disproportionation of the alkoxytitanium trichloride:

$$3CH_3OTiCl_3 \rightarrow CH_3OTiCl_3 \cdot (CH_3O)_2TiCl_2 + TiCl_4.$$

Other alkyls and aryls of quadrivalent titanium — dialkyltitanium dihalides, tetramethyltitanium, the monophenyl derivatives $C_6H_5TiX_3$, and tetraphenyltitanium — are readily oxidised.

Alkyl or aryl derivatives of monocyclopentadienyltitanium are also oxidised vigorously; cyclopentadienyltrimethyltitanium is pyrophoric [31].

The dicyclopentadienyl compounds $(C_5H_5)_2TiR_2$ are more stable towards oxygen. In the solid state they are stable in air at low temperatures. In solution, oxidation is more rapid. Dicyclopentadienyldiphenyltitanium is readily oxidised by atmospheric oxygen in solutions in benzene, chloroform, and carbon tetrachloride at 50–60°.

Oxidation in isopropanol is accompanied by the formation of phenol, cyclopentadiene, acetone, and the oxidised organometallic compound. In $CCl_4$ medium, dicyclopentadienyltitanium dichloride is formed in addition to biphenyl, chlorobenzene, and carbonyl chloride; this indicates that reaction with the solvent, initiated by oxygen, takes place.

The sandwich group $(C_5H_5)_2Ti$ is unaffected under these conditions. Oxidation with aqueous hydrogen peroxide at 40–50° leads to complete decomposition of the original compound to CO and $CO_2$. Considerable quantities of acetophenone are found among the reaction products in addition to phenol [39].

Reduction. The discovery and study of polymerisation catalysts of the Ziegler–Natta type led to the development of work on the reduction of organotitanium compounds. The alkylation of titanium halides taking place in the systems formed by these catalysts leads to reduction of the quadrivalent titanium to the tervalent and bivalent states. The second component of the catalyst is an organometallic compound of lithium, magnesium, or, most frequently, aluminium. We shall not deal with the widely studied processes of formation and mechanism of action of "bridged" catalysts for the polymerisation of alk-1-enes, but merely point out that reduction of $Ti^{4+}$ to $Ti^{3+}$ often takes place in the synthesis of organotitanium compounds if the reaction is carried out at higher temperatures. The monosubstituted product $RTiCl_3$ forms $TiCl_3$ on decomposition:

$$RTiCl_3 \rightarrow R' + TiCl_3.$$

The reduction of the mono- and di-alkyl compounds is accompanied by the liberation of methane and ethane in the case of the methyl derivatives, and of ethane, ethylene, and butane in the case of the ethyl derivatives. This is due to disproportionation or dimerisation of the radicals.

The reactions of alkyl derivatives of titanium with hydrogen have been studied recently [27]. $CH_3TiCl_3$ and its mixtures with $(CH_3)_nAlCl_{3-n}$ do not react at all with $H_2$, whereas $(C_5H_5)_2Ti(CH_3)_2$ is reduced immediately in aliphatic and alicyclic hydrocarbons at room temperature, with the formation of two moles of methane and the sparingly soluble dark green dicyclopentadienyltitanium:

$$(C_5H_5)_2Ti(CH_3)_2 + H_2 \rightarrow (C_5H_5)_2Ti + 2CH_4.$$

No reaction with hydrogen takes place in halogen-containing solvents. Methyldicyclopentadienyltitanium chloride does not react with hydrogen at 20°. Dicyclopentadienyldiphenyltitanium in toluene is reduced appreciably only at 60°.

There is an interesting analogy between reduction under the influence of hydrogen or another organometallic compound and the thermal decomposition of titanium compounds with the formation of lower-valency derivatives.

Qualitative test for the C–Ti bond. The reaction with Michler's ketone provides a qualitative test

for a bond between a radical and a metal in the first three groups of the Periodic System. Alkyl derivatives of titanium also give a positive Gilman test. The final reaction products in the case of titanium compounds, however, differ from the analogous products for organoaluminium derivatives.

A slow positive reaction with Michler's ketone was observed for $C_6H_5Ti(OC_3^iH_7)_3$ and also for the products of the reaction of titanium tetraisopropoxide with phenyllithium in the proportions 1 : 2 and 1 : 4; the rate of the colour reaction increases with increase in the number of phenyl groups[23]. Phenyltitanium triisopropoxide reacts with benzophenone with the formation of triphenylmethanol. Diphenyltitanium gives a colour reaction with Michler's ketone.

### Zirconium and Hafnium

There are isolated data on organometallic compounds of zirconium and hafnium. In Cotton's review[3] it is stated that zirconium tetrachloride does not react with diethylzinc and that metallic zirconium does not react with ethyl iodide or diethylmercury. According to recent data, however, exchange of radicals is observed in the systems formed by $ZrCl_4$ with $R_2Hg$ or RMgX. $ZrCl_4$ reacts with diethylmercury and diphenylmercury[40] and with organolithium and organomagnesium compounds[41]. The reaction of phenylmagnesium chloride with $ZrCl_4$ gives biphenyl in 56% yield; $ZrCl_4$ or $Zr(OC_6H_5)_4$ reacts with methyllithium to give up to 70% of methane[42]. Hydrolysis of the reaction mixture gives hydrogen in addition to hydrocarbons. The reaction of a phenyl Grignard reagent with zirconium tetrachloride to give a compound of the type $RZrCl_3$ has recently been reported[43]. Hafnium and zirconium chlorides have been used as additives to aluminium triisobutoxide in order to study the resulting propene-polymerisation catalysts. The relative reactivity of the catalyst increases in the order

$$HfCl_4<ZrCl_4<TiCl_4<VOCl_3<VCl_4.$$

The formation of organometallic compounds of hafnium and zirconium by halogen–radical exchange reactions is probable in these cases. A brief report of the preparation of $Zr(C_5H_{11})_2$ from hydrides and diazohydrocarbons at low temperatures appeared in the patent literature[44].

## GROUP V

### Vanadium

The early papers cited in Cotton's review[3] contained no convincing proof of the formation of alkyl or aryl compounds of vanadium. The reaction of $VOCl_3$ with a Grignard reagent gives a dark green crystalline product which burns in air with a smoky flame and contains vanadium[45]. This substance was not studied more closely.

Recent papers contain reliable evidence of the formation of a phenyl–vanadium bond. Thus the reaction of ten moles of phenyllithium with one mole of the tetrahydrofuran addition compound of vanadium(II) chloride in ether in the cold, in the absence of moisture and air, gave the paramagnetic complex $4C_6H_5Li.V(C_6H_5)_2.3.5(C_2H_5)_2O$. The complex is very sensitive towards air and moisture. It loses ether *in vacuo* at 50°, and decomposes above 80° with the formation of biphenyl. Chemical reactions confirm the presence of a phenyl–vanadium σ bond. Decomposition by acids, water, or alcohols leads to the formation of benzene. The reaction with iodine gives iodobenzene and the reaction with mercuric chloride gives phenylmercury chloride. The tetrahydrofuran addition compound of vanadium chloride reacts with phenylmagnesium chloride to form a complex containing vanadium and magnesium[46]. Vanadium halides react with organometallic compounds of aluminium, mercury, and titanium with exchange of halogen atoms for phenyl groups. It was shown that triisobutylaluminium containing added halides of the transition metals of Groups IV–VI (Ti, V, Cr) form catalysts for the polymerisation of alk-1-enes, the greatest activity being shown by vanadium halides[47,48]. In the process, reduction of quadrivalent and quinquevalent vanadium to the bivalent and tervalent states is observed, together with the formation of a black precipitate which fumes in air and contains aluminium, vanadium, halogen, and a hydrocarbon radical. It was shown convincingly for the analogous systems formed by organometallic compounds of aluminium with titanium halides that the complexes with a "bridged" structure are intermediate products in the formation of true organotitanium compounds. The formation of individual derivatives in the case of vanadium halides might also be expected.

It was shown that diphenylmercury reacts in cyclohexane solution under ordinary conditions with vanadium halides and oxide halides, with the quantitative formation of phenylmercury chloride and a red solution of phenyl derivatives of vanadium:

$$(C_6H_5)_2Hg + VOCl_3 \rightleftarrows C_6H_5VOCl_2 + C_6H_5HgCl,$$
$$(C_6H_5)_2Hg + VCl_4 \rightleftarrows C_6H_5VCl_3 + C_6H_5HgCl.$$

Their formation is confirmed by spectroscopic data and also by hydrolysis, which leads to the formation of benzene. Benzene is also formed by the action of hydrogen bromide:

$$C_6H_5VOCl_2 + HBr \rightarrow C_6H_6 + VOCl_2Br.$$

The phenyl derivatives of vanadium were not isolated in pure form, since they are thermally unstable. Decomposition gives biphenyl, evidently as a result of disproportionation:

$$2C_6H_5VOCl_2 \rightleftarrows (C_6H_5)_2VOCl + VOCl_3,$$
$$(C_6H_5)_2VOCl \rightleftarrows (C_6H_5)_2 + VOCl.$$

It was proved that free phenyl radicals are not formed at this stage[49].

In the $(C_6H_5)_4Sn + VCl_4$ ($VOCl_3$) system, exchange of phenyl radicals is observed under more severe conditions (100°).[50] Rapid reduction of vanadium and formation of biphenyl was observed on the addition of $AlCl_3$, $AlBr_3$, or $Al(OC_4^iH_9)_3$. Diphenylzinc and $CH_3TiCl_3$ bring about partial reduction of vanadium from the quadrivalent to the bivalent state and give catalysts for the polymerisation of ethylene[47].

Phenyl derivatives of vanadium can be obtained by replacing the cyclopentadienyl group of $C_5H_5V(CO)_4$ by a phenyl group. If a current of hydrogen chloride, a mixture of HCl and $O_2$, and, finally, pure oxygen are passed in turn through a benzene solution of $C_5H_5V(CO)_4$, the colour changes from violet to pale blue. Removal of the solvent and distillation in a high vacuum gives $C_6H_5VOCl_2$, which is soluble in benzene, chloroform, ether, methylene chloride, and other organic solvents[51].

Replacement of the halogen in $\pi$-$(C_5H_5)_2VCl$ by a phenyl group by the action of an equimolar quantity of phenyllithium gave $(C_5H_5)_2VC_6H_5$ in pure form[52]. The same compound was obtained by the action of phenyllithium on $\pi$-$(C_5H_5)_2VCl_2$ in the molar ratio 2 : 1 in 1,2-dimethoxyethane solution at -50°. The solvent was removed *in vacuo* and the residue was extracted with petroleum ether. Black crystals of $(C_5H_5)_2VC_6H_5$ with m.p. 92° were isolated in 50% yield by freezing to -80°. Phenyldicyclopentadienylvanadium solution is stable in the absence of oxygen at room temperature for one week. The presence of phenyl–vanadium $\sigma$ bond was proved by the formation of benzene on decomposition with HCl; the initial green colour of the solution changed to blue and then to green again, and crystals of $(C_5H_5)_2VCl$ separated from the reaction mixture:

$$(C_5H_5)_2\,V\,C_6H_5 + HCl \rightarrow C_6H_6 + (C_5H_5)_2VCl\,.$$

The vanadium derivatives are very sensitive towards oxygen.

### Niobium and Tantalum

Data on the reactions of niobium and tantalum halides with aromatic hydrocarbons are contradictory[3]. The reactions of $NbCl_5$ and $TaCl_5$ with benzene, naphthalene, anthracene, and tetralin in a boiling solvent (benzene, $CCl_4$, or $CS_2$) led to the formation of compounds containing metal, halogen, and an organic residue[53]. The formulae $RMX_4$ or $R_2MX_3$ were ascribed to the products, but the latter were not isolated in pure form, with the exception of the complex $C_6H_6.NbCl_5$. Attempts to repeat these reactions with specially purified benzene were unsuccessful[54].

Reaction of a Grignard reagent with tantalum compounds gives red solutions, which are unstable towards water and oxygen and contain tantalum compounds in the dissolved state. Complete hydrolysis gives the oxide $Ta_2O_5$.[55]

The preparation of a complex of tetraphenylniobium with phenyllithium by the reaction of $NbBr_5$ with phenyllithium in ethereal solution has recently been reported[56]:

$$NbBr_5 + 8C_6H_5Li + 3(C_2H_5)_2O \xrightarrow[N_2]{} \underset{(I)}{Li_3Nb(C_6H_5)_7.3(C_2H_5)_2O} + 5LiBr + \frac{1}{2}(C_6H_5)_2.$$

The complex (I) crystallises as a black-violet compound which is pyrophoric in the dry state. The ether is removed in a high vacuum at room temperature. The substance is non-volatile, stable up to 40–50°, and is readily oxidised and hydrolysed. The magnetic moment is 1.66 $\beta$, which is characteristic of $Nb^{4+}$. The infrared spectra confirmed the presence of a phenyl–niobium $\sigma$ bond; the formula $Nb(C_6H_5)_4.3C_6H_5Li.3(C_2H_5)_2O$ was ascribed to the substance.

## GROUP VI

### Chromium

Phenylchromium compounds became known as early as the 1920's, as a result of Hein's work. The compounds were prepared by the reaction of phenylmagnesium bromide with sublimed anhydrous chromium(III) chloride at -10°. Three series of compounds were isolated from the reaction mixture and these were named as derivatives of "triphenylchromium", "tetraphenylchromium", and "pentaphenylchromium". It appeared strange that all these compounds had the same orange colour, apparently indicating the same oxidation state. Reduction with lithium tetrahydroaluminate in all cases gave more biphenyl than benzene, and phenol was also obtained from the "penta"-derivative[57]. Reduction with $LiAlD_4$ showed that the biphenyl is formed at this stage and not by hydrolysis. It was thus established that each of these three products contains biphenyl, not phenyl, groups. The structure of Hein's polyphenylchromium compounds began to be explained in the light of a diarene $\pi$ structure analogous to that of dibenzenechromium.

Measurement of the magnetic properties, the X-ray and infrared spectra, and analytical data proved that dibiphenylchromium iodide obtained by the Grignard reaction[58] was identical to that obtained from biphenyl and chromium(III) chloride in the presence of Friedel–Crafts catalysts[59].

Further work showed the possibility of the existence of true organometallic compounds of chromium. The formation of phenylchromium compounds of the type $C_6H_5CrCl_2$ or $(C_6H_5CrCl_2)_2CrCl$ as intermediate products was postulated in 1956.[60] In a description of the reaction of triphenylaluminium with $CrCl_3$, mention was made of the formation of the tetrahydrofuran addition compound of phenylchromium dichloride $C_6H_5CrCl_2.3THF$†.[61] Anhydrous chromium(III) chloride reacts with phenyllithium in ethereal solution to form a red solid (A)[62]:

$$CrCl_3 + 6C_6H_5Li \xrightarrow{\text{ether}} (C_6H_5)_3Cr\cdot 3C_6H_5Li\cdot 2.5\,(C_2H_5)_2O\ (A)\,.$$

The compound (A) is extremely sensitive to oxygen and moisture. Hydrolysis leads to the formation of benzene, and biphenyl is formed in the absence of oxygen. With iodine, biphenyl and iodobenzene are formed:

$$Li_3Cr\,(C_6H_5)_6 + {}^9/_2I_2 \longrightarrow 3\,LiI + CrI_3 + 3C_6H_5I + {}^3/_2\,(C_6H_5)_2\,.$$

The product (A) is paramagnetic (3.87 $\beta$ and 3.61 $\beta$), which corresponds to tervalent chromium and confirms the presence of three phenyl–chromium $\sigma$ bonds. The triphenylchromium complex can be obtained free from ether by dissolving compound (A) in benzene with subsequent crystallisation. Under normal conditions, the solutions absorb hydrogen and form the hydro-pentaphenyl derivative $Li_3[CrH(C_6H_5)_5].3(C_2H_5)_2O$ as shiny red crystals. Further treatment with hydrogen leads to the formation of complex products[63]. The reaction of $3C_6H_5Li.(C_6H_5)_3Cr\,.\,2.5(C_2H_5)_2O$ with lithium tetrahydroaluminate in ether in a current of pure dry argon gave a pyrophoric substance decomposing above 75°, and having the composition $Li_6CrAl_3H_{16}.\frac{1}{3}(C_2H_5)_2O$ (apparently a complex hydride of univalent chromium). The compound is insoluble in the usual solvents, readily deposits chromium, reduces azobenzene to aniline, and reacts with phenyllithium under ordinary conditions to give a hydride of composition $Li[AlH(C_6H_5)_3]$.[64]

Reaction of phenylmagnesium bromide with chromium(III) chloride in tetrahydrofuran solution at -20° gave the tetrahydrofuran addition compound $(C_6H_5)_3Cr.3THF$, which is readily hydrolysed to green $[Cr(H_2O)_6]^{3+}$ and reacts with mercuric chloride to give a quantitative yield of phenylmercury chloride[65,66]:

$$(C_6H_5)_3Cr\cdot 3THF + 3HgCl_2 \xrightarrow{THF} 3C_6H_5HgCl + CrCl_3\,.$$

† THF represents tetrahydrofuran.

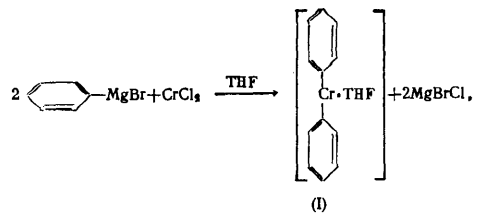
On being heated *in vacuo*, and also as a result of the addition of diethyl ether, the precipitate loses all its tetrahydrofuran with formation of a black substance, which on hydrolysis in the absence of oxygen gives the $\pi$ complexes dibenzenechromium and benzenebiphenylchromium[67]:

$$(C_6H_5)_3Cr\cdot 3THF \xrightarrow[H_2O]{heat} \pi\text{-}(C_6H_6)_2Cr + \pi\text{-}C_6H_6Cr(C_6H_5 - C_6H_5).$$

The double compound $(C_6H_5)_3Cr.3THF.3(MgBrCl.THF)$ (B) has also been isolated[68]. The action of ether on (B) gives the tetrahydrofuran addition compound of triphenylchromium. Drying *in vacuo* at 20–40° yields an extremely pyrophoric product, which on careful hydrolysis also gives a mixture of the $\pi$ complexes dibenzenechromium and benzenebiphenylchromium. The $\pi$ complexes can also be prepared by appropriate treatment of (B). The action of $D_2O$ on the black intermediate product in an atmosphere of nitrogen gives a mixture of bismonodeuterobenzenechromium and biphenylmonodeuterobenzenechromium[69].

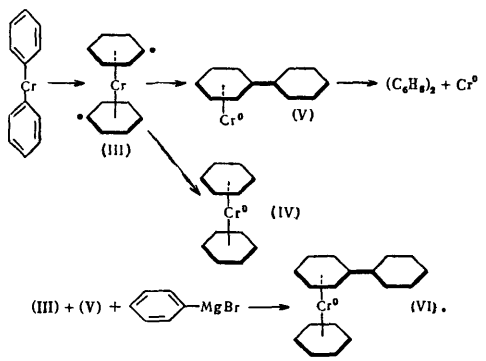
Carboxylation of the black intermediate product leads to the formation of carboxy-derivatives. Thus chromium(II) chloride in ethereal solution reacts with a phenyl Grignard reagent at -10°; after 4 h, saturation of the reaction mixture with carbon dioxide and hydrolysis with an aqueous solution of sodium tetraphenylborate give a red-orange precipitate having the composition[70]

$$(C_6H_5COOH)[(C_6H_5)_2Cr]^+(C_6H_5)_4B^- \text{ (yield 12\%, m.p. 144–147°).}$$



Substituted phenyl derivatives of chromium have recently been described. The action of *o*-methoxyphenyllithium on a chromium halide gives fine yellow crystals of bis-*o*-methoxyphenylchromium, which is pyrophoric in air, is slowly decomposed by alcohol, and has a low magnetic moment (0.55 $\beta$). Attempts to prepare this compound from the lithium derivative and the tetrahydrofuran addition compound of chromium(II) bromide led to formation of the red-brown crystalline complex $LiCr(o\text{-}CH_3OC_6H_4)_4.L$, where L is the solvent. This complex was also obtained by the disproportionation of bismethoxyphenylchromium with an ethereal solution of methoxyphenyllithium[71].

Tris-($\omega$-*NN*-diethylaminotolyl)chromium has been prepared by the reaction of chromium(III) chloride in ether with $\omega$-*NN*-diethylaminotolyllithium. The compound forms glistening garnet red crystals which are comparatively stable in air and even more stable in alcoholic solution; it was assumed to have an inner-complex structure[72]. The analogous reaction with $p\text{-}N(CH_3)_2C_6H_4Li$ gave a yellow substance of composition



$$[p\text{-}N(CH_3)_2C_6H_4]_3Cr.3p\text{-}N(CH_3)_2C_6H_4Li.3THF \text{ (Ref. 71),}$$

which is sensitive to air and sparingly soluble in ether.

Tsutsui regards the formation of true phenylchromium compounds as an intermediate stage in the formation of the more stable arene $\pi$ complexes. In his opinion[73] the reaction of chromium(II) chloride with a phenyl or mesityl Grignard reagent involves initially the formation of diphenyl- or dimesityl-chromium. Diphenylchromium was not isolated from the reaction products: it undergoes rapid rearrangement to dibenzenechromium and benzenebiphenylchromium. The true organochromium compounds formed initially undergo further rearrangement to the transition state — a $\pi$-radical hybrid — which may be stabilised in the form of the diradical sandwich $\pi$ complex (III) or the half-sandwich $\pi$ complex (V). In the process, the bivalent chromium is reduced to the zerovalent state.

(I)

The $\pi$ complexes (III) and (V) undergo rearrangement to sandwich compounds (IV) or (VI), with the stable electronic configuration of an inert gas, or else decompose with the formation of biphenyl, depending on the reaction conditions. Rearrangement to dibenzenechromium and benzenebiphenylchromium takes place as a result of hydrolysis or subsequent reaction with the Grignard reagent under the conditions of Hein's reaction. Decomposition to biphenyl takes place under more severe conditions.

Tsutsui suggests that the $\pi$-radical–electron hybridised complex (VII), in which the two phenyl groups are tilted relative to the chromium atom, is formed in an intermediate state between diphenylchromium and the $\pi$ complex (III) or (V).

(VII).

In the case of dimesitylchromium, there is an increase in the strength of the mesityl–chromium $\sigma$ bond. Dimesitylchromium is a stable compound, which can be isolated in the pure state and which does not undergo rearrangement to the $\pi$ complex under any conditions[74]. This is due to steric hindrance to free rotation of the mesityl groups about the central chromium atom. Formation of $\pi$ complex sandwich compounds cannot take place in this case, since it would require the two mesityl groups to be coplanar. For dimesitylchromium, only one reaction remains possible — formation of the biaryl under more severe experimental conditions — and bimesityl is in fact obtained in quantitative yield on boiling a tetrahydrofuran solution of dimesitylchromium.

The tetrahydrofuran addition compound of triphenylchromium, obtained by the reaction of phenylmagnesium bromide with chromium(III) chloride, can also be converted into a sandwich compound by rearrangement with the inter-

mediate formation of a $\pi$-radical hybrid complex, similar to diphenylchromium. At the instant of decomposition, which takes place by a free-radical mechanism, formation of a highly active "radical metal", which may attack the arene with formation of a stable $\pi$ complex (IV) or (VI), is possible. The suggestion that a "radical metal" is formed in the reduction of a halide of a transition metal has been confirmed by new syntheses of diarene complexes[75]. Triethylaluminium has been used successfully as reducing agent for this purpose. The dimesitylene $\pi$ complex of chromium has been obtained from mesitylene, chromium(III) chloride, and triethylaluminium in n-heptane solution at room temperature. The same method has been used to prepare the bridged dibenzenechromium 1,1'-($\beta\gamma$-diphenyltetramethylene)dibenzenechromium iodide[76].

Alkyl derivatives of chromium have not yet been isolated in the pure state. Mention of these compounds is made in a description of the reaction of methyllithium with chromium(II) chloride, which leads to the formation of a black solution, apparently of dimethylchromium. The reaction with chromium(III) chloride gives a brown-red solution, evidently of trimethylchromium[14].

$\sigma$-Trialkyl derivatives of chromium are of particular interest in connection with their use for the catalytic cyclisation of disubstituted acetylenes[77]. Triethylchromium cyclises diphenylacetylene to hexaphenylbenzene with the simultaneous formation of tetraphenylbenzene. In the presence of trimethylchromium, tetraphenylcyclopentadiene is obtained from diphenylacetylene. Condensation of disubstituted acetylenes also takes place with aryl derivatives of chromium. The tetrahydrofuran addition compound of triphenylchromium gives hexamethylbenzene and 1,2,3,4-tetramethylnaphthalene from but-2-yne, depending on the experimental conditions[78]. The intermediate formation of a complex of triphenylchromium with three molecules of the alkyne $R_3Cr.(H_3CC{:}CCCH_3)_3$ was postulated. The condensation of acetylene with triphenylchromium or triethylchromium in tetrahydrofuran solution gives only hexamethylbenzene. Trimethylchromium reacts exothermally with but-2-yne to give 2-mesitylbut-2-ene in addition to hexamethylbenzene[79]. The exothermic reaction of triphenylchromium with dimethyl acetylenedicarboxylate in tetrahydrofuran solution at room temperature leads to the attachment of two phenyl groups with the formation of dimethyl diphenylmaleate.

The addition of aryl groups with formation of derivatives of styrene or stilbene, and also condensation with ring closure, are explained as follows. The intermediate complex of the organochromium compound with acetylene is formed by the gradual replacement of solvent molecules. The final reaction products depend on the number of acetylene molecules coordinated to the triarylchromium molecule. The monosubstituted complex gives styrene or stilbene, and the disubstituted complex gives polycyclic aromatic hydrocarbons (e.g. naphthalene derivatives) if the *ortho*-position of the aryl is available for ring closure. The trisubstituted complexes given benzene derivatives.

Another important factor influencing the mechanism of the process is the effect of electron-repelling groups on the delocalisation of the $\pi$ electrons of the alkynes. Thus in the presence of the electron-repelling [sic] methoxycarbonyl groups, the products of cyclic condensation are not obtained. The reaction of dimethyl acetylenedicarboxylate with triphenylchromium takes place with the addition of two aryl groups to the acetylene derivative.

Alkenes such as hexenes, isoprene, stilbene, and styrene do not react with triphenylchromium. If the alkene is able to form a complex with chromium derivatives, addition reactions are observed. These properties are shown by 2,2,1-bicyclic dienes, e.g. bicyclo[2,2,1]hepta-2,5-diene and conjugated alkenes (maleic anhydride). It has been shown that cyclisation of alkenes does not take place on phenylchromium complexes[80].

At the present time this field of study is developing rapidly, since by selecting suitable derivatives of the arylchromium and unsaturated compounds it is possible to extend the synthesis of a variety of condensed aromatic systems and other compounds.

Chromium derivatives obtained by reducing alkyl halides with chromium(II) perchlorate constitute a group apart. The reaction of benzyl chloride with an aqueous molar solution of chromium perchlorate in dilute perchloric acid gave a yellow-brown solution of the benzyl derivative of chromium $[Cr(CH_2C_6H_5)(H_2O)_5]^{2+}$. The solution oxidises in air with the formation of benzaldehyde. In the absence of air, 1,2-diphenylethane is formed, evidently by dimerisation of the benzyl radicals. The half-life at room temperature is about $1\frac{1}{2}$ days. A rapid reaction takes place with mercuric chloride with the formation of benzylmercury chloride and the chromium ion without change in the pH of the medium[81]:

$$[Cr(CH_2C_6H_5)(H_2O)_5]^{2+} + HgCl_2 + H_2O \longrightarrow C_6H_5HgCl + [Cr(H_2O)_6]^{3+} + Cl'.$$

Benzylpentaaquochromium(II) solutions are decomposed by sulphur dioxide but are stable towards carbon dioxide; reaction with hydrogen in the presence of palladium gives toluene.

Methyl chloride and methylene chloride are not reduced by chromium(II) perchlorate. Chloroform and carbon tetrachloride are very readily reduced under these conditions. In both cases the pale blue colour of bivalent chromium changes to red within a few minutes. Carbon tetrachloride reacts with chromium(II) perchlorate to form unstable solutions, which have not been more closely studied. It is suggested that the reduction of chloroform takes place according to the following mechanism

$$CHCl_3 + 2[Cr(H_2O)_6]^{2+} \rightarrow [CrCl(H_2O)_5]^{2+} + [Cr(CHCl_2)(H_2O)_5]^{2+} + 2H_2O,$$
$$CHCl_3 + Cr^{2+} + 5H_2O \rightarrow [CrCl(H_2O)_5]^{2+} + \dot{C}HCl_2,$$
$$\dot{C}HCl_2 + Cr^{2+} + 5H_2O \rightarrow [Cr(CHCl_2)(H_2O)_5]^{2+}.$$

The chloroform derivative was not isolated in the pure state. The bond between chromium and the $CHCl_2$ group is evidently similar to a covalent bond of weak polar character. Unlike the benzyl derivative, the chloroform derivative does not react with mercuric chloride, oxygen, or sulphur dioxide[82], but it is reduced by hydrogen in the presence of a palladium catalyst. No tetrachloroethane or dichloroethylene is formed on heating; instead, the chloride ion is liberated. No volatile organic compounds are obtained.

An increase in the strength of the transition metal $\sigma$ bond, particularly that between chromium and carbon, is observed when a $\pi$-cyclopentadienyl group is introduced into the molecule. This is clearly illustrated for the case of organochromium compounds. Mixed cyclopentadienyl-nitrosyl derivatives of chromium with alkyl and aryl groups attached by $\sigma$ bonds are known. These are obtained via the sodium derivative $\pi$-$C_5H_5Cr(NO)_2Na$ by reaction with alkyl or aryl halides:

$$\pi\text{-}C_5H_5Cr(NO)_2Na + RX \rightarrow \pi\text{-}C_5H_5Cr(NO)_2R.$$

This method was used to prepare methyl, ethyl, and cyclopentadienyl derivatives containing σ bonds, and also the compound with R = $CH_2Cl$.[83,84] These compounds are diamagnetic, coloured, crystalline, or oily (R = $C_2H_5$ or $C_6H_5$) substances which are readily soluble in organic solvents and can be sublimed in a high vacuum. They decompose slowly in air. The stability of the compounds decreases in the order $C_6H_5 > CH_3 > C_2H_5$.

### Molybdenum and Tungsten

Molybdenum and tungsten halides react with phenyllithium or Grignard reagents; in a number of cases, only the dimerisation product biphenyl could be isolated[3]. Compounds of the type $(C_6H_5)_2Mo(OH, X)$, $C_6H_5MoO_2OH$, $C_6H_5Mo_2O_4H_4$, $(C_6H_5)_3Mo_2O_7H_7$, and $(C_6H_5)_2Mo_3O_9H_4$ may, however, be formed as intermediate products[84]. Analogous tungsten derivatives were obtained from $WCl_6$ or $W(OC_6H_5)_6$ with phenyl compounds of lithium or magnesium[85]. The properties of these molybdenum and tungsten compounds resemble those of the phenyl derivatives of chromium, but the former are less stable, so that they could not be isolated in the pure state.

Mixed π-cyclopentadienyl-carbonyl compounds of molybdenum and tungsten, containing a σ bond between the metal and the radical, have recently been reported. In these derivatives, stabilisation of the metal–carbon bond is due to the influence of the π-cyclopentadienyl group. σ-Substituted π-cyclopentadienyl-tricarbonyl compounds of molybdenum and tungsten have been obtained from the hydrides by reaction with diazomethane:

$$\pi\text{-}C_5H_5Mo(CO)_3H + CH_2N_2 \rightarrow \pi\text{-}C_5H_5Mo(CO)_3CH_3 + N_2,$$

or by reaction of the sodium salt of the π-cyclopentadienyl-tricarbonyl compound of the metal with alkyl halides[26,86]:

$$\pi\text{-}C_5H_5M(CO)_3Na + RI \rightarrow \pi\text{-}C_5H_5M(CO)_3R + NaI,$$

where R = methyl, ethyl, or isopropyl for M = Mo, and R = methyl or ethyl for M = W.

These compounds were isolated in 75–85% yield. They are relatively stable yellow crystalline substances with melting points from 80° to 150°. The stability of the compounds in air decreases in the order methyl > ethyl > isopropyl. The methyl compound of tungsten is more stable than that of molybdenum. All the compounds are insoluble in water and are slowly decomposed by acids and bases. Halogens bring about quantitative rupture of the alkyl–metal bond according to the equation

$$\pi\text{-}C_5H_5Mo(CO)_3CH_3 + I_2 \rightarrow \pi\text{-}C_5H_5Mo(CO)_3I + CH_3I.$$

The compounds react neither with $FeCl_2$ in tetrahydrofuran solution nor with maleic anhydride in benzene. Data obtained by infrared, ultraviolet, and nuclear magnetic resonance spectroscopy have established that all these derivatives have a cyclopentadienyl–metal π bond and a metal–radical σ bond.

The reaction of tungsten pentabromide with an ethereal solution of phenyllithium in a current of pure nitrogen gave crystalline tungsten compounds to which the formula $(C_6H_5)_3W.3C_6H_5Li.3(C_2H_5)_2O$ was at first ascribed[87]. This compound is a black substance which is readily soluble in benzene and readily ignites in air. According to recent data[88], the composition corresponds to the formula $(C_6H_5)_4W.2C_6H_5Li.3(C_2H_5)_2O$.

## GROUP VII

### Manganese and Rhenium

The stoichiometric coupling of a phenylmagnesium halide in the presence of manganese(II) chloride in ethereal solution gives biphenyl in quantitative yield[73]. Catalytic coupling (Kharasch's reaction) in the $C_6H_5MgX + C_6H_5X +$ + 3–5 mole % $MnX_2$ system produces 21% of biphenyl. The action of manganese bromide on ethylmagnesium bromide in the ratio 1 : 2 at 25° gave 63% of ethane and 29% of ethylene[42]. It was suggested that unstable intermediate organomanganese derivatives are formed, and this was confirmed by subsequent work. The reactions of phenylmagnesium iodide with manganese iodide in the ratio 3 : 1 in ethereal solution takes place with the formation of brown precipitates consisting of a mixture of the phenyl derivatives of manganese $(C_6H_5)_2Mn$ and $C_6H_5MnI$, which are unstable in air[3].

The reaction of alkyl and aryl Grignard reagents (methyl-, ethyl-, and benzyl-magnesium bromides, etc.) with manganese halides gives brownish oily liquids which are insoluble in organic solvents and unstable in air, and react readily with iodine in tetrahydrofuran or chloroform solution. With benzylmagnesium bromide, 1,2-diphenylethane was obtained. In other cases also, the manganese compounds could not be isolated in the pure state[89]. Replacement of the organomagnesium compound by RLi made it possible to obtain individual products. The reaction of methyllithium with manganese iodide gave methylmanganese iodide in the form of a brown oil, insoluble in ether:

$$CH_3Li + MnI_2 \rightarrow CH_3MnI + LiI.$$

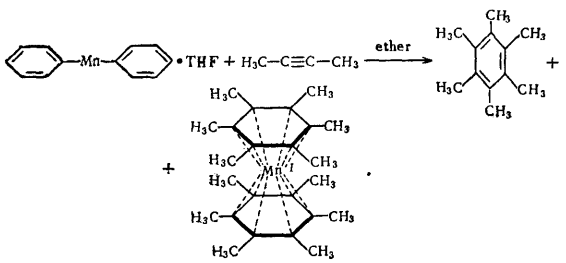
Reaction with another molecule of methyllithium gives colourless amorphous dimethylmanganese:

$$CH_3MnI + CH_3Li \rightarrow (CH_3)_2Mn + LiI.$$

Dimethylmanganese was obtained as a spontaneously inflammable yellow powder, exploding on impact. It is evidently polymeric. Diphenylmanganese, like the dimethyl derivative, is polymeric, but it can be crystallised from tetrahydrofuran.

Dimethylmanganese readily reacts with manganese iodide according to the scheme

$$(CH_3)_2Mn + MnI_2 \rightarrow 2CH_3MnI.$$



The reaction with excess of methyllithium gives the colourless amorphous complex $Li[Mn(CH_3)_3]$, insoluble in ether. This compound also reacts with $MnI_2$ to form dimethylmanganese and methylmanganese iodide:

$$(CH_3)_2Mn + CH_3Li \rightarrow Li[Mn(CH_3)_3],$$
$$Li[Mn(CH_3)_3] + MnI_2 \rightarrow (CH_3)_2Mn + CH_3MnI + LiI,$$
$$Li[Mn(CH_3)_3] + 2MnI_2 \rightarrow 3CH_3MnI + LiI.$$

Other complex products obtained were $Li[Mn(C_2H_5)_3]$ (a yellow amorphous powder, insoluble in ether), and also $Li[Mn(n\text{-}C_4H_9)_3]$, $Li[Mn(C_6H_5)_3]$, $Li[Mn(p\text{-}CH_3C_6H_4)_3]$, and $Li[Mn(p\text{-}CH_3OC_6H_4)_3]$.[89]

Diphenylmanganese can be obtained by the reaction of phenylmagnesium bromide with manganese chloride, or of phenyllithium with manganese iodide at -50° in tetrahydrofuran solution[90]. Dimethylmanganese forms a fairly stable pale yellow-green precipitate. Mesitylmagnesium bromide reacts with manganese chloride in the molar ratio 2 : 1 in

tetrahydrofuran solution to give a precipitate apparently consisting of dimesitylmanganese, but its structure has not been established. The substance is insoluble in organic solvents, very sensitive to the action of moisture and air, and does not react with alkynes, in particular but-2-yne. Diphenylmanganese similarly does not react with but-2-yne in tetrahydrofuran solution. When two volumes of diethyl ether are added to a tetrahydrofuran solution of diphenylmanganese, cyclic trimerisation of but-2-yne to hexamethylbenzene and the corresponding $\pi$ complex takes place:

$Mn^{II}$ is not as good an oxidising agent as $Cr^{III}$, so that the valency state of the manganese in this complex is unity, and this makes the complex isoelectronic with the zerovalent chromium complex[91]. The ability of phenylmanganese to coordinate solvent molecules is lower than that of the chromium compound[90]. Condensation with the formation of naphthalene derivatives is not observed. The fact that diphenylmanganese does not react with butyne in tetrahydrofuran solution is regarded as proof of the comparative stability of the phenyl–manganese bond. This is also illustrated by Tsutsui's data on the relative stabilities of the tetrahydrofuran addition compounds of diphenyl- and dimesityl-manganese[73]: the former decompose when the solvent is boiled, whereas the latter is quite stable at this temperature. This confirms Tsutsui's general hypothesis that the dimesityl derivatives of transition metals are generally more stable than the corresponding phenyl analogues.

Diphenyl- and dimethyl-manganese are decomposed by gaseous hydrogen. The solvent plays an important part in this process. In toluene, diphenylmanganese is unaffected when left to stand and agitated with hydrogen for 24 h, whereas in tetrahydrofuran at 20°, reaction begins rapidly with the formation of benzene and a black powder evidently consisting of the pyrophoric metal[27]. The quantity of hydrogen used corresponds to 0.85 mole per mole of substance; the reaction takes place according to the equation

$$(C_6H_5)_2Mn + H_2 \xrightarrow[20^\circ]{THF} Mn + 2C_6H_6.$$

The reduction of dimethylmanganese takes place in analogous fashion.

Stable organic derivatives of pentacarbonyl manganese, containing $\sigma$ bonds, are known. The donor carbonyl groups joined to the metal increase the strength of the $\sigma$ bond between manganese and substituents such as methyl, benzyl, and allyl, and also acetyl, benzoyl, and other acyls. The methyl derivative has been prepared by reaction of the sodium salt of pentacarbonyl manganese with dimethyl sulphate or methyl iodide[92]:

$$NaMn(CO)_5 + CH_3I \rightarrow CH_3Mn(CO)_5 + NaI.$$

Methylpentacarbonylmanganese forms colourless crystals which melt at 95°, are stable in air, and volatilise in a current of gas. The diamagnetic $CH_3Mn(CO)_5$ can be obtained by the action of diazomethane on the "carbonyl hydride"[94]:

$$HMn(CO)_5 + CH_2N_2 \rightarrow CH_3Mn(CO)_5 + N_2.$$

With carbon monoxide, methylpentacarbonylmanganese is converted into an acyl derivative, the process being reversible:

$$CH_3Mn(CO)_5 + CO \underset{t}{\overset{500\ atm,\ 20^\circ}{\rightleftharpoons}} CH_3COMn(CO)_5.$$

The acetyl derivative — a volatile white crystalline product of m.p. 54–55° — can be obtained in 51% yield by reaction of the sodium salt of pentacarbonyl manganese with acetyl chloride[92].

$\sigma$-Benzylpentacarbonylmanganese is prepared by a method analogous to that used for the methyl analogue. It is a pale yellow solid melting at 37.5–38.5°, stable to the action of air in the solid state, and less volatile in steam than the methyl derivative[92]. The phenyl-substituted product (m.p. 95–96°) has been obtained by the decarbonylation of benzoylpentacarbonylmanganese:

$$C_6H_5COMn(CO)_5 \rightarrow CO + C_6H_5Mn(CO)_5.$$

The presence of alkyl–manganese and acyl–manganese bonds is proved by the formation of the alkyl bromide or acyl bromide respectively on bromination[92].

$\sigma$-Allylpentacarbonylmanganese — an oily lemon yellow liquid which can be distilled *in vacuo* — has been obtained in 82% yield by the action of allyl chloride on the sodium salt of pentacarbonyl manganese in tetrahydrofuran solution[93]. It can be converted into $\pi$-allyltetracarbonylmanganese with the liberation of ~1 mole of carbon monoxide, by pyrolysis in a sealed tube at 80° for 12 h.

In Cotton's review[3] it is noted that methylmagnesium iodide in ether reacts vigorously with rhenium trichloride. After hydrolysis of the reaction mixture and removal of the solvent by distillation, fractionation at 60° gave trimethylrhenium in the form of a colourless oil, which burns with the formation of $Re_2O_7$. When this work was repeated, large quantities of methane and ethane were obtained[95] but no organorhenium compound was isolated. Like manganese, rhenium forms stable derivatives of the metal pentacarbonyl, containing an alkyl–metal $\sigma$ bond[96].

## GROUP VIII

### Iron

Covalent compounds of $Fe^{2+}$ and $Fe^{3+}$ have not been isolated in the pure state. Their possible formation in solution during the reaction of iron halides with organometallic compounds of lithium, magnesium, zinc, etc. has been reported[3]. This is indicated by change in colour of the reaction solutions, absorption of hydrogen and acetylene[97], and reduction of the iron. The organic radicals of the organometallic reactants dimerise or disproportionate in the process. Thus the reaction of methyllithium with $FeCl_2$ at ordinary temperatures gives 56% of methane and 24% of ethane[42].

The greatest number of attempts to prepare iron derivatives has been made with the alkyl and aryl organomagnesium compounds. Ethylmagnesium bromide reacts with $FeCl_2$ at 35° to give 49% of ethane and 40% of ethylene. Phenylmercury iodide in the presence of the halides of iron and other metals of Group VIII ($RuCl_3$, $OsCl_3$) undergoes

53–99% conversion into biphenyl[42]. The action of iron(III) chloride on phenylmagnesium bromide in the molar ratio 2 : 1 under ordinary conditions gives chlorobenzene in 40% yield[28].

Reduction of the metal during the synthesis, noted above, may indicate decomposition of intermediate unstable organometallic compounds of iron. In the reaction with phenylmagnesium bromide, the $Fe^{3+}$ is reduced to $Fe^{2+}$, and in a number of cases reduction to metallic iron takes place. Liberation of highly dispersed metal was observed when the temperature was raised above -40° in a reaction mixture having the composition $6C_6H_5MgBr + 2FeCl_3$.[98]

When the organomagnesium compound was replaced by $C_2H_5ZnI$, decomposition of the intermediate organoiron compounds did not take place. In this case the change in the ratio $Fe(OH)_2/Zn(OH)_2$ with time was studied by hydrolysed specimens of ethereal solutions of the reaction mixture $C_2H_5ZnI + FeI_2$. It was established that the ratio increased gradually and that after 6 h no ethylzinc iodide remained in solution. On hydrolysis of the final solutions, the quantity of ethane and $Fe(OH)_2$ corresponded to the formation of ethyliron iodide as intermediate product[99]:

$$2\,C_2H_5FeI + HI \xrightarrow{H_2O} 2C_2H_6 + Fe(OH)_2 + FeI_2.$$

This compound could not be isolated in the pure state.

Indirect indications of the possible formation of iron derivatives were obtained in the reaction of $FeCl_3$ or $FeCl_2$ with tetraethyllead, tetraethylsilicon, triphenylbismuth, etc.[101]. The reported formation of organoiron compounds by the reaction of pure iron with alkyl bromides is extremely doubtful[100].

Reports of the preparation of diaryl derivatives of iron by reaction of the corresponding mercury derivatives with iron powder at 120–125° [102] were found to be erroneous[103]. The tetrahydrofuran addition compounds of diphenyliron and dimesityliron are more stable, but these compounds are also decomposed at temperatures below -10°.[73]

The more stable mixed $\pi$-cyclopentadienyl compounds of the type $\pi$-$C_5H_5Fe(CO)_2R$, containing a $\sigma$ bond between the metal and the methyl, ethyl, phenyl, or cyclopentadienyl groups, have been isolated in the pure state[26,104]. The methyl derivative was obtained in 50% yield by the reaction of a methylmagnesium halide with a halogeno-$\pi$-cyclopentadienyldicarbonyl compound of iron in ethereal solution:

$$\pi\text{-}C_5H_5Fe(CO)_2I + CH_3MgI \rightarrow \pi\text{-}C_5H_5Fe(CO)_2CH_3 + MgI_2.$$

The yield of this compound is increased to 70% in the reaction of an alkyl halide with the sodium salt of the $\pi$-cyclopentadienyl derivative. When ethyl iodide is used, the ethyl derivative is formed in 60% yield. The yield of the phenyl analogue is only 2–5%.

The action of cyclopentadienylsodium on the bromide $\pi$-$C_5H_5Fe(CO)_2Br$ in tetrahydrofuran solution gave the compound $\pi$-$C_5H_5Fe(CO)_2$-$\sigma$-$C_5H_5$, in which the second cyclopentadienyl group is joined to the metal atom by a simple $\sigma$ bond.

These compounds are diamagnetic coloured products with definite melting points[26]. They are soluble in organic solvents, sublime readily in a high vacuum at 25–50°, and have characteristic odours. In solution, all the compounds are decomposed by air. The stability of the organoiron compounds decreases in the order phenyl > methyl > ethyl. These compounds are insoluble in water and do not react with it; they are decomposed by acids and bases. The action of acids gives the cation $[Fe(\pi\text{-}C_5H_5)(CO_2)]^{2+}$ (possibly hydrated), which yields characteristic Reinecke's salts. The action of iodine leads to quantitative formation of the iodide and the corresponding aryl or alkyl iodide. With the exception of the $\sigma$-cyclopentadienyl derivative, these compounds do not react with maleic anhydride. The reaction with the latter leads to a rapid change in colour, but the adduct obtained with maleic anhydride is unstable and cannot be isolated and identified.

## Cobalt

Coupling of $C_6H_5MgX$ takes place readily in the presence of added cobalt(II) chloride. The stoichiometric coupling of 0.03 mole of phenylmagnesium iodide with 0.01 mole of $CoCl_2$ gave 98% of biphenyl[42]. In the catalytic coupling, the yield of biphenyl is slightly lower and amounts to 86%.

The first papers on the preparation of organometallic compounds of cobalt of the type $RCoX_3$ and $R_2CoX_2$ appeared during 1949–1951. It was reported that the reaction of organomagnesium derivatives with cobalt bromide or iodide gave products with R representing methyl, ethyl, propyl, isopropyl, 1-naphthyl, and 2-naphthyl[105-107]. The compounds were obtained as coloured products decomposing at 65–160°. Some of their properties appeared to contradict the assumed formulae. For example, hydrolysis of a naphthyl derivative with water or dilute acids yielded chiefly binaphthyl. This gave the impression that the naphthyl groups were joined to one another in the same way as the phenyl groups in Hein's polyphenylchromium compounds. At the same time, doubt was cast on the possibility of formation of quadrivalent cobalt compounds under the conditions of the reducing medium in Grignard reactions[3].

The preparation of diallylcobalt, proposed as an additive to drying oils, has been reported in the patent literature[108,109], but there is no information on the methods of synthesis and the properties of this compound.

The formation of organometallic compounds of cobalt is indicated by the abnormal reactions of organomagnesium compounds in the presence of added cobalt salts. Kharasch and his coworkers have shown that the addition of 2–5 mole % of $CoCl_2$ to a Grignard reagent leads to a change in the mechanism of the reactions from ionic to free-radical[110-114]. An analogous but less marked effect is produced by iron(II) chloride and nickel(II) chloride. These results were attributed to the existence of intermediate unstable organocobalt compounds, which decompose with the formation of a cobalt subhalide; the latter brings about chain decomposition of the aryl or acyl halides:

$$RMgX + CoCl_2 \rightarrow RCoCl + MgXCl,$$

$$RCoCl \rightarrow R^{\cdot} + {}^{\cdot}CoCl,$$

$${}^{\cdot}CoCl + R'X \rightarrow R'^{\cdot} + CoXCl,$$

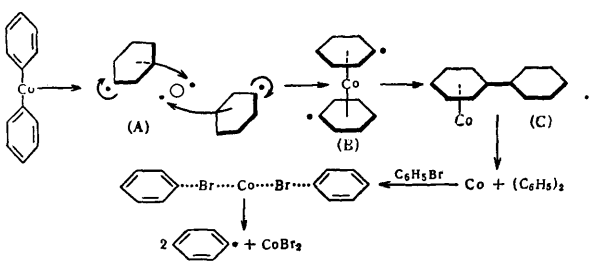
$$n\,R'^{\cdot} \rightarrow R'H + R'_2 + \text{other products.}$$

The conditions for the decomposition of RCoX may characterise the relative stability of the alkyl–cobalt and aryl–cobalt bonds. The reaction mixture of methylmagnesium bromide with added cobalt chloride loses its ability to bring about the dimerisation of phenyl radicals from bromobenzene after being heated for $1\frac{1}{2}$ h.[110] Coupling takes place quantitatively with a freshly prepared ethereal solution. Under the same conditions, phenylmagnesium bromide containing added $CoCl_2$, without preliminary heating, gives 98–99% of biphenyl from the phenyl radicals

of bromobenzene, but after heating for $1\frac{1}{2}$ h the yield of biphenyl amounts to only 50%. This indicates that the methyl–cobalt bond is less stable than the phenyl–cobalt bond. Contrary to Kharasch's opinion, however, the formation of symmetrical organocobalt compounds by the action of $CoCl_2$ on an organomagnesium compound is now considered more probable [115]:

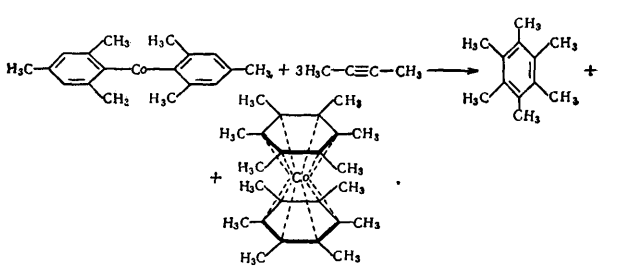
$$2C_6H_5MgBr + CoCl_2 \rightarrow MgBr_2 + MgCl_2 + (C_6H_5)_2Co,$$

$$(C_6H_5)_2Co \rightarrow C_6H_6 + C_6H_4 + Co.$$



Decomposition of these compounds takes place with the separation of finely divided metallic cobalt, which brings about the chain reaction.

Proof of the existence of diaryls of cobalt is provided by the ability of phenylmagnesium bromide solutions containing $CoX_2$ to absorb hydrogen. The formation of benzene and cobalt hydride in the process is attributed to hydrogenation of the intermediate unstable diarylcobalt [97]:



$$(C_6H_5)_2Co + 2H_2 \rightarrow CoH_2 + 2C_6H_6.$$

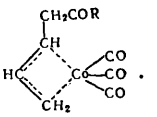
Finally, it has been possible to isolate diphenylcobalt and dimesitylcobalt in the form of the tetrahydrofuran addition compounds [74,90]. The dimesityl compound was obtained by the reaction of mesitylmagnesium bromide with cobalt chloride in tetrahydrofuran solution. The product is a yellow-green powder which is stable in the form of the tetrahydrofuran addition compound at -10° but which begins to decompose rapidly at room temperature. The presence of a mesityl–cobalt bond was proved by the quantitative formation of mesitylmercury chloride on reaction with mercuric chloride [90].

Tsutsui describes the conversion of the diarylcobalt compounds into the $\pi$ complexes. The unstable diphenylcobalt formed initially undergoes gradual rearrangement with rotation of the aromatic rings via the $\pi$-radical hybrid (A) and the diradical $\pi$ complex (B) to the half-sandwich $\pi$ complex (C): [73]

Dimesitylcobalt catalyses the cyclic condensation of but-2-yne. The reaction takes place between -30° and -50° in tetrahydrofuran solution, with the formation of hexamethylbenzene (the yield varies in the range 50–100%, calculated on the organocobalt compound) and the $\pi$ complex bishexamethylbenzenecobalt, the yield of which (20%) is independent of the alkyne concentration [91]:

The exceptional catalytic properties of dimesitylcobalt in this reaction are due to the unusual electronic structure of the $\pi$ complex.

The organocobalt compounds confirm the general hypothesis that the complexes of organic derivatives of the transition metals are more stable than the diaryls. Stabilisation of the aryl–cobalt bond is observed in the complexes of a diarylcobalt with phosphines [116]. The *trans*-planar complexes of dimesitylcobalt and bismethylnaphthylcobalt with phenyldiethylphosphine $[C_6H_5P(C_2H_5)_2]_2CoR_2$ have a very small or no dipole moment, in conformity with their structure.



A methyl–cobalt bond is present in the mixed carbonyl of cobalt obtained by reaction of the sodium salt of the carbonyl with methyl iodide [117]:

$$Na[Co(CO)_4] + CH_3I \rightarrow CH_3Co(CO)_4 + NaI.$$

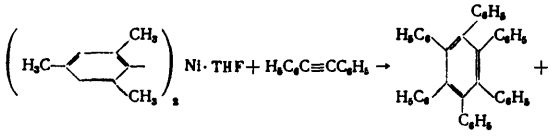
A number of interesting reactions of this unstable product have been described. Methyltetracarbonylcobalt readily undergoes rearrangement to acetyltricarbonylcobalt, and treatment of the latter with carbon monoxide leads to the formation of the acyltetracarbonylcobalt:

$$RCo(CO)_4 \rightleftarrows RCOCo(CO)_3 \underset{-CO}{\overset{+CO}{\rightleftharpoons}} RCOCo(CO)_4.$$

Alkyl- and acyl-tetracarbonylcobalts react with conjugated dienes — butadiene, isoprene, cyclopentadiene, etc. — to form complexes of the type [118]

The same type of complex, with a bond between cobalt and the alkene, like that in the alkene complexes of platinum [119], has been obtained by reaction of the potassium salt of cobalt carbonyl with butadiene [120]. Study of the proton resonance, infrared, and ultraviolet spectra indicate that the compound is diamagnetic and contains no conjugated diene.

## Nickel



A great deal of indirect data indicates that the simplest organonickel compounds exist in solution, but these have not been isolated in the pure state [121–123]. The most noteworthy reaction is the coupling of phenyl Grignard reagents, which takes place readily in the presence of nickel salts. With aliphatic organomagnesium compounds, liberation of ethylene, acetylene, etc. is observed. In the presence of gaseous hydrogen, a freshly prepared reaction suspension of phenylmagnesium bromide in ether containing added $NiCl_2$ absorbs 2 moles of hydrogen per gramme-atom of nickel to give pyrophoric black nickel hydride [124]. It was suggested that the latter was produced by reduction of the hypothetical diphenylnickel formed in the initial stage:

$$NiCl_2 + 2C_6H_5MgBr \rightarrow (C_6H_5)_2Ni + MgCl_2 + MgBr_2,$$
$$(C_6H_5)_2Ni + H_2 \rightarrow 2C_6H_6 + NiH_2.$$

The instability of diphenylnickel is indicated by the following facts. If the reaction suspension containing $NiCl_2$ is kept for some time before the reaction of hydrogen, the yield of hydride is decreased considerably. After standing for 4 h at room temperature the system does not absorb hydrogen; no nickel hydride was found in the reaction products.

The formation of phenyl and mesityl compounds of nickel is indicated by the deep colour produced by the action of nickel chloride on the corresponding organomagnesium compound in tetrahydrofuran solution. The reddish brown colour is attributed to the tetrahydrofuran addition compounds of diphenylnickel and dimesitylnickel. Thus reaction of 0.01 mole of $NiCl_2$ in 50 ml of tetrahydrofuran with 0.02 mole of RMgBr between -30° and -70° gives tetrahydrofuran addition compounds which cannot be isolated in the pure state because of their low thermal stability. They begin to decompose at temperatures below -10°.[73]

The thermally unstable tetrahydrofuran addition compounds of $R_2Ni$ are used in solution for the characteristic reactions involving cyclisation of disubstituted alkynes. Diethylnickel converts diphenylacetylene into tetraphenylcyclohexadiene[125]. Reaction of diphenylacetylene with the tetrahydrofuran addition compound of dimesitylnickel gives hexaphenylbenzene and a nickel-containing polymer. At an original component ratio of 1 : 4 the chief reaction product is the polymer, which is precipitated from solution as a dark orange, insoluble, amorphous precipitate:

$$+ [(H_5C_6C{\equiv}CC_6H_5)_4Ni]_n.$$

With increase in the ratio from 1 : 4 to 1 : 6, the chief reaction product becomes hexaphenylbenzene, which can be isolated in yields corresponding to 1.7–2.0 moles per mole of the organonickel compound[74,91]. Cyclisation of this type is attributed to the formation of an intermediate cyclobutadiene compound.

The complexes of $R_2Ni$ with triethyl- or triphenyl-phosphines $(R'_3P)_2NiR_2$ and $(R'_3P)_2Ni(R)X$ are more stable. These compounds can be obtained by the reaction of the corresponding dihalide with an organomagnesium compound in liquid ammonia[116]. They are brightly coloured products, usually yellow-brown, with characteristic melting points. The derivatives with R = phenyl, *o*-tolyl, *o*-chloro- and *o*-bromo-phenyl, *o*-methoxyphenyl, mesityl, biphenylyl, pentachlorophenyl, and naphthyl, and R′ = phenyl, ethyl, propyl, and mixtures of these, have been isolated.

The thermal stability of these complexes depends to a marked extent on the nature of the radical from the organomagnesium compound, increasing in the order alkyl < phenyl < *m*- and *p*-substituted phenyl < *o*-substituted phenyl[126]. The alkyl complexes are less stable and have not been isolated in the pure state. The phenyl derivative decomposes rapidly in ethanol solution and melts with decomposition at 125–130°. The symmetrical mesityl compound melts at 148–150°, and the unsymmetrical compound sublimes *in vacuo* without decomposition at 150°.

The influence of *ortho*-substituents is due to steric hindrance to free rotation of the aryl groups about the nickel–carbon bond. The electronic systems of the aromatic rings undergo more energetic interaction with the *d* orbitals of the metal.

These compounds are diamagnetic and symmetrical, and have a low dipole moment. With the symmetrical and unsymmetrical derivatives, *trans*-planar arrangement of the groups relative to the nickel atom is observed. The chemical reactions indicate the mobility of the metal–radical bond, which is readily broken by hydrogen chloride with formation of a hydrocarbon and an unsymmetrical product:

$$trans\text{-}[(R'_3P)_2NiR_2] + HCl \rightarrow trans\text{-}[(R'_3P)_2Ni(R)Cl] + RH.$$

In the unsymmetrical derivatives, the chlorine atom is readily replaced by bromine or iodine atoms or nitro- or thiocyanato-groups[126].

---o0o---

The above review shows that organic compounds of metals of the transition periods, containing a covalent metal–carbon bond, form a special class of compounds. Unlike the organometallic compounds of non-transition elements, which exhibit different characteristic chemical properties according to the groups of the Periodic System, the alkyls and aryls of the transition metals show a number of common chemical properties. Thus, for example, the covalent metal–carbon bond is readily broken by the action of hydroxyl-containing compounds, such as water, alcohols, acids, etc. The reaction of alkyls and aryls of the transition metals with halogens and halides is characteristic. These reactions are often used as analytical tests to prove the presence of an element–radical σ bond. Another typical property of most of these derivatives is their ready oxidation by oxygen and other oxidising agents.

The most characteristic property of these compounds — their thermal instability — is due to the presence of the incomplete electron sublevel of the central transition metal atom. The general characteristics of the electronic structure of the transition elements and the associated types of hybridisation involved in the formation of σ bonds have been examined more than once by Krause and von Grosse[1], Zeiss[4], Jaffé[127], and other workers.

The presence of vacant *d* sublevels in the transition metal atom makes possible the filling of these levels by various electron-donating ligands, such as amines, phosphines, ethers, and also carbonyl, nitrosyl, π-cyclopentadienyl, etc. These mixed sandwiches, carbonyls, or complexes with phosphines and other ligands are generally more stable to heat and also to oxidation and the action of other agents.

These compounds are of considerable interest in the study of the nature of the chemical bond. The intensified development of this field, however, is due not only to the theoretical importance of the subject but also to its considerable value in applied chemistry.

This review has not dealt with the exceptionally important problems associated with the use of catalytic systems based on organometallic derivatives of the transition metals. The mechanism of the stereoregular polymerisation of alk-1-enes depends to a marked extent on the properties of the intermediate covalent compounds of titanium, vanadium, and other transition metals[28,128,129]. Brief mention has been made of the interesting processes involving the cyclisation of disubstituted acetylenes with the participation of compounds of chromium, nickel, cobalt, etc.[77,78,91,130].

This young and rapidly developing field of chemistry dealing with the organometallic compounds of the transition metals promises to provide much of both theoretical and practical interest in the future.

# ADDITION OF α-CHLOROALKYL ETHERS TO UNSATURATED COMPOUNDS

S. A. Vartanyan and A. O. Tosunyan

CONTENTS

1. Introduction 267
2. Addition of α-chloroalkyl ethers to olefins 267
3. Addition of α-chloroalkyl ethers to conjugated diolefins 268
4. Addition of α-chloroalkyl ethers to acetylenic, vinylacetylenic, and divinylacetylenic systems 270

## 1. INTRODUCTION

In his review of the addition of alkyl halides to olefins Arbuzov[1] dealt in some detail with the El'tekov[2] and Kondakov[3,4] reaction, and Summers[5] reviewed the preparation and reactions of α-chloro-ethers, covering the literature up to 1955; however, in neither review did the addition of α-chloro-ethers to unsaturated compounds receive much attention. Nevertheless, in recent years much interesting work on the electrophilic addition of chloro-ethers to multiple bonds has appeared. In the present paper we have attempted to collect and classify the considerable material which has now accumulated on this subject.

## 2. ADDITION OF α-CHLOROALKYL ETHERS TO OLEFINS

α-Chloroalkyl ethers are much more reactive than alkyl halides, and they behave analogously to hydrogen halides. Cocker et al.[6] associate the activity of the labile chlorine atom in α-chloro-ethers with the simultaneous existence of a carbonium ion and an oxonium ion:

$$R-\overset{+}{C}H-\ddot{O}-R' \longleftrightarrow R-CH=\overset{+}{\ddot{O}}-R'.$$

Chloromethyl ether undergoes rapid hydrolysis and alcoholysis in aqueous and alcoholic solutions, yielding formaldehyde and a dialkoxymethane respectively. The rapidity of such processes has led many workers to conclude that the reactions are unimolecular, and this has been confirmed kinetically[7]. The rate-determining step is ionisation of the chloro-ether to produce a mesomeric carbonium ion, which rapidly adds on a hydroxide or alkoxide ion from the solvent:

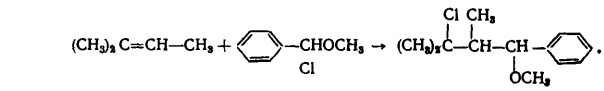
$$CH_3-\ddot{O}-CH_2-Cl \xrightarrow[\text{slow}]{} CH_3-O-\overset{+}{C}H_2 + Cl^-,$$

$$ROH + CH_3O-\overset{+}{C}H_2 \xrightarrow[\text{fast}]{} CH_3OCH_2OR + H^+$$

(R = H or alkyl).

At room temperature in anhydrous solvents (or in the absence of a solvent), α-chloroalkyl ethers add to olefins in the presence of acidic catalysts by an ionic mechanism

in almost every case[8]. Various catalysts may be used, e.g. bismuth trichloride[9,10], mercuric chloride[11], or, most frequently, zinc chloride[9,11].



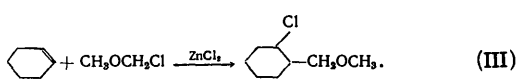
Scott in 1935 was the first to show[12] that chloromethyl ethers add to propene in the presence of bismuth trichloride to form 3-chloro-1-methoxybutane; the addition follows the Markovnikov rule:

$$CH_3{-}CH{=}CH_2 + CH_3OCH_2Cl \xrightarrow{BiCl_3} CH_3CHCl{-}CH_2CH_2OCH_3.$$

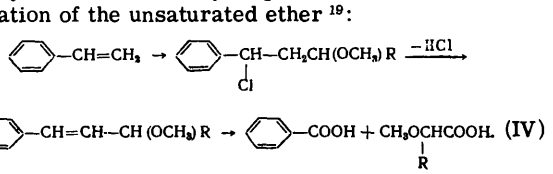
Straus and Thiel[11] investigated the addition of chloromethyl ethers to isobutene in the presence of mercuric chloride, and obtained the corresponding chloro-ethers (I):

$$(CH_3)_2C{=}CH_2 + ROCH_2Cl \xrightarrow{HgCl_2} (CH_3)_2CCl{-}CH_2CH_2OR. \qquad (I)$$

They also found that the $\alpha$-chlorobenzyl ether can add to olefins under these conditions[11]:

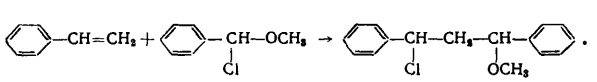


Mamedov, Zeinalov, and Pishnamez-zade[13-15] developed a simple method for the preparation of $\gamma$-halogeno-ethers (II) by addition of various chloro- or bromo-methyl ethers to olefins in the presence of zinc chloride:



$$R{-}CH{=}CH{-}R' + R''OCH_2X \rightarrow \underset{X}{\overset{}{R}}CH{-}\underset{R'}{\overset{}{C}}H{-}CH_2OR''. \qquad (II)$$

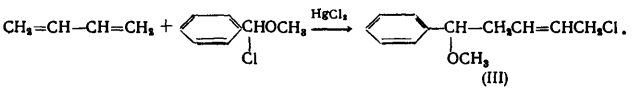
The product yield is lower with ethylene than with its homologues. Certain of the resulting $\gamma$-halogeno-ethers possess acaricidal and insecticidal properties[16].



Chloromethyl ethers also add to cycloalkenes in the presence of zinc chloride. Straus[11] and Nenitzescu[17] obtained 1-chloro-2-methoxymethylcyclohexane (III) from cyclohexene and chloromethyl ether:

$\alpha$-Chloroalkyl ethers add to styrene to form the corresponding chloro-ether[18,19]; the structure of the product (IV) is proved by the removal of hydrogen chloride and subsequent oxidation of the unsaturated ether[19]:

$\alpha$-Chlorobenzyl ether also adds to styrene[11]:



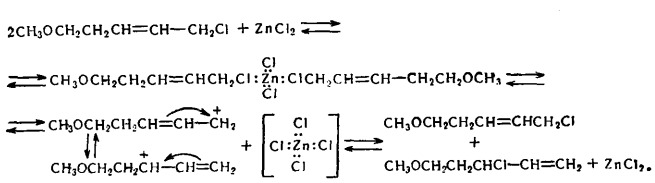
## 3. ADDITION OF $\alpha$-CHLOROALKYL ETHERS TO CONJUGATED DIOLEFINS

The addition of chloromethyl ethers to butadiene was accomplished in 1935–1936 by Scott[12] and Straus[11] in the presence of mercuric chloride or zinc chloride, giving a mixture of two isomeric chlorides, the 1,2-addition product 3-chloro-5-methoxypent-1-ene (I) and the 1,4-addition product 1-chloro-5-methoxypent-2-ene (II):

$$CH_2{=}CH{-}CH{=}CH_2 + CH_3OCH_2Cl \xrightarrow{ZnCl_2} \underset{(I)}{CH_3OCH_2CH_2CHCl{-}CH{=}CH_2} + \underset{(II)}{CH_3OCH_2CH_2CH{=}CHCH_2Cl}.$$

When distilled under normal conditions the 1,2-addition product isomerised completely into the 1,4-addition product.

In the reaction of $\alpha$-chlorobenzyl methyl ether with butadiene the only product is that of 1,4-addition (III):[11]

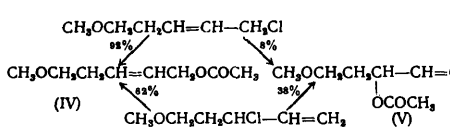


Pudovik, Arbuzov, and coworkers[20,21] investigated the addition of chloromethyl ethers to butadiene in some detail, and studied the resulting alkoxyalkyl chlorides; similar results were also obtained by other workers[22]. The total yield is 75%, comprising 75–80% of 1,2-addition product and 25–20% of 1,4-addition product. Under the influence of the zinc chloride catalyst there is mutual isomerisation of the alkoxyalkyl chlorides, so that a mixture is obtained containing 55% of the 1,4-addition product and 45% of the 1,2-addition product:

$$ROCH_2CH_2CH_2CHCl{-}CH{=}CH_2 \xrightarrow{ZnCl_2} ROCH_2CH_2CH{=}CHCH_2Cl.$$

In the absence of catalyst, both isomers remain unchanged for at least one year: i.e. they do not isomerise[20].

The action of 10% zinc chloride causes 90–93% isomerisation of the 1,2-addition product to the 1,4-addition product, the reverse process occurring only to the extent of 4–7%.[20] Pudovik and Arbuzov also show that in the absence of catalysts the alkoxyalkyl chlorides do not isomerise at 100°, while at 140° the 1,2-addition product is quantitatively isomerised into the 1,4-addition product.

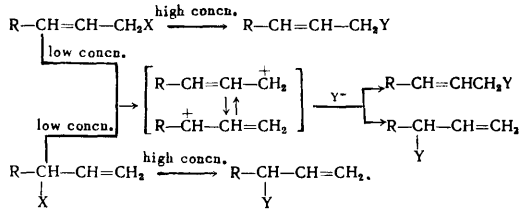


In the presence of zinc chloride the mutual isomerisation of the two isomeric chlorides is represented as follows[20]:

Meisenheimer and Schmidt[23] show that the allylic rearrangement can also occur under the influence of various chance factors (composition of the glass, contamination).

From the above, it may be said that chloromethyl ethers add to butadiene almost exclusively in the 1,2-position, but since the 1,2-addition products are very readily isomerised into the 1,4-addition products under the experimental conditions, the 1,4-isomer predominates in the final reaction product.

Allylic rearrangements occur not only with the products of the addition of chloromethyl ethers to butadiene, but also in the preparation of their derivatives. For example, with sodium acetate 1-chloro-5-methoxypent-2-ene gives the normal substitution product (IV) in 92% yield and the isomeric product (V) in 8% yield, while 3-chloro-5-methoxypent-1-ene gives 62% of the isomeric product (IV) and only 38% of the normal product (V):[24]

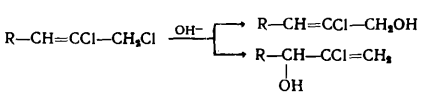


Both isomeric chlorides react analogously with sodiomalonic ester[25], phenylmagnesium bromide[26], and ammonium thiocyanate[22], but with alcohols in the presence of potassium hydroxide 1-chloro-5-methoxypent-2-ene gives the corresponding normal product, a 1,5-dialkoxypent-2-ene, in almost quantitative yield[8].

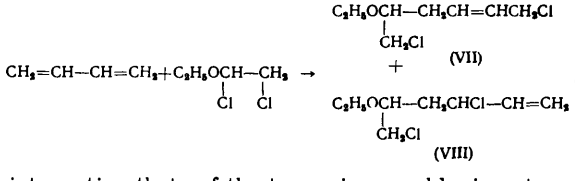
There have been many examples of the production of two isomers, depending on the reaction conditions, in the nucleophilic substitution of the chlorine in allyl chlorides, and various explanations for this have been proposed[27-33]. Prevost[30] considers it to be the result of ionisation of the rearranging molecule to produce the corresponding carbonium ion:

$$R{-}CH{=}CH{-}CH_2Cl \rightarrow R{-}\overset{+\delta}{C}H{-}CH{-}\overset{+\delta}{C}H_2.$$

It has been shown that nucleophilic substitution in allenic systems can take place by either a unimolecular or a bimolecular mechanism[34]: if the attacking reagent is added in small portions, the reaction proceeds by a unimolecular mechanism, either of the isomeric chlorides producing a mixture of the isomeric products corresponding to the two isomeric carbonium ions; while if the attacking reagent is added in high concentrations, it is mainly the normal reaction products which are formed:



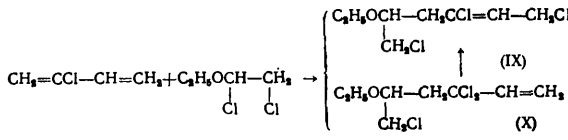
However, allylic systems do exist where no rearrangement occurs. For example, no isomeric products are obtained when the primary chlorine atom of 5-alkoxy-1,3-dichloroalk-2-enes (VI) is hydrolysed to give the corresponding alcohols or react to produce ethers, amines, etc.[35,36]:



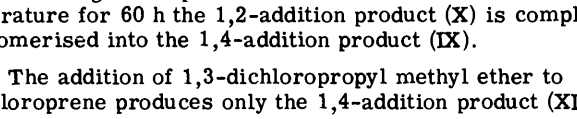
$$ROCH_2CH_2CCl{=}CH{-}CH_2Cl \xrightarrow{Y^-} ROCH_2CH_2CCl{=}CHCH_2Y.$$
(VI)

Y=OH, N<; OR'

Some allylic rearrangement occurs in the hydrolysis of 1,2-dichloroalk-2-enes, the isomeric chloro-alcohols being obtained in addition to the normal products[37]:

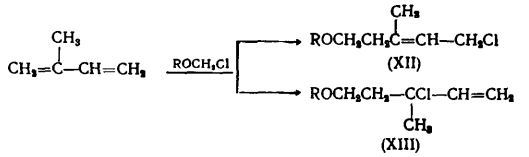


Pudovik[38] was the first to treat 1,2-dichlorodiethyl ether with butadiene in the presence of zinc chloride, obtaining 74% of the 1,4-addition product (VII) and 26% of the 1,2-addition product (VIII):

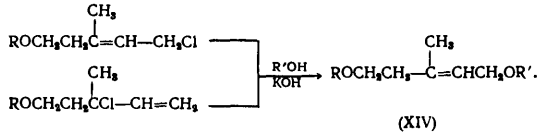


It is interesting that, of the two primary chlorine atoms in the 1,4-addition product (VII), only the $\alpha$-chlorine atom can react further, the $\gamma$-chlorine atom being unreactive[38].

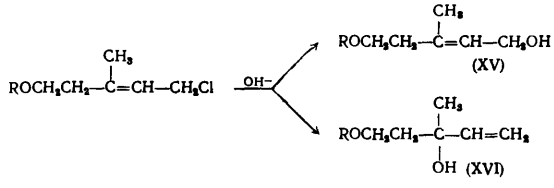
In the presence of zinc chloride 1,2-dichlorodiethyl ether also adds to chloroprene by 1,4- and 1,2-addition, forming 1,3,6-trichloro-5-ethoxyhex-2-ene (IX) and 3,3,6-trichloro-5-ethoxyhex-1-ene (X):[39]



On standing in the presence of zinc chloride at room temperature for 60 h the 1,2-addition product (X) is completely isomerised into the 1,4-addition product (IX).



The addition of 1,3-dichloropropyl methyl ether to chloroprene produces only the 1,4-addition product (XI):[40]

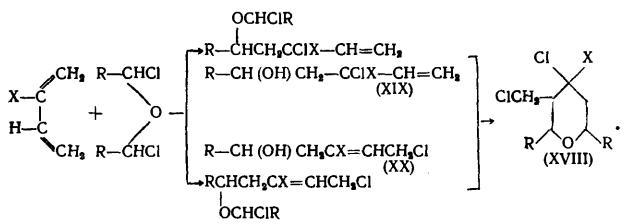


Chloromethyl ethers add to isoprene analogously to the above reactions, but the yield does not exceed 30–37%, and in the reaction products (XII) and (XIII) the 1,4-addition product (XII) predominates[41]. The mutual isomerisation of these two isomers is very rapid[41], and the equilibrium concentration of the 1,4-addition product (XII) is 90–92%

In the presence of potassium hydroxide the two isomers give the same product (XIV) with alcohols[41]:

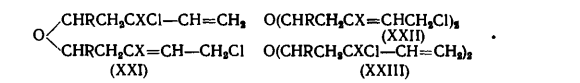
Hydrolysis of 5-alkoxy-1-chloro-3-methylpent-2-enes (XII) with 15% aqueous potassium carbonate gives the two isomeric alkoxy-alcohols (XV) and (XVI):[42]

The addition of chloromethyl ethers to chloroprene in the presence of zinc chloride has been studied in some detail; the only product is that of 1,4-addition, the 5-alkoxy-1,3-dichloropent-2-ene (XVII):[35,43]:



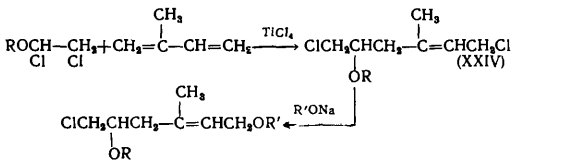
$$CH_2{=}CCl{-}CH{=}CH_2{+}ROCH_2Cl \xrightarrow{ZnCl_2} ROCH_2CH_2CCl{=}CHCH_2Cl.$$
(XVII)

These dichlorides are very reactive, and the primary chlorine atom takes part in all the reactions typical of alkyl halides[44-48].



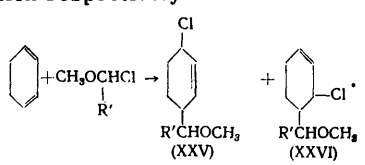
$\alpha$-Chloroalkyl ethers add to isoprene, chloroprene, and butadiene in the presence of zinc chloride in an analogous manner[40,49]:

$$CH_2{=}\underset{X}{C}{-}CH{=}CH_2{+}ROCHCl \rightarrow ROCH\underset{R'}{C}H_2C{=}CH\underset{R'}{C}H_2Cl.$$
(X=H; $CH_3$; Cl)



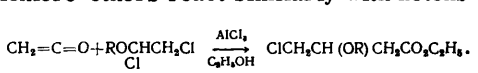
The addition of bis-$\alpha$-chloroalkyl ethers to chloroprene and isoprene in the presence of zinc chloride produces mainly the tetrahydropyran derivatives (XVIII):[50]

There are also obtained small amounts of chloro-alcohols (XIX) and (XX) produced by hydrolysis of the intermediate ethers, and products of the addition of the bis-$\alpha$-chloroalkyl ethers to two molecules of the diene (XXI)–(XXIII):[54]



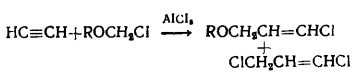
In the production of the vitamin A side-chain, a 1,2-dichloroethyl ether was added to isoprene in the presence of titanium chloride, to give the 1,4-addition product (XXIV),[51] only one primary chlorine atom of which undergoes further reaction:

(R′ = $CH_3CO$ or Alk).

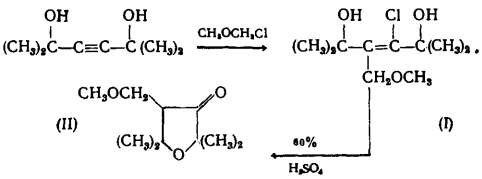


Chloromethyl ethers add analogously to cyclic conjugated dienes, e.g. cyclohexadiene, giving the two isomeric chlorides (XXV) and (XXVI), which are the products of 1,4- and 1,2-addition respectively [11]:

Chloromethyl ethers add to ketens in the presence of aluminium chloride. However, the expected alkoxylated acid chlorides (XXVII) have not been isolated, but have been treated with alcohol to give ethyl $\beta$-alkoxypropionates (XXVIII):[52]

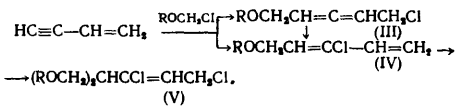


$\alpha\beta$-Dichloro-ethers react similarly with ketens [53]:



## 4. ADDITION OF $\alpha$-CHLOROALKYL ETHERS TO ACETYLENIC, VINYLACETYLENIC, AND DIVINYLACETYLENIC SYSTEMS

Chloromethyl ethers add to acetylene in the presence of aluminium chloride to give mainly 3-alkoxy-1-chloroprop--1-ene but with some 1,3-dichloroprop-1-ene [54]:

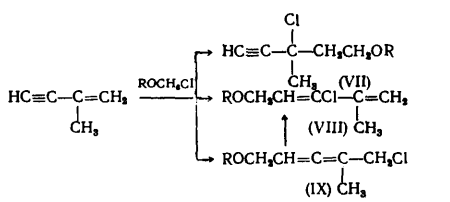


Phenoxymethyl chloride does not add to acetylene under these conditions [54].

Chloromethyl ethers add to the triple bond of tetramethylbutynediol in the presence of aluminium, tin, or zinc chloride to produce the corresponding chlorovinyl glycol (I), which when treated with 60% sulphuric acid forms tetrahydro-4-methoxymethyl-2,2,5,5-tetramethyl--3-oxofuran (II):[55]

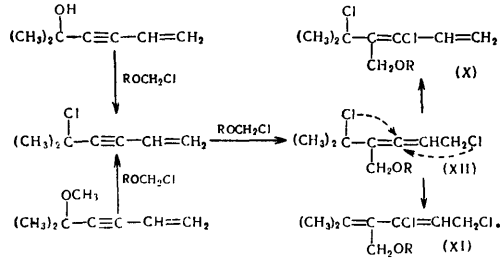
The addition of chloromethyl ethers to butyne-1,4-diols and their mono- and di-ethers proceeds analogously [55].

The addition of chloromethyl ethers to vinylacetylenic compounds has also been investigated. Dykstra [10] was the first to show that in the presence of bismuth trichloride they add to butenyne itself in the 1- and 4-positions. The product (III) can isomerise under the experimental conditions, or in the presence of cuprous chloride in 18% hydrochloric acid, and the resulting alkoxy-chloride (IV) can add a further molecule of chloromethyl ether under the given conditions, to form the dichloride (V):[56]



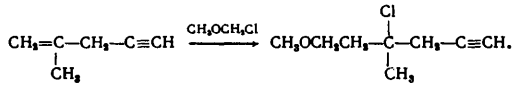
Zinc chloride produces the same reactions [56,57]. Dykstra prepared these chlorides in order to investigate their polymerisation, but the polymers obtained were not considered to be of good quality.

Under the conditions given above, chloromethyl ethers add to hept-1-en-3-yne to produce only the 1,4-addition product (VI), the isomeric chloride not being obtained. The product (VI) does not isomerise either under the experimental conditions or under the influence of cuprous chloride in 18% or 36% hydrochloric acid [56]:

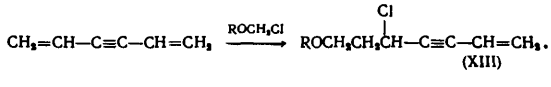


With 2-methylbut-1-en-3-yne, however, addition under the above conditions produces the three difficultly separable alkoxy-chlorides (VII)–(IX):[58]

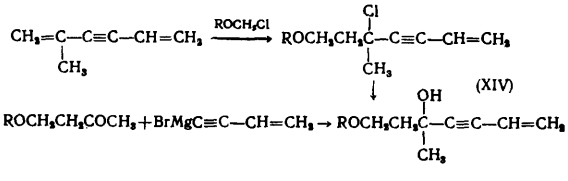
The addition of chloromethyl ethers to 2-methylhex-5--en-3-yn-2-ol, to its methyl ether [59], or to 5-chloro-5--methylhex-1-en-3-yne [60] produces, in all cases, the same mixture of the two isomeric dichlorides (X) and (XI). Apparently the alkoxy- or hydroxy-group is first replaced by chlorine from the chloromethyl ether to give the corresponding chloro-compound, and the latter then undergoes



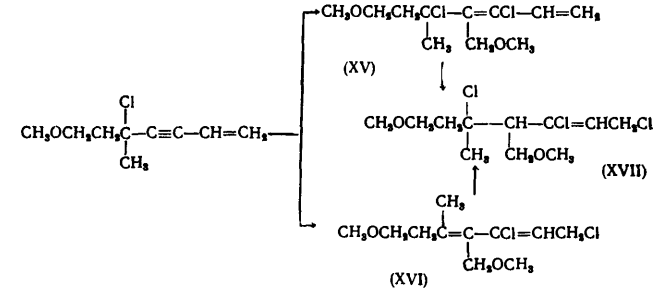
1,4-addition to the chloromethyl ether (as it does to hydrogen chloride[61]) to form the intermediate allenic dichloride (XII), which under the experimental conditions isomerises to produce a mixture of the two dichlorides (X) and (XI):



Unlike the ethers of dimethyl(vinylethynyl)carbinol [2-methylhex-5-en-3-yn-2-ol], those of primary and secondary vinylethynylcarbinols add chloromethyl ethers normally, i.e. by 1,4-addition, producing an allenic chloride which is not isomerised under the experimental conditions or under the influence of cuprous chloride in 18% or 36% hydrochloric acid[59]:



The addition of chloromethyl ethers to allylacetylenes [pent-1-en-4-ynes] has not been investigated; there is only one patent, describing the addition to 2-methylpent-1-en-4-yne, which takes place at the double bond according to Markovnikov's rule[62]:



In the presence of zinc chloride chloromethyl ethers add to hexa-1,5-dien-3-yne in the 1,2-position to form a 7-alkoxy-5-chlorohept-1-en-3-yne (XIII):[63]

The addition of chloromethyl ethers to homologues of hexa-1,5-dien-3-yne, e.g. the 2-methylhexadienyne, is a selective process occurring at the double bond which is richer in electrons: i.e. it takes place by an electrophilic mechanism[64]. Hydrolysis of the resulting vinylacetylenic alkoxy-chloride (XIV) gives the corresponding vinylacetylenic carbinol, which has also been prepared by condensation of the appropriate 2-alkoxyethyl methyl ketone with but-3-en-1-ynyl bromide[65]:

A second molecule of the chloromethyl ether adds to the alkoxy-chloride (XIV) to give a mixture of the two isomeric dichlorides (XV) and (XVI), which with hydrogen chloride in the presence of cuprous chloride produce the same trichloride (XVII):

Certain derivatives of the two dichlorides (XV) and (XVI) have also been obtained[64].

The addition of α-halogeno-ethers to unsaturated compounds opens up great possibilities for the production of new halogen compounds of various types of structure. The ease and simplicity of production of these chlorides allow them to be used as starting materials for the preparation of new insecticides and fungicides, high-boiling solvents, plasticisers, etc. Certain of the α-chloro-ethers and new products obtained from them have already found practical application as insecticides[16,66], water-repellent agents in the textile industry[67,68], and for the treatment of wool to render it stable to washing[69,70].

# THE DEVELOPMENT OF CATALYTIC SYNTHESES OF ORGANIC COMPOUNDS FROM CARBON MONOXIDE AND HYDROGEN

B. K. Nefedov and Ya. T. Eidus

## CONTENTS

Introduction 272

I. Fischer–Tropsch synthesis of hydrocarbons 273
1. Iron catalysts 273
2. Oxide catalysts 277

II. Directed syntheses of organic compounds from carbon monoxide and hydrogen 278
1. Synthesis of higher hydrocarbons 278
2. Synthesis of ethylene 279
3. Synthesis of alcohols 279

III. Kölbel–Engelhardt synthesis of organic compounds from carbon monoxide and water vapour 279

## INTRODUCTION

The catalytic synthesis of hydrocarbons and oxygen-containing compounds from carbon monoxide and hydrogen, particularly on an industrial and semi-industrial scale (Fischer–Tropsch hydrocarbon synthesis, synthesis of alcohols), is of great practical and theoretical interest[1-7]. The most recent reviews in this field were published by one of us in 1950–1951.[1,2] In the present review the main

advances during the past decade in the development of syntheses based on the catalytic reduction of carbon monoxide are considered†.

## I. FISCHER–TROPSCH SYNTHESIS OF HYDROCARBONS

The object of the synthesis of hydrocarbons from carbon monoxide and hydrogen, discovered in Germany in 1925 and adopted there industrially at the end of the 1930's, was to obtain liquid fuel[5,8,9]. Between 1936 and 1942 more than fifteen plants were set up in different countries (Germany, Japan, France) in which cobalt catalysts were used, mainly at atmospheric pressure[10]. In the post-war years intensive study of the process continued in the United States, Great Britain, West Germany, Japan, and India and also in the Soviet Union, Poland, East Germany, and China. A number of new plants were constructed, for example in South Africa and the United States, in which valuable chemical products (compressed gas, alcohols, solvents, paraffin wax) were obtained, in addition to liquid fuel, at moderate pressures in the presence of cobalt and iron catalysts[11–16]. At the same time new methods of obtaining cheap starting materials and highly productive and stable catalysts were developed, and new technological schemes of synthesis appeared[11,17–23].

### 1. Iron Catalysts

Iron catalysts have a number of advantages over cobalt catalysts: they are cheap and readily available, and they enable the synthetic process to be intensified by factors of 10–20; they are active and stable over a comparatively wide range of temperature and pressure with different $H_2$ : CO ratios in the starting gas.

(a) Methods of preparation. The first iron catalysts were prepared by the thermal decomposition of nitrates, and they contained activating copper and alkali additives[24,25]. However, *precipitated* iron catalysts were found to be considerably more active, especially when they contained activating additions of copper, alkalis ($K_2CO_3$, KOH, $Rb_2CO_3$), alkali-metal borates and silicates, several difficultly reducible oxides (MnO, MgO, $Al_2O_3$, $ThO_2$, CaO, $TiO_2$), and also cobalt and nickel[1,26–34]. The mechanical strength of the carriers was increased by depositing magnesium oxide, silica, kieselguhr, pumice, dolomite, diatomite, infusorial earth, and activated charcoal on them[16,35]. On the best iron catalysts (100 Fe, 5–25 Cu, 0.08–2 alkalis) at 200–280° and 1–30 atm, a CO–$H_2$ mixture (0.5–2 : 1) at a space velocity of ~ 100 $h^{-1}$ gave, per cubic metre at s.t.p., 100–130 g of liquid products, with a total yield of all products of 140–160 g $m^{-3}$. The hydrocarbons obtained at 10 atm and 212–218° in the presence of iron-copper catalysts promoted by silicates (10–20% on the Fe content), with a total yield of 131–134 g $m^{-3}$ consisted of 52–55% of solid paraffins with boiling points above 300°.[36] Active catalysts for the synthesis of the lower hydrocarbons were prepared on carriers of finely ground natural minerals containing over 10% of soluble silicates[37].

In recent years, in connection with the development of highly efficient synthetic processes, fused, sintered, and cemented iron catalysts have been intensively studied[1,16,38].

Fused catalysts are prepared by roasting powdered electrolytic iron or iron carbonyl vapour in oxygen with the subsequent addition of activators to the melt, or by fusing magnetic iron oxide with these activators[39–43]. Fused iron catalysts of the contact type used in ammonia syntheses began to be employed in the synthesis of hydrocarbons as early as the 1930's.[3,44] Later in Germany the Synthol process was developed in which a similar catalyst of composition 100 Fe : 4.9 $Al_2O_3$ : 0.9 $K_2O$ : 2.9 CaO was used; this had an activity approaching that of precipitated iron catalysts. Similar catalysts were also developed in the United States[16]. After reduction with hydrogen at 450–500°, they gave yields of hydrocarbons of up to 114–117 g × × $m^{-3}$ at 247–254°, 7–8 atm, and a space velocity (1 CO : 1 $H_2$) of 100–300 $h^{-1}$. However, all these catalysts were unstable.

Bashkirov and his coworkers found that fused iron catalysts, promoted by alumina, silica, and potassium carbonate, and reduced with hydrogen and carbon monoxide at 900–1150°, have higher activity and stability than those reduced at lower temperatures[40–43,45]. At 300–310°, 20–25 atm, and a space velocity (1 CO : 1 $H_2$ mixture) of 1500 $h^{-1}$, 85% conversion was achieved with a total hydrocarbon yield of 140–150 g $m^{-3}$. The most active catalyst had the composition $Fe_3O_4$ + 4–7% $Al_2O_3$ + 4–6% $SiO_2$ + + 1–1.4% $K_2CO_3$; it was necessary to introduce the potassium carbonate in such a way that reaction with the silica was avoided. The stability increased sharply when 0.3–1% of chromium, vanadium, or titanium, or of both chromium and vanadium, was introduced into the catalyst; the duration of the working cycle reached 600 h. The addition of 0.5% of molybdenum or 1% of manganese had no effect on the activity, and the addition of silicon and tungsten had a deactivating effect.

Sintered and cemented catalysts are prepared by sintering iron or its oxides with binding additives — $Al_2(NO_3)_6$, $Na_2B_4O_7$, $Na_2SiO_3$, etc.[3,16,46–50] — and also by sintering precipitated iron–alumina catalysts[51]. Catalysts sintered in a hydrogen atmosphere are active at 20 atm and 300° without preliminary activation. A catalyst of 100 Fe + + 10 $Al_2O_3$ remained active for more than 1000 h; in the range of space velocities of 100–300 $h^{-1}$, the degree of conversion of carbon monoxide reached ~ 98%, and the mean total yield of hydrocarbons 140–145 g $m^{-3}$.

(b) Physical properties and preliminary treatment. Unreduced precipitated iron–copper catalysts have the structure of an iron oxide gel with small pores and a large surface area (up to 300 $m^2 g^{-1}$)[35,52–54], but unreduced fused and sintered iron catalysts have a magnetite structure[16,54] with a very small surface area (< 1 $m^2$ × × $g^{-1}$), and consist, according to X-ray analysis, of the oxides FeO and $Fe_3O_4$.[42] Promoters are uniformly distributed in the melt[40,42]; this is apparently due to the formation in the fusion process of iron aluminates, silicates, and possibly aluminosilicates, partly dissolved in the iron oxides and partly concentrated as crystals or amorphous layers between the grains of solid solution[40,42,55]. Thermomagnetic results show that the alkali-metal oxides also form solid solutions with magnetite[56], but there is evidence against this: over 70% of the surface is covered by alkali, which can be easily removed from the catalyst, and the properties of the catalyst are independent of whether the alkali has been added before or after fusion[16].

† The mechanism of these processes will be considered in a separate review.

Before use in synthesis the precipitated iron–copper catalysts are usually treated with hydrogen, carbon monoxide, ammonia, or mixtures of carbon monoxide and hydrogen. The method of treatment has no effect on the activity (Table 1), but materially affects the duration of further development of the catalyst, its selectivity, and its stability[3,16,57,58]. According to some data, when iron oxides are treated with hydrogen at 230–250° they are almost completely reduced to the metal; but according to other data[35] no metallic iron, or at most 1–2%, is observed after such treatment, and the catalysts consist to the extent of 50–60% of FeO and compounds of the spinel type — $FeO.Fe_2O_3(Fe.Fe_2O_4)$, $CuO.Fe_2O_3(Cu.Fe_2O_4)$, $MgO.Fe_2O_3$, or $MnO.Fe_2O_3$ [59] — which is evidently explained by differences in the degree of reduction of the iron oxides depending on the duration of reduction. Treatment with carbon monoxide or a mixture of carbon monoxide and hydrogen gives magnetite and Hägg's carbide, and treatment with ammonia gives magnetite and iron nitrides[54]. Catalysts treated with hydrogen and particularly with ammonia promote the formation of products of lower molecular weight (and also considerable quantities of alcohols) than do catalysts treated with a mixture of carbon monoxide and hydrogen. Nitrided catalysts were less stable than those treated with hydrogen or a mixture of carbon monoxide and hydrogen. The greater the alkali content and the lower the copper content of catalysts, the higher the temperature and the longer the time required for reduction. When the starting gas contained carbon monoxide, the temperature and duration of treatment could be decreased[57]. Reduction by a gas containing carbon dioxide, and particularly water vapour, had a deleterious effect on activity. Treatment with a mixture of carbon monoxide and hydrogen gives catalysts that are insensitive to sulphur compounds[60]. After precipitated catalysts have been treated with a mixture of hydrogen and carbon monoxide, their surface area has decreased from ~300 to ~20 $m^2 g^{-1}$,[35,53,61] but the surface area of catalysts precipitated on a carrier evidently remains unchanged or slightly increases[10].

Fused catalysts are reduced by hydrogen at 375–500° in 25–60 h,[16,62-64] or at ~1000° in 1.5–6 h[41-43,65-67] at atmospheric or higher pressure (up to 10 atm). In this case also water vapour or carbon dioxide has a deleterious effect on the activity of the catalysts[63]. In reduction at 450° the surface area of the catalysts and the volume of the pores increase linearly with the degree of reduction up to ~80% reduction[62]. Pores with a mean diameter of ~333 Å are formed. With a degree of reduction of over 80% the surface area increases more rapidly than the pore volume. With reduction between 99.5% and 100% there is some decrease in the surface area. At 550° catalysts having a mean pore diameter of 830 Å are formed. With reduction in the range 400–650°, the particle size of the catalyst does not change; the porous structure is formed by removal of the oxygen from the iron oxides. The volume of the pores increases and the surface area decreases[62,64]. The reduction process becomes more rapid with increasing temperature. The surface area of reduced fused catalysts is 1–50 $m^2 g^{-1}$.[10,62] Promoters stabilise the structure produced on reduction, but they do not prevent diminution in the surface area with increasing temperature. In the course of reduction the promoters are extruded on to the surface of the $\alpha$-iron crystals, in which they are insoluble[42,68]. $\alpha$-Iron, $\alpha$-quartzite, $\gamma$-alumina, and compounds of the andalusite type have been detected in reduced samples of fused catalysts. Extraction with hot water improved the activity of sintered catalysts; the improvement is due to the removal of sulphur compounds present as impurities and to the formation of a finely dispersed highly active iron oxide by decomposition of the ferrites formed in the preparation of the catalysts[49,50].

TABLE 1. The effect of preliminary treatment at 250° on the activity of precipitated iron–copper catalysts[16].

| Preliminary treatment | Duration of treatment, h | Activity of catalyst | |

| With natural gas | 16 | 250 | 67 |
| With hydrogen | 17 | 250 | 65 |
| With carbon dioxide | 21 | 250 | 69 |
| With air | 16 | 248 | 67 |

The thermal conductivity of precipitated iron–copper catalysts is 2–3 times that of cobalt–thoria catalysts[69], and the conductivity of fused catalysts is greater than that of precipitated catalysts. The thermal conductivity of all catalysts approximately doubles in operation, as a result of saturation with reaction products. This is important because when a reactor is being brought into operation, the temperature and the gas charge must be increased slowly for effective removal of the heat of reaction. Only when the catalyst has become saturated with the reaction products (paraffin is sometimes poured over it for this purpose) and its thermal conductivity has been increased can the synthesis function under normal conditions.

(c) Development. Fused iron catalysts, reduced at ~1000°, are inactive immediately on reduction, and acquire a high activity only after the starting gas has been passed over them for 7–50 h.[65-67] Precipitated and fused catalysts are at once activated at 375–500°, but it is only in the process of synthesis that the active catalyst surface is formed; its structure and phase composition are changed as a result of the chemical reaction of iron compounds with starting reagents and reaction products[35,70-72]. Metallic iron, iron carbides, and iron oxides do not separately catalyse the synthesis of organic compounds from carbon monoxide and hydrogen[65,72]. In the initial period of the synthesis a number of competing reactions occur on the catalyst surface between its components and the gases in the reaction mixture; these include carbidation of the iron, hydrogenation of carbides, oxidation of the iron by water, reduction of the iron oxides by carbon monoxide and hydrogen, etc. Dynamic equilibrium is established between the surface phases[70,73-77]. In the course of these reactions, proceeding at the interphase boundaries of the surface, molecules of carbon monoxide and hydrogen are activated and, when the necessary geometrical relationship with the surface arises, they interact[66,72]. To acquire such properties, catalysts reduced at 375–500°, either carbided[78-80] or nitrided[80-86], do not require a long activation process. The formation of their active surface apparently consists in the rapid production of the phase combination necessary for the synthesis. In the formation of the surface and then in the synthesis, water vapour and carbon dioxide have a deleterious effect on the activity and selectivity: oxidative deactivation occurs with change in the phase composition[70,73,76,87,88].

(d) Catalysts based on natural ores. Work has been carried on for a long time on the use of natural

minerals or ores containing iron or its oxides as catalysts in the reduction of carbon monoxide. After reduction with hydrogen at 450° these proved to be active at 230–300° and 7 atm with a space velocity of starting gas ($CO_2 + H_2$, 1 : 1) of ~ 1000 $h^{-1}$.[3,16,89-92] Krivorog ochre haematite ($79Fe_2O_3$, $7Al_2O_3$, $1.0SiO_2$), Khallilovo ore ($56Fe_2O_3$, $12Al_2O_3$, $10SiO_2$), red mud, a by-product of the aluminium industry ($55.4Fe_2O_3$, $20.3Al_2O_3$, $12.5SiO_2$, $4.8CaO$), titanomagnetite ($50Fe_2O_3$. $.24FeO.3Al_2O_3.3SiO_2.13TiO_2$), and magnetic iron ore ($60Fe_2O_3.14FeO.3Al_2O_3.6SiO_2.6CaO + MgO$) have been used[93]. After reduction at 800–1000° and saturation with potassium carbonate or sodium borate solution, the catalysts work stably at 20–40 atm, 300–320°, and a space velocity of 500–1500 $h^{-1}$ (with a 1 : 1 mixture of carbon monoxide and hydrogen), giving a yield of liquid products up to 90 g $m^{-3}$. For catalytic activity, iron ores must have a high content of iron oxides and an alkali additive. Oxides in the ore that are difficult to reduce serve as structural promoters. The catalytic properties of iron ores are improved by fusion, which leads to a more uniform distribution of the oxide promoters and the removal of some compounds that lower activity. Such catalysts are active in the same way as ordinary fused catalysts, but they are rapidly destroyed by the deposition of carbon.

(e) Industrial methods of synthesising hydrocarbons from carbon monoxide and hydrogen in the presence of iron catalysts. The intensive investigation of iron catalysts led to the development of a highly efficient process accomplished by different technological methods (Table 2).[46,94-99] The earliest of these, in which the process was carried out *in the gas phase* with stationary precipitated iron–copper catalysts, was inefficient. Its disadvantages were: (1) low efficiency because of the low space velocity of the starting gas necessitated by the difficulty of removing the heat of reaction; (2) the narrow temperature range of the reaction; (3) non-uniform distribution of temperature and composition of the reaction mixture along the layer of catalyst, which led to choking up by coke formation and oxidation of the catalyst by water vapour; and (4) the ratio in which hydrogen and carbon monoxide were consumed differed from the ratio in the starting gas, and this led to a decrease in the theoretical yield of product. The problem of effectively removing the heat of reaction was partly solved by the use of fused, sintered, or cemented catalysts, operating at high degrees of conversion of the gas and over a wide range of space velocities, and also by recirculating the effluent gases. When recirculation is used, the reaction, which ordinarily proceeds at constant temperature and pressure in the region of kinetic control, passes to the external diffusion region, because of changes in the concentrations of carbon monoxide and hydrogen in the gas, its linear velocity, and the hydrodynamic conditions[35,97,100,101]. When the coefficient of recirculation is greater than unity, the reaction passes into the internal diffusion region. With recirculation[102,103], or increase in the linear velocity of the starting gas[13], the productivity of the process is increased 6–8 times and the yield of products approaches the theoretical. On fused catalysts the optimal consumption ratio of $H_2$ : CO establishes itself at a space velocity of 100–50 000 $h^{-1}$ and a recirculation coefficient of 0–50.[102]

The best removal of heat is achieved with a *fluidised bed* of catalyst suspended in the gas phase. With this method the efficiency is 2–4 times that achieved with a stationary layer, there is a high degree of conversion of the starting gas, and the catalyst can be easily replaced or regenerated (Table 2).[1,46,63,104-107] Fused and sintered catalysts of particle size 2–100 μm are used; they are active for more than 350 h without regeneration. Such a process is operated at a works in South Africa. The precipitated catalyst ($86.6Fe + 5Cu + 8Mg + 0.4K_2O$) in a fluidised layer worked at a lower temperature and pressure, but its activity, selectivity, and stability were less than those of fused catalysts[63,107]. Catalysts in a fluidised

bed must have high mechanical strength. Polymeric products must not be formed, as their deposition on the surface of the catalyst would bring about defluidisation, so that a higher temperature is also required. However, this may greatly accelerate side-reactions of carbon monoxide with water (the water-gas reaction) and carbon formation, and lead to a decrease in the selectivity and stability of the catalysts. These undesirable effects may be prevented by carrying out the synthesis with hydrogen-enriched gas ($H_2 : CO = 1.95–2.5$) and by using circulation.

Highly active, selective, and stable nitrided catalysts are of considerable interest in this process[63]. Synthesis on these takes place at 260–275° and 15–25 atm with a starting gas consisting of $H_2 : CO = 1.2–1.3$. They had a working cycle without regeneration of over 1500 h.

In *liquid-phase* synthesis, precipitated and fused iron catalysts are used both stationary[108,109] and suspended in oil[35,104,110–116]. Hydrocarbon fractions of b.p. 200–450° and 300–450° were used as medium. The heat of reaction went to heat the circulating oil and evaporate its lighter components. The rise in temperature of the oil did not exceed 50 deg. Precipitated iron catalysts were very active, but were rapidly destroyed by the circulating oil. The less active and more stable fused catalysts (Table 2), however, did not work for more than 2–3 months, because of cementation and a sharp rise in hydraulic resistance. This disadvantage is eliminated when a catalyst of 6–20 mesh particle size forms a circulating or stationary suspension in the oil. According to the conditions of synthesis and the catalyst, the product may consist mainly of gasoline, diesel oil, or solid paraffins. The solubility of the gases and reaction products in the liquid phase plays an important part[112]. The process is characterised by good heat removal, high selectivity, flexibility, uniform loading of the catalyst, ease and simplicity of plant layout, and high efficiency.

Processes using a stationary layer of iron catalyst with circulating gas, but particularly in the liquid phase with the iron catalyst suspended in oil, are most selective (lowest yield of methane) and are characterised by high stability and productivity, good heat exchange, comparatively low reaction temperatures and pressures, and also great flexibility. Gasoline as the main product, or gasoline with diesel fuel, or solid paraffins can be obtained from gases with an $H_2 : CO$ ratio of 0.6–2.0, and consequently from effluent gases of a number of plants (Table 3). Considerable amounts of oxygen-containing compounds, mainly alcohols, are formed on fused and sintered catalysts[11,117–125]. The gasolines have much better engine characteristics than those obtained from carbon monoxide and hydrogen on cobalt catalysts.[3,11,21,118,126] After the addition of R-9 or polymer motor fuel (0.5–1.5 ml $kg^{-1}$) or after thermal treatment in the presence of alumina, commercial A-66 or A-70 motor fuels are obtained. Diesel fuel obtained on

iron catalysts is of low quality, and can be used only as a component of high-quality diesel fuels [126].

A gas-phase process on fluidised iron catalysts is used for the preparation of high-quality motor fuels, although it is less selective than the previous two, and requires higher temperatures and pressures and the use of a hydrogen-enriched starting gas [46].

The synthesis of hydrocarbon fuels from carbon monoxide and hydrogen is of definite value for countries that have no, or very limited, natural oil sources [11,18,19,21,127]. However, it is more expedient to obtain from these gases raw materials for organic synthesis in the form of unsaturated hydrocarbons and oxygen-containing compounds [45,118,128]. For the synthesis of $C_2$–$C_4$ unsaturated hydrocarbons [129] or a mixture of liquid and gaseous olefins [130–134], iron catalysts in a stationary or fluidised layer are recommended, with addition to the starting gas of halogens, hydrogen halides, or organic halogen compounds that give hydrogen halides on dissociation. The catalyst may be promoted with iron halides or alkali-metal halides [134], with lead [135,136], and also by the addition of 0.02–0.5 wt.% of sulphur [129,137,138]. The process operates at high pressure, 295–400°, and a space velocity of starting gas (2.25 CO : 1 $H_2$) of 3100 $h^{-1}$.

## 2. Oxide Catalysts

(a) Metal oxides. Oxides that are difficult to reduce — $ThO_2$, $Al_2O_3$, $SiO_2$, ZnO, etc., — are known as promoters of nickel, cobalt, and iron catalysts in the synthesis of hydrocarbons from carbon monoxide and hydrogen. Pichler and Ziesecke found that, at temperatures of ~450° and pressures of over 100 atm, liquid and gaseous aliphatic hydrocarbons, mainly with branched structures, can be synthesised from carbon monoxide and hydrogen on these oxides [139–142]. Thoria, zirconia, and ceria were found to be active [139,143,144], as were also the mixed catalysts $ThO_2$–$Al_2O_3$, $ThO_2$–ZnO, and ZnO–$Al_2O_3$. [143] In the presence of these catalysts at 400–450° and 250 atm, 70–80% conversion of carbon monoxide was achieved; the total yield of hydrocarbons was 105 g $m^{-3}$, of which up to 57 g $m^{-3}$ represented liquid hydrocarbons. At 30 atm the degree of conversion of carbon monoxide and the yield of products were small. At increased temperatures (above 450°) the gaseous products increased, and below 375° alcohols were mainly formed. When potassium carbonate, kieselguhr, or iron was added to $ThO_2$ or $ThO_2$–$Al_2O_3$, the activity of these catalysts was diminished and methane formation was increased [143]. The reaction products contained large amounts of unsaturated aliphatic hydrocarbons, over 90% of which had branched structures; small amounts of aromatic hydrocarbons and naphthenes were found. Catalysts consisting of the oxides of aluminium, tungsten, zirconium, uranium, and the rare earths, with the addition of zinc oxide, chromic oxide, or copper, have been proposed for the preparation of high quality motor fuel from carbon monoxide and hydrogen; they are active at pressures above 100 atm and temperatures above 350–400°. [145] On oxides of molybdenum, tungsten, chromium, manganese, vanadium, and magnesium promoted with 1–5% of potassium carbonate the degree of conversion of carbon monoxide at 30 atm and 400–470° was 87–92%, but gaseous products were mainly formed. Oxides of titanium and strontium, and also metal oxides that are easily reduced, e.g. PbO, $SnO_2$, and CdO, were inactive [146,147]. Catalysts prepared from bauxites by impregnation or fusion with potassium carbonate and borax, and containing $Fe_3O_4$, are active at 280° and 20 atm with a gas mixture (1CO : 1$H_2$) at a space velocity of 1250 $h^{-1}$; these operated for more 120 h without loss in activity, giving a yield of $C_2$ and higher hydrocarbons up to 110 g $m^{-3}$. [148]

(b) Silicic acid catalysts. Promoted silicic acid catalysts form a large group of oxide catalysts for the reduction of carbon monoxide; they are prepared both from soluble silicates and from natural silicate-containing minerals [144]. Silicon dioxide with 2% of potassium carbonate, potassium hydroxide, or sodium borate is active at 350–450° and 20–40 atm after preliminary treatment [146,148]. The degree of conversion of carbon monoxide with a gas mixture (1 CO : 1 $H_2$) at a space velocity of 100–300 $h^{-1}$ was 80–95%; the yield of hydrocarbons was 110–130 g $m^{-3}$, up to 65 g $m^{-3}$ being liquid. At temperatures above 450° more liquid products and much gas were obtained, and at 500° methane was the main product. The addition of small quantities of alumina promoted the reaction, but the oxides of magnesium, calcium, tungsten, and thorium were inactive [144].

Natural silicate minerals are active at 350–470°, pressures above 20 atm, and a space velocity (1 CO : 1 $H_2$) of 100–300 $h^{-1}$. [149,154] Alkaline additives (potassium and sodium carbonates, potassium hydroxide) generally increased the activity and promoted the formation of hydrocarbons of higher molecular weight. The minerals rhodonite (Mn, Ca)$[Si_2O_6]$, kaolin $Al_2[Si_2O_5](OH)_4$, montmorillonite (Mg, Ca)O.$Al_2O_3$.5$SiO_2$.7$H_2O$, nontronite $H_2Fe_2Si_2O_5.H_2O$, and microcline $K[AlSi_3O_8]$ were virtually inactive. The minerals beryl $Be_3Al_2[SiO_3]_6$, dumortierite $HBAl_8Si_3O_{20}$, spodumene (Li, Na)$Al[Si_2O_6]$, and albite $Na[AlSi_3O_8]$ gave methane as the main product with a high conversion of carbon monoxide. Liquid hydrocarbons were formed only in the presence of almandite $Fe_3Al_2[SiO_4]_3$, diopside $CaMg[Si_2O_6]$, actinolite $Ca_2(Mg, Fe)_5[Si_4O_{11}](OH)_2$, gedrite, anthophyllite $(Mg, Fe)_7[Si_4O_{11}]_2(OH)_2$, talc $Mg_3[Si_4O_{10}](OH)_2$, biotite $K(Mg, Fe)_3[Si_3AlO_{10}](F, OH)_2$, and kieselguhr.

The most active minerals were talc and kieselguhr; these gave yields of liquid products of 75 and 95 g $m^{-3}$ with total yields of 130 and 140 g $m^{-3}$ respectively. The reaction started only at 320°. The optimum temperature of the reaction was 350–450° on kieselguhr, and 415–450° on talc. Above 450° methane formation and coking up sharply increased. At atmospheric pressure the reaction did not occur even at temperatures above 450°; the optimum pressure was 20–40 atm. Increasing the pressure to 200 atm reduced the yield of liquid hydrocarbons, and increased the formation of oxygen-containing products and coke.

Alkaline additives ($K_2CO_3$, $Na_2CO_3$, KOH, $Na_2B_4O_7$, etc.) and also the salts $KNO_3$, $KMnO_4$, etc. are activators. With salts the efficacy of the cations diminished in the order K > Na > Li. Carbonates, nitrates, and fluorides were the most effective, but chlorides, bromides, and sulphates deactivated the catalysts. The degree of conversion of carbon monoxide and the total yield of hydrocarbons increased continuously as the potassium carbonate content increased from 0 to 10%. With further increase up to 50%, the yield of products decreased and the stability of the catalyst diminished. The activity of talc catalysts depends largely on preliminary thermal treatment. The best results are obtained by preliminary heating to 600°. According to X-ray analysis, this promoted the removal of all adsorbed interplanar and interstitial water without destroying the

structure of the talc. At 850–1000° the structure was destroyed, and the surface area was reduced by a factor of 2–3. Talc roasted at 600° together with an alkaline additive had a low activity, apparently because of sintering of the particles and reduction of the surface area.

The maximum total yield and also yield of liquid hydrocarbons were observed with 54–60% of CO in the starting gas. As the space velocity is increased in the range 100–1650 $h^{-1}$, the efficiency of the catalysts continuously increases, but its stability falls sharply. Silicate catalysts are regenerated by air at 450°. Gaseous and liquid hydrocarbons, oxygen-containing compounds, water, and carbon dioxide are formed on silica catalysts. The content of oxygen-containing compounds, mainly alcohols and carbonyl compounds, in the products of the reaction on kieselguhr catalysts is small (5–8%); on talc it reaches 80%. The hydrocarbons, which are mostly volatile below 170°, contain 60–70% of unsaturated compounds and consist mainly of aliphatic hydrocarbons with branched structures. The content of aromatic hydrocarbons does not exceed 6–10%. The octane number of the motor fuel obtained from carbon monoxide and hydrogen on silicic acid catalysts reaches 76–81.

A characteristic feature of natural silicate minerals is their crystalline structure, which is based on different arrangements in space of $[SiO_4]^{4-}$ tetrahedra. Only lower, mainly gaseous hydrocarbons are formed on silicates with single or double tetrahedra, but liquid hydrocarbons are formed on silicates with a layer structure.

Oxide catalysts therefore constitute a new class of catalyst for the reduction of carbon monoxide. They form neither carbides nor carbonyls with the latter, but decompose it, promoting its conversion by water vapour. They are not oxidised by water and carbon dioxide, but under the conditions of the synthesis they may perhaps react with carbon dioxide to form carbonates. The reduction of carbon monoxide on oxide catalysts proceeds at high temperatures (350–500°) and pressures (20–600 atm) with the formation of hydrocarbons, mainly with branched structures.

According to the semi-contact hypothesis on the hydrogenation of carbon monoxide to branched hydrocarbons [155], oxide catalysts are not capable of activating hydrogen directly, which leads to an increased concentration of CHOH groups together with $CH_2$ groups on the surface of the catalyst. Branched compounds are formed by catalytic dehydration and condensation, in which the hydroxy-groups on the secondary carbon atoms react with hydrogen atoms of the hydrocarbon chain.

## II. DIRECTED SYNTHESES OF ORGANIC COMPOUNDS FROM CARBON MONOXIDE AND HYDROGEN

The Fischer–Tropsch synthesis of hydrocarbons from carbon monoxide and hydrogen on catalysts based on iron, cobalt, and nickel is not selective [5]. For this reason, the directed syntheses of valuable chemical products from carbon monoxide and hydrogen are of great interest.

### 1. Synthesis of Higher Hydrocarbons

(a) Ruthenium catalysts. As early as 1938, a yield of hydrocarbons of 140–150 g $m^{-3}$ (60–70% solid paraffin) was obtained from a mixture of $1CO + 2H_2$ on finely divided metallic ruthenium at 180–200° and 100–800 atm. [156,157] At the present time, in connection with the development of radio-electronic and other processes, the demand for synthetic paraffins with a number of properties superior to those of petroleum paraffins has greatly increased. New work has been done on the synthesis of solid paraffins in the presence of ruthenium catalysts [158–160]. It was found that, as the temperature increased in the range 165–275°, the degree of conversion of the starting gas continuously increased, but the yield of paraffins passed through a maximum at 170–180°. Increasing the total pressure to 1500 atm and reduction of the contact time promoted the formation of solid paraffins, their content in the reaction products reaching up to 65%. At the same time the optimum reaction temperature was lowered. The maximum yield of solid and liquid hydrocarbons was obtained from a 1 : 2 mixture of carbon monoxide and hydrogen. More liquid and gaseous hydrocarbons were formed on ruthenium with the addition of 20% of thorium, aluminium, and magnesium oxides. However, it was later shown that the addition of small amounts of metal oxides, for example 1.5% of magnesium oxide, led to a sharp increase in the yield of solid hydrocarbons. Preliminary treatment of the catalysts with hydrogen at 220–420° led to a 20% reduction in activity, but sharply increased the selectivity, apparently by the formation of a definite microstructure with pores of 400–1000 Å diameter and a total surface area of 7–15 $m^2\ g^{-1}$. Catalysts containing traces of alkali and having a pore diameter of 1200–1600 Å were much less selective. Catalysts nitrided at 250–300° with the formation of ruthenium nitrides gave mainly liquid and gaseous hydrocarbons, but catalysts nitrided at 400–450° had high selectivity and stability to oxygen and gave products containing 93–95% of solid paraffins.

Therefore the conditions for activating ruthenium catalysts for very selective synthesis of solid paraffins having m.p. 50–140° have now been established.

(b) Modified cobalt catalysts. Thorium dioxide in cobalt catalysts for the synthesis of hydrocarbons from carbon monoxide and hydrogen may be replaced by zirconium or titanium dioxide [161]. Such catalysts, after preliminary reduction with hydrogen at 400° for 12 h, operated at 190° and atmospheric pressure with yields of liquid hydrocarbons of 150–170 g $m^{-3}$ of starting gas (1 CO : 2 $H_2$). With a pressure of 10 atm on catalysts of composition 100Co : $6ZrO_2$, or $TiO_2$ : 10MgO: 200 kieselguhr, the reduction of carbon monoxide in the first 144 h proceeded, as at atmospheric pressure, with the formation mainly of liquid hydrocarbons. Then solid paraffins began to be mainly formed having m.p. 70–98°, with an average yield of ~92 and a maximum yield of 116 g $m^{-3}$. The catalysts worked for over 800 h with no loss in activity [162].

(c) Molybdophosphoric catalysts. Solid paraffins are obtained from mixtures (10 : 1 to 1 : 5) of carbon monoxide and hydrogen at 125–350° and 450–500 atm in the presence of molybdophosphoric acids $P_2Mo_xO_y$ ($x$ = 20–24 and $y$ = 31–60) and their salts $M_yP_2Mo_xO_z$ (M is a metal — Li, Na, K, Rb, Cs, Cu, Ag, Au, Zn, Cd, Hg, Al, Ga, In, Mg, Mn, Fe, Co, Ni — $y$ = 2–10, $x$ = 20–26, and $z$ = 37–65). [163,164] The following acids and salts have been used as catalysts $P_2Mo_{22}O_{39}$, $P_2Mo_{21}O_{47}$, $P_2Mo_{22}O_{48}$, $Ni_2P_2O_5(Mo_2O_5)_{11}$, $Co_3P_2O_5(Mo_2O_5)_{22}$, $Fe_3P_2O_5(Mo_2O_5)_{10}$, $Cu_3P_2O_5(Mo_2O_4)_{12}$, and $Zn_3P_2O_5(Mo_2O_3)_{12}$. The catalyst, used in 1.5–30% quantities, was first reduced in hydrogen at 400° for 17–19 h. The synthesis was carried out in cyclohexane, methanol,

decahydronaphthalene, tetrahydronaphthalene, aromatic hydrocarbons, or cyclohexanone as diluents.

### 2. Synthesis of Ethylene

Ethylene is a valuable raw material for organic synthesis in industry [165], and for this reason, attempts have been made to prepare it from carbon monoxide and hydrogen [166-170]. This synthesis was first carried out by Orlov in 1908 at 95–100° and atmospheric pressure on nickel–palladium catalysts [171,172]. According to modern patent information, ethylene is formed on iron catalysts promoted by compounds of copper, titanium, manganese, chromium, molybdenum, aluminium, thorium, cerium, and zirconium, and containing 20–50% of aluminium, magnesium, and zinc silicates. The reaction occurs at atmospheric or slightly increased pressure, 470–600°, and a space velocity of circulating gas mixture of 500–5000 $h^{-1}$ ($CO : H_2$ 1 : 1–2, circulation coefficient 0.5–5). It is necessary to add to the reaction zone small amounts of ammonium chloride or fluoride or other compounds that form hydrogen halides under the reaction conditions [166]. The following catalysts have also been proposed [168]: (1) zinc and chromic oxides with the addition of magnesium oxide; the chromic oxide may be replaced by the oxides of vanadium, niobium, tantalum, molybdenum, or tungsten, and the zinc oxide by oxides of cadmium, copper, or silver; (2) one of several metals in Group VIII of the Periodic System or their compounds; (3) the oxide or hydroxide of aluminium and/or the oxides of silicon, titanium, zirconium, hafnium, thorium, cerium, vanadium, or rare-earth elements; and finally (4) carbonates, oxides or hydroxides of the alkali metals. The catalysts may be deposited on a carrier of kieselguhr, silica gel, or clay. On a catalyst of composition $51Zn + 0.13Cr_2O_3 + 0.64Co + 0.04K_2O + 100Al_2O_3$ at atmospheric pressure, a temperature of 430°, and a space velocity of 350 $h^{-1}$, 25 litres of $C_2H_4$ and 2 litres of $C_2H_6$ were obtained per cubic metre of gas (1 $CO : 1\ H_2$). A catalyst of 3% CuO on $Al_2O_3$ is active at 20–40 atm and 250°. [169] Ethylene is also formed by passing a gas mixture (1–3 $CO : 1\ H_2$) at 350–550° and atmospheric pressure through a copper tube at a space velocity of 370–2500 $h^{-1}$. [170]

### 3. Synthesis of Alcohols

As early as 1913 it was discovered in the Badische Anilin- und Soda-Fabrik that a mixture of alcohols, aldehydes, ketones, and acids with a small admixture of hydrocarbons is formed from carbon monoxide and hydrogen at 300–400° and 100–200 atm in the presence of cobalt and osmium oxides deposited on asbestos and activated by alkalis [173]. Fischer and Tropsch set up the Synthol process operating at 400–450° and 100–150 atm in the presence of iron oxide promoted by alkali; this gave a complex mixture of alcohols, aldehydes, ketones, and acids from carbon monoxide and hydrogen [174]. Later, in Germany the Synthol process with fused iron catalysts, of the type used in ammonia synthesis, at 190–220° and 20 atm was used to obtain a liquid product (yield 170–180 g $m^{-3}$) containing 60–70% of alcohols from a $1\ H_2 : 1–1.3$ CO mixture [5,175,176]. The products obtained on precipitated iron–copper catalysts at 180–220° and 30 atm also contained a large amount of oxygenated compounds, comprising 75–80% of alcohols and ethers and 25–20% of carbonyl compounds, or under slightly different conditions, 80% of alcohols and 20% of ethers and carbonyl compounds [177]. The alcohols were primary with only a small amount of branching.

An important step forward in the synthesis of alcohols from carbon monoxide and hydrogen was the development of zinc–copper and zinc–chromium catalysts, in the presence of which methyl alcohol is selectively formed [178-181]. Methanol is synthesised industrially at 300–325 atm, 325–375°, and a space velocity of circulating gas (1 $CO : 2\ H_2$) of 10 000 $h^{-1}$. When the starting gas contained stoichiometric proportions of carbon monoxide and hydrogen, difficulty was encountered in controlling the reaction temperature. The process was considerably improved by reducing the concentration of carbon monoxide in the circulating gas to 5–6%. [182,183] It was found possible to combine the synthesis of methanol with degradative hydrogenation processes in vapour and liquid phases and with the ammonia synthesis; this made the product cheaper.

The synthesis of higher alcohols from carbon monoxide and hydrogen is thermodynamically more favoured than the synthesis of methanol [5,184]. Displacement of the reaction towards the production of higher alcohols is promoted by a higher temperature (above 400°), a lower space velocity of starting gas, and alkaline additives in the catalyst. Higher alcohols were formed at 380–490°, 150–250 atm, and a space velocity (of $H_2 : CO = 5–1 : 1$) of 2000–20 000 $h^{-1}$ on modified oxide catalysts. [184] The alcohol content of the reaction product reached 60% with methanol and primary isobutanol predominating [184-185]. At lower temperatures the reaction product contained up to 20% of ethanol. Selective catalysts for the synthesis of ethanol are obtained on the basis of Group VIII metals [186-191].

In the presence of fused iron catalysts [188-191], promoted by oxides that are difficult to reduce ($ZrO_2$, $Al_2O_3$, ZnO, $TiO_2$, $V_2O_5$, $Cr_2O_3$) and alkaline additives, at 150–180°, 200 atm, and a space velocity of 300–2000 $h^{-1}$, a yield of liquod product of 160–170 g $m^{-3}$ was obtained from a 1 CO : : 2 $H_2$ gas mixture. The product contained 85–100% of oxygen-containing compounds, 80–90% of which were normal alcohols and 5–10% carbonyl compounds. Ethanol and unsaturated hydrocarbons have been synthesised from a $3\ CO_2 : 1\ H_2$ gas mixture at 200–350 atm, 335–370°, and a space velocity of circulating gas of 10 000–20 000 $h^{-1}$ on fused iron catalysts with oxide ($K_2O$, $Al_2O_3$, $SiO_2$, MnO, etc.) additives [190].

Natural mineral talc with the addition of barium aluminate and potassium carbonate may be used as catalyst in the synthesis of oxygen-containing compounds [149-154,192]. The reaction product obtained at 430°, 30 atm, and a space velocity of 500 $h^{-1}$ with a mixture (1 : 1) of carbon monoxide and hydrogen contained up to 80% of alcohols and carbonyl compounds. After supplementary hydrogenation it consisted of a mixture of alcohols with n-propyl and isopropyl alcohols predominating.

## III. KÖBEL–ENGELHARDT SYNTHESIS OF ORGANIC COMPOUNDS FROM CARBON MONOXIDE AND WATER VAPOUR

The synthesis of hydrocarbons from carbon monoxide and water vapour, discovered by Kölbel and Engelhardt in connection with a study of the mechanism of the Fischer–Tropsch synthesis on iron catalysts, proceeds according to the following overall reaction [35,70,193]

$$3CO + H_2O = 2CO_2 + CH_2 + 58.4\ \text{kcal mole}^{-1}. \quad (1)$$

This discovery became practicable after it had been shown experimentally that the formation of carbon dioxide is due to a secondary water-gas reaction[87,88]

$$CO+H_2O \rightleftarrows CO_2+H_2+9.5 \text{ kcal mole}^{-1}. \quad (2)$$

Water is formed by the primary reduction of carbon monoxide:

$$CO+2H_2=CH_2+H_2O+39.4 \text{ kcal mole}^{-1}. \quad (3)$$

On examination of the thermodynamics of the reduction of carbon dioxide to higher hydrocarbons[194-196]

$$CO_2+3H_2=CH_2+2H_2O+29.9 \text{ kcal mole}^{-1} \quad (4)$$

of the Fischer–Tropsch synthesis with the separation of water (3) or $CO_2$

$$2CO+H_2=CH_2+CO_2+48.9 \text{ kcal mole}^{-1}, \quad (5)$$

and of the interaction of carbon monoxide and water vapour by reaction (1), it was found that at 200–250° conditions are much more favourable for the formation of hydrocarbons from carbon monoxide and water vapour (1) than for the Fischer–Tropsch reaction (3). All the reactions examined are formally derived from the Fischer–Tropsch reaction (3), when account is taken of the water-gas reaction (2). The formation of hydrocarbons from carbon monoxide and water is possible at temperatures up to ~500°.

Kölbel–Engelhardt catalysts have as basis metals of Group VIII — iron, cobalt, nickel, or ruthenium — and they do not differ in composition and method of preparation from Fischer–Tropsch catalysts[113,197-202]. Optimum conditions for the synthesis of hydrocarbons from carbon monoxide and water vapour are given in Table 4. In addition to the formation of hydrocarbons, side-reactions also occur: these include the water-gas reaction, the decomposition of carbon monoxide

$$2CO \rightarrow C+CO_2, \quad (6)$$

methane formation

$$CO+3H_2 \rightarrow CH_4+H_2O, \quad (7)$$

and oxidation of iron present in the catalyst. These side-reactions can be kept to a minimum by changing the conditions of the process and the composition of the catalysts.

TABLE 4. Conditions and yield of products in synthesis of hydrocarbons from carbon monoxide and water vapour.

| Conditions | Catalyst based on | | | | |
|---|---|---|---|---|---|
| | Fe | | Co | Ni | Ru |
| | stationary layer | liquid-phase synthesis | | | |
| Temperature, °C | 220—240 | 240—280 | 200—240 | 190—205 | 160—199 |
| Pressure, atm | 1—100 | 15—20 | 1—10 | 2.5 | 50—110 |
| Space velocity of initial vapour–gas mixture, $h^{-1}$ | 10—100 | — | 10—50 | — | 16—48 |
| Initial $CO:H_2O$ ratio | 3:1—2:1 | 3:1,15 | 3:1—1:1 | 2:1 | — |
| Degree of conversion of CO, % | 92—98 | 93 | 86—97 | 50—60 | 34—71 |
| Yield, g $m^{-3}$ CO | | | | | |
| $C_1$ | 4—12 | } 22 | 2—4 | 25.0** | } 2.8—4.4 |
| $C_2$ | 11—14 | | } 204 | 0.3 | |
| $C_3$ and higher | 140—190 | 160 | | 74.7 | 66—142 |
| Total hydrocarbons | 160—210 | 182 | 206—208 | 100 | 70—145 |

* Duration of reaction, h.

** Composition of products of synthesis, %.

The addition of alkaline agents to the catalyst considerably diminishes methane formation, and the addition of oxides that are difficult to reduce prevents the formation of carbon[194-196]. In the presence of iron and cobalt catalysts the formation of hydrocarbons proceeds most smoothly in the temperature range 200–240°, 93–98% of the carbon monoxide being converted into liquid products. At temperatures below 200° only the water-gas reaction occurs. At temperatures above 240° the formation of methane and carbon is accelerated, and the proportion of carbon monoxide that goes to form liquid products decreases[195,203,204]. Increasing the space velocity at atmospheric pressure leads to a decrease in side-reactions and in the total yield of liquid hydrocarbons. It has been found that, in general, the maximum space velocity, expressed in $hour^{-1}$ with 90% conversion of carbon monoxide, should be 9–12 times the total pressure expressed in atmospheres. In contrast to the Fischer–Tropsch synthesis, increasing the total pressure leads to an increase in catalyst efficiency and to a weakening of side-reactions. To ensure normal operation of the synthesis it is necessary to adhere to a stoichiometric $CO:H_2O$ ratio in the gas mixture of 3:1 for the preparation of hydrocarbons and of 2:1 for the synthesis of oxygen-containing compounds. An excess of carbon monoxide leads to an increase in coke formation, especially at atmospheric pressure[203], and an excess of water vapour leads to oxidation and deactivation of the catalysts[196,203,205,206]. Iron catalysts are the most easily oxidised, and for these the $CO:H_2O$ ratio should not be less than 2:1. The stability of the catalysts is increased by treating them with a 3 CO : 1 $H_2$ mixture at 220°; cobalt catalysts are treated at 200° and a space velocity of 80 $h^{-1}$, or with ammonia at 200° and 300 $h^{-1}$.[206]

The reaction products obtained under optimum conditions are saturated and unsaturated aliphatic hydrocarbons mixed with small quantities of oxygen compounds. The reaction products obtained on iron and cobalt catalysts contain 50–70% of olefins. On nickel catalysts the main products are saturated hydrocarbons[207,208]. When the partial pressure of the water vapour is increased, the molecular weight of the products and their content of unsaturated compounds decrease; a total pressure up to 16 atm with a 1 CO : 1 $H_2O$ mixture as starting gas has no effect on the degree of saturation of the reaction products[203]. An increase in pressure to 100 atm promoted the formation of ~30% of oxygen-containing compounds, mainly alcohols. In the presence of ruthenium catalysts[209], as in Pichler's synthesis[156,157], solid paraffin hydrocarbons with a mean molecular weight of 500–7000 are formed. Gases, free from catalyst poisons, containing even small amounts of carbon monoxide, such as blast-furnace and other industrial gases, may be used as raw materials in the synthesis of hydrocarbons from carbon monoxide and water vapour[194-196,210]. The synthesis is carried out on a very large scale in the presence of iron catalysts in the liquid phase with a space efficiency of 272 kg of hydrocarbons ($C_3$ and higher) per day per cubic metre of reaction space[113]. Petrol, diesel fuel, or solid paraffin can be obtained as the main product according to the conditions of the process and the composition of the catalyst. In all cases the products contained 70–80% of unsaturated hydrocarbons.

As kinetic measurements have shown, the process by which hydrocarbons are synthesised from carbon monoxide and water vapour consists of a series of very fast successive water-gas (2) and carbon monoxide reduction (3) reactions[208,211-214]. When the time of contact with iron, cobalt, and nickel catalysts is increased, the content of carbon

dioxide and hydrocarbons in the reaction mixture increases, while that of carbon monoxide and water vapour falls continuously. The hydrogen content passes through a maximum, which decreases as pressure increases, and increases with increase in the $H_2O:CO$ ratio. In the region of high partial pressures of carbon monoxide and water vapour, the rate of formation of hydrogen according to Eqn. (2)

$$r_1 = k_1 P_{CO}^a P_{H_2O}^b, \quad (8)$$

predominates over the rate of its disappearance by reaction (3)

$$r_2 = k_2 P_{CO}^c P_{H_2}^d. \quad (9)$$

As the partial pressures of carbon monoxide and water vapour decrease, the rate of formation of hydrogen decreases, but the rate at which it enters into reaction increases. The two rates become equal when the reaction products contain the maximum amount of hydrogen as a function of the time of contact. As the partial pressures of carbon monoxide and water vapour are further decreased, $r_2$ becomes greater than $r_1$. The numerical values of the exponents of the partial pressures — $a$, $b$, $c$, and $d$ — in Eqns. (8) and (9) depend mainly on the surface concentrations, and differ little with iron, cobalt, and nickel catalysts (Table 5),

The rate constants $k_1$ and $k_2$ are determined by adsorption factors and differ from one another in different ways with different catalysts. With iron catalysts $k_1 > k_2$, with cobalt catalysts $k_1 \simeq k_2$, and the ratio of the rate constants of the hydrogen formation and consumption reactions decrease in the sequence

$$\left(\frac{k_1}{k_2}\right)_{Fe} > \left(\frac{k_1}{k_2}\right)_{Co} > \left(\frac{k_1}{k_2}\right)_{Ni}. \quad (10)$$

After hydrogen has been formed by reaction (2) it is desorbed into the gas phase to the extent of two-thirds on iron catalysts, one-third on cobalt catalysts, and one-sixth on nickel catalysts. The synthesis of organic compounds from carbon monoxide and hydrogen has many features in common with the synthesis from carbon monoxide and water vapour; they are both based on the catalytic reduction of carbon monoxide by hydrogen. They occur on the same catalysts, they are accompanied by the same side-reactions, and their apparent activation energies are closely similar. The reaction products from the two processes have virtually the same fractional composition, but the products of the carbon monoxide and water vapour synthesis contain more olefins and oxygen-containing compounds. The temperature in the synthesis from carbon monoxide and water vapour is ~30 deg higher than in the Fischer–Tropsch synthesis. Material advantages of the synthesis of hydrocarbons and oxygen-containing compounds from carbon monoxide and water vapour are the insignificant amount of methane formation and the possibility of using cheap technical and effluent gases containing small amounts of carbon monoxide and large admixtures of inert gases.

TABLE 5. Reaction order of formation and consumption of hydrogen on iron, cobalt, and nickel catalysts in the synthesis of hydrocarbons from carbon monoxide and water vapour.

| Catalyst | Total pressure, atm | Reaction $CO+H_2O=H_2+CO_2$, $r_1=k_1 P_{CO}^a P_{H_2O}^b$ | | Reaction $CO+2H_2=CH_2+H_2O$, $r_2=k_2 P_{CO}^c P_{H_2}^d$ | |
|---|---|---|---|---|---|
| | | $a$ | $b$ | $c$ | $d$ |
| Fe | 11 | 0.5 | 0.2 | 0.2 | 1.5 |
| Co | 21 | 1.0 | 0.3 | −0.3...+0.3 | 1.0 |
| Ni | 5 | 0 | 0.6 | 0 | 0.6 |

---o0o---

The synthesis of hydrocarbons and oxygen-containing compounds has thus been further developed in the last ten years. New technological schemes have been worked out, and cheap, readily obtainable, and effective catalysts have been developed on the basis of iron. A new method of reducing carbon monoxide with water vapour has been worked out; with this process effluent gases can be used and valuable products can be obtained. Interesting results have been obtained in putting into practice directed synthesis of oxygen compounds, mainly alcohols, macromolecular solid paraffins, and ethylene.

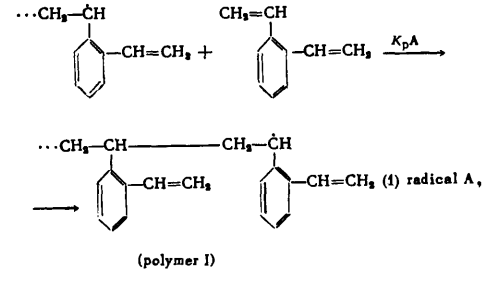
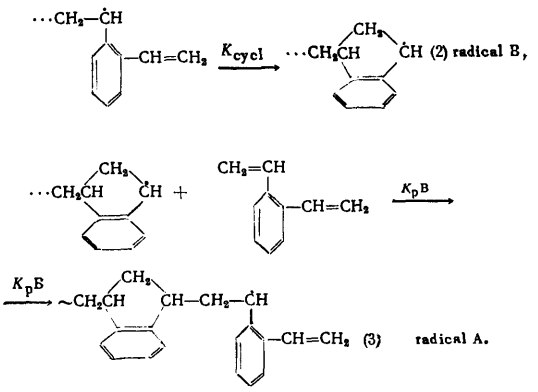
# SOME REGULARITIES IN THE POLYMERISATION OF BIFUNCTIONAL MONOMERS



V. V. Amerik and B. A. Krentsel'

The development of processes of linear and stereospecific polymerisation, which has considerably extended the range of polymerisable compounds and opened up new possibilities for controlling the growth of macromolecules, has given rise to a natural interest in the polymerisation of bifunctional monomers. Several new regularities have been discovered in the polymerisation of these monomers, which are of scientific and practical importance.



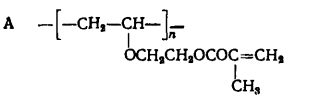
In the polymerisation of the simplest symmetrical bifunctional monomer, butadiene, either 1,2- or 1,4-addition is possible. A polymer chain of desired structure can be obtained by using a definite type of catalyst. The polymerisation of bifunctional compounds in which the two carbon–carbon double bonds differ in electron density is still more influenced by the type of catalyst (cationic or anionic) and by the solvent.

If a bifunctional compound containing a heteroatom attached to one of the double bonds is used as monomer, the structure of the resulting polymer depends not only on the nature of the catalyst and the solvent but also on the temperature of polymerisation. In spite of several investigations published in the literature, these questions are still far from being completely elucidated.

The polymerisation of bifunctional compounds containing two double bonds in the *ortho*-position has been studied with *o*-divinylbenzene as example [1]. This monomer was polymerised by a radical mechanism (with $\alpha\alpha'$-azoisobutyronitrile as initiator) in benzene solution. The resulting soluble polymer still contained double bonds, as was confirmed by their spectra and by bromination in carbon tetrachloride. Therefore the following three reactions can be assumed for growth of the polymer chain:

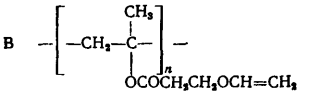
(polymer I)

The mole fraction of monomer units containing unchanged vinyl groups is given by the equation



$$-\frac{dm}{dM}=\frac{2[M]}{2[M]+r_c}\quad r_c=\frac{K_{cycl}}{K_pA},$$

where [M] is the molar concentration of monomer and $m$ the concentration of polymer (I). It is obvious from this equation that the content of monomer units containing unchanged vinyl groups will depend on the initial concentration of the monomer, since $r_c$ is constant.



If the polymer contains one vinyl group per monomer unit, the content of polymer (I) is taken as 100%. Usually, however, it was always less than 100%, varying from 30% to 90% depending on the conditions of polymerisation. The content of monomer units containing vinyl groups falls with a decrease in the concentration of monomer in the initial mixture and with a rise in the temperature of polymerisation, since conditions favouring the cyclisation reaction (2) are produced. This fact is explained by the difference in activation energy between the bimolecular growth in the polymer chain (1) and the intramolecular cyclisation (2). Addition of *o*-divinylbenzene in the growth reaction occurs in the same way as with styrene. The growing radical A has a rather larger delocalisation energy than the styrene radical, while the cyclic radical B possesses a far smaller delocalisation energy. Hence a higher activation energy is required for intramolecular cyclisation than for addition of the monomer. The thermal polymerisation of *o*-divinylbenzene therefore results in formation of a linear polymer containing five-membered rings. Chain growth takes place mainly in conformity with Eqn. (1).

Various bifunctional monomers containing two or more carbon–carbon double bonds have been synthesised[2], and found to differ greatly in their tendency to form growing ions or free radicals depending on the mode of initiation of the reaction. Vinyl ethers of phenols containing the unsaturated side-chain $CH_2:CHOCH_2CH_2OR$, where R represents phenyl, allylphenyl, methylallylphenyl, 2-allyl-4-chlorophenyl, or but-2-enyl, were subjected to low-temperature polymerisation in the presence of boron trifluoride. Linear polymers were obtained, whose infrared spectra confirmed that the vinyloxy-group was involved in the polymerisation. This is explained by the greater electron density on the vinyloxy-bond and the greater reactivity of the latter compared with the allyl functional group.

The unsuccessful attempt to polymerise the resulting oligomers at the allyl double bond by using radical initiators is explained by the so-called degradation mechanism of chain transfer[3]. The radical which is formed is strongly stabilised by delocalisation of the unpaired electron. Polymerisation of 2-vinyloxyethyl methacrylate with cationic and anionic catalysts gave polymers of varying structures. This compound $CH_2:C(CH_3)COOCH_2CH_2OCH:CH_2$ contains two types of double bonds, the electron-rich vinyloxy-bond and the electron-deficient methacrylate double bond[4]. Chain growth takes place differently with cationic and with anionic catalysts, giving polymers of structures A and B respectively

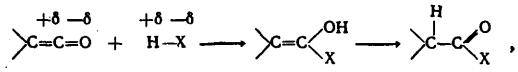
(cationic catalyst),

(anionic catalyst).

The polymerisation of 2-vinyloxyethyl methacrylate over tin(IV) chloride has been described[5]. The infrared spectra of the polymer obtained by polymerisation in solution in carbon tetrachloride at 0° showed complete disappearance of the 1780 $cm^{-1}$ band characteristic of the vinyloxy-group, while the bands at 1000–1650 $cm^{-1}$ characteristic of the methacrylate double bond remained. Consequently the resulting polymer had structure A. Polymerisation of 2-vinyloxyethyl methacrylate on a Ziegler catalyst at -20° gave a polymer of structure B, soluble in benzene. Polymerisation on the same catalyst at +25° gives a mixture of A and B polymers (see Table 1).

It can be assumed from these results that the nature of the active centres in Ziegler catalysts depends not only on the proportions of the components but also on the temperature of polymerisation. This is probably the reason for the contradictory results obtained by many authors in attempting to classify these catalysts as anionic or cationic.

A no less interesting class of bifunctional compounds are those in which a carbon–carbon double bond is accompanied by a carbonyl double bond. Among such monomers are keten, dimethylketen, biketen, and acrylaldehyde. The presence of cumulative carbon–carbon and carbonyl double bonds in ketens



makes them highly reactive towards polar and non-polar molecules. The latter add on at the carbon–carbon double bond, and polar molecules at the carbonyl double bond. In many reactions, however, the products of addition to the

TABLE 1. Polymerisation of 2-vinyloxyethyl methacrylate on various catalysts.

| Catalyst | Solvent | Temp., °C | Conversion, % |
|---|---|---|---|
| $SnCl_4$ | $CCl_4$ | −20 | 90A |

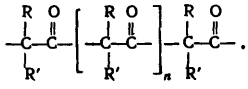
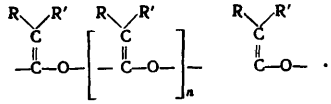
| Li tri-n-butylamine | $(C_4H_9)_3N$ | −25 | 30B |
| Triethylboron | $C_6H_6$ | 25 | 12A |

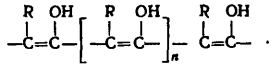
carbonyl group, which are in the enolic form, pass into carbonyl compounds:



where HX is a substance containing polar groups.

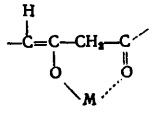


Structural units retaining the original form can therefore be observed only when keto–enol rearrangement in the reaction products is impossible, i.e. in the polymerisation of ketens. Linear and regular polymers of ketens may contain two structural units



Regular "head-to-tail" addition of $\alpha$-monomer units gives macromolecules having an $\alpha$-ketonic structure

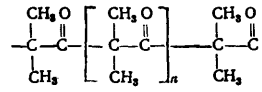
Similar addition of $\beta$-monomer units gives a polyacetal structure



If R and R′ are hydrogen atoms, the $\alpha$-ketonic structure is in equilibrium with the enolic structure

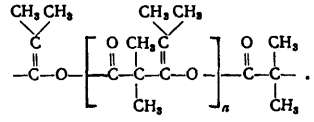
In most cases only products of low molecular weight were isolated in the polymerisation of keten (see Table 2).

Natta and his coworkers[9] have attempted to polymerise keten using Friedel–Crafts catalysts ($ZnCl_2$, $AlCl_3$) and organometallic catalysts (triethylaluminium and butyllithium, di-n-butylzinc), and have obtained compounds having a chelate type of structure



where M represents the metal. Degrees of conversion were low owing to deactivation of the catalyst.

Chelate structures are not formed if hydrogen atoms are not present in the monomer. At an early date Staudinger observed[7,10] the polymerisation of dimethylketen in the presence of trimethylamine as catalyst at -80°. The polymer had no regular chemical structure, and was completely converted into the monomer over the temperature range 100–200°.



Polymers of dimethylketen having a regular structure have been obtained[9,11] with several types of catalysts — (1) acidic catalysts, which in most cases act by a cationic mechanism, and have the formula $AlX_nR_{3-n}$, where X is a halogen, R is an alkyl or an aryl radical, and $n$ = 1–3; and (2) catalysts of anionic type, containing metals of small ionic radius and possessing electronegativities not exceeding 1.6, such as triethylaluminium, diethylberyllium, ethyllithium, etc. (see Table 3).

With the first group of catalysts dimethylketen yields a white polymer of 60–80% crystallinity. The polymer is soluble only in strongly polar solvents of high boiling point. It melts close to 250°, and is thermally stable up to 300°, within which temperature limits it is not depolymerised to the monomer. Intense absorption bands in the region of 5.9 $\mu$m in the infrared spectra, and in the region of 259 m$\mu$m in the ultraviolet spectra, indicate the presence of carbonyl groups in the polymer, which suggests an $\alpha$-ketonic structure

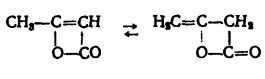
(I)

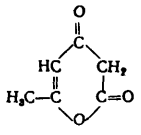
The dimethylketen polymer (II), obtained in the presence of catalysts of the second group, differs markedly in structure from polymer (I). Its infrared and ultraviolet spectra confirm its polyester structure, since the absorption band due to carbonyl groups is weak, while a band is observed in the region of 5.74 $\mu$m, which is characteristic of ester groups

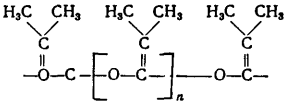
(II)

The structures of polymers (I) and (II) are confirmed also by chemical methods.

TABLE 2. Products of the polymerisation of keten.

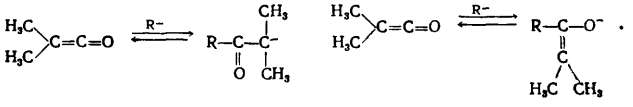






| Conditions of polymerisation | Products obtained | Ref. |
|---|---|---|
| 0–50°, no catalyst |  | 6 |
| 70–120°, pyridine as catalyst |  | 7 |
| -78° in acetone solution | $(C_2H_2O)_4$ | 8 |

TABLE 3. Polymerisation of dimethylketen in the presence of various catalysts at -78°.



| Catalyst | Solvent | Conversion, % | Time, min | Structure of polymer | | |

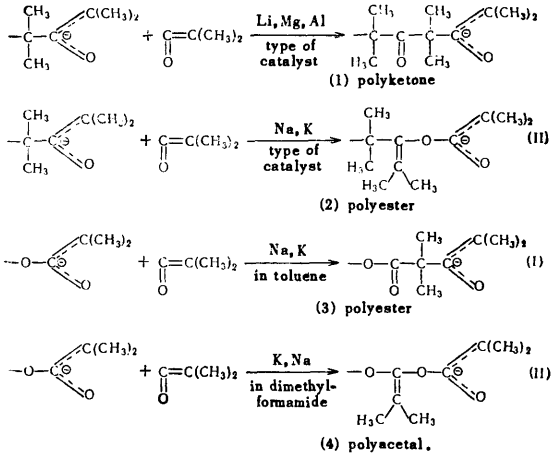
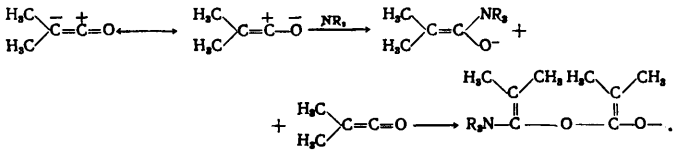
* Polymerisation carried out at -50°.

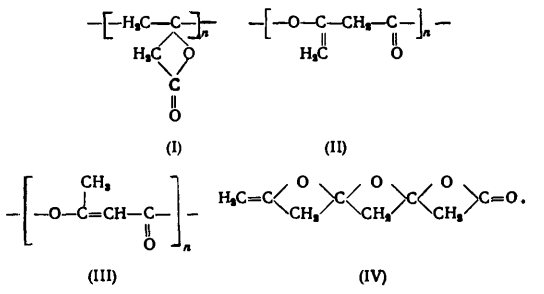


Polymers of dimethylketen which have a predominantly polyacetal structure have been obtained [11,12] by polymerisation in the presence of anionic catalysts ($C_4H_9Li$, $C_4H_9OLi$, Na–naphthalene, $C_2H_5ONa$). The polarity of the solvent influences the structure of the polymer obtained [12]. When dimethylketen is polymerised in the presence of the sodium–naphthalene complex as catalyst in toluene solution, polymers of polyester structure are obtained. Replacement of toluene (dielectric constant $\epsilon = 2.379$) by dimethylformamide (35.0) results in formation of a polymer of polyacetal structure. The infrared spectra of these polymers exhibit a band characteristic of carbon–carbon double bonds, and the products of acid alcoholysis and of hydrogenolysis in the presence of lithium tetrahydroaluminate indicate the presence of acetal links

The various reactions in the polymerisation of dimethylketen can be explained by postulating the following scheme for initiation and growth of the polymer chain [11,13,14]



The following four types of reaction can be postulated in the stage of chain growth



The driving force in the reaction of ketens with nucleophilic reagents is electrostatic interaction of the polarised keten molecule with electron-rich centres [15]. The anion (1) usually reacts with the next molecule of dimethylketen through the more electronegative oxygen atom according to Eqn. (2). The ester ion (II), under the influence of the oxygen atom, reacts more readily with the next monomeric molecule through the carbanion structure according to Eqn. (3). Polymerisation is also possible at the same time according to Eqns. (2) and (3) in the presence of catalysts containing sodium and potassium ions in toluene solution, which results in the formation of polyesters. Polyacetals are obtained, according to Eqn. (4), predominantly in polar solvents, such as dimethylformamide and triethylamine, which stabilise the enolic structure (II) by solvation. Japanese authors [14] give data on the polymerisation of dimethylketen in the presence of tertiary aliphatic amines. A more detailed study has shown [16] that the catalytic activity of tertiary amines increases with their dissociation constant. Increase in the polarity of the solvent results in an increased content of polyacetal structure in the polymer (see Table 4).

Polymerisation of dimethylketen in toluene also yields a considerable quantity of polyacetal structure, which represents an exception to the general rule of the effect of solvent polarity on polymer structure. It is interesting that, in dimethylformamide solution, dimethylketen polymerises in the absence of a catalyst. Dimethylformamide is probably sufficiently basic to initiate the polymerisation of dimethylketen in the absence of any other catalyst. In any case, rise in temperature results in a decrease in the proportion of polyacetal structure in the resulting polymer. The suggested mechanism of polymerisation when a series of amines are used as catalysts is that the first stage involves nucleophilic attack by the bases on the carbonyl group:

The influence of conditions on the polymerisation of biketen and the structure of the resulting polymer has been studied in less detail. The following four polymer structures can be imagined [17,18]

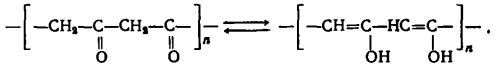
At room temperature biketen yields a dimer.

Fairly recently [19] a polymer of biketen of molecular weight ~ 1630 has been obtained in the presence of mercuric chloride as catalyst. It has the polyester structure (II).

TABLE 4. Effect of nature of solvent on polymerisation of dimethylketen at -40°; 50 ml of solvent, 0.4 vol. % of $(C_2H_5)_3N$.

| Solvent | Dimethylketen, ml | Time of reaction, min | Yield of polymer, % | $\frac{D_{5.85\,\mu m}^{*}}{D_{5.66\,\mu m}}$ |
|---|---|---|---|---|
| Cyclohexanone | 10 | 30 | 70 | 4.7 |
| Acetone | 10 | 15 | 65 | 11.7 |
| Diethyl ketone | 10 | 15 | 65 | 9.0 |
| Acetonitrile | 10 | 15 | 83 | 6.3 |
| Diethyl ether | 10 | 15 | 4 | (a) |
| Dimethylformamide (b) | 10 | 15 | 100 | 5.3 |

* $D_{5.85\,\mu m}$ = intensity of absorption band characteristic of polyacetal structure;

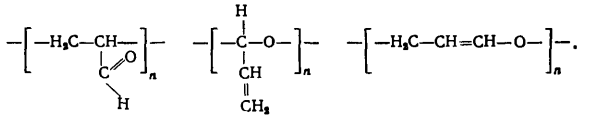


$D_{5.66\,\mu m}$ = intensity of absorption band characteristic of isolated polyester links.

(a) Mixture of polyester and polyacetal structures obtained.

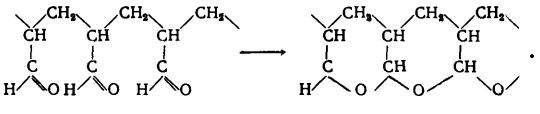
(b) No catalyst present.

A polymer of polyester structure is also obtained[20] from biketen in the presence of aluminium ethoxide.



In the presence of boron trifluoride an amorphous polymer has been obtained[21,22] whose structure differs from those suggested previously. The molecular weight is comparatively low (2080) and the infrared spectra support a β-diketone structure

In ethylene glycol solution the ketonic form of the polymer is in equilibrium with the enolic form. This structure is confirmed also by the product obtained on reaction with phenylhydrazine, whose infrared spectrum has a band in the range 1600–1500 $cm^{-1}$, which is characteristic of the –C=C–C=N– grouping.

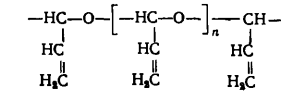


It is difficult to polymerise keten under these conditions, but the use of benzonitrile as catalyst has enabled a polymer of β-diketone structure to be obtained[22].

In the acrylaldehyde molecule, in contrast to dimethylketen, the two double bonds, carbon–carbon and carbon–oxygen, are conjugated. In the Diels–Alder reaction, acrylaldehyde acts as a diene[23,24], which suggests the formation of polymers having the structures

Several workers[25–27] have investigated the polymerisation of acrylaldehyde and studied the properties of the resulting polymers. Cationic polymerisation in the presence of aluminium chloride, zinc chloride, and ether complexes of boron trifluoride in various solvents (at 0–30°) yields soluble polymers containing reactive aldehyde groups (15–20%).

Koton and his coworkers have investigated[28] the polymerisation of acrylaldehyde in the presence of gaseous boron trifluoride with various additives over the range 0–80°. They obtained a vitreous polymer containing no free aldehyde groups. It is evident that the aldehyde group plays an active part in the polymerisation. The polymer is insoluble in organic solvents, but dissolves readily in sulphuric acid. Polymerisation takes place by a "head-to-tail" mechanism, all the aldehyde groups being located on the same side of the chain, which favours cyclisation through the $-C\overset{O}{\underset{H}{<}}$ group:



The cyclic structure of the polymer is indicated by its high thermal stability, while the absence of cross-linked structures is confirmed by the sharp melting point. Cyclisation does not occur on polymerisation on dilute solution.

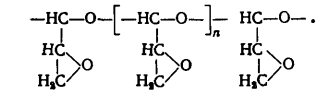
Acrylaldehyde undergoes polymerisation in the 1,4-position in the presence of metallic sodium in boiling benzene[29]. The resulting polymer contains 5 mole % of aldehyde groups and 10–15% of double bonds.

Infrared and nuclear magnetic resonance data confirm that the polymer has the structure

$$[CH_2-CH=CH-O-CH_2-CH=CH-O]_n.$$

Anionic polymerisation of acrylaldehyde in the presence of various catalysts (see Table 5) between +25° and -78° yields polymers in whose infrared spectra the absorption band due to the carbonyl group (5.85 μm) has been considerably weakened or is completely absent[30]. The quantity of –C=C– double bonds, determined by hydrogenation of a solution of the polymer in glacial acetic acid, is 50–70%. Aldehyde groups were identified in the polymer by treating it with phenylhydrazine and then determining the nitrogen content. The proportion of aldehyde groups in polyacrylaldehyde obtained in the presence of anionic catalysts varies from 1% to 9%. The nature of the solvent affects not only the rate of polymerisation but also the chemical structure of the product. A decrease in the temperature of polymerisation and an increase in the polarity of the solvent decreases the quantity of free carbonyl groups in the polymer, which has the polyacetal structure

The epoxypropionaldehyde molecule, like that of acrylaldehyde, contains a reactive carbonyl group, but the position of the vinyl group is occupied by a heterocyclic ring, which can be regarded as a functional group. This aldehyde polymerises readily under the influence of catalysts of various types[20]. Thus triethylaluminium at -78° yields a polymer of polyacetal structure



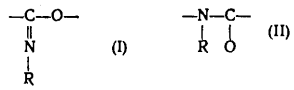


TABLE 5. Polymerisation of acrylaldehyde.

| Solvent | ml | Acrylaldehyde, ml | Catalyst | mole % | Time, min | Temp., °C | Yield of polymer, % |
|---|---|---|---|---|---|---|---|
| Petroleum ether | 25 | 5 | n-$C_4H_9Li$ | 0.5 | 300 | -20 to 30 | – |

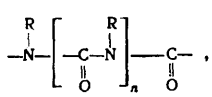
With aluminium isopropoxide, however, a polymer of polyepoxide structure is obtained

Isocyanates give dimers and trimers [31] in the presence of bases, triethylamine and pyridine. Two fundamental polymer structures

are possible on the stereospecific polymerisation of isocyanates. Regular opening of the carbonyl double bond gives a macromolecule of polyacetal structure



whereas regular opening of the carbon–nitrogen double bond yields an amide structure

Natta and others have obtained polymers of phenyl and butyl isocyanates by low-temperature polymerisation [32,33]. Only traces of polymers were formed in the presence of catalysts of cationic type, but with the corresponding anionic catalysts crystalline polymers of these isocyanates were formed (see Table 6).

The presence in the infrared spectra of an intense band characteristic of disubstituted amides suggests that the polymer has a polyamide structure

where R represents phenyl or butyl. Polymers having the polyacetal or mixed structure were not obtained.

Analysis of the above results on the polymerisation of bifunctional monomers enables the following general conclusions to be drawn:

1. In the polymerisation of a bifunctional compound containing double bonds differing in electron density, the structure of the resulting polymer is determined to a considerable extent by the choice of catalyst (anionic or cationic).

TABLE 6. Polymerisation of phenyl and n-butyl isocyanates.

| Isocyanate | Catalyst | Solvent | Temperature, °C | Conversion, % |
|---|---|---|---|---|
| Phenyl | $AlBr_3$ in heptane | toluene | −60 | trace |
| Butyl | | toluene | −78 | – |
| Phenyl | $C_2H_5Li$ in benzene | $CS_2$ | −78 | 34.5 |
| Butyl | | $CS_2$ | −78 | 76.0 |
| Phenyl | | toluene | −78 | 45 |
| Butyl | $C_2H_5Li$ | toluene | −78 | 43 |

2. Growth of the polymer chain is determined not only by the reactivity of each bond but also by the polar effect. In the polymerisation of dimethylketen, for example, a polyester structure is formed: i.e. there is a strongly marked tendency for alternating polymerisation at the carbon–carbon and the carbonyl double bond. This results in formation of a characteristic copolymer.

3. Decrease in the temperature of polymerisation of monomers containing carbon–carbon and carbonyl double bonds results in increased specific gravity in the polymer of polyacetal structure. The structure of the polymer is probably determined by the thermodynamics of the process. At lower temperatures polymerisation becomes possible with a small heat of reaction: i.e. a polymer of mixed and polyacetal structure can be formed.

4. The polarity of the solvent affects not only the rate of polymerisation but also the structure of the polymer chain. An extreme case is provided by dimethylformamide, in which dimethylketen polymerises in the absence of a catalyst.

# THE FREE-RADICAL COPOLYMERISATION OF ETHYLENE

R. A. Terteryan, E. E. Braudo, and A. I. Dintses

CONTENTS

I. Introduction 290
II. General problems of the copolymerisation of ethylene 290
III. The reactivity of ethylene in radical copolymerisation 293
IV. Copolymerisation of ethylene with various monomers 295

## I. INTRODUCTION

Copolymerisation has now acquired considerable importance as a method which makes it possible to alter the properties of a polymer in a required direction. By selecting different combinations of ethylene with appropriate monomers, it is possible to vary over a wide range such properties of the polymer as its strength, elasticity, melting point, adhesive properties, solubility, etc.[1,2] Copolymers of ethylene can be prepared both by free-radical copolymerisation and by ionic copolymerisation. The free-radical process, in particular, is of considerable interest, since in this case the number of monomers which can be used with ethylene is much greater than for ionic copolymerisation. The ionic process is carried out chiefly with monoalkene and diene hydrocarbons, whereas the copolymerisation of ethylene by the free-radical mechanism can be carried out not only with these hydrocarbons but also with a large number of compounds of different types, including halogenated alkenes, vinyl esters and ethers, acrylic monomers, and even compounds which do not polymerise independently, such as sulphur dioxide and carbon monoxide[1,2]. Moreover, the presence of different functional groups (e.g. acetate and carbonyl groups) in the copolymers prepared by radical copolymerisation makes it possible to convert these polymers, by means of chemical reactions, into a number of new copolymers (binary or ternary in the case of partial replacement of the functional groups) which cannot be obtained by direct copolymerisation with ethylene.

The present review deals with copolymers of ethylene prepared by radical copolymerisation, and covers the literature up to September 1964. Work published before 1959 is mentioned only briefly, since this has been described in detail in monographs devoted to polyethylene[1,2], and more recent work is examined in greater detail.

## II. GENERAL PROBLEMS OF THE COPOLYMERISATION OF ETHYLENE

Copolymers of ethylene, with such readily polymerised monomers as styrene, vinyl acetate, and acrylic acid, were first prepared as early as 1930,[3] i.e. before polymers of ethylene itself had been prepared. In the presence of peroxo-compounds under conditions of low pressure, a small quantity of ethylene was introduced into the polymer. However, the copolymerisation of ethylene with unsaturated compounds of different types[4] was described for the most part after the discovery of polyethylene. Styrene, isobutene, methyl acrylate, n-butyl acrylate, methyl methacrylate, vinyl acetate, butadiene, etc. were proposed as secondary components. The copolymerisation was carried out by a method analogous to that used for the polymerisation of ethylene, by the block method under conditions of high pressure (1000–2000 bars) and relatively high temperature (100–300°), in the presence of oxygen or peroxo-compounds as initiators[5-9]. It has been shown comparatively recently that it is possible to copolymerise ethylene under the influence of ionising radiation with alkenes[10], vinyl chloride, vinyl acetate, and carbon monoxide[11].

Colombo and Steinberg[12-14] describe the radiation copolymerisation of ethylene with a large number of monomers — propene, but-1-ene, *cis*- and *trans*-but-2-ene, isobutene, isoprene, vinyl chloride, chlorotrifluoroethylene, vinyl acetate, allyl acetate, allyl alcohol, acrylonitrile, methyl methacrylate, styrene, divinylbenzene, vinylpyrrolidone, methyl vinyl ketone, and carbon monoxide. In a number of cases, however, the data on the composition and properties of the resulting copolymers, given by Colombo and Steinberg, are of doubtful accuracy, since the copolymerisation was carried out to high degrees of conversion. On the basis of the data given below on the relative activities of monomers, it may be assumed that, in the case of copolymerisation with methyl methacrylate, methyl acrylate, vinylpyrrolidone, methyl vinyl ketone, and also possibly with propene and allyl acetate, the reaction products contained polyethylene.

Kolesnikov and his coworkers[15,16] showed that it is possible to copolymerise ethylene with certain monomers (vinyl chloride, styrene, vinyl acetate, acrylonitrile, and methyl methacrylate) under the influence of alkylborons.

The copolymerisation temperature for ethylene covers a very wide range, from -70° to 250°. The process is usually carried out at 180–250° in the case of initiation of copolymerisation by molecular oxygen[4] or within the range 50–150° for initiation by organic peroxides[5-9]. The use of $\gamma$-radiation[12] and alkylborons[16] makes it possible to carry out the copolymerisation at or below room temperature. The possibility is not excluded that at temperatures below 0° the process takes place partly or completely by an ionic mechanism. In particular, ethylene is known to polymerise by a cationic mechanism under the influence of $^{60}Co$ $\gamma$-radiation at -78°.[17,18]

The radical copolymerisation of ethylene is most frequently carried out at a pressure of ~ 1000 bars[4,8,9]. The use of such high pressures is apparently necessary in order to produce a high concentration of ethylene to ensure sufficiently rapid reaction and to obtain copolymers of optimum

molecular mass. It may be assumed, however, that this condition to some extent applies only to the copolymerisation of ethylene with a small quantity of a second component in the gas phase. In the case of copolymerisation in the liquid phase, pressure plays a smaller part and may be reduced to 100–300 bars[5,15,16].

The process is carried out, not only by block copolymerisation, but also in low-boiling organic solvents (e.g. benzene, toluene, or isooctane)[9,15,16], in water[7,8], and in emulsion[6].

Some idea of the physical properties of copolymers of ethylene can be obtained on the basis of a comparatively simple model consisting of a polymethylene chain in which hydrogen atoms have been replaced by different side-groups. The properties of the copolymers will be determined by the nature of the second component, its concentration in the copolymer, and the nature of the distribution of monomer units of the second component along the length of the chain.

The influence of the nature of the second component involves chiefly two factors, the polarity and the dimensions of the monomer units. The presence of polar units in the polyethylene chain brings about intermolecular and intramolecular interaction between the permanent and induced dipoles, leading to an increase in the rigidity and a rise in the melting point; at the same time there is a deterioration in the dielectric properties of the polymer, and its adhesion to various materials increases.

In the molecules of ethylene copolymers containing a small quantity of the second component, the units of the latter will generally be attached only to non-polar and unpolarised methylene groups, which have no significant influence on their dipole moment. In this case the dipole moment of the units can be taken as approximately equal to that of the corresponding hydrogenated compound. The dipole moments of compounds which are the hydrogenated analogues of the second components in ethylene copolymers are given in Table 1. In conformity with the data in Table 1, the greatest rigidity and highest melting point among the known types of ethylene copolymer are shown by the copolymers with carbon monoxide and sulphur dioxide.

TABLE 1. Dipole moments of various hydrogenated analogues of second components in copolymers of ethylene[19].

| Compound | Dipole moment, D |
|---|---|
| Hydrogenated analogues of methyl acrylate*, vinyl alcohol, methyl methacrylate**, ethyl acrylate, n-butyl acrylate, vinyl chloride, vinyl acetate, vinyl fluoride, and vinylidene chloride | 1.7–1.9 |
| 1,1-Difluoroethane (vinylidene fluoride) | 2.2 |
| Diethyl ketone (carbon monoxide) | 2.7 |
| Acetonitrile (acrylonitrile) | 3.3 |
| Succinic anhydride (maleic anhydride) | 3.8 |
| Diethyl sulphone (sulphur dioxide) | 4.4 |
| Ethylene carbonate (vinylene carbonate) | 4.7 |

* The dipole moment of the monomer unit of methyl acrylate attached to two monomer units of styrene in the copolymer of methyl acrylate with styrene is 1.61 D, and that of methyl methacrylate is 1.68 D. The production of induced dipoles in neighbouring phenyl groups possibly leads to a slight decrease in the dipole moments of the monomer units of methyl acrylate and methacrylate relative to those for the corresponding homopolymers[20,21].

** Shima's data[21].

The dimensions of the units of the second component influence the properties of the ethylene copolymer as follows. When side-groups whose dimensions differ little from those of the methylene groups are introduced into the polyethylene chain, the crystal structure of the polyethylene is not broken down: there is merely a change in some parameters of the crystal lattice, accompanied by a change in the physical properties of the polymer[22–25]. In particular, the melting points of these copolymers change monotonically with change in composition, from the melting point of polyethylene to that of the second homopolymer. This phenomenon, which is analogous to the formation of mixed crystals in the cocrystallisation of compounds of low molecular weight, has been termed isomorphism of monomer units in macromolecules[26]. Values of the van der Waals radii of some substituents are given in Table 2.[27] In conformity with these data, the formation of crystalline copolymers over a wide range of composition was observed in the copolymerisation of ethylene with tetrafluoroethylene and carbon monoxide†, and also in copolymers of ethylene with vinyl alcohol[22–25,28,29]. Determination of the crystal structure of copolymers of ethylene with vinyl alcohol led to a re-examination of previously held ideas on the nature of the crystallinity of high polymers[24,25].

If the dimensions of the side-groups are so great that packing of the copolymer molecules into the crystal lattice of polyethylene becomes impossible, the introduction of copolymer molecules into the polyethylene chain leads to a gradual decrease in the crystallinity of the copolymer. At a low concentration of the second component, the melting point of these copolymers falls rapidly, in agreement with Flory's formula[30]. At the same time there is a decrease in the hardness of the polymers and increases in their elasticity and solubility. At a low concentration of the second component the nature of these changes apparently depends chiefly on the quantity of added monomer and not on its nature. Thus the copolymers of ethylene with vinyl acetate, ethyl acrylate, *N*-vinylpyrrolidone, and *N*-vinylsuccinimide, obtained at 1000 bars and 70–90°, showed an approximately linear relationship between the logarithm of

TABLE 2. Van der Waals radii of substituents[27].

| Substituent | Van der Waals radius, Å |
|---|---|
| H | 1.17 |
| F | 1.35 |
| O | 1.35* |
| Cl | 1.80 |
| $CH_3$ | 1.90 |

* Bunn's data[24].

† The structure of the copolymer is

$$[(-CH_2CH_2-)_n-\underset{\underset{O}{\|}}{C}]_m$$

the modulus of rigidity and the molar content of the second component in the polymer, irrespective of the nature of the second component [31].

The influence of the dimensions of the unit of the second component on the crystallinity of the copolymers is clearly revealed on comparing the properties of the copolymers of ethylene with carbon monoxide and with propene (the latter copolymer was prepared on a Ziegler–Natta catalyst): the crystallinity of ethylene–carbon monoxide copolymers amounts to ~ 70% and is independent of the content of the second component; the crystallinity of ethylene–propene copolymers decreases linearly to zero with increase in the content of the second component from 0 to 15%. [32] This shows that carbonyl groups enter the polyethylene crystal lattice, whereas $CHCH_3$ groups break down the lattice‡.

The phenomenon of isomorphism of monomer units in macromolecules can be observed in the copolymers of ethylene and carbon monoxide. According to the data of Chatany et al. [34,35], copolymers obtained at room temperature in the gas phase have the crystal structure of polyethylene, but the lattice parameters change with increase in the carbon monoxide content.

Thus the two factors examined — the polarity and the dimensions of the unit of the second component — have opposite effects on the properties of the ethylene copolymers. If the unit of the second component is sufficiently large, steric factors predominate. For example, the copolymerisation of ethylene with small quantities of polar monomers such as vinyl acetate gives products whose rigidity and melting points are lower than those of polyethylene. On saponification of these copolymers, however, the opposite effects are observed, as a result of the replacement of the large acetate group by the comparatively small hydroxy-group, despite the fact that the dipole moment of the unit of the second component remains almost unchanged (see Table 1).

One of the most important factors influencing the properties of a copolymer is its composition. The nature of the dependence of the properties of ethylene copolymers on the relative proportions of the monomers is determined by the dimensions of the molecules of the second component. Where isomorphous crystalline structures are formed, we must expect a monotonic change in the properties of the copolymer with increasing content of the second component. If introduction of molecules of the latter leads to breakdown of the copolymer structure, the properties of the copolymer show a marked dependence on composition. The addition of even small quantities of monomers such as vinyl chloride and vinyl acetate leads to a marked fall in the melting point and the crystallinity of the copolymer. At a high concentration of the second component, the product acquires properties characteristic of the homopolymer of the second monomer. The influence of the composition of ethylene copolymers is not shown with all properties, however. In particular, the dependence of the temperatures of vitrification of ethylene copolymers on their composition is specific in character [36,37].

‡ Here and subsequently, conclusions regarding the crystallinity of copolymers are based on data obtained by X-ray structural analysis. However, structural criteria of crystallinity do not always agree with thermodynamic criteria [33]. Similarly no account is taken of the influence of intermolecular interaction in the molten state, the rigidity of the chain, and other factors on the kinetics of crystallisation and the tendency of the copolymers to undergo supercooling.

The dependence of the vitrification temperature of ordinary vinyl copolymers on their composition is described, to a first approximation, by the straight line joining the glass points of the corresponding homopolymers [38]. The vinyl chloride–vinyl acetate and vinyl chloride–acrylonitrile systems provide examples. It was to be expected that copolymers of ethylene would exhibit analogous properties, but they in fact exhibit quite different behaviour, as shown by Reding et al. [37] By means of a torsion balance and an apparatus for determining the maximum mechanical losses (Instron tester), they detected two glass points (two temperature transitions) in ethylene copolymers. The first, low-temperature transition takes place at -125° and is almost independent of the composition of the copolymers. The existence of this glass point was attributed [37] to the movement of segments comprising 3–5 $CH_2$ groups. The second, high-temperature transition is observed between -25° and +50°, and is independent of composition only at high ethylene contents (35–100 wt.%); at high concentrations of the second component, the glass point of the copolymer rises sharply, approaching linearly that of the corresponding homopolymer. It was not clear why the glass point of the copolymer remains unchanged over a wide range of compositions. Mandelkern et al. [39] suggested that in crystalline copolymers it is determined by the composition of the amorphous phase. Since in ethylene copolymers only the ethylene units crystallise with increase in the ethylene content, the composition of the amorphous phase remains constant, so that the vitrification temperature remains constant. A similar explanation for copolymers of ethylene with vinyl acetate was given by Nielsen [36], but, as correctly noted by Reding et al. [37], this explanation does not reflect the true situation, since with ethylene–vinyl acetate copolymers the last traces of crystallinity disappear at a content of the latter of 45 wt.%, whereas the glass point remains constant up to 65%. Reding and his coworkers suggest that the high-temperature transition in ethylene copolymers is associated with the localised movement of small segments of the main chain, attached to tertiary carbon atoms. This movement is independent of the nature of the remainder of the molecule. At a high concentration of the second component, as a result of steric hindrance or dipole–dipole interaction between the side-groups, this movement is transformed into movement of large sections of the macromolecules, including long sections of the chain and side-groups, analogous to that taking place in copolymers of the vinyl chloride–vinyl acetate type.

The two glass points of copolymers of ethylene with many monomers depend little on the nature of the second component [37].

It is evident that the properties of copolymers also depend on the distribution of the monomer units along the chain, which is determined by the product of the relative activities of the monomers (see Section III); if this quantity is close to unity, the monomer units are distributed irregularly; but with decrease in the magnitude of the product, the extent to which the monomers alternate increases. In particular, if the crystallinity of the copolymers is determined by the crystallisation of chain segments consisting of the units of only one monomer (e.g. ethylene), the crystallinity of such a copolymer increases with increase in the product of the relative activities of the monomers. This was confirmed for copolymers of ethylene with propene, having up to 10% crystallinity, obtained on Ziegler–Natta catalysts [40,41]. The crystallinity of ethylene copolymers has been studied by Killian [42].

The uses of ethylene copolymers have been dealt with in a number of reviews[43,44]. Some information on their applications is given in Section IV.

## III. THE REACTIVITY OF ETHYLENE IN RADICAL COPOLYMERISATION

Because of the experimental difficulties involved in carrying out copolymerisation under high pressures, data on relative activities have until now been published only for a comparatively small number of systems containing ethylene (Table 3). We ignore the values given by Pieski[55] for the relative activities in the copolymerisation of ethylene with styrene ($r_{ethylene} = 0.0069$, $r_{styrene} = 345$), since the conditions and methods of determination are unknown.

Since there is no conjugation of the double bond, the reactivity of ethylene as a monomer is low, so that the rate of attachment of ethylene molecules to both types of copolymer radical in copolymerisation with vinyl chloride, acrylonitrile, and n-butyl acrylate is less than the rate of attachment of molecules of the second component ($r_1 < 1$, $r_2 > 1$); the opposite relationship is observed in copolymerisation with vinyl fluoride.

If we take ethylene as standard monomer, the relative rates of attachment of monomers to copolymer radicals terminating in an ethylene group, in reactions of chain growth in the radical copolymerisation of ethylene, are given by the corresponding values of $1/r_1$. In Table 4 the values of $1/r_1$ for various monomers are compared with the relative rates of attachment of the same monomers to the methyl radical in the liquid phase at 65°, calculated from Szwarc's data given in Bagdasar'yan's monograph[56]. Since the relative activities generally depend little on temperature, the values of $r_1$ are taken from Table 3 without correction for temperature§. The relative rate of addition of propene to the methyl radical was calculated from the data of Mandelkern and Steacie[56] for a temperature of 175° (reaction in the gas phase). It can be seen from Table 4 that the relative reactivity of monomers towards both the methyl radical and copolymer radicals terminating in an ethylene group increases in the order propene < vinyl acetate < < tetrafluoroethylene < acrylonitrile. The values do not, however, show a quantitative relationship corresponding to Szwarc's equation[57] ($n$ not constant).

TABLE 4. Relative rates of attachment of monomers to the methyl radical and to copolymer radicals terminating in an ethylene group.

| Monomer ($M_i$) | $\frac{K_{CH_3^\cdot M_i}}{K_{CH_3^\cdot C_2H_4}}$ | $\frac{1}{r_1}$ | $n=\frac{\log\frac{K_{CH_3^\cdot M_i}}{K_{CH_3^\cdot C_2H_4}}}{\log 1/r_1}$ |
|---|---|---|---|
| Propene | 1.22 | 0.29 | —0.16 |
| Tetrafluoroethylene | 10 | 6.7 | 1.2 |
| Vinyl acetate* | 2.2 | 1.3 | 3.0 |
| Acrylonitrile | 91 | 50—1000 | — |

* The relative rate of attachment to the ethyl radical at 90° is 2.0; $1/r_1 = 0.93$.[48]

The relative rates of addition of propene to methyl and to copolymer radicals are quite different. The rate of attachment of propene to the methyl radical is greater than that of ethylene, whereas the opposite relationship is observed in the addition of these monomers to a copolymer hydrocarbon radical. The lower reactivity of propene in the latter case does not agree with the theory of ideal radical reactivity applicable to the reactions of hydrocarbons[58]. The reasons for the above discrepancies are not clear.

According to Alfrey and Price[58], the relative activities of monomers in copolymerisation reactions can be calculated by means of constants characteristic of individual monomers — the activity factor $Q$ and the polarity factor $e$ — which are calculated from experimental data. The values taken for styrene are $Q = 1.0$ and $e = -0.8$. A theoretical interpretation of the method of Alfrey and Price has

§ For vinyl acetate the value of $r_1$ at 70° has been taken.

TABLE 3. Experimental values of the relative activities and parameters for the copolymerisation of ethylene.

** Values taken from Young's summary[49].
*** Assumed by the authors of the works cited.

been given by a number of authors[60-69]. Despite certain difficulties associated with the interpretation of the physical significance of the polarity factor[66,67], this method is useful for a preliminary estimation of the behaviour of monomers in copolymerisation reactions. Table 3 gives the values of the parameters $Q$ and $e$ which we have calculated for ethylene; those for other monomers have been taken from Young's summary[49].

Since the Alfrey–Price method is semi-empirical in character, various modifications have been proposed. In particular, it appears more appropriate to take as standard monomer not styrene but ethylene, assuming for the latter $Q = 1$ and $e = 0$, since, of all monomers containing a carbon–carbon double bond, ethylene has the simplest molecular structure. The establishment of the true zero on the scale of polarity factors would make it possible to obtain more accurate values for the activity and polarity factors of various monomers. The relative activities for the copolymerisation of several monomers have been calculated by Zutty and Burkhart[47,48], using a $Q-e$ scale based on ethylene. Allowance must be made for the fact that these values correspond only to a pressure of about 1000 bars, at which the copolymerisation of ethylene was carried out, since the relative activities and hence the activity and polarity factors depend on pressure[47].

Kawabata et al.[66,67] consider it advisable to take $e = 0$ for styrene; the same conclusion has been reached by Bamford and Jenkins[65]. Values of the activity and polarity factors for ethylene which we have calculated using the method of Kawabata et al. are given in Table 3. Price[70], however, objects to the choice of zero for the polarity factor of ethylene or styrene. In his opinion, the polarity factor for ethylene should be negative, since the double bond in the ethylene molecules carries a negative charge; the zero on the scale of polarity factors should correspond to vinyl chloride, and this corresponds to a value of $e$ for styrene of -0.8. He refers, in particular, to the data of Zutty and Burkhart[48], who, on the basis of values of $Q$ and $e$ for other monomers taken from Alfrey et al.[59] and from Thompson and Raines[71], calculated for ethylene the mean values $Q = 0.03$ and $e = -0.43$. The mean value of the polarity factor which we have obtained for ethylene by the Alfrey–Price method is close to zero; at the same time, Young's summary gives for vinyl chloride $e = 0.20$. The value of the polarity factor can evidently vary over a fairly wide range, depending on the choice of data taken as a basis for the calculation.

In the method of Spasskii and Karas'[72], the activity factor $Q$ is replaced by the product of two quantities — a factor $\alpha$ representing the influence of the polarisability of the $\pi$ bonds, characterised by the refraction, and a factor $\beta$ representing the influence of the structure of the monomer, not taken into account by the refraction. Values of the parameters for the copolymerisation of ethylene, which we have calculated by this method, are given in Table 3.

From the mean values of the activity and polarity factors for ethylene (Table 3) we have calculated, by the methods of Alfrey and Price, Kawabata et al., and Spasskii and Karas', values of the relative activities for the copolymerisation of ethylene with monomers of different classes. The results of the calculation are given in Table 5, the copolymerisation parameters of the monomers having been taken from published data[49,66,67,72]. The order of magnitude is generally the same for the relative activities calculated by different methods; discrepancies are observed only with maleic anhydride and diethyl fumarate. Comparison of the calculated (Table 5) and experimental (Table 3) values of the relative activities for the copolymerisation of ethylene shows that the methods of calculation used are sufficiently accurate.

* The experimental values are given in Table 3.

The results of the calculations given in Table 5 naturally require experimental verification. These data may prove useful, however, in the planning of experiments on the radical copolymerisation of ethylene.

The production of a copolymer of uniform composition in high yield can be achieved only if the relative activities of the monomers used do not differ too greatly. The data in Tables 3 and 5 show that the most "convenient" monomers in this sense for copolymerisation with ethylene are fluoroalkenes, vinyl esters of aliphatic acids, and carbon monoxide.

In particular, considerable difficulties should be encountered in the copolymerisation of ethylene with small quantities of acrylic and, more particularly, methacrylic monomers. Copolymers of ethylene with ethyl acrylate, containing a small quantity of the latter, are, however, now being produced in the USA,[73] on equipment designed for the production of high-pressure polyethylene, i.e. as a continuous process. It is evident that it is much easier to keep the composition of the monomer mixture constant in this type of process than in a batch process.

Kawabata et al.[68,69], on the basis of the method proposed by Fukui and his coworkers[61,74,75] for the quantitative characterisation of the activation energy for growth reactions in vinyl polymerisation, have calculated the additional energies of conjugation in the transition state for reaction of the ethylene radical with various monomers ($E_{R\cdot M}$) and also of various radicals with ethylene ($E_{RM\cdot}$). If it is assumed, following these authors, that the preexponential factors for

the addition of different monomers to the same radical are equal, the relative activities of ethylene in copolymerisation with different monomers will be given by the equation

$$\ln r_1 = -q\frac{E_M}{RT},$$

where $E_M$ is the difference between the additional energies of conjugation for reaction of the ethylene radical with the second component and with ethylene, and $q$ is a proportionality coefficient. The polarity factors in reactions involving the ethylene molecule or the ethylene radical were taken as zero.

As will be seen from the results discussed below, however, the assumption that the preexponential factors for the copolymerisation of ethylene are equal is unjustified, so that the relative activities in the copolymerisation of ethylene with vinyl acetate and vinyl chloride (Table 3) do not correspond to the above equation. For many monomers, however, an approximately linear relationship is observed between $E_M$ and the values of the activity factors calculated on the scale proposed by Kawabata et al. ($Q$ = 1.0 and $e$ = 0 for styrene) or on the scale based on ethylene ($Q$ = 1.0 and $e$ = 0 for ethylene)[68,69,76].

## IV. COPOLYMERISATION OF ETHYLENE WITH VARIOUS MONOMERS

### (a) Copolymerisation with Hydrocarbons

The ionic copolymerisation of ethylene with alkene, alkyne, and diene hydrocarbons has been studied in considerable detail (particularly the copolymerisation of ethylene with propene and butenes on organometallic complexes or a chromium-oxide catalyst), but the free-radical copolymerisation of ethylene with these hydrocarbons has been little studied.

In early patents on the copolymerisation of ethylene[4,5,7], the second components included such alkenes as propene, butene, and methylpropene. No reliable proof of the formation of a copolymer was given, however. Later, solid high-molecular copolymers of ethylene with a small quantity of propene or octadec-1-ene were prepared at higher pressures, of 2000–2500 bars[77]. The copolymerisation was carried out by a continuous block method at ~ 200° in the presence of oxygen as initiator. The products obtained differed from polyethylene in their high content of vinyl groups, determined by infrared spectrophotometry. Thus polyethylene prepared by the usual high-pressure method contains 0.02–0.06 double bond per 1000 carbon atoms, whereas the copolymer of ethylene with propene contains 0.2–0.6 double bond[77].

According to Boghetich et al.[45], the only way in which the unsaturation of the polymer can increase is by chain transfer via the alk-1-ene:

$$\cdots CH_2{-}CH_2^{\cdot} + CH_2{=}CH{-}CH_3 \longrightarrow \cdots CH_2{-}CH_3 + CH_2{=}CH{-}CH_2^{\cdot},$$

$$CH_2{=}CH{-}CH_2^{\cdot} + CH_2{=}CH_2 \longrightarrow CH_2{=}CH{-}CH_2{-}CH_2{-}CH_2^{\cdot},$$

since none of the four growth reactions in the copolymerisation of ethylene with alk-1-enes leads to an increase in the content of double bonds in the copolymer.

Boghetich et al.[45] give convincing proof of the copolymerisation of ethylene with alk-1-enes by a radical mechanism. Formation of a copolymer was confirmed by carrying out the copolymerisation of ethylene with $^{14}C$-labelled propene, but-1-ene, and oct-1-ene, and then determining the activity of the product. The copolymerisation was carried out at 1050–1750 bars and 130–200° under the influence of t-butyl peroxide and acetoxime. The values of the relative activity of ethylene in copolymerisation with different alk-1-enes (Table 3) are close to one another and lie in the range 3.4–3.6, with a correction for chain transfer; in other words, under the conditions studied, ethylene is a more active monomer than the alk-1-enes. Chain transfer was estimated from the decrease in molecular mass and the increase in unsaturation of the polymer with increase in the alk-1-ene content of the original mixture. The values of the chain-transfer constants are given in Table 6. Comparison of the data on the unsaturation and on the radioactivity of the copolymers shows that only a small quantity of alk-1-ene (< 10%) enters the copolymer by chain transfer, and that the predominant reaction is copolymerisation.

Study of the continuous copolymerisation of ethylene with propene in the presence of oxygen as initiator at 1500–1800 bars in the range 170–240° showed that the process can be carried out at a concentration of propene in the original mixture not greater than 15%.[78]

As stated in Section II, ethylene copolymerises under the influence of $^{60}Co$ $\gamma$-radiation with alkenes, styrene, isoprene, and divinylbenzene[10,12–14].

The copolymerisation of ethylene with styrene has also been carried out under the influence of tributylboron at 18–50°[15] and of triisobutylboron between -70° and 18°.[16] In the latter case, ethylene copolymerises with styrene much more slowly than with vinyl chloride and acrylonitrile. The low yield of copolymer was attributed to the fact that styrene, which is the more active monomer, does not polymerise readily in solution in the presence of alkylborons. Copolymers of ethylene with styrene dissolve readily in toluene, dichloroethane, and tetralin at room temperature, and have vitrification temperatures in the range 55–95°.[16] The copolymerisation of ethylene with 9-methylenefluorene has also been described[79].

The free-radical copolymerisation of ethylene with acetylene and diene hydrocarbons is carried out at high pressures (of about 1000 bars) and temperatures up to 200° under the influence of oxygen, organic peroxides[7,9,80–82], and $^{60}Co$ $\gamma$-radiation[10,12,13]. Among diene hydrocarbons, butadiene, isoprene[7,9,12,13,81], and norbornadiene[82] have been used. According to our calculations (Table 5), the relative activity of monomers such as butadiene and isoprene is much greater than that of ethylene, which is zero. Thus the content of the second component in the copolymer will always be greater than its content in the original mixture. A characteristic feature is that the copolymers of

TABLE 6. Chain-transfer constants for the copolymerisation of ethylene with alk-1-enes[45] (pressure 1400 bars, temperature 130°).

| Alk-1-ene | Chain-transfer constant from | |
|---|---|---|
| | infrared spectrophotometry | decrease in molecular mass |
| Propene | 0.011±0.003 | 0.015±0.003 |
| But-1-ene | 0.033±0.007 | 0.047±0.002 |
| Oct-1-ene | — | 0.036±0.002 |

ethylene with acetylene and diene hydrocarbons contain double bonds, by means of which vulcanisation can be carried out. The molecular mass of the ethylene–acetylene copolymers decreases with increase in the content of the latter [80].

Mortimer and Arnold [83] have shown that ethylene does not copolymerise with benzene in the presence of t-butyl peroxide at 1400 bars and 130°.

(b) Copolymerisation with Halogenated Alkenes

According to many patents, ethylene copolymerises with halogen-containing alkenes of different types: the comonomers are chlorine- and fluorine-containing compounds, and alkenes containing one, two, or more halogen substituents may be used. Copolymerisation is carried out chiefly at high pressures (700–1500 bars) and temperatures of 50–200° under the influence of peroxide initiators in the presence of water or in block. Under these conditions, copolymers of ethylene have been obtained with vinyl chloride [84,85], vinylidene chloride [86], vinylidene fluoride [87–89], tetrafluoroethylene [90], chlorotrifluoroethylene [91], 1-chloro-1-fluoroethylene [92], 1,1-dichloro-2,2-difluoroethylene [93], 3,3,3-trifluoropropene [94], and hexafluorocyclobutene [95]. With some monomers (tetrafluoroethylene [96] and 3,3,3-trichloropropene [97]) the copolymerisation initiated by organic peroxides was carried out at a relatively low pressure (up to 200 bars).

Ethylene copolymerises with vinyl chloride and chlorotrifluoroethylene under the influence of $^{60}Co$ $\gamma$-radiation [11–14,98]. The copolymerisation is usually carried out at room temperature. With chlorotrifluoroethylene, development of an explosive reaction is observed at a definite dose rate, of about 3000 J $kg^{-1}$ $h^{-1}$. [13,98] In the separate polymerisation of ethylene and chlorotrifluoroethylene under analogous conditions, no explosion was observed. Tabata and his coworkers [28,29,99,100] have shown that it is possible to carry out the radiation copolymerisation of ethylene and tetrafluoroethylene in the liquid state at -78°. They suggest that under these conditions the reaction proceeds in a homogeneous medium. A characteristic feature is that the copolymerisation takes place by a radical mechanism, whereas at this temperature ethylene polymerises only by a cationic mechanism [17,18].

The copolymerisation of ethylene with a number of halogen-containing alkenes (vinyl chloride, vinyl fluoride, vinylidene chloride, vinylidene fluoride, and chlorotrifluoroethylene) has been carried out under the influence of alkylborons, e.g. triethylboron and tributylboron [16,101–105]. An important feature is that in this case the copolymerisation is carried out at extremely low temperatures, between -70° and -80°. [16,102]

Experimental relative activities for the copolymerisation of ethylene with vinyl chloride [46,48], vinyl fluoride [48], and tetrafluoroethylene [49] are given in Table 3; calculated values for copolymerisation with other halogen-containing alkenes are given in Table 5. A noteworthy feature is that the relative activity of vinyl fluoride and also, apparently, chlorotrifluoroethylene and dichlorodifluoroethylene, is much lower than that of ethylene, whereas the relative activity of vinyl chloride is much greater than that of ethylene. It may be assumed that vinylidene chloride has an even higher relative activity than vinyl chloride.

Duntov and Erusalimskii [46,106] have studied the copolymerisation of ethylene with vinyl chloride under the influence of azoisobutyronitrile at 70° and pressures up to 300 bars. According to their data, copolymerisation in the ethylene–vinyl chloride system is homogeneous under the conditions studied. The order of the initial reaction rate with respect to initiator at an equimolar monomer ratio is 0.5, indicating that the ethylene–vinyl chloride–initiator system is homogeneous. When the reaction was carried out to a high degree of conversion at a vinyl chloride content of 5 mole % (in this case the proportion of vinyl chloride in the copolymer varied between 13% and 17%, and the melting point of the copolymer, determined from thermomechanical curves, was 52–53°), the degree of copolymerisation was found to increase with increase in the degree of conversion; this is explained by the heterogeneity of the monomer–polymer system at the given monomer ratio. The relative activities determined by these authors are close to those established by Zutty and Burkhart [47] for the process at 90° and 1000 bars.

Kolesnikov et al. [16] studied the copolymerisation of ethylene with vinyl chloride in the presence of triisobutylboron at an ethylene pressure of 98 bars and temperatures from -70° (initial) to 18° (final) in toluene medium. The yield of copolymer increases with increase in the ethylene content of the original mixture. Their statement that under the conditions of this process ethylene is a more active monomer than vinyl chloride is open to doubt, since the composition of the original mixture of monomers was, in fact, unknown (the experiments were carried out over a wide temperature range, for the most part below the critical temperature of ethylene).

We must also expect differences in the properties of the copolymers of ethylene with fluorinated and with chlorinated alkenes. As noted above, replacement of hydrogen atoms in the polyethylene chain by fluorine atoms can take place without breakdown of the polyethylene lattice. Thus, for example, copolymers of ethylene with tetrafluoroethylene are crystalline throughout the composition range [28,29,99,100]. Analogous properties may be expected for copolymers of ethylene with other fluorine-substituted ethylenes. But the introduction of chlorine atoms into the polyethylene chain, because of their large dimensions (Table 2), should lead to breakdown of the crystal structure. Thus in the case of the copolymer of ethylene with vinyl chloride [16,84,85], the rigidity first decreases with increase in the vinyl chloride content, and then increases. Rubberlike products are formed in the intermediate composition range. The addition of small quantities of copolymer phasticises poly(vinyl chloride) [107].

The melting points of the copolymers of ethylene with tetrafluoroethylene rise sharply with increase in the content of the latter within the composition range close to polyethylene. An interesting feature is that, for the same fluorine content, the melting points of the copolymers are 100–140 deg higher than those of poly(vinyl fluoride) and poly(vinylidene fluoride) [28,29].

Thermostable oils are obtained by the copolymerisation of ethylene with tetrafluoroethylene in a tertiary hydrocarbon (telogen) medium under the influence of peroxo-compounds [108].

Tarutina [109] has studied the thermal aging of copolymers of ethylene and tetrafluoroethylene at 200°, 240°, and 290°. The infrared spectra of these copolymers indicate the presence of side-branches with terminal methyl groups. It was established that the rate of aging depended on the number of branches. It is suggested [109] that aging takes place chiefly at the tertiary carbon atom, without influencing the number of methyl groups, since the intensity of the bands

due to the $CH_3$ groups remains unchanged on aging. Thus to obtain products with a high stability towards aging it is necessary to prepare copolymers having a predominantly linear structure.

(c) Copolymerisation with Vinyl Acetate and Other Vinyl Esters

The copolymerisation of ethylene with vinyl esters opens up extensive possibilities for the preparation of a variety of polymers, since in this case, in addition to the products formed directly during copolymerisation, it is possible to bring about conversion to a number of different macromolecular compounds by polymer-analogue reactions involving the ester group.

Vinyl acetate is one of the most readily available vinyl esters, and the copolymerisation of ethylene with this compound has been studied in greatest detail. Copolymers of ethylene with vinyl acetate can be obtained in block, solution, and emulsion; organic peroxides, alkylborons, and ionising radiation are used to initiate the reaction.

The composition of an ethylene–vinyl acetate copolymer determines its properties, and the possibilities of further modification and application. A number of patents [110–117] deal with the preparation of copolymers of low vinyl acetate content, up to 20 mole %. These copolymers can be obtained by polymerisation at 800–1500 bars and 50–150° under the influence of peroxide initiators in aqueous medium [110,111] or in emulsion [112].

A continuous process operating under the same conditions but in a propane, benzene, or cyclohexane medium has been described [113]. Continuous emulsion copolymerisation has been carried out in the presence of redox initiators at 30°. [114]

Ethylene copolymers of low vinyl acetate content can also be prepared at a pressure of 400–600 bars. [115–117] The use of low temperatures (60–70°) and solvents having low chain-transfer constants makes it possible to obtain copolymers with a fairly high molecular mass; in this case a satisfactory reaction rate is ensured by using initiators which exhibit a high activity at these temperatures, such as lauryl peroxide, peroxodicarbonates, and azoisobutyronitrile.

Although the preparation of copolymers of low vinyl acetate content requires the use of high pressure, this is not the case for the copolymerisation of ethylene with a large quantity of vinyl acetate [118,119]. Thus even at a pressure of 50–60 bars, under the influence of free-radical initiators, it is possible to prepare copolymers of fairly high molecular mass, containing more than 50% of vinyl acetate [118]. Liquid copolymers of low molecular mass containing 60–75% of vinyl acetate are obtained either by carrying out the copolymerisation in chain-terminating solvents such as ethyl methyl ketone, ethyl acetate, and acetone, or by adding to the reaction mixture a small quantity of a chain-terminating agent, such as an aldehyde or a thiol [120].

The present reviewers, together with Rysakov [50], have studied the copolymerisation of ethylene with vinyl acetate throughout the whole range of compositions of the original mixture. The copolymerisation was carried out at 400 bars in benzene medium at 70° in the presence of azoisobutyronitrile, and at 130° under the influence of t-butyl peroxide. The observed values of the relative activities (Table 3) show that the relative activity of ethylene increases with increase in the temperature of the process, whereas that of vinyl acetate remains constant. Thus at 130° both relative activities are close to unity. Data obtained for the relative activities at 90° and 1000 bars (Table 3) [48] indicate that, as with temperature, a marked increase in pressure leads to an increase in the relative activity of ethylene.

The temperature dependence of the relative activity is given by the equation [59]

$$r_1 = \exp\left(\frac{\Delta S_{11}^{\ddagger} - \Delta S_{12}^{\ddagger}}{R}\right)\exp\left(-\frac{\Delta H_{11}^{\ddagger} - \Delta H_{12}^{\ddagger}}{RT}\right),$$

where $\Delta S_{11}^{\ddagger}$, $\Delta S_{12}^{\ddagger}$, $\Delta H_{11}^{\ddagger}$, and $\Delta H_{12}^{\ddagger}$ are the activation entropies and enthalpies in reactions of the radical $M_1$ with molecules of the monomers $M_1$ and $M_2$.

Since the relative activity of vinyl acetate remains unchanged with increase in the temperature of the process, the differences in the heats and entropies of activation of the reactions of growth of the vinyl acetate radical are zero. For the ethylene radical

$$\Delta H_{11}^{\ddagger} - \Delta H_{12}^{\ddagger} = 4530 \text{ J mole}^{-1},$$

$$\Delta S_{11}^{\ddagger} - \Delta S_{12}^{\ddagger} = 10.9 \text{ J mole}^{-1} \text{ deg}^{-1},$$

The rate of copolymerisation of ethylene with vinyl acetate, throughout the range of monomer ratios at 70° and 130°, increases monotonically with increase in the vinyl acetate content of the original mixture. The intrinsic viscosity of the copolymers, determined in *p*-xylene solution at 85°, has a minimum value at a vinyl acetate content of 40–60 mole %. [50]

Analogous relationships are observed for the block process carried out at a pressure of 500 bars and temperatures of 60°, 100°, and 150° in the presence of various initiators of the peroxide type: dicyclohexyl peroxodicarbonate, benzoyl peroxide, and t-butyl peroxide. The fact that the nature of the dependence of the copolymer composition on the original monomer ratio is the same in each case indicates that the ethylene–vinyl acetate system is homogeneous under the conditions studied [122].

Interesting results have been obtained in a study of the influence of the benzene concentration on the rate and degree of copolymerisation at vinyl acetate contents in the original mixture of 10 and 50 mole % and temperatures of 70° and 130°. For both these monomer ratios at 70° and for the equimolar ratio at 130°, a decrease in the rate and degree of copolymerisation with increase in the benzene concentration is observed, as a result of the homogeneity of the monomer–solvent–initiator system, in which increase in the relative quantity of solvent leads to a decrease in the total molar concentration of the monomers. A quite different pattern is observed in the copolymerisation of ethylene with 10 mole % of vinyl acetate at 130°: the rate and the degree of copolymerisation increase considerably with the addition of benzene to the system, the optimum molar ratio of benzene to monomers being 0.2–0.25. This phenomenon can be explained as follows. Under these conditions the reaction mixture apparently consists of molten copolymer saturated with all the components, and a gas phase consisting of monomers and initiator. In this case the addition of benzene and increase of its concentration to a definite limit will facilitate the diffusion of monomers into the molten copolymer, accelerating the growth of the macroradicals. The decrease in the rate and degree of copoly-

merisation with further increase in the benzene concentration is due to the decrease in the total molar concentration of monomers in the homogeneous system [119].

The dependence of the rate of copolymerisation in block and in solution on the ratio of the monomers is almost linear throughout the concentration range, indicating that the probability of chain-termination reactions is the same between radicals of different types and between radicals of the same type [119].

The properties of copolymers of ethylene and vinyl acetate show the following changes with increasing content of the latter [50]: copolymers containing up to 10–12 mole % of vinyl acetate are strong plastics, similar to high-pressure polyethylene, but differing from the latter in their higher elasticity and transparency and lower melting point. At vinyl acetate contents of 13–25% the products are rubberlike, and at 30–80% they are resins which are soft and sticky at room temperature. Copolymers containing more than 80% of vinyl acetate are again rigid and strong. The solubility of the copolymers in solvents such as benzene, xylene, carbon tetrachloride, alcohol, and acetone increases with increase in the vinyl acetate content, the copolymers becoming soluble in alcohol and acetone at vinyl acetate contents greater than 40%. [50,121]

X-Ray structural analysis of copolymers of ethylene with vinyl acetate has shown that their crystallinity decreases with increase in the vinyl acetate content [36,122] (Fig. 1). The density of the copolymer at first decreases, and then increases, approaching the value 1.2 characteristic of poly(vinyl acetate) [122]. The dependence of the tensile strength and the relative elongation of the copolymer on the vinyl acetate content is shown in Fig. 2. [122]

Data have been published [36,37,123] on the glass points of copolymers of ethylene with vinyl acetate and vinyl propionate.

The frost-resistance of copolymers of ethylene with low vinyl acetate content is almost independent of the monomer ratio. All specimens, irrespective of composition, withstand a temperature of -70° (bending test method) [121].

According to published data [36,121], the melting point of ethylene–vinyl acetate copolymers falls with increase in the content of the latter in the range 0–20 mole %, in accordance with Flory's formula [30]. The similarity in the curves giving the dependence of the melting point on the number of

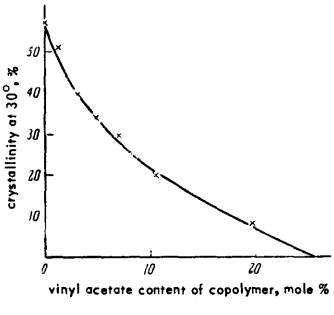

Fig. 1. Dependence of the crystallinity of copolymers of ethylene and vinyl acetate on composition (from Nielsen's data [36]).

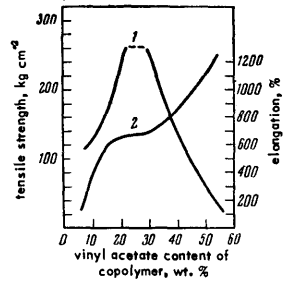

Fig. 2. Dependence of the tensile strength and relative elongation of copolymers of ethylene and vinyl acetate on composition [122]: 1) tensile strength; 2) relative elongation.

carbon atoms in normal paraffins and in polyethylene units of average length in the copolymers shows that the melting point of the copolymers is determined by [the melting point of crystals containing polyethylene sequences whose lengths are near] the average [sequence] length of the polyethylene units in the copolymers [36].

Copolymers of ethylene and vinyl acetate show strong adhesion to various synthetic materials (e.g. to polyethylene and to polyester films), wood, metal, and paper [124,125], and can be used as components in a variety of adhesives [126–128]. These copolymers mix readily with many resins, rosin, paraffin wax, and other waxes [124,129–132], poly(vinyl chloride) [133], and mineral oils containing more than 40% of aromatic hydrocarbons [134]. They can be used as elastomers in mixtures with fillers [134–136].

When ethylene–vinyl acetate copolymers are heated to 280–320°, acetic acid is split off with the formation of double bonds between neighbouring carbon atoms; no breakdown of the polymer chain was observed [137]. When the copolymers are heated above 350°, acetic acid and methane are split off; with further rise in temperature to 490°, the quantity of methane increases but the acetic acid remains constant [138]. This indicates that at 350° the removal of acetic acid from the copolymer is almost complete. This made it possible to develop a method for determining the composition of copolymers of ethylene and vinyl acetate by gas-chromatographic analysis of the pyrolysis products, from the quantity of acetic acid removed [138]. Good agreement is observed between the results obtained by this method and data obtained by high-resolution nuclear magnetic resonance and neutron activation analysis [139]. When combined with differential thermal analysis, this method can be used to establish the nature of the distribution of the monomer units in the copolymer [140].

The properties of copolymers of ethylene with vinyl acetate are altered appreciably when the copolymer molecules are cross-linked; this may be brought about by the action of peroxides [122,141–143], polycarboxylic acids [141,144], or ionising radiation [121,145]. The cross-linking of these copolymers by means of peroxo-compounds, and the properties of the products obtained in admixture with various fillers, have been described in detail by Bartl and Peter [122]. The degree of cross-linking increases with increase in the vinyl acetate content of the copolymer; it is suggested that cross-linking of the macromolecules takes place at the tertiary carbon atoms of the main chain and also at the primary

carbon atoms of the acetate groups. Vulcanised ethylene–vinyl acetate copolymers exhibit a number of valuable properties, such as high resistance to heat, aging, the action of light and ultraviolet rays, ozone, oxygen, and atmospheric conditions, together with excellent mechanical properties. It is suggested that these products are of particular interest to the rubber industry, since their addition to certain types of rubber produces a marked improvement in the properties of the latter [122]. Vulcanised elastomers based on a copolymer of ethylene and vinyl acetate can also be obtained by pyrolytic elimination of acetic acid followed by vulcanisation of the product at the double bonds [137].

According to data obtained by the reviewers [121], the action of $^{60}Co$ $\gamma$-radiation leads to a considerable increase in strength and melting point, with a comparatively small decrease in the relative elongation and frost-resistance, of the ethylene–vinyl acetate copolymer.

There are reports [128,146,147] that copolymers of ethylene and vinyl acetate are produced on the industrial scale and are used as elastomers, plastics, coatings, adhesives, etc.

Copolymers of ethylene and vinyl acetate are readily hydrolysed with the formation of copolymers of ethylene and vinyl alcohol or, in the case of partial hydrolysis, three-component ethylene–vinyl acetate–vinyl alcohol copolymers [148-151]. The hydrolysed copolymers are of considerable practical interest, since they exhibit valuable properties such as strength, rigidity, and resistance to common solvents; a significant advantage over poly(vinyl alcohol) is their insolubility in water [148-154]. The range of application of hydrolysed copolymers of ethylene with vinyl acetate can be extended considerably by chemical modification of these products [155-167].

Ethylene copolymerises with other vinyl esters besides vinyl acetate. Almost all the patents cited above mention, in addition to vinyl acetate, esters such as vinyl propionate, vinyl butyrate, and vinyl benzoate. Ethylene can be copolymerised also with vinyl esters of branched carboxylic acids (vinyl $\alpha\alpha$-dimethylpropionate, vinyl $\beta\beta$-dimethylbutyrate, etc.) [168], vinyl esters of thio-acids [169], methyl vinyl ether and ethyl vinyl ether [170,171], divinyl ether [172], 2,2′-vinyloxyethoxyethanol [173], 2-vinyloxyethanol [174], and divinyl and diallyl oxalate and sebacate [175]. The copolymerisation of ethylene with all these vinyl esters and ethers is generally carried out at high pressures (1000-2000 bars) under the influence of oxygen or peroxide initiators. Calculation (Table 5) shows that the relative activities of the monomers in the copolymerisation of ethylene with vinyl esters of aliphatic acids are close to one another.

Kurian and Muthana [176] showed that copolymerisation of ethylene with vinyl $\gamma$-methylvalerate is possible at 50–200 bars and 80° under the influence of benzoyl peroxide. According to their results, vinyl $\gamma$-methylvalerate under these conditions shows a higher relative activity than ethylene.

Copolymers of ethylene with vinyl and allyl salicylate are of considerable interest because of their ability to form chelate compounds [177].

Three-component copolymerisation involving ethylene and vinyl acetate has been described in a number of patents [174,177-181]. Vinyloxyalkanols [174,179], vinyl and allyl salicylates [177], alkyl acrylates [178], and carbon monoxide [180,181] have been used as third component. The copolymerisation of ethylene, vinyl acetate, and ethyl acrylate [178] is of particular interest. The process was carried out at 800–1500 bars in benzene medium under the influence of azoisobutyronitrile or a peroxide. The copolymerisation products were hydrolysed to give copolymers consisting of 25–60 mole % of ethylene, 10–30% of vinyl alcohol, and 25–60% of acrylic acid; the tensile strength of these copolymers reached 300–400 kg $cm^{-2}$.

(d) Copolymerisation with Vinylene Compounds

Known copolymers of ethylene with monomers of the vinylene type include compounds with maleic acid derivatives, diethyl fumarate, and vinylene carbonate. Copolymerisation of ethylene with maleic anhydride is carried out at comparatively low pressure under the influence of free-radical initiators in various organic solvents [182,183]. Copolymers of high maleic anhydride content and low molecular weight are formed at 20–30 bars under the influence of peroxide initiators in the presence of a chain-terminating agent such as cumene or an aldehyde [184-188]. The relative activities of this pair of monomers are apparently less than unity (Table 5). Copolymers of ethylene and maleic anhydride are soluble in water [189]. They are now produced on the industrial scale as the anhydride, acid, or ammonium maleamate, and are used in the production of transparent films, adhesives, fungicides, paint thickeners, etc. [147,189-197]. Ethylene copolymerises also with monoesters of maleic acid [198].

Hopff and Stark [199,200] have shown that the emulsion copolymerisation of ethylene with diethyl fumarate is possible, with the formation of products whose softening temperatures are lower than room temperature. The molecular mass (determined by the osmotic method) of the fraction with highest molecular mass was 41 000. According to our calculations (Table 5), diethyl fumarate should have a much greater relative activity than ethylene.

An interesting feature of the copolymerisation of ethylene with vinylene carbonate is the apparently much greater relative activity of ethylene compared with vinylene carbonate (Table 5). Their copolymerisation under high pressure in the presence of free-radical initiators gives products which are at least as valuable as polyethylene and have a number of advantages, such as high strength, stability during processing, satisfactory flow properties, absence of cross-linked molecules, transparency, and gloss [201]. Copolymers containing up to 30 wt. % of vinylene carbonate can be used as additives to poly(vinylidene chloride fluoride) [202], polyvinylformal [203], and styrene–acrylonitrile copolymers [204], to improve their quality. The addition of small quantities (up to 10%) of a copolymer of ethylene and vinylene carbonate during the polymerisation of styrene gives a polymer with an increased tensile strength [205].

The hydrolysis of copolymers of ethylene with vinylene carbonate gives compounds of the ethylene–vinyl alcohol copolymer type, in which the hydroxy-groups are present on neighbouring carbon atoms [201]. Copolymers of ethylene with hydroxy-groups in the side-chains can also be prepared directly by the copolymerisation of ethylene with allyl or methallyl alcohol at high pressure, but in this case the products are waxlike, with low molecular mass of $\sim 1500$. [206]

(e) Copolymerisation with Acrylic Monomers

Ethylene copolymerises readily with acrylic compounds such as acrylic acid, acrylonitrile, and acrylic and meth-

acrylic esters [3-7,9]. The reaction can be initiated by oxygen, organic peroxides [5-7], $^{60}Co$ $\gamma$-radiation [12-14], and alkylborons [15,16]. Copolymers with perfluoroacrylonitrile have also been prepared [207].

Table 5 gives the calculated values of the relative activities for the copolymerisation of ethylene with various acrylic and methacrylic monomers. On the basis of these data it may be assumed that compounds of this type have a much greater relative activity than ethylene, the relative activity of the latter being close to zero. Thus copolymers with acrylic monomers will always be enriched in the second component. These conclusions agree with the experimental relative activities for acrylonitrile and n-butyl acrylate (Table 3).

The copolymerisation of ethylene with acrylonitrile has been studied in greatest detail. The radiation copolymerisation of these monomers has been investigated by Gromov et al. [51] The process is carried out in toluene solution at an ethylene pressure of 10–44 bars, an absorbed dose rate of 1080 J $kg^{-1}$ $h^{-1}$, and a temperature of 20°. The yield of copolymer for acrylonitrile concentrations in the monomer mixture of 10 and 50 mole % depends linearly on the duration of polymerisation up to 40% conversion; at an acrylonitrile concentration of 70%, the rate increases with time (up to 25% conversion), and this is attributed to the heterogeneous character of the process. This is indicated also by the fact that the intrinsic viscosity of the copolymer increases with increase in the degree of conversion. The rate of copolymerisation and the intrinsic viscosity of the products increase with increase in the acrylonitrile content in the original monomer mixture.

$\gamma$-Irradiation of a mixture of acrylonitrile and liquid ethylene at -78° leads to formation of only the acrylonitrile homopolymer; and when the acrylonitrile content of the mixture is low, polymerisation takes place exclusively at the $-C\equiv N$ bond. In solutions with a moderate concentration of acrylonitrile in ethylene, polymerisation takes place both at the $-C\equiv N$ bond and at the $\rangle C=C\langle$ bond [208,209].

Kolesnikov et al. [16] studied the copolymerisation of ethylene with acrylonitrile under the influence of triisobutylboron at an ethylene pressure of 98 bars in solvent naphtha medium. As in the case of radiation copolymerisation, increase in the concentration of acrylonitrile in the original monomer mixture leads to an increased yield of copolymer; at the same time, however, a decrease in its intrinsic viscosity is observed. With increase in the triisobutylboron concentration from 1 to 2 wt.%, the yield of copolymer increases from 10 to 25%; further increase in catalyst concentration, however, leads not to an increase in the yield but to a slight decrease. Lowering the initial temperature of polymerisation from 18° to -70° results in an increased content of ethylene units in the copolymer; this effect is observed for the most part at considerable concentrations of ethylene in the original mixture. In all cases decrease in the initial temperature leads to an increase in the yield of copolymer.

Good agreement is observed between the values of the relative activities calculated by Gromov et al. [51] from published data [16] and those established in radiation copolymerisation (Table 3). This may indicate that the copolymerisation process initiated by alkylborons takes place by a radical mechanism.

An interesting feature is that copolymerisation of ethylene with acrylonitrile does not take place on organometallic complexes [210].

There is almost no published information on the properties of copolymers with acrylonitrile. It is known [16] merely that the copolymers are soluble only in dimethylformamide and that X-ray structural analysis indicates a high degree of order inside the chain bundles; their vitrification temperature is almost independent of the monomer ratio and the reaction temperature, and lies in the range 60–70°.

Copolymers of ethylene with alkyl acrylates (e.g. ethyl acrylate and n-butyl acrylate) can be obtained by a continuous process in a tubular reaction vessel at 1500–2000 bars and 100–200° in the presence of oxygen or organic peroxides [211,212]. The copolymerisation was carried out at very low concentrations of the comonomers in the original mixture (0.2–1.5 mole %), apparently because of their extremely high relative activity (see Tables 3 and 5).

The composition of copolymers of ethylene with ethyl acrylate can be determined by gas chromatography of the pyrolysis products [138], high-resolution nuclear magnetic resonance [139], neutron activation analysis [139], infrared spectrophotometry, and hydrolysis [213]. In the last case, to obtain satisfactory results, the analytical reaction must be carried out in a homogeneous medium. The distribution of the monomer units in the copolymer can be established by a combination of gas chromatography of the pyrolysis products and differential thermal analysis [140,214].

Liquid copolymers of ethylene with a content of ~ 30 mole % of an alkyl acrylate or alkyl methacrylate are formed by copolymerisation under the influence of peroxide initiators at about 300 bars in hexane, cumene, etc. medium [215]. Other known compounds include copolymers of ethylene with esters of hydroxybenzophenones and acrylic or methacrylic acid [216] and with $\omega$-methacrylamidoundecanoic acid [217], and three-component copolymers of ethylene, ethyl acrylate, and vinyl acetate [178] and of ethylene, an alkyl acrylate, and a monoester of maleic or fumaric acid [218], prepared under approximately analogous conditions.

The alkyl acrylate most widely used as comonomer with ethylene is ethyl acrylate; copolymerisation with this compound is now carried out on the industrial scale [73,219]. Published data [73,219-233] show that these copolymers exhibit properties such as flexibility over a wide temperature range, high resistance to cracking under stress, high strength at low temperatures, and excellent engineering properties. An extremely important advantage of these copolymers over polyethylene is their low embrittlement temperature, which in some specimens reaches -100°. The copolymers exhibit high adhesion and mix well with paraffin wax [224] and polyethylene [218], whose mechanical properties are improved by the addition of small quantities of copolymers of ethylene and ethyl acrylate containing up to 8 mole % of the latter.

The dependence on composition of the glass point of copolymers of ethylene with ethyl acrylate and n-butyl acrylate is shown in Fig. 3. [37] A characteristic feature of these copolymers, which distinguishes them from those of ethylene with vinyl chloride or vinyl acetate, is the decrease in their glass point (particularly in the case of the copolymers with n-butyl acrylate) with increase in the content of the comonomer.

### (f) Copolymerisation with Heterocyclic Compounds

According to data given in patents, ethylene copolymerises with *N*-vinyl compounds such as *N*-vinylphthalimide, *N*-vinylsuccinimide [225], and *N*-vinylcarbazole [226] at

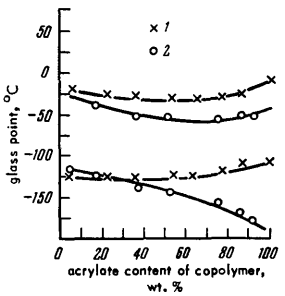

Fig. 3. Dependence on composition of the vitrification temperature of copolymers of ethylene with: 1) ethyl acrylate; 2) n-butyl acrylate. (Upper curves constructed from measurements on Instron tester; lower curves from data obtained with a torsion balance.)[37]

1000–2000 bars and 50–150° under the influence of organic peroxides or azo compounds, in water or a hydrocarbon solvent. The radiation copolymerisation of ethylene with *N*-vinylpyrrolidone has been carried out[12].

On the basis of the calculated values of the relative activities for the radical copolymerisation of ethylene with *N*-vinylcarbazole, *N*-vinylpyrrolidone, and *N*-vinylsuccinimide (Table 5) it may be assumed that these compounds have a much higher relative activity than ethylene.

The rigidity of copolymers of ethylene with small amounts of *N*-vinylsuccinimide and *N*-vinylpyrrolidone decreases with increase in the content of these compounds[31]. Copolymers containing 5–30 wt.% of *N*-vinylcarbazole have a much higher strength, elasticity, resistance to solvents, and better adhesion properties than high-pressure polyethylene[226].

According to data given in patents, copolymers of ethylene can be obtained with alkylene 1,2-oxides (e.g. ethylene oxide)[227,228], β-propiolactone[229], but-3-eno-3-lactone[230], and vinyloxoisochromans[231]. The copolymerisation is carried out at high pressures (500–1500 bars) and 50–200° under the influence of peroxide initiators. In the first two cases, however, the mechanism of the process is not clear.

(g) Copolymerisation with Compounds Incapable of Homopolymerisation

Compounds which are unable to undergo homopolymerisation but which form copolymers with ethylene include carbon monoxide, carbon dioxide, and sulphur dioxide.

1. Copolymerisation with carbon monoxide. Copolymers of ethylene with carbon monoxide were first prepared by one of the reviewers and his coworkers[232,233]. Copolymerisation of the monomers at 2000–2500 bars and 300° gave macromolecular products, consisting of viscous liquids or solids depending on the conditions of the experiment and the proportions of the original components. Copolymerisation was apparently initiated by molecular oxygen. Subsequently, methods have been described for the copolymerisation of ethylene and carbon monoxide under the influence of molecular oxygen[180], orthosilicates[234], complex nickel cyanides[235–237], alkali metals, their hydrides, and organic derivatives[238], Friedel–Crafts catalysts, carbonyl-forming heavy metals and their derivatives[239] (in the last two works cited, the process was initiated by traces of oxygen[240]), and $^{60}Co$ γ-radiation[11–14,34,52,53,241]. The greatest amount of work has been done on copolymerisation initiated by organic peroxides[54,180,234,242–259].

In the case of radiation copolymerisation in the gas phase at 70° and 160–180 bars, the rate of the process is proportional to the absorbed dose rate (rate of initiation) to the power 1.3. The fact that the rate of radical polymerisation is not proportional to the square root of the rate of initiation has been attributed to the heterogeneous character of the process[53].

The copolymerisation of ethylene with carbon monoxide takes place in the range 75–275° and also at room temperature in the case of initiation by γ-radiation. At high temperatures the process is complicated by side-reactions[260]. In the initiation of copolymerisation by peroxides at a pressure of 600 bars, increase in temperature from 200° to 260° led to a decrease in the molecular mass of the products of the reaction by a factor of about 3.[54] The maximum rate of radiation copolymerisation at 120–300 bars was observed at 70–120°.[53]

The copolymerisation pressure was varied over a wide range, from 14 to 2500 bars. At pressures below 100 bars, only products of low molecular weight are formed[180,257,258]. Copolymerisation under the influence of peroxide initiators was carried out in most cases at 600–1000 bars, and radiation copolymerisation at 120–300 bars and at 650–700 bars[12–14].

Copolymerisation initiated by peroxides has been carried out in the gas phase[54,180,246,248] and also in different reaction media, such as isooctane, benzene, cyclohexane, dioxan, water, etc.[54,180,243–258] In the presence of chlorinated hydrocarbons, isopropanol, thiols, ketones, esters, and chlorine, telomers of low molecular weight are formed[258,261–263]. Telomerisation was carried out at 30–8000 bars and 75–130° under the influence of peroxides or nitriles of azo-acids; under these conditions hydrogen sulphide inhibits copolymerisation[263]. The radiation copolymerisation of ethylene and carbon monoxide has generally been carried out in the gas phase.

The copolymerisation of ethylene and carbon monoxide is carried out both by batch and by continuous methods[32,54,234]. To prevent the formation of iron carbonyl during the reaction, it is recommended that the reaction vessel be lined with aluminium[53], silver, or other inert material[180].

The values of the relative activities of this pair of monomers (Table 3) show that the relative activity of carbon monoxide is in all cases zero¶. This means that, in the course of chain growth, the carbon monoxide molecules add only to radicals terminating in methylene groups. Thus the resulting copolymer contains no α-dicarbonyl groups, and the carbon monoxide content cannot exceed 50% (mole and weight percentages identical). This pair of monomers exhibit a high tendency to alternate, so that the composition of the copolymer depends little on the original monomer ratio over a wide range of original monomer concentrations.

¶ The values of the relative activities calculated by Gromov et al.[51] from the data of Brubaker et al.[257] — $r_{C_2H_4} = 0.57$ and $r_{CO} = 0.25$ — are incorrect, since no allowance was made for soluble monomers. An analogous error has been made by Steinberg and Colombo[13,52].

The composition of copolymers of ethylene and carbon monoxide shows a marked temperature dependence: the carbon monoxide content of the copolymer decreases with increase in the reaction temperature. The temperature dependence of the relative activity of ethylene corresponds to the equation given above [Section IV (c)] in the range 70–150°.[53] The parameters of this equation are

$$\Delta H_{11}^{\ddagger} - \Delta H_{12}^{\ddagger} = 19300 \pm 1700 \text{ J mole}^{-1},$$

$$\Delta S_{11}^{\ddagger} - \Delta S_{12}^{\ddagger} = 41.9 \pm 3.8 \text{ J mole}^{-1} \text{ deg}^{-1}.$$

According to the data of Coffman et al.[54], in the temperature range 200–260°,

$$\Delta H_{11}^{\ddagger} - \Delta H_{12}^{\ddagger} = 36000 \text{ J mole}^{-1},$$

$$\Delta S_{11}^{\ddagger} - \Delta S_{12}^{\ddagger} = 67 \text{ J mole}^{-1} \text{ deg}^{-1}.$$

As noted above, side-reactions take place at these high temperatures, and this possibly explains the marked discrepancy in the above data.

A noteworthy feature is the unusually large differences in the activation entropies and enthalpies of addition of ethylene and carbon monoxide to a radical terminating in a methylene group (see, for example, the data given by Alfrey et al.[264]).

An interesting feature of the copolymerisation of ethylene and carbon monoxide is the pressure dependence of the copolymer composition. Data have been published[257] indicating that, with increase in pressure in the reaction system from 14 to 1000 bars, the carbon monoxide content of the copolymer increases from 13 to 45% (the copolymerisation was carried out in cyclohexane solution in the presence of t-butyl peroxide at 135° with a carbon monoxide content in the original mixture of 42%). An explanation for this fact was put forward by Barb[265,266]†, who considered that carbon monoxide takes part in the copolymerisation not directly but in the form of an unstable equimolecular complex with ethylene, by a process similar to that occurring in the copolymerisation of alkenes with sulphur dioxide[237].

A consequence of this assumption is that the following relationship should be observed between the ratio $n$ of the numbers of molecules of ethylene and carbon monoxide in the copolymer and the carbon monoxide concentration [CO] in the reaction system

$$n = 1 + \frac{\text{const}}{[CO]}.$$

As shown by Walling[268–270], this relationship can also be obtained on the assumption that one of the elementary reactions of chain growth is reversible

$$RCH_2CH_2 + CO \rightleftarrows CH_2CH_2CO^{\cdot}, \qquad (1)$$

Using the experimental data of Brubaker and his coworkers, Barb showed that the above relationship is in fact observed at pressures up to 300 bars. Barb, however, assumed without justification that the solubility coefficients for ethylene and carbon monoxide in cyclohexane are constant up to partial pressures of 200 bars, and that the ideal gas laws are applicable to the ethylene–carbon monoxide system at partial pressures of ethylene greater than the critical pressure. It is possible that the change in the composition of the copolymer with change in the total pressure in the system is due to a change in the relative solubilities of ethylene and carbon monoxide in cyclohexane‡. Evidence in support of this suggestion is provided, in particular, by the fact that in the case of copolymerisation in the gas phase at 70°, no change was observed in the relative activity of ethylene with change in the total pressure from 120 to 270 bars, or with change in the concentration of carbon monoxide in the reaction system from 0.2 to 6.3 mole dm$^{-3}$.[53]

It is nevertheless possible that at higher temperatures the composition of the copolymer does depend on pressure because of the reversibility of reaction (1). This may explain the following facts — (1) the considerable decrease in the carbon monoxide content of the copolymer with increase in the temperature of copolymerisation, (2) the decrease in the yield and molecular weight of the copolymers with increase in temperature, and (3) the increase, unusual for radical copolymerisation, in the tendency of the monomers to alternate in the polymer with increase in pressure (at 120° and 220–230 bars, $r_{C_2H_4} = 0.33$;[53] at 120–130° and 850–1000 bars, $r_{C_2H_4} = 0.15$[54]). Further studies are required to clarify this question.

The rate of radiation copolymerisation increases with increase in the concentration of carbon monoxide in the original mixture[53].

Copolymers of ethylene and carbon monoxide have the structure of linear polyketones. This has been proved by infrared spectrophotometry[12,257,260] and also by the chemical reactions of the copolymers[257]. The composition of the copolymer can be determined by elementary analysis or by infrared spectrophotometry (from the intensity of absorption of the carbonyl group[272] or from the ratio of the intensities of absorption of the methylene groups attached and unattached to carbonyl[260]).

Copolymers of ethylene and carbon monoxide of sufficiently high molecular mass are crystalline[32,180]. X-Ray structural analysis indicates a high degree of order in copolymers obtained by radiation copolymerisation in the gas phase at 25–70°.[34,35,53] As noted above, these products retain the crystal structure of polyethylene. The structure of the orthorhombic cell of polyethylene and of two copolymers with different carbon monoxide contents is shown in Fig. 4.[35]

Natta et al.[26] point out that the absorption bands in the infrared spectra of homopolymers, usually related to the crystallinity of the specimen, disappear rapidly even on isomorphous replacement of the units in the polymer chains. This phenomenon is observed, in particular, in the spectra of copolymers of ethylene and carbon monoxide. Thus the spectrum of a copolymer containing 21% of carbon monoxide still shows the 730 cm$^{-1}$ band associated with the crystalline structure of polyethylene. This band disappears with increase in the carbon monoxide content to 43%; at the same time the appearance of a band at 1338 cm$^{-1}$ and splitting of the band due to stretching vibrations of the carbonyl group are observed. These phenomena are related to the crystal structure of the polyketone[260].

The melting points of ethylene–carbon monoxide copolymers of high molecular weight lie in the range 90–200°. With increase in the carbon monoxide content, the melting point falls slightly, possibly owing to a decrease in the molecular mass[53] or the heat of fusion of the copolymer[32].

† Speculations regarding the mechanism of the process have also been put forward by Curphy[259] and by Vatsulik[267].

‡ Gonikberg[271] considers that increase in pressure produces an extremely marked increase in the rate of attachment of –CO– groups to the growing polymer chain.

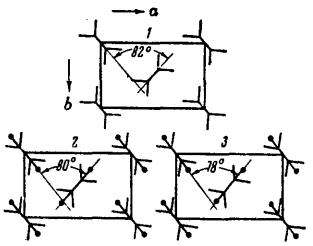

Fig. 4. Crystal structure of polyethylene and of copolymers of ethylene with carbon monoxide[35]: 1) polyethylene; 2) copolymer containing 31% of carbon monoxide; 3) copolymer containing ~50% of carbon monoxide.

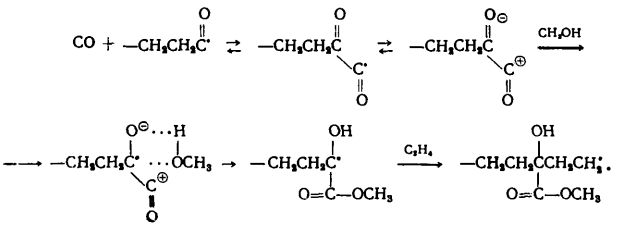
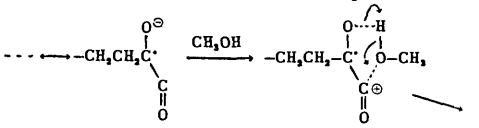
With further increase in the carbon monoxide content, the melting point of the copolymer increases. A copolymer containing 10–20% of carbon monoxide has a vitrification temperature in the range between -25° and -125°.[37]

Copolymers of ethylene and carbon monoxide, obtained in the gas phase at 25–120° under the influence of $^{60}Co$ $\gamma$-radiation, are almost insoluble in paraffinic and naphthenic hydrocarbons, *m*-cresol, and pyridine[13,14,53]. The density of these copolymers lies in the range 1.1–1.2 (these are close to the calculated values)[13,14,34,35,53]. The density of copolymers obtained at 200–250° and 700–1100 bars increases from 0.92 to 1.02 with increase in the carbon monoxide content from 3 to 23%.[32] Copolymers of ethylene and carbon monoxide blend well with paraffin wax and other waxes[252], polyurethane elastomers[258], and chlorine-containing polymers[261]; the compatibility of the latter with the copolymers increases with increase in the carbon monoxide content of the copolymers. A disadvantage of copolymers of ethylene and carbon monoxide, which restricts their possible applications, is their brittleness. The optimum combination of mechanical properties is apparently shown by copolymers with a very low carbon monoxide content[180].



A characteristic property of copolymers of ethylene and carbon monoxide is their thermal reactivity[180,234,259,260]. When these products are heated above their melting points in air or *in vacuo*, they are rapidly converted into hard, brittle, infusible, insoluble substances, which soften when heated. This casts doubt on the accuracy of conclusions[32,257] based on the viscosity of the molten copolymers. The changes in the copolymers are accompanied by the liberation of water. The reaction rate increases sharply with temperature. It has been suggested[259,260] that this process involves the thermal initiation of crotonic condensation. The possibility of reaction is determined to a considerable extent by the mobility of the molecular chains, so that the rate of the process increases sharply on fusion of the copolymer. The process apparently takes place by an intermolecular mechanism, as indicated by the autoretardation of the reaction and the infusibility and insolubility of the products[260]. The polyketones can undergo condensation also under the influence of alkali[180,243,247,250,259,273,274].

The cross-linking of copolymers of ethylene and carbon monoxide by peroxides[180,275], chloramine[275], and nitrogen-containing bases[180,248] leads to an increase in their strength, a rise in their softening temperature, and a decrease in their solubility.



The high reactivity of the polyketones opens up extensive possibilities of chemical modification of these products and their utilisation for the preparation of macromolecular compounds of different classes — polyoximes[180,257], hetero-chain polyamides and polytetrazoles[160,276,277], poly-$\alpha$-ketone oximes and dioximes[278] and chelate compounds based on them[279], allyl derivatives[181], phosphorus-containing polymers[256], polyketo-nitriles and polyketo-acids[180,242,260], polycyanhydrins[251,257], polyhydantoins[255], polyalcohols[180,245,253,257,281-284], polyurethanes[245,253,282-287], polythiols and polysulphides[254], and polyamines and their derivatives[249,259,285-296]. The oxidation of copolymers of ethylene and carbon monoxide with nitric acid gives a mixture of dicarboxylic acids, whose composition yields information on the distribution of carbonyl groups in the copolymer chain[180,246,257].

In addition to copolymers of ethylene and carbon monoxide, patents describe the preparation of three-component copolymers of ethylene and carbon monoxide with propene[180,181,240,245,248,253,261,262], methylpropene[180,181,240,261], butadiene[180,181], vinyl acetate[180,181], diethyl maleate[180,181,247], diallyl phthalate[180], and sulphur dioxide[297]; and also the four-component copolymer of ethylene, carbon monoxide, vinyl acetate, and diethyl maleate[180]. The conditions of copolymerisation do not differ in principle from those for the copolymerisation of ethylene and carbon monoxide. The three-component copolymers can be subjected to the same chemical changes as those of ethylene and carbon monoxide.

If the copolymerisation of ethylene with carbon monoxide at high pressures is carried out in the presence of alcohols or alkyl formates, the molecules of these substances combine chemically with the copolymer and modify its structure (the copolymerisation was carried out at 130° in the presence of t-butyl peroxide)[298,299]. The quantity of chemically combined alcohol increases with increase in pressure; thus the copolymer obtained in the presence of methanol at 1000 bars contains 7% of methoxy-groups, whereas that obtained at 8000 bars contains 27%. Increase in the concentration of carbon monoxide in the original mixture decreases the yield and increases the concentration of alkoxy-groups in the copolymer. Chemical and spectroscopic data indicate that these copolymers contain the groups $-CH_2-CH_2-$, $-CO-$, and $-C(OH)(COOR)-$.[289,299] Special experiments showed that copolymers of ethylene and carbon monoxide do not react with carbon monoxide and methanol under the conditions of this reaction, so that the molecules of the alcohol combine with the copolymer directly during copolymerisation. Cairns et al.[299] suggested the following reaction mechanism§

§ Cairns et al. write the third and fourth species as

(Ed. of Translation).

This reaction mechanism is difficult to reconcile with the fact that $\alpha$-dicarbonyl groups are not formed in the copolymerisation of ethylene and carbon monoxide.

Products obtained by chemical transformation of the copolymers (hydrolysis, oxidation, hydrogenation, and treatment with formaldehyde and peroxides [298-300]) have also been described.

The catalytic hydrocondensation of ethylene and carbon monoxide is an unusual free-radical process: hydrogenation of the carbon monoxide gives methylene radicals, which copolymerise with the ethylene [301].

2. Copolymerisation with carbon dioxide. According to data given in patents [302], ethylene copolymerises with carbon dioxide under the influence of peroxide initiators at elevated temperatures and pressures up to 1000 bars. Vatsulik [267] suggests the following reaction mechanism

$$CH_2{=}CH_2 + CO_2 \rightarrow \dot{C}H_2{-}CH_2{-}O{-}CO{-}CH_2{-}\dot{C}H_2 \rightarrow$$
$$\rightarrow CH_3{-}CH_2{-}O{-}CO{-}(CH_2{-}CH_2{-}O{-}CO)_n{-}CH_2{-}CH_2{-}O{-}CO{-}CH_2{-}CH_3,$$

but gives no arguments in support of this scheme.

3. Copolymerisation with sulphur dioxide. The copolymerisation of alkenes with sulphur dioxide is of considerable theoretical and practical interest, and much work has been done on this reaction. In these studies, ethylene has been assigned a modest role. Since a number of fairly detailed reviews have been published [303-310], we shall merely discuss a few papers on the copolymerisation of ethylene, and shall not deal with general problems of the copolymerisation of alkenes with sulphur dioxide.

Ethylene copolymerises readily with sulphur dioxide under the influence of peroxides [311-313], azo-compounds [314-316], sunlight [317], ultraviolet rays [317,318], and $^{60}Co$ $\gamma$-radiation [319-321].

The substances used as copolymerisation initiators include, in particular, the peroxide products of the autoxidation of diethyl ether and ethylbenzene [311-313]. In the latter case, liquid sulphur dioxide copolymerises at temperatures from -20° to -30° and atmospheric pressure with pure ethylene and also with the technical product containing only 50% of ethylene [312,313].

A characteristic feature of the copolymerisation of alkenes with sulphur dioxide is the existence of a limiting temperature, specific for each alkenes, above which the reaction does not take place. This temperature is independent of the nature of the initiator, but depends on the monomer concentration [310]. It has not been determined for ethylene but is much higher than for other alkenes [318,322].

The kinetics of the radiation copolymerisation of ethylene and sulphur dioxide at 0° was studied by Bray et al. [321] on the basis of the following scheme for the copolymerisation process —

initiation

$$C_2H_4 \rightarrow R_1,$$
$$SO_2 \rightarrow R_2,$$

chain growth

$$RCH_2\dot{C}H_2 + SO_2 \rightarrow RCH_2CH_2SO_2^{\cdot},$$
$$RSO_2^{\cdot} + C_2H_4 \rightarrow RSO_2CH_2\dot{C}H_2,$$

chain termination

$$R_2CH_2\dot{C}H_2 + R_2CH_2\dot{C}H_2 \rightarrow P,$$
$$R_1CH_2\dot{C}H_2 + R_2SO_2^{\cdot} \rightarrow P,$$
$$R_1SO_2^{\cdot} + R_2SO_2^{\cdot} \rightarrow P.$$

It can be seen from the above scheme that Bray et al. considered that the two values of the relative activities for the copolymerisation of ethylene and sulphur dioxide are zero (the monomers do not add on to "their own" radicals). This assumption is not strictly justified, since the studies were carried out only with an equimolar mixture of monomers (the ratio of the original molar concentrations of ethylene and sulphur dioxide lay in the range 0.9–1.4); moreover, the sulphur content of the reaction products was slightly lower than that corresponding to an equimolar monomer ratio. According to the experimental data, almost no depolymerisation of the growing radicals takes place in the copolymerisation process.

In the copolymerisation of ethylene with sulphur dioxide, linear copolymers having a polysulphone structure are formed [311]. In most cases copolymers with an equimolar monomer ratio were obtained. The structure of these copolymers can be represented by the formula

$$\left[-CH_2-CH_2-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-\right]_n.$$

Products of this type have a crystalline structure [323] and unusually high melting points. Thus the copolymers obtained at 0° under the influence of $^{60}Co$ $\gamma$-radiation melted over the range 312–341°, fusion being accompanied by decomposition of the copolymer [321]. The melting points of the copolymers generally lie above the temperatures of their thermal decomposition. Such high melting points are apparently due to the marked polarity of the sulphonyl groups (Table 1) and the regular structure of the copolymer.

Equimolecular copolymers of ethylene and sulphur dioxide do not dissolve in any known solvents, including concentrated sulphuric and nitric acids [311,324] (according to Bray et al. [321] these copolymers are very sparingly soluble in aliphatic ketones). They are stable towards powerful oxidising agents but decompose under the influence of dilute alkalis, forming salts of sulphinic acids and a small quantity of neutral products [311]. The equimolecular copolymers have high thermal stability. Staudinger and Ritzenhalter [311] noted that these copolymers broke down into the original components above 300°. According to Naylor and Anderson [315] the decomposition of copolymers of monoalkenes with sulphur dioxide takes place in conformity with a unimolecular mechanism.

Of all the equimolecular copolymers of alkenes with sulphur dioxide, those of ethylene have the highest melting point, lowest solubility, and highest thermal stability. The infusibility and the insolubility of these products make their processing extremely difficult, so that they have not found practical application. According to data given in patents, considerably improved properties are shown by polysulphones containing less than 50 mole % of sulphur dioxide [316,325]. These copolymers, which have a high tensile strength, can be processed by casting under pressure or by extrusion at 200°. The copolymers can be used as additives to drying oils [326].

Naylor and Anderson [315] describe the preparation, and give data on the rate of thermal degradation, of the three-component copolymer of ethylene, propene, and sulphur dioxide. They point out that this type of three-component copolymerisation can be carried out at temperatures lower than the limiting temperature of each alkene with sulphur dioxide. A continuous process for the ternary copolymerisation of ethylene, but-1-ene, and sulphur dioxide has also been described [327]. The ratio of the reactivities of cyclohexene and ethylene under the conditions of three-compo-

nent copolymerisation with sulphur dioxide has been determined by Hazell and Ivin [328]. The three-component copolymer of ethylene, carbon monoxide, and sulphur dioxide was mentioned above [297].

# SALTING-OUT AND SALTING-IN OF NON-ELECTROLYTES

V. F. Sergeeva

The problem of the effect of electrolytes on the solubility of non-electrolytes is of great theoretical and practical importance. A great deal of work[1-57] has shown that electrolytes can either decrease or increase the solubility of neutral substances in water, the phenomenon being termed *salting-out* or *salting-in* respectively.

Processes associated with salting-out are widely used in the production of dyes, amines, soaps, etc. At the present time the employment of salting-out agents in extraction is becoming especially important[58-74]. On the other hand, substances which increase the solubility of non-electrolytes in water (hydrotropic substances) are beginning to find application in industry.

McKee[75] reported the employment of alkanesulphonates of the alkali and alkaline earth metals in papermaking, and referred to the possibility of replacing organic solvents by solutions of hydrotropic salts in the electrolysis of organic substances. The presence of a second phase in the system is known to diminish the rate of many organic reactions. By the use of hydrotropic salts the system can be made homogeneous, and the rate of the process thereby increased. In addition, salts influence the course of a reaction[76-79].

The behaviour of salts in aqueous solutions of non-electrolytes is a complicated phenomenon owing to the occurrence in the water–electrolyte–non-electrolyte system of various types of interaction: water–electrolyte, water–non-electrolyte, and electrolyte–non-electrolyte.

Systematic study of the effect of salts on the solubility of neutral substances in water has revealed several regularities, which have subsequently formed a basis for theories of salting-out and salting-in. The influences of some substances on the solubility of others has been investigated by various methods — by direct measurement of solubilities, determination of partition coefficients, determination of

freezing-point depression, and measurement of partial vapour pressures. The results obtained can be summarised briefly as follows:

1. In the overwhelming majority of cases, electrolytes diminish the solubility of non-electrolytes in water.

2. The smaller an ion having a given charge, the greater its salting-out action.

3. The sequence of salts remains the same for their action on many but not all non-electrolytes.

4. Increase in ionic radius (of cation or anion) results in a decrease in the salting-out effect and a change to salting-in.

5. The salting-out constant can be calculated from Sechenov's equation

$$\log\frac{S_0}{S} = K_S C_S, \qquad (1)$$

where $S_0$ and $S$ are the solubilities of the non-electrolyte in water and in the aqueous salt solution, $C_S$ is the concentration of the salt, and $K_S$ is the salting-out constant.

6. The change in the logarithm of the activity coefficient of the non-electrolyte is found to be proportional to the salt concentration expressed in moles or equivalents per litre.

Sechenov's equation has been tested many times[80-84], and, although the constant varies with the electrolyte concentration, especially at high values of the concentration, the equation has so far found wide application for assessing the effects of different salts.

Rendall and Failey[5-7] proposed as measure of the salt effect the ratio of the logarithm of the activity coefficient of the non-electrolyte $f_S$ to the ionic strength of the solution $\mu_{soln}$. In their view this quantity $(1/\mu_{soln})\log f_S$ has the advantage that it does not involve the valencies of the ions, and it remains constant in solutions of different ionic strength. Rendall and Failey's results for benzoic acid in solutions of sodium chloride at 25° may serve as illustration (Table 1).

Rendall and Failey give the following sequence for the action of the ions

$$OH^- > SO_4^{2-} > CO_3^{2-} > ClO_3^- > BrO_3^- > Cl^- > CH_3COO^- > IO_3^- > ClO_4^- > Br^-,$$
$$I^- > NO_3^- > Na^+ > K^+ > Li^+ > Ba^{2+} > Ca^{2+} > Ni^{2+} > Co^{2+} > Mg^{2+} > Fe^{2+} >$$
$$> Zn^{2+} > Mn^{2+} > Al^{3+} > NH_4^+ > H^+$$

This sequence is approximately maintained for many non-electrolytes, but investigations of the effect of 0.5 M NaCl solution on the solubility of various substances in water at 30° showed that the salting-out effect depends also on the nature of the non-electrolyte (Table 2).

TABLE 1. Activity coefficient and values of $(1/\mu_{soln})\log f_S$ in solutions of different ionic strengths[5].

| $\mu_{soln}$ | $f_s$ | $(1/\mu_{soln})\log f_s$ |
|---|---|---|
| 0.01982 | 1.007 | 0.153 |
| 0.02502 | 1.010 | 0.173 |
| 0.03320 | 1.014 | 0.182 |
| 0.05010 | 1.023 | 0.197 |
| 0.1002 | 1.045 | 0.191 |
| 0.2009 | 1.092 | 0.190 |
| 0.3356 | 1.154 | 0.185 |
| 0.5022 | 1.231 | 0.180 |

It is difficult from the data in Table 2 to establish a relation between the polarity of the non-electrolyte and the salting-out effect of the given electrolyte. Although the percentage salting-out is greatest for substances which possess no dipole moment $\mu$, it is also high with ethyl iodide ($\mu$ = 1.7) and low with chlorobenzene (1.56).

We can also examine Long and McDevit's data[4] in Table 3, in which the dipole moments and the salting-out constants of organic compounds are compared (with potassium chloride as electrolyte).

No very clear parallelism is observed on comparing the variation in salting-out constant with dipole moment. Thus nitrobenzene and benzene, which differ greatly in their polar properties, have the same salting-out constants, but if nitrobenzene and *p*-phenylenediamine are excluded, an increase in dipole moment entails a decrease in salting-out constant. Where the tables give no indication of salt concentration, the values of $K_S$ relate to infinite dilution, and have been calculated from the slope of the linear dependence of $\log f_S$ on salt concentration.

Interesting observations were made by Linderstrøm-Lang[86] on the effect of substituted ammonium chlorides on the solubility of benzoquinone and quinol in water. That of quinol increases and the salting-in constant changes with change in size of the cation, whereas benzoquinone is salted-out by all these salts, and the salting-out constant is small and unchanged.

Long and McDevit[87] examined the difference in the action of salts on acidic and basic non-electrolytes. If the non-electrolyte is basic in character, sensitivity to the charge on the anion is observed, and lithium salts cause salting-in. The salting-out of weak acids increases with the charge on the cation, and cations show the normal sequence in their action: i.e. salting-out is more intense with lithium than with sodium salts. In the view of these workers the difference in the action of salts on non-electrolytes of acidic and basic character is associated with the orientation of water

TABLE 2. Effect of 0.5 M NaCl solution on the solubility of various substances in water at 30°.[85]

| Compound | Salting out, % | $10^{18}\mu$ | Compound | Salting out, % | $10^{18}\mu$ |

molecules in the hydration sphere of the ion. Water molecules hydrating a cation are oriented with the protons on the outside, non-electrolyte molecules of basic character being attracted to them, while those of acidic character are repelled. In studying the phenomenon of salting-out, many workers have noted that the effect diminishes with increase in size of the ions, and a change to salting-in is observed [88-94].

Neuberg [95] established that aqueous solutions of many salts, such as benzoates, benzenesulphonates, and their homologues, are able to bring into solution substances of various classes which are insoluble in water (hydrocarbons, alkaloids, aldehydes, ketones, nitro-compounds, proteins, fats, etc.). Numerous experiments have shown the widespread occurrence of this phenomenon, which is termed hydrotropism.

Hydrotropic substances are usually saltlike in character, containing COOM, $SO_3M$, $SO_2M$, or $OSO_3M$ groups. They can have either a chain or a ring structure, and may also contain halogeno-, amino-, nitro-, or hydroxy-groups.

Neuberg [95] noted that hydrotropic salts are specific in their action: sulphonates bring proteins and alkaloids into solution, but not essential oils, higher alcohols, or ketones. Table 4 shows the change from salting-out to salting-in with increase in size of the ions in the electrolyte.

Interesting results were obtained by Bockris et al. in a study of the effect of the radius of the cation on the solubility of benzoic acid in water [97]. Table 5 shows that the salting-in action increases with increase in radius of the cation.

Licht and Wiener [98] studied phase equilibria in the water–benzoic acid system containing sodium salts of benzene-, toluene-, and xylene-sulphonic acids. They noted that all the salts increase the solubility of benzoic acid in water, and that the hydrotropic effect increases as the alkyl group becomes longer, i.e. with increase in molecular weight of the salt. Introduction of a bromine atom (sodium *p*-bromobenzenesulphonate) gives the same result as increasing the size of the alkyl group. It is curious that introduction of a second sulpho-group (sodium benzene-*m*-disulphonate) destroys the salting-in property of the salt for benzoic acid, and a slight salting-out is observed. These workers remarked that the phase diagrams which they obtained give no indication of the formation of chemical compounds.

Booth and Everson [99] studied the effect of sodium *o*-, *m*-, and *p*-xylenesulphonates on the aqueous solubility of acetophenone, aniline, benzaldehyde, *o*-cresol, cyclohexanone, and diethyl ether, and found that all three salts increase the solubility of these substances to the same extent. Another paper by these workers [100] describes the action of the

sodium salts of benzene-, toluene-, xylene-, and cymene--sulphonic acids on the solubility of various kinds of substances in water. They found that hydrotropic salts, which increase the solubility of benzoic acid, behave altogether differently towards some non-electrolytes. Thus the solubility of benzene, carbon tetrachloride, cottonseed oil, and n-hexane is not increased in solutions of these salts, whereas that of *o*-cresol and cyclohexane is greatly increased.

Larsson [101-104] and Kolthoff and Bosch [105] studied the effect of sodium and potassium benzoates on the solubility of benzoic acid in water. It would appear from the law of mass action that salts containing the same ion as the acid should diminish the solubility of benzoic acid, but the opposite results were obtained: the presence of salts of benzoic acid in water led to an increase in the solubility of the acid. Similar effects were found by Ross et al. [106] in a study of the influence of salts of mandelic acid on the solubility of this acid, and by Osol and Kilpatrick [107,108] with *o*-chlorobenzoic acid and the corresponding sodium salt.

Kolthoff and Bosch [105] attribute this action of salts on the solubility of weak acids to interaction between the ion of the salt and a molecule of the acid according to the equation

$$HB + B^- \rightleftarrows HB_2^-.$$

Observations of salting-in effects were accompanied by attempts to explain this phenomenon. Some authors assumed it to result from chemical interaction between electrolyte and non-electrolyte [18,106,109], but Neuberg [95] did not regard this as the sole cause, since in many cases the observed increase in solubility is not the result of a chemical process.

Gross [85] suggested that cations and anions have opposite effects, the former salting-out and the latter salting-in, and the overall action of a salt being the net effect of cationic and anionic components.

Gross [85] and Larsson [101-104] suggested that the constant of the salt effect is an additive function of two constants characteristic of the anion and the cation:

$$\log f_s = K_s C_s = (K_K + K_A) C_s.$$

Larsson assumed that $K_{K^+} = K_{Cl^-}$, and since $K_{KCl} = 0.14$, it follows that $K_{K^+} = K_{Cl^-} = 0.07$. This hypothesis was used as a basis for calculating salting-out constants for other ions.

It is seen from the data for benzoic acid in Table 6 that the ionic salting-out constants for many large anions are negative, showing that these ions have a salting-in action. Further investigation established that not only bulky anions but also large cations (quaternary ammonium halides) exert a salting-in effect [97,108].

TABLE 6. Ionic salting-out constants for benzoic acid[85].

| | | | | | | | |
|---|---|---|---|---|---|---|---|

| $Rb^+$ | 0.02 | $Ba^{2+}$ | 0.08 | $ClO_4^-$ | 0.06 | $OSO_3C_{10}H_7^-$ | −0.86 |

All these investigations led to the development of theories to explain the action of salts on the solubility of non-electrolytes. The earliest of these was the hydration theory. During the 1890's a study of the solubility of carbon dioxide in water and salt solutions led Sechenov[1] to the conclusion that the gas was always less soluble in the presence of salts than in pure water. He put forward the hypothesis that "Salt solutions are compounds of the salt and water. On this basis we could regard the solution as if only the solvent, water, were the absorbing medium for the gas, while the salt combines with water, and weakens its absorbing power". Thus Sechenov was the first to express the opinion that the decrease in solubility of the non-electrolyte is due to hydration of the salt.

Rothmund[2], Philip[110-112], and later Glasstone[113-116] as well as Eucken and Herzberg[117] have assumed that the salting-out action of electrolytes is due to ions binding water molecules and diminishing the quantity of free solvent, so that the solubility of neutral molecules decreases. But this apparently extremely plausible view cannot explain the dependence of the hydration numbers of the ions during salting-out on the nature of the non-electrolyte. Moreover, the hydration theory cannot explain the increase in solubility of a non-electrolyte caused by the addition of certain electrolytes.

Another attempt to provide a theoretical basis for salting-out phenomena is due to Debye and McAulay[118,119], who take into account only the effect of one type of forces, the coulombic forces. Ions are regarded as spheres having a definite radius. The work done in discharging ions is calculated for the pure solvent of dielectric constant $D_0$ and for a medium of dielectric constant $D$, which medium may be the solution containing both electrolyte and non-electrolyte. This leads to the appearance of an additional component of the chemical potential, and thus the activity coefficient of the neutral molecules was found to be given by the equation

$$\log f_s = \log \frac{S_0}{S} = \frac{\beta}{2KTD_0} \sum \frac{n_j l_j^2}{r_j}, \qquad (2)$$

where $K$ is Boltzmann's constant, $T$ the absolute temperature, $n_j$ the number of ions of a given kind, $l_j$ the ionic charge, $r_j$ the ionic radius, $D_0$ the dielectric constant of water, $D$ that of the solution, and $n$ the number of moles of the non-electrolyte.

The constant $\beta$, characterising the non-electrolyte, can be found from the equation

$$D = D_0(1 + \beta n). \qquad (3)$$

This equation shows that, if the dielectric constant is smaller than that of the pure solvent, $\beta$ will be positive, indicating salting-out. If, however, the value of $D$ for the solution is greater than that for water, $\beta$ will be negative, and salting-in will occur. A single example satisfying this condition has been reported in the literature: the experiments of Gross[120] on the distribution of hydrogen cyanide and acetone between benzene and aqueous solutions of salts show that acetone is salted-out, since it decreases the dielectric constant of water, whereas hydrogen cyanide is salted-in, because hydrocyanic acid possesses a higher dielectric constant than water, and its addition to the latter increases the value of $D$ for the solution.

According to the equation of Debye and McAulay, $\log f_s$ should vary linearly with electrolyte concentration, as is also observed in most cases. Figs. 1 and 2 show as example the effect of various electrolytes on the solubility of hydrogen and benzoic acid[4]. It is noteworthy that this equation is similar in form to the empirical equation of Sechenov. Furthermore, the equation of Debye and McAulay gives the dependence of the salting-out action of an electrolyte on the radius of its ions: the smaller the radius of the cation, the greater the diminution in solubility of the non-electrolyte produced by a given electrolyte. Later Debye developed a more exact theory of salting-out, which was further developed in papers by Gross[121-124], Butler[125], Kirkwood[126], and others[127-132].

Long and McDevit[44] compare the effect of salts on the solubility of benzene in water with values calculated from the equations of Debye and of Kirkwood. It is seen from Table 7 that values calculated by means of the two equations differ little between themselves. They predict the general order of change on passing from one salt to another, but give an inadequate idea of the specific action of salts observed experimentally. This is understandable, since the

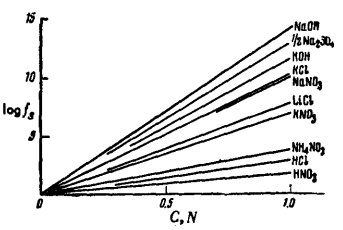

Fig. 1. Action of salts on the solubility of $H_2$.[4]

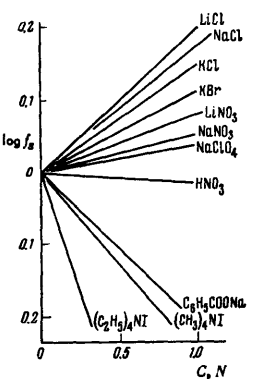

Fig. 2. Effect of salts on the solubility of benzoic acid in water at 25°.[4]

TABLE 7. Comparison of calculated and experimental salting-out constants for benzene[44].

| Salt | $K_{obs}$ | $K_{Debye}$ | $K_{Kirkwood}$ |
|---|---|---|---|
| NaF | 0.254 | 0.130 | 0.133 |
| NaCl | 0.195 | 0.126 | 0.125 |
| $NH_4Cl$ | 0.103 | 0.124 | 0.109 |
| LiCl | 0.141 | 0.127 | 0.143 |
| NaI | 0.095 | 0.122 | 0.120 |
| CsCl | 0.088 | 0.121 | 0.105 |
| $(CH_3)_4NBr$ | —0.24 | 0.110 | 0.093 |

whole specific action of an electrolyte is contained, in these equations, in the ionic radii, which differ little among themselves, so that the salting-out constants calculated from these equations vary insignificantly, and differ appreciably from the observed values. It is noteworthy that neither equation provides for salting-in.

Mikhailov[133] has attempted to refine the Debye equation by introducing the concept of a salting-out sphere of finite radius. A new term appears in the equation, which takes into account both the actual volume of the ion and the change in the salting-out sphere with increase in electrolyte concentration. Agreement between calculated and observed values is unsatisfactory. Thus for the water–benzene–sodium chloride system the calculated coefficient is 0.114, while the actual value is 0.260. The discrepancy between calculated and experimental values is attributed by the author to disregard of non-electrostatic interactions in the solution.

The defects of the Debye theory are not removed by refinements of a different type. As before, experimental activity coefficients differ substantially from the calculated values, and the Debye–McAulay equation gives no transition from salting-out to salting-in. It was mentioned above that several authors found an increase in solubility of a non-electrolyte to be produced by electrolytes having large ions, and it was therefore suggested that salting-in by large ions is due to the action of van der Waals forces. On this basis Bockris[97,132] put forward a theory which took into account the action of both coulombic and dispersion forces. If the latter predominate, salting-in is observed; if coulombic forces are predominant, salting-out occurs. Bockris has shown that, with ions of high polarising power, ion–non-electrolyte dispersion interaction may predominate over ion–water coulombic interaction. Large ions, of high polarisability, interact more strongly with non-electrolyte molecules than with the small water molecules, and therefore salting-in is observed.

The proposed equation is[97,132]

$$\frac{\Delta S}{S_0} = m_i\left(P_C - P_B\frac{v_C}{v_B}\right)\frac{2\pi l_0^2 N_A}{1000\epsilon_s^2 KT}\left(\frac{1}{a_+}-\frac{1}{a_-}\right)+\left(\frac{\alpha_C\nu_C}{\nu_{A\pm}+\nu_c}-\frac{\alpha_B\nu_B}{\nu_{A\pm}+\nu_B}\,\frac{v_C}{v_B}\right)\times$$
$$\times\frac{2\pi\times N_A h}{1000\epsilon_0^2 KT}\left(\frac{\alpha_{A+}\nu_{A+}}{a_+^2}+\frac{\alpha_{A-}\nu_{A-}}{a_-^2}\right), \qquad (4)$$

where $A$ represents the electrolyte, $B$ the solvent, $C$ the non-electrolyte, $a$ ionic radii, $P$ total molecular polarisations, $\gamma$ characteristic frequencies, $\alpha$ electron polarisabilities, $v$ molecular volumes, $\epsilon$ dielectric constants, $m_i$ the electrolyte concentration in g-ions litre$^{-1}$, $l_0$ the ionic charge, $h$ Planck's constant, and $N_A$ Avogadro's number. The first term in this equation represents coulombic interaction, and the second term dispersion interaction. Only these two types of forces are considered in this theoretical approach, other components of the van der Waals forces being ignored, since calculations by Bockris and his co-workers showed them to constitute, e.g. for the tetraethylammonium ion, less than 1% of the total dispersion energy.

Results calculated from Eqn. (4) are compared with experimental data in Table 8. Bockris et al.[97] comment on the table that, in view of the approximate character of the equation, it shows a certain agreement, giving the correct sign and sequence of change. In contrast to the Debye–McAulay equation, the possibility of two effects — salting-in and salting-out — is predicted by the present equation. Thus according to the views of Bockris[97] the increase in solubility of a non-electrolyte in the presence of a salt containing large ions results from the predominance of dispersion interaction between the non-electrolyte molecule and the large ion of the salt. Similar views had been expressed earlier by Kruyt and Robinson[86], Gross[85], etc. Thus Gross writes: "The reason for aggregation about the anion is more difficult to see, at least for the simple spherical ions such as the halogens. For the complex ions it is not so difficult. An ion like the benzoate ion consists of a large non-polar phenyl group and a small polar carboxy-group. The field around such an ion is highly unsymmetrical, and water molecules can accumulate around the carboxy-group, with non-electrolyte molecules at the other end. The size of the ion, the distribution of polar portions, and the possibility of orientation inherent in the non-electrolyte molecule should result in a highly specific character in the solubility effect".

Albright and Williams[134] concluded, from a comparison of experimental results for the action of various salts on the solubility of ethyl acetate in water with values calculated by means of various equations, that salt constants calculated on the basis of electrostatic theories disagree most with experimental data, and therefore dispersion interactions must be taken into account.

Work on other lines links the action of salting-in and salting-out agents with structural changes in the solvent (water) itself. At the end of the past century Tammann[135–140] pointed out that, if a substance which dissociates into ions is dissolved in water, the water behaves as if it were under an additional pressure, and the volume of the solution decreases owing to compression of the water itself.

Using this hypothesis, Gibson[141–143] suggested an extrapolation equation representing the property of water as a function of pressure and taking into account the change in volume of pure water when a salt is dissolved in it.

TABLE 8. Comparison of experimental salting-out with values calculated from Eqn. (4).[97]

| System | $\frac{\Delta S}{S_0 m}$ coulombic | $\frac{\Delta S}{S_0 m}$ dispersion | $\frac{\Delta S}{S_0 m}$ total | $\frac{\Delta S}{S_0 m}$ expt. |
|---|---|---|---|---|
| $N(C_2H_5)_4I$–ethylene glycol–benzoic acid | —0.480 | +0.536 | +0.06 | +0.26 |

| $N(CH_3)_4I$–water–benzoic acid | —0.279 | +1.224 | +0.95 | +0.80 |
| $N(C_2H_5)_4I$–water–benzoic acid | —0.257 | +1.224 | +0.97 | +0.22 |
| $N(C_3H_7)_4I$–water–benzoic acid | —0.242 | +1.224 | +0.98 | +8.3 |
| $N(C_4H_9)_4N$–water–benzoic acid | —0.231 | +1.224 | +0.99 | +2.0 |

Euler [144-146] was the first to point out the link between the decrease in solubility of a neutral substance and the magnitude of the compression produced by the added electrolyte. He states that a certain parallelism exists between the compression of the solvent and the diminution in solubility, but no quantitative relations have yet been found. Euler then compares the surface tension of the solution with the solvent power of the salt solutions, and shows that only a qualitative relation exists between decrease in surface tension and change in solubility.

Geffcken [147] also concluded, from determinations of the solubility of $H_2$, $O_2$, $N_2O$, and $CO_2$ in aqueous acids and bases, that the cause of the decrease in solubility of the gases must be sought in compression of the water itself.

Long and McDevit [44] measured the activity coefficients of benzene in aqueous salt solutions. This non-electrolyte was chosen as having a non-polar molecule, which almost completely excludes any type of interaction between the solution components and simplifies explanation of the results. These workers obtained for univalent anions the following salting-out sequence

$$OH^- > Cl^- > Br^- > NO_3^- > ClO_4^- > I^-,$$

and for alkali-metal cations

$$Na^+ > K^+ > Li^+ > Rb^+ > Cs^+.$$

Compounds containing large ions, such as $(CH_3)_4NBr$ and $C_6H_5COOK$, increase the solubility of benzene in water. These results were explained on the basis of Tammann's views: compression of the solvent under the influence of the ions impedes entry of neutral molecules into the solution, as a result of which the solubility diminishes; and conversely, large ions loosen the structure of water and thereby facilitate dissolution of neutral molecules.

In order to assess quantitatively the action of electrolytes on the solubility of non-electrolytes, Long and McDevit [44] proposed an equation of the form

$$K_s = \lim \frac{d \ln f_s}{dC_s} = \lim \frac{v_i^0 dP_e}{RTdC_s} = \frac{v_i^0 (v_s - v_s^0)}{RT\beta_0}, \qquad (5)$$

where $v_S^0$ is the partial molar volume of the salt at infinite dilution, $C_S$ the molar concentration of the salt, $\beta_0$ the compressibility of water, $v_S$ the molar volume of the liquid salt, $v_i$ the partial molar volume of the non-electrolyte, and $P_e$ the effective pressure. The quantity $v_S$ cannot be found directly, and therefore data on compression are mostly used and the quantity $dP_e/dC_S$ is employed.

Table 9 gives a comparison of salting-out constants for benzene, hydrogen, and oxygen from aqueous solutions of various salts as calculated by means of Eqn. (5) and found experimentally. With oxygen and hydrogen satisfactory agreement is observed between calculated and experimental values of the salting-out constants, but in the case of benzene the calculated value exceeds the experimental value by factors of 2–3. It was supposed [44] that, if a correction is introduced into Eqn. (5) to allow for the closest distance of approach of an ion and a non-electrolyte molecule, the equation would become

$$\lim \frac{d \ln f_s}{dC_s} = \frac{v_i^0 (v_s - v_s^0)}{RT\beta_0} \cdot \frac{a}{a+b}, \qquad (6)$$

where $a$ and $b$ are the radii of the ion and the neutral molecule. With this correction better agreement is obtained between experiment and calculation for benzene molecules.

A characteristic feature of Eqn. (5) is its prediction of salting-in by such substances as tetramethylammonium bromide and perchloric acid. According to the equation a linear dependence of $\log f_S$ on salt concentration corresponds to a linear dependence of $P_e$ on $C_S$ (Fig. 3), and the sequence of salting-out effects of the salts is approximately the same as that of the effective pressure.

This theory is in essence the same as the view expressed earlier by Bernal and Fowler [148] that in liquid water the molecules tend to form a tetrahedral structure, with the oxygen atoms at the corners. When a substance which dissociates into ions is introduced, the water molecules begin to orient themselves around these ions. The number of water molecules surrounding an ion depends on the relative size of ion and water molecule, the charge on the ion, and hence on the force field at the surface of this ion. These factors will determine the degree of hydration of ions in aqueous solution and the extent to which the water structure is compacted or loosened.

Small ions carrying a high charge will make the water structure more rigid, produce compression of the solvent or increase its internal pressure, and thereby impede penetration of non-electrolyte molecules into the solution:

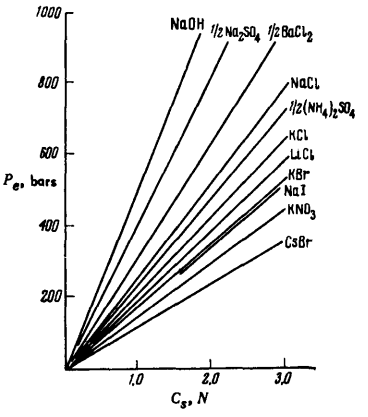

Fig. 3. Dependence of effective pressure $P_e$ on salt concentration [142,143].

they will diminish the solubility of the non-electrolyte, i.e. salt it out. Large ions having the same charge, on the other hand, will loosen the structure of water, diminish its internal pressure, and thereby favour the passage of molecules of non-electrolyte into the solution: they will salt it in.

The effect of ions on the structure of water is shown in many papers [149-159]. Gurikov [160], for example, links the salting-out action of ions with changes in the structure of water itself. The passage of water into a condensed state is accompanied by the formation of hydrogen bonds. This leads to a redistribution of electron density in the molecule and in the hydrogen bond, resulting in the appearance of a dipole possessing its own moment. In estimating the salting-out effect of electrolytes, therefore, we must take into account the structural correction produced by the action of "hydrogen dipoles" on the structure of water in the electrostatic field of the ions. The complete salting-out coefficient is made up of two terms: $K = K_S + \Delta K_S$, where $K$ is the salting-out constant calculated from Eqn. (5) and $\Delta K_S$ a structural correction which can be calculated from an equation suggested by Gurikov. Calculations made for singly charged ions give satisfactory agreement with experimental values of the salting-out constants of benzene at 20° (Table 10).

Samoilov and his coworkers [161-164] have examined the influence of the nature of the salting-out agent on the extraction of certain mineral salts from aqueous solution. The process of extraction involves complete or partial replacement of water molecules by molecules of the organic solvent. The role of the salting-out agent is in effect to facilitate this process. Regarding the thermal motion of the solvent molecules as consisting of vibrations and rotational oscillations about temporary equilibrium positions, together with intermittent displacements from one state of equilibrium to another, Samoilov considers that a molecule must have a certain activation energy in order to accomplish such a jump. This activation energy is affected by the salting-out agent, and may either decrease, which results in salting-out, or increase, which leads to salting-in.

In a study of the influence of various substances on the solubility of benzoic acid in water, alcohols, and water–alcohol mixtures [165-168] the reviewer and her collaborators have observed both salting-in and salting-out. If alkali-metal halides and perchlorates, biphenyl, phenanthrene, resorcinol, and diphenylamine are used as additives, the solubility of benzoic acid is diminished; whereas methylpyridinium, ethylpyridinium, and tetraalkylammonium iodides and urea increase the solubility of benzoic acid in water.

On the basis of these results we have put forward a hypothesis which enables the salting-in and the salting-out of non-electrolytes to be considered from a unified viewpoint. The essence of this hypothesis is that salting-in will be observed if the added solid dissolves the salted-in substance better than does the solvent (water, alcohol, or a mixture thereof) in which the solubility is determined; and conversely, if the added substance dissolves the non-electrolyte less well than does the solvent, salting-out will be observed. Similar views were put forward, but in a more general form, by Bancroft [169].

In order to test our hypothesis experimentally, we have made direct determinations of the solubility of benzoic acid in the substances added as electrolyte. Sodium and lithium chlorides, sodium iodide, lithium perchlorate, etc. do not lower the melting point of benzoic acid: i.e. they do not dissolve in it, and salt it out from any solvent (water or alcohol). Such salts as methylpyridinium and ethylpyridinium iodides and quaternary ammonium salts, which dissolve benzoic acid many times better than water, increase its solubility in water. For example, the solubility of benzoic acid in water at 100° is 0.108 mole fraction, whereas in tetraethylammonium iodide under the same conditions it is 0.680. On the other hand, these same substances salt out benzoic acid from ethanol, which, as is evident from Fig. 4, dissolves benzoic acid better than do the above electrolytes.

These results led us to study the effect of methylpyridinium, ethylpyridinium, and tetraethylammonium iodides on the solubility of benzoic acid in water–alcohol mixtures, since it should then be possible to observe the interesting phenomenon of a gradual transition from salting-out to salting-in. The experiments confirmed the correctness of this suggestion (Fig. 5). In aqueous–alcoholic solutions a change from salting-out to salting-in is observed, and in a mixture containing ~ 50% of alcohol the salt effect is zero [170-172]. Nevertheless, lithium perchlorate salts-out benzoic acid from water, alcohol, and water–alcohol mixtures (Fig. 5).

A study of the effect of electrolytes and non-electrolytes on the solubility of naphthalene in methanol has yielded similar results [173,174]. Substances which do not dissolve naphthalene (sodium iodide and bromide, lithium chloride and perchlorate, urea, etc.) salt it out from methanol. Biphenyl and phenanthrene form with naphthalene an ideal system obeying the Schröder–Le Châtelier equation, but nevertheless they salt naphthalene into methanol, since it is less soluble in this solvent than in phenanthrene and

biphenyl (Fig. 6). Benzoic acid is salted-out of methanol by these substances, because it is more soluble in methanol than in them.

Table 11 shows the effect of various substances on the solubility of naphthalene and of benzoic acid in methanol. The salting-out constant was calculated from Sechenov's equation. Experiments on the effect of biphenyl and phenanthrene on the solubility of naphthalene in methanol show that chemical interaction between these substances is not a necessary condition for a salting-in action.

# STEPWISE REACTIONS IN ELECTROCHEMICAL KINETICS

M. V. Simonova and A. L. Rotinyan

CONTENTS

I. Introduction 318

II. Fundamentals of the theory of the stepwise occurrence of electrode reactions 319

III. Criteria of the stepwise occurrence of electrode reactions 319

1. Method based on determination of heat of activation of intermediate and final stages in the electrode process 319

2. Method based on analysis of polarisation curves 320

3. Methods based on concentration relations 321

IV. Some examples of the stepwise occurrence of electrode reactions 321

1. Reactions having one slow stage 321

2. Reactions having two slow stages 322

3. Participation of hydroxide ions in electrode processes 324

4. Reactions of the oxygen electrode 326

## I. INTRODUCTION

A cathodic process is usually divided into stages — (*a*) supply of the ion to the electrode surface, (*b*) reduction of the ion, and (*c*) desorption of the reaction product or its interaction with the electrode material — and an anodic process consists correspondingly of the reverse sequence of analogous stages. The departure of the electrode potential from the equilibrium value is governed by the rate of the slowest stage.

During 1930–1933 Erdey-Grůz and Volmer[1] and also Frumkin[2] linked the polarisation accompanying the discharge and ionisation of hydrogen with the stage actually involving reduction of the ion and oxidation of a neutral atom of hydrogen.

The concept of discharge–ionisation as the slow stage proved to be extremely fruitful, and led to a theory of so-called electrochemical kinetics which in several cases provided a quantitative account of experimental results. In this theory reduction or oxidation was usually regarded as a process occurring in a single act. In other words, it was assumed that an ion undergoing reduction added on at once all the electrons required to form the final product, and that in oxidation simultaneous removal of electrons at once yielded an ion of the required valency.

Recently, however, it has become clear that this simplest form of the theory is not always consistent with the experimental data. This has led to attempts to develop

fundamental ideas, both on the lines of refining the structure of the electrical double layer and on the lines of a detailed account of the actual act of discharge or ionisation.

Following the work of Kabanov et al.[3], the act of discharge or ionisation came to be regarded quite often as a series of consecutive electrochemical reactions, the slowest of which determined the overall rate of the process.

A kinetic equation for the dependence of current density on potential is then set up on the basis of the following general principles:

(*a*) If the electrochemical stages are preceded by a rapid chemical reaction, the concentrations of the reagents are determined by means of the equilibrium constant.

(*b*) Concentrations of intermediate products formed as a result of a rapid electrochemical reaction, i.e. under equilibrium conditions, are determined by means of the Nernst equation.

(*c*) The slow electrochemical stage is described by the usual kinetic equation with the concentrations determined from (*a*) and (*b*).

(*d*) Rapid stages following the slow stage are ignored.

The present paper examines the basic assumptions of the theory of stepwise reactions and surveys critically the most characteristic cases of processes of this type.

## II. FUNDAMENTALS OF THE THEORY OF THE STEPWISE OCCURRENCE OF ELECTRODE REACTIONS

Cathodic reduction, and correspondingly anodic oxidation, are inevitably accompanied by transfer of electric charges across the electrode–electrolyte boundary. There are two possibilities:

1. Charge transfer through the electrical double layer is effected by electrons. This process occurs in a pure form during electrolysis in redox systems, e.g. $NO_3^-/NO_2^-$, $Mn^{4+}/Mn^{2+}$, $Fe^{3+}/Fe^{2+}$, etc., in which only the valency of the reactants changes, without change in phase.

2. Charge transfer is effected by ions. This case is realised, for example, during electrolysis in metal–metal ion systems, in which the ions change phase between electrode and electrolyte.

The theory is based on the proposition that, in the discharge of multivalent ions, the transfer of $n$ electrons in a single elementary act is far less probable than the transfer of the same electrons in $n$ successive one-electron stages. This principle follows from views of the analogous course of redox processes at electrodes and of homogeneous oxidation–reduction reactions[4-8].

In the case of redox electrode processes, when charge is transferred through the phase boundary by electrons, the above hypothesis has a definite basis, although in Frumkin's opinion[4] "the possibility of simultaneous transfer of two electrons cannot be excluded". Bockris[7] also supposes that, in spite of the high probability of one-electron transitions in homogeneous redox reactions, it is not yet entirely clear whether spontaneous two-electron transfers are possible. A similar view is held by Basolo and Pearson[8], who regard bivalent transfers as possible when appropriate intermediate valencies are absent from the reactants.

Thus the basic assumption of one-electron transfers is not generally accepted even for the case of charge transfer by electrons. Nor is this assumption generally accepted for ionic transfers.

In the discharge–ionisation of metals, according to Grahame[6] "electrons do not leave the metallic phase, and therefore there is no theoretical necessity to postulate a one-electron transfer". Actually, the transport of charges through the phase boundary is effected in this case by charged metal ions, interaction with electrons ensuing already in the metallic phase, where, as Bockris remarks[7,9-11], the energetically most probable result is formation not of a neutral atom but of a complex of the adsorbed ion with $n$ electrons. Thus preferential interaction with any electron in such a complex is hardly possible.

If, however, the discharge of a multivalent, e.g. an $n$-valent, ion takes place in stages, the transfer of such an ion must be preceded by electrochemical redox reactions accompanied by the transfer of electrons. The last stage of discharge remains, as before, transfer of the ion. Either electron transfer or ion transfer may be the slow stage in the process.

Although transfer of a univalent ion does require a lower activation energy than that of a multivalent ion, and as a result the stepwise process would appear to be the more probable, nevertheless the formation of ions of lower valency may prove to be energetically unfavourable, and transfer of electrons will not be achieved. In this case direct transfer of the $n$-valent ion is possible. If, however, the ion of lower valency is relatively stable in solution, occurrence of the stepwise process becomes more probable†.

## III. CRITERIA OF THE STEPWISE OCCURRENCE OF ELECTRODE REACTIONS

At the present time three methods exist for establishing the stepwise occurrence of electrode reactions, and these have been termed "criteria for the stepwise occurrence of electrode reactions". One method is based on the theory of the transition state, which enables the heats of activation of all stages in the electrode reaction to be calculated; two methods involve an analysis of the fundamental equation of electrochemical kinetics.

### 1. Method Based on Determination of Heat of Activation of Intermediate and Final Stages in the Electrode Process

Conway and Bockris[7,9,10] have used the theory of the transition state to calculate potential-energy diagrams for the transfer of an ion from solution to the crystal lattice of the metal. By means of these diagrams it is possible to determine the free energies of the particle in each of the intermediate states, and hence to establish the stage which determines the rate of the electrode reaction.

The method has been employed by these workers to examine the conditions for the electrodeposition of $Ag^+$, $Cu^{2+}$, and $Ni^{2+}$. They showed that the transfer and formation of adsorbed neutral atoms requires a greater heat of

† It is interesting that the formation with anions of complexes adsorbed on the metal surface, especially of hydroxo-complexes, often facilitates the transfer of electrons and makes a stepwise occurrence of the process possible. This case will be examined in detail later.

activation than does the formation of adsorbed ions on the metal surface; in the discharge of $Ag^+$, $Cu^{2+}$, and $Ni^{2+}$, for example, ionic transfer is effected, with adsorption on the surface in the form of adsorbed ion + $n$ electrons.

For bivalent ions direct transfer to any part of the metal surface (i.e. a process which does not include successive dehydration or an intermediate redox stage) must be difficult because of the higher heat of activation for the discharge of bivalent ions compared with univalent ions; furthermore, the hydration of bivalent ions requires a greater consumption of heat than does that of univalent ions. If, therefore, stable intermediate ions exist, a stepwise process of discharge will be more probable than discharge involving simultaneously two or more electrons.

In the discharge of copper, for example, the direct process $Cu^{2+} + 2e \rightarrow Cu$ requires a greater heat of activation than does the stepwise process $Cu^{2+} + e \rightarrow Cu^+$ and $Cu^+ + e \rightarrow Cu$, and the latter is therefore the more probable. In the case of the discharge of nickel, the stage $Ni^{2+} + e \rightarrow Ni^+$, if it does occur, must involve a higher activation barrier than does the corresponding stage for copper, since in the opinion of the above authors a stable univalent nickel ion does not exist in aqueous solution. Consequently the non-stepwise transfer of $Ni^{2+}$ is possible, characterised by a high heat of activation and a low exchange current. In the opinion of Bockris low values of $i_0$ cannot be due to difficulties in building up the metal lattice, since $i_{0,Ni}$ is abnormally low even for deposition on liquid mercury (see also Ref. 12).

## 2. Method Based on Analysis of Polarisation Curves

The main theoretical regularities enabling the stepwise transfer of electrons to be established have been formulated by Parsons[13], Vetter[14-17], Losev[18-20], Mauser[21], and others. They are formally valid both for electronic and for ionic transfer of charge. Stepwise character is revealed sufficiently clearly only by the simultaneous study of cathodic and anodic polarisation.

Let us assume that the overall electrode reaction is represented by the equation

$$\text{cathodic:} \quad S_{ox} + ne \rightarrow S_{red}, \tag{1}$$

$$\text{anodic:} \quad S_{red} - ne \rightarrow S_{ox}, \tag{2}$$

where $S_{ox}$ represents a species (ion or neutral particle) in the extreme oxidised state, and $S_{red}$ in the extreme reduced state, the remaining subscripts denoting intermediate redox states (these symbols apply throughout the paper).

If this reaction occurs in one stage, the corresponding kinetic equations, for potentials sufficiently far from the equilibrium potential, are of the usual form

$$i_c = k_-[S_{ox}]e^{-\frac{\alpha nF\varphi}{RT}}, \tag{3}$$

$$i_a = k_+[S_{red}]e^{\frac{\beta nF\varphi}{RT}}. \tag{4}$$

If, however, reactions (1) and (2) involve $n$ one-electron stages —

cathodic

$$\begin{gathered} S_{ox} + e \rightarrow S_{ox-1}, \\ S_{ox-1} + e \rightarrow S_{ox-2}, \\ \cdots\cdots\cdots \\ S_{ox-(n-1)} + e \rightarrow S_{red}, \end{gathered}$$

anodic

$$\begin{gathered} S_{red} - e \rightarrow S_{ox-(n-1)}, \\ \cdots\cdots\cdots \\ S_{ox-2} - e \rightarrow S_{ox-1}, \\ S_{ox-1} - e \rightarrow S_{ox}, \end{gathered}$$

the character of the kinetic curves will depend on the nature and sequence of these stages. Let us consider the following most characteristic cases.

($a$) Slow stage is cathodic addition of first electron or anodic detachment of last electron. The equation will be for the cathodic process

$$i_c = k_-[S_{ox}]e^{-\frac{\alpha_1 F\varphi}{RT}}, \tag{5}$$

and for the anodic process

$$i_a = k_+[S_{ox-1}]e^{\frac{\beta_1 F\varphi}{RT}}, \tag{6}$$

where $\alpha_1$ and $\beta_1$ are the transfer coefficients for the slow stage. We determine $[S_{ox-1}]$ from the Nernst equation

$$[S_{ox-1}] = k'[S_{red}]e^{\frac{(n-1)F\varphi}{RT}}. \tag{7}$$

Substitution of Eqn. (7) in (6) yields

$$i_a = k'_+[S_{red}]e^{\frac{(n-1+\beta_1)F\varphi}{RT}}. \tag{8}$$

Thus if the transfer coefficient $\beta'$

$$\beta' = n - 1 + \beta_1, \tag{9}$$

determined experimentally from the slope of the Tafel plot for the anodic process exceeds unity, while the coefficient $\alpha'$ has its normal value close to 0.5, a consecutive reaction with a slow first stage must be assumed.

($b$) Slow stage is cathodic addition of last electron or anodic detachment of first electron. It is readily shown that in this case the relations will be the opposite of those in the previous case:

$$i_c = k_-[S_{ox}]e^{-\frac{(n-1+\alpha_n)F\varphi}{RT}}, \tag{10}$$

$$i_a = k_+[S_{red}]e^{\frac{\beta_n F\varphi}{RT}}, \tag{11}$$

and the transfer coefficient $\alpha$ determined from the slope of the Tafel straight line for the cathodic process will exceed unity.

($c$) Slow stage is addition or abstraction of some intermediate electron. In this case the slow stage in cathodic and anodic processes is preceded by equilibrium electrochemical stages, and both transfer coefficients exceed unity. If, for example, the reaction takes place in $n$ stages of which the $m$th stage is slow, we have

$$i_c = k_-[S_{ox}]e^{-\frac{(m-1+\alpha_m)F\varphi}{RT}}, \tag{12}$$

$$i_a = k_+[S_{red}]e^{\frac{(n-m+\beta_m)F\varphi}{RT}}. \tag{13}$$

It is seen from Eqns. (12) and (13) that if, for example, the reaction occurs in four stages of which the third is slow, then

$$\alpha' = 3 - 1 + \alpha_m = 2 + \alpha_m,$$

and

$$\beta' = 4 - 3 + \beta_m = 1 + \beta_m.$$

It is evident from these relationships that the experimental transfer coefficients $\alpha'$ and $\beta'$ differ appreciably from one

another. However, in the particular case in which the middle stage of three is slow, it is impossible to establish from the experimental values of the transfer coefficients any differences between the stepwise and the direct course of the three-electron reaction.

(*d*) A two-stage process comprises a slow first stage followed by disproportionation:

$$S_{ox} + e \rightarrow S_{ox-1},$$
$$2S_{ox-1} \rightleftarrows S_{ox} + S_{red}.$$

The kinetic equation for the cathodic process is

$$i_c = k_-[S_{ox}]e^{-\frac{\alpha_1 F\varphi}{RT}}, \quad (14)$$

and that for the anodic process

$$i_a = k_+[S_{ox-1}]e^{\frac{\beta_1 F\varphi}{RT}} = k'[S_{ox}]^{\frac{1}{2}}[S_{red}]^{\frac{1}{2}}e^{\frac{\beta_1 F\varphi}{RT}}. \quad (15)$$

In this case the kinetic equations for both cathodic and anodic processes are of the form characteristic of one-electron reactions.

(*e*) The separate stages have comparable rates. Let us consider for simplicity the two-stage reaction

$$S_{ox} + e \underset{k_2}{\overset{k_1}{\rightleftarrows}} S_{ox-1} \qquad S_{ox-1} + e \underset{k_4}{\overset{k_3}{\rightleftarrows}} S_{red}.$$

The sum of the current densities $i_1$ and $i_2$ for each reaction gives the total current $i$, and for steady-state conditions we must have

$$i = i_1 + i_2 = 2i_1 = 2i_2 \quad (16)$$

otherwise the concentration of the intermediate product will not remain constant with time. Apart from the constancy of $[S_{ox-1}]$ with time, we must also assume the concentration of the intermediate product to be so low that its diffusion from the electrode surface can be neglected.

Let us write the kinetic equations in the form

$$i_1 = k_2[S_{ox-1}]e^{\frac{\beta_1 F\varphi}{RT}} - k_1[S_{ox}]e^{-\frac{\alpha_1 F\varphi}{RT}}, \quad (17)$$

$$i_2 = k_4[S_{red}]e^{\frac{\beta_2 F\varphi}{RT}} - k_3[S_{ox-1}]e^{-\frac{\alpha_2 F\varphi}{RT}}. \quad (18)$$

We determine the concentration of the intermediate product by Bodenstein's method of quasi-stationary concentrations:

$$\frac{d[S_{ox-1}]}{dt} = k_1[S_{ox}]e^{-\frac{\alpha_1 F\varphi}{RT}} + k_4[S_{red}]e^{\frac{\beta_2 F\varphi}{RT}} -$$
$$- k_2[S_{ox-1}]e^{\frac{\beta_1 F\varphi}{RT}} - k_3[S_{ox-1}]e^{-\frac{\alpha_2 F\varphi}{RT}} = 0,$$

whence

$$[S_{ox-1}] = \frac{k_1[S_{ox}]e^{-\frac{\alpha_1 F\varphi}{RT}} + k_4[S_{red}]e^{\frac{\beta_2 F\varphi}{RT}}}{k_2 e^{\frac{\beta_1 F\varphi}{RT}} + k_3 e^{-\frac{\alpha_2 F\varphi}{RT}}}. \quad (19)$$

On substituting for $[S_{ox-1}]$ from Eqn. (19) in (17) and (18), we obtain

$$i = 2k_1[S_{ox}]e^{-\frac{\alpha_1 F\varphi}{RT}} \frac{1 - \frac{k_2 k_4}{k_1 k_3}\frac{[S_{red}]}{[S_{ox}]}e^{\frac{2F\varphi}{RT}}}{1 + \frac{k_2}{k_3}e^{\frac{(\beta_1+\alpha_2)F\varphi}{RT}}} \equiv 2k_4[S_{red}]e^{\frac{\beta_2 F\varphi}{RT}} \frac{1 - \frac{k_1 k_3}{k_2 k_4}\frac{[S_{ox}]}{[S_{red}]}e^{-\frac{2F\varphi}{RT}}}{1 + \frac{k_2}{k_3}e^{-\frac{(\beta_1+\alpha_2)F\varphi}{RT}}}. \quad (20)$$

At sufficiently high cathodic potentials Eqn. (20) becomes

$$i_c = 2k_1[S_{red}]e^{-\frac{\alpha_1 F\varphi}{RT}} = 2i_{0,1}e^{-\frac{\alpha_1 F\Delta\varphi}{RT}}, \quad (21)$$

and at sufficiently high anodic potentials it becomes

$$i_a = 2k_4[S_{red}]e^{\frac{\beta_2 F\varphi}{RT}} = 2i_{0,2}e^{\frac{\beta_1 F\Delta\varphi}{RT}}. \quad (22)$$

Thus when the rates of the two stages are comparable, the transfer coefficients determined from Tafel straight lines for cathodic and anodic processes are not linked by the equation $\alpha + \beta = 1$, since they relate to different reactions. Furthermore, it follows from these same equations that extrapolation of these Tafel straight lines to the equilibrium potential gives different values of the exchange current for cathodic and anodic processes, since these values of $i_0$ correspond to different stages of the process.

On the basis of the above, the following criteria can be formulated for the stepwise occurrence of an electrode process: (1) the transfer coefficients determined from the slopes of the Tafel straight lines for anodic and cathodic processes have anomalous values; and (2) exchange currents determined from these straight lines have different values (for cases in which the separate stages occur at comparable rates).

### 3. Methods Based on Concentration Relations

These methods [14-17,22-27] are closely linked with the preceding methods, since they derive essentially from the same fundamental equations of electrochemical kinetics. In fact, the equations of electrochemical kinetics contain the concentrations (activities) of the reactants. Consequently the potential, overpotential, or exchange current must depend on the concentration of species taking part in the electrode reaction. The values of the partial derivatives with respect to concentration will depend on the coefficient of potential in the equation, i.e. on the number and sequence of stages and the prior occurrence of a rapid chemical reaction. Concentration criteria supplement criteria obtained from an analysis of polarisation curves. From the above equations of electrochemical kinetics we can obtain the partial derivatives

$$\left(\frac{\partial\varphi}{\partial\log[S_{ox}]}\right)_i = -\frac{2.3RT}{\alpha' F} \text{ and } \left(\frac{\partial\varphi}{\partial\log[S_{red}]}\right)_i = \frac{2.3RT}{\beta' F}.$$

Moreover, the derivative of current density with respect to the concentrations of components of the solution gives the order of reaction $\nu_i$:

$$\left(\frac{\partial\log i}{\partial\log[S_i]}\right)_\varphi = \nu_i, \quad (23)$$

which enables us to determine which substances take part in the slow stage.

In cases in which reactions occur so rapidly that polarisation curves cannot be obtained, and only exchange currents can be measured, concentration criteria provide the sole criteria of the stepwise character of reactions, as follows from the relations

$$\left(\frac{\partial\varphi_{eq}}{\partial\log i_{ox}}\right)_{S_{ox}} = \frac{2.3RT}{\beta' F}, \quad (24)$$

$$\left(\frac{\partial\varphi_{eq}}{\partial\log i_{ox}}\right)_{S_{red}} = -\frac{2.3RT}{\alpha' F}. \quad (25)$$

## IV. SOME EXAMPLES OF THE STEPWISE OCCURRENCE OF ELECTRODE REACTIONS

### 1. Reactions Having One Slow Stage

(*a*) Zn(Hg)/$Zn^{2+}$ electrode. The anodic behaviour of zinc in sulphate solutions has been investigated by Losev and his coworkers [28-35]. Application of Eqns. (24) and (25)

to the concentration relations of $i_0$ gives the transfer coefficients $\beta' = 1.40$ and $\alpha' = 0.52$: i.e. $\beta' > 1$ and $\beta' > \alpha'$, which corresponds to a case of slow detachment of the last electron in the ionisation of zinc — see Eqns. (8) and (9).

The true transfer coefficients, corresponding to the slow stage of the process, are $\alpha_2 = \alpha' = 0.52$ and $\beta_2 = \beta' - 1 = 0.40$. The possibility of the existence of the singly charged ion $Zn^+$ in aqueous solution[36-38] confirms the correctness of the above mechanism. It is therefore hardly possible to justify Gerischer's view[39,40] that, although he obtained the same values of $\alpha'$ and $\beta'$, the process was a two-electron process with $\alpha$ and $\beta$ respectively 0.3 and 0.7.

It must be noted, however, that lack of symmetry of the potential barrier is not by itself a sufficient criterion of the stepwise occurrence of a process, since reactions of the singly charged silver ion, which occur in one stage, have values of $\alpha \simeq 0.3$ and $\beta \simeq 0.7$.[41]

(*b*) In(Hg)/$In^{3+}$ electrode. Losev and his coworkers have investigated the anodic behaviour of indium in perchlorate solutions[42-46]. They obtained values for the transfer coefficients of $\beta' = 2.2$ from polarisation curves and concentration relations of the exchange current (24), and $\alpha' = 0.9$ from the concentration relations of the exchange current (25). Here $\beta' > 2$ and $\beta' > \alpha'$ — see Eqns. (8) and (9) — and therefore the anodic process can be regarded as occurring in stages. These workers consider that three stages are involved: $In - e \rightleftharpoons In^+$, $In^+ - e \rightleftharpoons In^{2+}$, and $In^{2+} - e \rightarrow In^{3+}$, the last stage being slow. The transfer coefficients for this stage are then $\alpha_3 = \alpha' = 0.9$ and $\beta_3 = \beta' - 2 = 0.2$. In this case an extremely unsymmetrical energy barrier is already obtained for the one-electron transfer.

Similar results have been obtained by other workers[47] in sulphate electrolytes at current densities below 0.001 A $\times$ $\times$ $cm^{-2}$. A more acceptable scheme is probably one involving a two-electron slow stage: $In - e \rightleftharpoons In^+$ and $In^+ - 2e \rightarrow In^{3+}$. We then have $\alpha_2 = \frac{1}{2}\alpha' = 0.45$ and $\beta_2 = \frac{1}{2}(\beta' - 1) = 0.6$.

On the basis of the results for zinc and indium, Losev and his collaborators[20,42] suggested that, with all multivalent metals, electrode processes take place in stages. They give results for transfer coefficients in the cases of copper, cadmium, iron, nickel, and cobalt. Analysis of these data shows that this hypothesis can be applied to the discharge and ionisation of copper, for example[48,49]; with cadmium there are two groups of contradictory data[50-53]; and in the case of the iron-group metals, discharge of the simple hydrated ions in a non-complexing medium, and in the absence of specific adsorption of anions, is most probably a one-stage process involving bivalent ions[7,9,10,54-58].

(*c*) $Hg/Hg(CN)_4^{2-}$ electrode. Gerischer and Perez-Fernandes[59] have investigated the reaction $Hg(CN)_4^{2-} + 2e \rightleftharpoons Hg + 4CN^-$ under conditions such that the complex $[Hg(CN)_4]^{2-}$ predominated in the solution. The slopes of the Tafel curves gave values of $\alpha' = 0.30 \pm 0.03$ and $\beta' = 1.67 \pm 0.05$. From the dependence of $i_c$ and $i_0$ on the concentrations of $CN^-$ and $Hg(CN)_4^{2-}$ it was established that the complex $[Hg(CN)_3]^-$ participates in charge transfer. Consequently the transfer reaction $Hg(CN)_3^- + 2e \rightarrow Hg + 3CN^-$ is accompanied by the chemical equilibrium $Hg(CN)_4^{2-} \rightleftharpoons Hg(CN)_3^- + CN^-$.

If, however, transfer coefficients are calculated for a simultaneous two-electron transfer, values are obtained of $\alpha < 0.2$ and $\beta > 0.8$. The possibility was therefore considered that the reaction took place in stages according to the scheme

$$Hg(CN)_3^- + e \rightleftarrows HgCN_{ads} + 2CN^-,$$
$$HgCN_{ads} + e \rightleftarrows Hg + CN^-.$$

The experimental data indicate that the first of these stages is slow. Then $\beta' = 1.67 \pm 0.05 = 1 + \beta_1$, whence $\beta_1 = 0.67 \pm 0.05$ and correspondingly $\alpha_1 = 0.30 \pm 0.03$.

The hypothesis that the transfer reaction takes place in stages has been tested by measuring the capacitance by the charging method. If the reaction occurs in stages, and the first stage is slow, a charging pulse should not only charge the double layer but also cause the establishment of a new equilibirum concentration of $HgCN_{ads}$, which is shown in an apparent increase in capacitance. The experimental relation obtained supports the accepted mechanism for the electrode reaction.

(*d*) $Ni/Ni^{2+}$ electrode. In a study of the electrolysis of nickel in chloride electrolytes containing boric acid, Fedot'ev and Dmitreshova[60] found that at 80° discharge–ionisation takes place according to the simple scheme $Ni^{2+} + 2e \rightarrow Ni$ with transfer coefficients of $\alpha = 0.4$ and $\beta = 0.6$, whereas at 25° they found that $\alpha + \beta = 1$ only when $n = 1$. On this basis a stepwise scheme $Ni^{2+} + e \rightarrow Ni^+$ and $Ni^+ + e \rightarrow Ni$ was suggested, in which one of the stages was slow. Such a suggestion can apply if the first stage is slow in both anodic and cathodic processes. Values of $\alpha + \beta = 1$ satisfy also a one-electron transfer with subsequent disproportionation $Ni^{2+} + e \rightarrow Ni^+$ and $2Ni^+ \rightleftharpoons Ni + Ni^{2+}$.

A stepwise course for the electrode process involving the $Ni^+$ ion has been suggested by several workers[61-64] who have studied the polarographic behaviour of nickel. The existence of $Ni^+$ has been demonstrated by Khlopin[65]. Nevertheless, calculations by Conway and Bockris[7,9,10], as well as several experimental results[54-56,66], justify a simple two-electron scheme for the process. However, more detailed investigations are desirable.

A stepwise mechanism can be expected for electrode reactions with all other metals where ions of lower intermediate valencies can exist in the solution. The presence of univalent states has been detected, for example, with simple ions of the metals Mg,[37,67-69] Al,[37,67,71] Be,[37,67,71] Zn, La, Ce, Ti, U, Hg, Cu, In, and Ga,[37,67] as well as with complex ions of Cr, Mn, Co, etc.[72]

## 2. Reactions Having Two Slow Stages

(*a*) Quinhydrone electrode. For the quinhydrone electrode Vetter[73] has established that the electrode reaction has different mechanisms in acid and alkaline media. On the basis of experimental results he states that the two electrons of the overall reaction are transferred successively, the rates of the two stages of the reaction being comparable.

However, examination of the experimental data in Ref. 73 reveals insufficient grounds for such a conclusion in the case of results obtained in the acid region, since the anodic Tafel line has been drawn rather arbitrarily (see Fig. 1). Even with these straight lines, values of $\beta_2 = 0.46$ and $1 - \alpha_1 = 0.54$ were obtained, which are hardly sufficient for the conclusion reached by this worker.

In the alkaline region, anodic and cathodic polarisation curves have well-defined Tafel sections with different

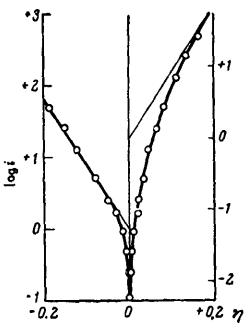

Fig. 1. Polarisation curves for the quinone–quinol system at high acidities (0.001 m quinone + 0.01 m quinol in 1 M HCl).

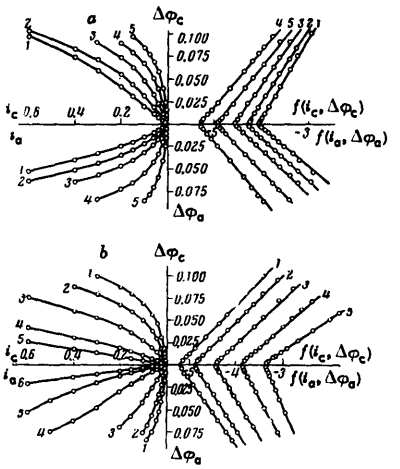

Fig. 2. Effect of pH on polarisation of cathodic and anodic processes in the quinone–quinol system in the region of:
*a*) high acidities (pH): 1) 0.48; 2) 1.07; 3) 1.52; 4) 2.01; 5) 3.01;
*b*) low acidities (pH): 1) 3.92; 2) 5.06; 3) 6.02; 4) 7.06; 5) 7.92; 6) 8.6.

slopes, of $1 - \alpha_1 = 0.37$ and $\beta_2 = 0.19$. Exchange currents determined by extrapolation of anodic and cathodic Tafel lines do not coincide. Thus the totality of experimental data not only support Vetter's theoretical conclusions, but also provide one of the very few examples of more than one slow electron transfer in the same overall reaction.

The electrochemical behaviour of the quinhydrone electrode has been investigated also by Loshkarev and his coworkers[74]. Their experimental results contradict Vetter's data, since exchange currents determined from anodic and cathodic Tafel lines coincide at all pH values (Fig. 2). According to Loshkarev and Tomilov, the slow stage is the complete electrode process involving two electrons.

Bagotskii et al.[75] have attempted to ascertain the reason for such a sharp discrepancy in the experimental data in these papers. They have shown that the results of Ref. 74 are due to the carrying out of experiments at low current densities and small polarisations, when the rate of the reverse reaction still cannot be neglected. These workers' own data are on the whole close to Vetter's results. In contrast to the latter, however, Bagotskii and his coworkers consider that the slow stage of the cathodic process in the quinone–quinol system is addition of the first electron, while that in the anodic process is abstraction of the first electron. It must be noted, however, that the experimental data obtained by Bagotskii et al. also fit a scheme in which the slow stage is addition of the first electron (and abstraction of the last) combined with rapid disproportionation. This system, too, requires further investigation.

(*b*) $Tl^{3+}/Tl^{+}$ redox electrode. Antropov and Mizgireva[76], probably the first to investigate this system, concluded that both concentration polarisation and chemical polarisation were present. In their opinion the chemical polarisation was associated not with a slow discharge–ionisation stage but with slow desorption of secondary (reduced) ions.

Vetter and Thiemke[77] have also shown that the overpotential is determined not only by a slow electrochemical reaction but also by diffusion, and therefore curves corresponding to the experimental points have no linear sections. Curves were plotted on the basis of Eqn. (20) after allowing for diffusion. Transfer coefficients were so chosen that the curves corresponded to the experimental points (Fig. 3). The values determined in this way were $\beta_2 = 0.67$ and $\alpha_1 = 0.36$. Their sum was taken as not equalling unity, although the difference was only 0.03. By means of Eqns. (21) and (22), with the values of $\beta_2$ and $\alpha_1$ substituted in them, straight lines were then plotted representing the relation between $\eta$ and $\log i$ in the absence of diffusion hindrances. Exchange currents found by extrapolation of such hypothetical straight lines were also found to be rather different (Fig. 3).

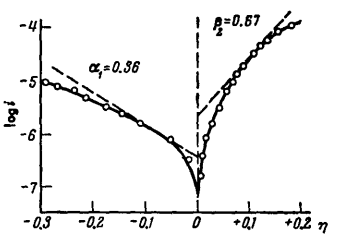

Fig. 3. Polarisation curves for the $Tl^{3+}/Tl^{+}$ system: points represent experimental data; full curves calculated from Eqn. (20) with correction for diffusion; broken lines from Eqns. (21) and (22).

It was concluded from these results that the kinetics of the process was determined by two stages

$$Tl^{+} \rightarrow Tl^{2+} + e \text{ and } Tl^{2+} \rightarrow Tl^{3+} + e.$$

It is noted in the paper that the data were processed on the hypothesis that two electrons were transferred simultaneously, and that this hypothesis is inconsistent with the experimental results.

There is an indication in the literature that the homogeneous exchange $Tl^{+}$–$Tl^{3+}$ may occur in stages with the formation of $Tl^{2+}$.[78] It has also been suggested that the reduction of $Tl^{3+}$ ions on the electrode by atomic hydrogen to $Tl^{+}$ takes place in two stages[79].

Thus the possibility of the stepwise occurrence of the electrode process is to some extent supported by hypotheses concerning the presence of $Tl^{2+}$ ions, but the experimental data reported in Ref. 77 cannot provide adequate evidence of a stepwise mechanism.

### 3. Participation of Hydroxide Ions in Electrode Processes

Anions play an important part in homogeneous redox reactions between multicharged cations in the bulk of the electrolyte, by facilitating the transfer of charge from one cation to another. Thus, for example, $Cl^{-}$ accelerates the exchange of charges between $Fe^{3+}$ and $Cr^{3+}$, an activated complex of the type $[Cr-Cl-Fe]^{4+}$ being formed in which $Cl^{-}$ acts as an "anionic bridge" for the transfer of charge[4].

Hydroxide ions have a similar effect. The participation of $OH^{-}$ ions in electrode processes in the discharge–ionisation of metals is revealed by the fact that the rate of the electrode reaction depends on the pH of the electrolyte. Here, too, hydroxide ions have an accelerating effect, the exchange of charges between the metal surface and ions in solution through the hydroxide "bridge" being made so easy that conditions are produced for the stepwise transfer of electrons in the discharge–ionisation even of such stable bivalent aquo-ions as those of the iron-group metals.

The exchange of charges is some thousandfold more rapid between $Fe(OH)^{2+}$ and $Fe^{2+}$ than between $Fe^{3+}$ and $Fe^{2+}$. Similar results are obtained in a study of the effect of pH on the rate of exchange between chromium, cerium, plutonium, and praseodymium ions of different degrees of oxidation, as well as on the rate of oxidation of $U^{4+}$ by $Tl^{3+}$ and $Fe^{3+}$ ions, and of $Cr^{2+}$ by $[CoH_2O(NH_3)_5]^{3+}$ ions[4,80].

The kinetics of the elementary electrochemical act depends in general on the potential difference at the electrode–solution interface, the reactant concentrations at the electrode surface, and the strength of the bonds which are ruptured or formed on participation of the reactant species in the electrode process. Therefore the catalytic action of $OH^{-}$ ions in the formation of active complexes of the reactant species with these ions can be explained by the fact that they produce changes both in the total charge on the reactant species and in its electronic structure[4].

Let us examine the effect of hydroxide ions on the electrode process with a few metal electrodes as examples.

(*a*) $Fe/Fe^{2+}$ electrode. Study of the part played by hydroxide ions in the anodic dissolution of iron in alkaline solutions, undertaken by Kabanov and others[3,81], established that the rate of anodic dissolution is far greater in alkaline than in acid solutions, $i_a$ being proportional to $[OH^{-}]^2$. An electrochemically active layer of adsorbed product is present on the electrode surface, and produces unusually high values for the capacitance of the double layer (of the order of 1500 $\mu F\ cm^{-2}$). The results were explained on the basis of the stepwise mechanism of the electrode process involving $OH^{-}$ ions

$$Fe + OH^{-} \rightleftarrows FeOH_{ads} + e,$$
$$FeOH_{ads} + OH^{-} \rightarrow FeO_{ads} + H_2O + e \text{ (slow stage)},$$
$$FeO_{ads} + OH^{-} \rightleftarrows HFeO_2^{-},$$
$$HFeO_2^{-} + H_2O \rightleftarrows Fe(OH)_2 + OH^{-}.$$

The corresponding kinetic equation is

$$i_a = k_1 [FeOH]_{ads} [OH^{-}] e^{\frac{\beta F\varphi}{RT}} = k_2 [OH^{-}]^2 e^{\frac{(1+\beta)F\varphi}{RT}}. \quad (26)$$

With $\beta = 0.5$, the slope of the Tafel straight line is $2RT/3F$, as has been obtained experimentally.

Bonhoeffer and Heusler[82,83] found that the rate of anodic dissolution of very pure iron in perchloric and sulphuric acids (under conditions of constant corrosion, when $\varphi_{eq}$ is independent of pH) depends on the pH, the relation being the same for acid and alkaline solutions when the process occurs under steady-state conditions. The high values obtained for the capacitance from galvanostatic charging curves could also be explained by the presence of an active layer of an intermediate product. These results indicate that hydroxide ions take part in the electrode process in acid solutions, and, because of the better adsorbability of hydroxide ions, displacement of the equilibrium $H_2O \rightleftharpoons H^{+} + OH^{-}$ in the catholyte can ensure an $OH^{-}$ concentration sufficient to have a catalytic effect. These workers determined the orders of reaction — see Eqn. (23) — from the $OH^{-}$ concentration for the non-stationary process ($\nu_{OH^-} = 1$) and the steady-state process ($\nu_{OH^-} = 2$, compared with an experimental value of 1.55) in the anodic dissolution of iron. Determination of the slopes of the Tafel lines gave $b_a$ (non-stationary) = 0.063 V and $b_a$ (stationary) = 0.030 V, which formed the basis for the following scheme for the process

$$Fe + OH^{-} \rightleftarrows FeOH_{ads} + e,$$
$$Fe + OH^{-} + FeOH_{ads} \rightarrow FeOH^{+} + FeOH_{ads} + 2e \text{ (slow stage)}.$$

The corresponding kinetic equation is written

$$i_{a,stat} = k_{+} [OH^{-}]^2 e^{\frac{(1+2\beta)F\varphi}{RT}}, \quad (27)$$

where $\beta = 0.46$ (determined from the non-stationary polarisation curve).

It was suggested that the cathodic deposition of iron takes place in a similar manner, formation of the surface catalyst being associated with the chemical equilibrium $Fe^{2+}.aq + OH^{-} \rightleftharpoons FeOH^{+} + aq$. This is followed by the discharge of $FeOH^{+}$ with formation of the catalyst: $FeOH^{+} + e \rightleftharpoons \rightleftharpoons FeOH_{ads}$. The slow stage is

$$FeOH^{+} + FeOH_{ads} + 2e \rightarrow Fe + OH^{-} + FeOH_{ads},$$

which corresponds to the kinetic equation

$$i_{c,stat} = k_{-} [OH^{-}]^2 [Fe^{2+}]^2 e^{-\frac{(2\alpha+1)F\varphi}{RT}}. \quad (27a)$$

With $\alpha = 1 - \beta = 0.54$, the slope of the Tafel straight line should be $\sim 0.028$ V.

Similar values, of 0.027–0.030 V, were found for the slopes $b_a$ and $b_c$ by Hurlen and Hoar[84–87] in a study of the kinetics of the discharge–ionisation of iron in sulphate and chloride solutions, using a slow galvanostatic method with determination of current efficiencies and construction of partial polarisation curves for iron and hydrogen.

However, according to these results, the rate of the cathodic deposition and anodic dissolution of iron is proportional to the hydroxide-ion concentration to the first power, not the second as required by Eqns. (26) and (27). The cathodic reaction is of the second order with respect to $[Fe^{2+}]$. The combined effect of the data is to give a scheme for the process involving two atoms (or ions) of iron and four electrons in the rate-determining stage

$$2\,Fe + OH^- \rightarrow 2\,Fe^{2+} + OH^- + 4e.$$

Hurlen[85,86] suggested that this process can occur in stages, but his proposed reactions correspond not to successive stages of one process but to two independent modes of oxidation of iron

$$Fe + OH^- \rightleftarrows \text{active complex A} \rightleftarrows Fe^{2+} + OH^- + 2e,$$
$$Fe + H_2O \rightleftarrows \text{active complex B} \rightleftarrows Fe^{2+} + H_2O + 2e.$$

Thus if the process does occur in stages, they comprise different reactions.

Ivanov and Iofa[58] have shown that at a dropping mercury electrode the rate of reduction of iron actually depends on the relative proportions of the complexes A′ and B′, which themselves depend on the pH of the solution.

$$\underset{B'}{[Fe(H_2O)_n]^{2+}} + H_2O \rightleftarrows \underset{A'}{[FeOH(H_2O)_{n-x}]^+} + H^+ + x\,H_2O.$$

At low pH values the kinetics of the process is determined by discharge of the ion B′, whereas with rise in pH the equilibrium shifts towards the formation of A′, and the rate of the process is determined by the stage

$$[FeOH(H_2O)_{n-x}]^+ + 2e \rightarrow Fe + OH^- + (n-x)\,H_2O.$$

Unfortunately, the paper does not give results for the determination of $b_c$ and $\alpha$.

Bockris et al.[88] have put forward the hypothesis that the difference in activation energy between the different paths for the electrode reaction is extraordinarily small in the case of iron, and therefore even a slight change in the conditions of electrolysis may change the mechanism of the electrode process.

(*b*) Ni/$Ni^{2+}$ electrode. The effect of hydroxide ions on the anodic dissolution of nickel has been studied by Hollnagel and Landsberg[89] using a non-stationary galvanostatic method at 60°. They find that the anodic potential decreases with increase in pH. These workers assume that the adsorption of hydroxide ions facilitates the escape of nickel ions through the intermediate formation of NiOH, in an analogous manner to Heusler's scheme[83] for iron.

Solov'eva and Abrarov[90] investigated the effect of solution pH on the electrodeposition of nickel and cobalt at constant current density. They noted a sharp decrease in cathodic potential within a definite narrow pH range, which was explained by the conversion of aquo-complexes of the metal ions into partly hydrolysed active complexes containing the $OH^-$ group.

The same workers reached a similar conclusion concerning the dependence of the kinetics of discharge on changes in the composition of the species undergoing discharge on studying the effect of boric acid on the discharge of cobalt and nickel[91], as did also Kovalenko and Nadezhdina[92] from an investigation of the effect of various complexing agents on the discharge of aquo-ions of nickel and cobalt at a dropping mercury cathode.

Matulis and Slizhys[93] concluded, from a study of the effect of catholyte pH on the cathodic process in a nickel sulphate electrolyte, that the sharp decrease in cathode potential at $pH_S \simeq 4$ is due to the discharge of $NiOH^+$ ions which are formed in the bulk of the solution at pH 4 as a result of hydrolysis

$$Ni^{2+} + OH^- \rightleftarrows NiOH^+.$$

At pH ⩾ 4 a stepwise process is assumed with formation of a neutral species

$$NiOH^+ + e \rightarrow NiOH_{ads}.$$

The following stage is desorption of hydrogen evolved simultaneously on the metal surface

$$NiH_{ads} + NiOH_{ads} \rightleftarrows Ni + H_2O.$$

In the more acid region the process of discharge corresponds to the simple scheme

$$Ni^{2+} + 2e \rightarrow Ni.$$

(*c*) $Co/Co^{2+}$ electrode. Kravtsov and his coworkers[94,95] have suggested a possible mechanism, involving hydroxide ions, for the discharge of cobalt ions at an electrode. An oscillographic method was used to obtain cathodic polarisation curves at pH 3.5 and 4.2 [95] in 1 *N* $CoSO_4 + H_3BO_3$ solutions at room temperature, as well as stationary and non-stationary anodic curves under these conditions.

The values obtained for $b_a$ of 0.064 and 0.040 V under non-stationary and stationary conditions respectively suggest that the mechanism of the anodic dissolution of cobalt resembles that proposed by Heusler for iron[83]. It was also suggested that the two electrons involved in the anodic reaction are split off successively, not in a single act, which is consistent with the large slopes of $b_c$ = 0.111–0.114 V obtained for the cathodic curves and the low values of $b_a$.

The rates of corrosion and of anodic dissolution of cobalt have been studied as a function of pH over a wide range of the latter by Iofa and Wei Pao-ming[96]. The values of $b_a$ = 0.026 V and $\nu_{OH^-} = 2$ obtained experimentally correspond to the mechanism of the anodic dissolution of iron described in Refs. 81–83.

Heusler has investigated[97,98] the effect of the acidity of the solution on the mechanism of anodic and cathodic processes in the discharge–ionisation of cobalt from perchlorate solutions. His experimental results corresponded to the scheme which he had suggested for iron[83].

The effect of pH on the cathodic deposition of cobalt from sulphate solutions at 55° has been investigated with simultaneous measurement of the pH of the catholyte[57]. The totality of experimental data[57] obtained for the partial polarisation curves of cobalt in the $pH_S$ range (in the catholyte) of 0.5–2.2 ($b_c$ = -0.085 V, $\nu_{OH^-} = 0$, and $\nu_{Co^{2+}} = 1$) shows that the discharge of cobalt takes place according to the simple two-electron scheme

$$Co^{2+} + 2e \rightarrow Co.$$

In the $pH_S$ range 2.5–4.0 an increase in $b_c$ from 0.085 to 0.150 V is observed on a negatively charged surface, which can be explained by partial hydrolysis of the aquo-ions of cobalt according to the equation

$$Co^{2+} + H_2O \rightleftarrows CoOH^+ + H^+,$$

with simultaneous participation of the ions $Co^{2+}$ and $CoOH^+$ in the electrode process. Increase in pH is accompanied

by displacement of the equilibrium towards formation of $CoOH^+$, and discharge takes place in the stages

$$CoOH^+ + e \rightarrow CoOH \text{ (slow stage)},$$
$$CoOH + e \rightleftarrows Co + OH^-,$$

which is consistent with Kravtsov's experimental results[95]. In this same pH range the discharge of cobalt occurs on a positively charged electrode surface (zero-charge potential about -0.45 V), where the experimental values of $b_c = -0.026$ V, $\nu_{Co^{2+}} = 2$, and $\nu_{OH^-} = 1$ correspond to an overall reaction involving four electrons, analogous to the scheme suggested by Hurlen and Hoar[84-87] for iron:

$$2Co^{3+} + OH^- + 4e \rightarrow 2Co + OH^-,$$

$$i_c = k[Co^{3+}]^2[OH^-]e^{-\frac{\alpha' F\varphi}{RT}}. \quad (28)$$

Such a process may be supposed to occur in one stage if the species transferring the charge is assumed to be the complex $[Co_2OH]^{3+}$. In this case the transfer coefficients $\alpha' = 2.5$ and $\beta' = 1.5$ [55,95] (value of $\beta'$ taken from Ref. 55 is 1.4 at 60°) are regarded as $\alpha' = 4\alpha$ ($\alpha = 0.62$) and $\beta' = 4\beta$ ($\beta = 0.38$). However, the high activation energy required for the transfer of a triply charged species, and also the possibility of the transfer of electrons from the cathode surface through a hydroxyl "bridge", suggest that the process takes place in stages, with the following possibilities:

I. $$Co^{3+} + H_2O \rightleftarrows CoOH^+ + H^+, \quad (a)$$

$$CoOH^+ + e \rightleftarrows CoOH \text{ rapid}, \quad (b)$$

$$\underbrace{CoOH + Co^{3+}}_{Co_2OH^{3+}} + 3e \rightarrow 2Co + OH^- \text{ slow}. \quad (c)$$

In this case $\alpha' = 1 + 3\alpha$ ($\alpha = 0.5$) and $\beta' = 3\beta$ ($\beta = 0.5$).

II. Stages ($a$) and ($b$) remain as before, but subsequent electrons are also added on successively:

$$CoOH + Co^{3+} + e \rightleftarrows Co_2OH^+ \text{ rapid},$$
$$Co_2OH^+ + e \rightarrow Co_2OH \text{ slow},$$
$$Co_2OH + e \rightleftarrows 2Co + OH^- \text{ rapid}.$$

The experimental values of $\alpha'$ and $\beta'$ correspond to slow addition of the third electron — see Eqn. (16). In fact, with $n = 4$ and $m = 3$, $\alpha' = \alpha_3 + 3 - 1 = \alpha_3 + 2$ ($\alpha_3 = 0.5$) and $\beta' = \beta_3 + 4 - 3 = \beta_3 + 1$ ($\beta_3 = 0.5$).

In order to choose between the possibilities suggested, it is necessary to obtain additional data on the intermediate products involved in the electrode process.

It must be noted that the reaction order with respect to hydroxide ions of $\nu_{OH^-} = 1$, which determines the mechanism of the electrode process (see, for example, Heusler's scheme[83,97], where $\nu_{OH^-} = 2$) is obtained only when the pH adjacent to the cathode is taken into account. Relations based on the pH in the bulk of the solution give values of $\nu_{OH^-} \simeq 2$. This illustrates the necessity of measuring pH in the layer adjacent to the electrode, and taking this quantity into account in investigating the mechanism of electrode reactions.

($d$) In(Hg)/$In^{3+}$ electrode. The pH dependence of the electrode process has been investigated by Losev and Molodov[44]. At $HClO_4$ concentrations below 0.1 M the rate of anodic dissolution of indium is proportional to the hydroxide-concentration to the first power, and the process is described by the equation

$$i_a = k[In][OH^-]e^{\frac{\beta' F\varphi}{RT}} \text{ (where } \beta' = 2.2).$$

The overall process is

$$In + 5H_2O + OH^- \rightleftarrows In(H_2O)_5OH^{2+} + 3e.$$

The possibility of stepwise occurrence of this process has been discussed above. Cathodic and anodic polarisation curves obtained at various pH values in this work are reproduced in Fig. 4. The unusually steep slope of the cathodic curves was explained as due to a prior chemical stage of hydrolysis, and the decrease in slope with increase in cathode potential as due to acceleration of this reaction.

However, curves of this type can be explained by a change in the charge on the cathode surface. In fact, the zero-charge potential for indium amalgam (~ 0.1 at. %) calculated by Antropov's method[99] gives a value of about -0.4 V (zero-charge potential for indium taken from Ref. 100), which corresponds to a potential region in which the polarisation curves slope steeply. Consequently the more gently sloping linear section at potentials between -0.6 and -0.8 V on the cathodic curves corresponds to the discharge of indium ions on a negatively charged surface. The slope of this section is ~ 0.14 V, which gives a transfer coefficient $\alpha'$ of around 0.4. Such kinetic parameters may correspond to a slow stage involving addition of an electron to the $In^{3+}$ ion, while determination of the order of reaction with respect to hydroxide ions may show whether indium ions exist in the form of aquo-complexes or partly hydrolysed complexes.

## 4. Reactions of the Oxygen Electrode

The great practical importance of electrode reactions involving oxygen has given rise to several investigations of their mechanism. The overall four-electron process undoubtedly comprises a series of stages. In this case the presence of at least one intermediate product — hydrogen peroxide — has been firmly established experimentally both in the cathodic reduction of oxygen molecules and in the anodic oxidation of water molecules or hydroxide ions[101].

Investigation of the electrochemical reactions of oxygen is complicated by oxidation of the electrode surface, not only in the course of anodic evolution but in several cases even during the cathodic reduction of $O_2$ molecules[102]. As a result, the mechanism may differ on different electrodes.

Krasil'shchikov[102] established that the cathodic reduction of oxygen on silver and gold electrodes in acid medium takes place according to the scheme

$$O_2 + e \rightarrow O_2^- \text{ (slow stage)},$$
$$O_2^- + H^+ \rightleftarrows HO_2,$$
$$HO_2 + e \rightleftarrows HO_2^-,$$
$$HO_2^- + H^+ \rightleftarrows H_2O_2.$$

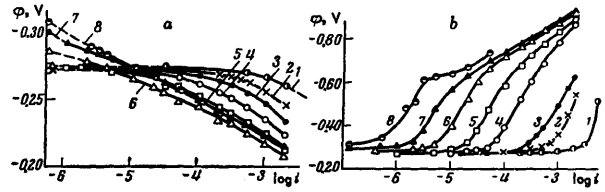

Fig. 4. Dependence of: $a$) anodic; $b$) cathodic polarisation curves for indium on acidity of electrolyte ($HClO_4$, M): 1) 0.002 ($a$) and 0.00095 ($b$); 2) 0.0077; 3) 0.016; 4) 0.05; 5) 0.1; 6) 0.5; 7) 1.3; 8) 3.3.

According to Krasil'shchikov's results, the slow stage is the same in alkaline medium as in acid solutions. Bagotskii and Yablokova [103] accept the above scheme for acid solutions, but suggest a different mechanism for alkaline solutions, at any rate on a mercury electrode, because in this case the reduction of oxygen takes place under nearly equilibrium conditions.

In the anodic evolution of oxygen all electrodes are oxidised, so that the process actually takes place on an oxidised surface. Depending on the electrode potential (current density), either chemisorbed layers can be formed in which the metal–oxygen bonding energy varies with time, or oxides of different compositions as separate phases. Their participation in the electrode process has been discussed many times in the literature (e.g. Ref. 104).

Krasil'shchikov [105] regards the following scheme

$$OH^- - e \rightleftarrows OH,$$
$$OH + OH^- \rightleftarrows H_2O + O^-,$$
$$O^- - e \rightarrow O \text{ (slow stage)},$$

as valid for oxygen evolution from alkaline solutions on nickel and cobalt. Kheifets and Rivlin [106] suggest for acid solutions a mechanism including two-electron stages. Other views have also been held on the mechanism of oxygen evolution [11]. It is significant that they all start from the assumption that the overall reaction consists of several stages.

---o0o---

Examination of the above results undoubtedly shows that the concept of stepwise (consecutive) electrochemical reactions has in several cases opened up new possibilities in the theory of the slow discharge of ions and has permitted a deeper insight into the mechanism of electrode processes. However, the view that a many-electron reaction must necessarily involve a series of successive one-electron stages is not justified. Actually, non-stepwise reactions and reactions having two-electron intermediate stages are also observed.

Published data do not always provide convincing evidence of the stepwise character of processes. If we ignore papers in which the conclusions of the authors are supported neither by their own experimental results, nor by later publications, there still remain a large number of cases in which the experimental results are quite contradictory, and not always sufficient for a definite conclusion to be reached. Furthermore, the electrochemical criteria themselves are such that it is not always possible to use them to substantiate details of the mechanism of a process. However, this must not be regarded as a rejection of the whole idea of successive stages. In several cases the stepwise occurrence of electrochemical reactions has been demonstrated convincingly, as in the electrode reactions of oxygen (see above), the anodic production of peroxodisulphuric acid [101] and of the higher oxygen compounds of chlorine [107,108], a considerable number of processes involving the oxidation or reduction of organic compounds [109], the reduction of nitric acid [109], etc.
