VI. Some questions connected with the mechanism of oxidative ammonolysis of organic compounds 661

## I. INTRODUCTION

Oxidative ammonolysis is a new catalytic process that combines the reactions of oxidation and ammonolysis. Each of these catalytic reactions has long attracted attention as very suitable for the technological design of methods of synthesising oxygen- and nitrogen-containing compounds; in these processes cheap raw materials, such as atmospheric oxygen and ammonia, may be used.

Catalytic oxidation of organic compounds was used as early as at the beginning of the twentieth century for the preparation of phthalic anhydride, anthraquinone, maleic anhydride and formaldehyde[1,2]. The replacement of expensive oxidising agents by air in the synthesis of these products was economically favourable; for this reason, a large number of papers appeared which described attempts to extent this method of synthesis to more and more organic compounds of different types. Apart from the development of new oxidative processes that found use in industry[3-10], much information was obtained on the mechanism of the reactions occurring. In particular it was shown that catalytic oxidation on oxide catalysts proceeds by a radical mechanism through a large number of intermediate stages comprising parallel and successive oxidations of the initial products and of stable and unstable intermediate products[11-15].

The catalytic ammonolysis of organic compounds has been less studied, but in this field, too, there is a fairly extensive literature[16-38]. As Andrussov showed, nitriles can be obtained directly from hydrocarbons by this reaction[39]. Catalytic ammonolysis of saturated hydrocarbons is effected in the vapour phase, as a rule, on oxide catalysts[28,29,40,41]; in contrast to the oxidation, it requires higher temperatures (500–1000°) and the yield of desired products (nitriles) generally does not exceed 20–25%. Ammonolysis of alkenes proceeds under somewhat milder conditions (400–600°)[32,42-44], but here the yield of nitriles is also low (up to 50%). The yield of nitriles is higher (up to 90%) in the ammonolysis of carboxylic acids under comparatively mild conditions[45], when the reaction may be carried out in the liquid phase in the presence of homogeneous and heterogeneous catalysts; the yield is not low even in the absence of a catalyst[45].

If ammonia is introduced into the reaction zone during the catalytic oxidation of naphthalene, phthalimide is formed in up to 50% yield instead of phthalic anhydride[47]. In the 1950's Erchak and Cosby and coworkers[48,50], and also Klimatis and Rasmussen[51,52] observed the formation of nitriles in the catalytic oxidation of alkenes, naphthene hydrocarbons, and alkylbenzenes in the presence of ammonia. Similar observations were made in the oxidation of pyridine homologues[53]. Oxides and salts of metals activated with carbon, silica gel, etc. were recommended as catalysts; the reaction could also be carried out without a catalyst. The yields of the corresponding aliphatic and aromatic nitriles never exceeded 50%, that is, they were the same as in catalytic ammonolysis.

On the other hand nitrogen-containing products were not observed when hydrocarbons, including *p*-cymene and cumene, were oxidised in the vapour phase[54,55].

Thus, up to 1950, there were only scattered observations indicating the possibility of preparing nitrogen-containing products by the catalytic oxidation of hydrocarbons in the presence of ammonia. However, there was no information in the literature on the mechanism of the reactions or on the part played by oxygen, ammonia, and catalysts in the process.

Systematic investigation of the catalytic oxidation of organic compounds of different classes in the presence of ammonia began only in the 1950's.[56-62] Experimental results showed that, when oxygen and ammonia are present simultaneously in the reaction zone, very complex parallel and successive coupled oxidations and ammonolyses of both the hydrocarbons and intermediate products occur. Oxidation takes a leading part in the process; because it proceeds by chain reactions, stable and unstable intermediates (free radicals, aldehydes, acids, etc.) that react readily with ammonia are accumulated. On the other hand, under the conditions of catalytic oxidation, ammonia too is easily converted into more active products, such as hydrazine and free radicals, which can react with hydrocarbons and intermediate products of their oxidation.

From such an interpretation of the mechanism of this complex process it received the name oxidative ammonolysis[57-59]. In recent years in non-Soviet literature the similar term "ammoxydation" has appeared[63,64] and the term "cyanodemethylation" has been used for a special case[65].

Oxidative ammonolysis is said to be used on an industrial scale for the preparation of acrylonitrile[66].

## II. OXIDATIVE AMMONOLYSIS OF AROMATIC HYDROCARBONS

As mentioned above, catalytic oxidation in the presence of ammonia in the aromatic series was first carried out by Wohl[47]. Using fused vanadium(V) oxide as a catalyst, he obtained phthalimide from naphthalene in 50% yield. Later it was shown that, under conditions of oxidative ammonolysis, naphthalene can also be converted into the *o*-phthalodinitrile. According to patent information[67], phthalodinitrile is formed in 88% yield (based on starting material)

when a catalyst of vanadium(V) oxide precipitated on aluminium oxide is used together with a naphthalene : ammonia : oxygen molar ratio of 1 : (4–20) : (9–40) at a reaction temperature of ~425°. In addition to vanadium(V) oxide, the reaction is catalysed by the oxides of molybdenum, chromium, cobalt, iron, manganese, copper, tin, tungsten, thorium, aluminium, and uranium. Air may be used instead of oxygen.

A method has also been proposed for the synthesis of benzonitrile from naphthalene[68,69]. The process is effected in two stages. In the first, naphthalene is oxidised to phthalic anhydride in the absence of ammonia on a vanadium oxide catalyst promoted by potassium sulphate. Ammonia (3–5 moles per mole of naphthalene) is added to the hot gases issuing from the convertor and they are passed over porous silica gel at 390–430° in a second reactor. The yield of benzonitrile is ~70%.

Benzonitrile is more conveniently synthesised by the oxidative ammonolysis of monoalkylbenzenes.

Toluene can be converted into benzonitrile by the action of air and ammonia over a wide range of conditions and on a variety of catalysts. At 480–550° the reaction goes even on silicon oxide and aluminium oxide or on activated carbon, but the yield of benzonitrile is then low[51,52]. Catalysts consisting of oxides of metals of variable valency are much more active. Moreover, they enable the reaction to be carried out at lower optimal temperatures, and, as a result, the proportion of pyrolysis by-products is reduced. For example, on a catalyst of oxides of vanadium, molybdenum, and phosphorus in the proportions 11.4 : 3.9 : 0.034 and with a feed of 2 moles of ammonia and 75 moles of air per mole of toluene and a temperature range of 430–450°, benzonitrile was obtained in 75 mole % yield; the total conversion of starting material was 95%.[50] Satisfactory results were also obtained with vanadium(V) oxide precipitated on alumina[70] or on aluminium oxide that had been heated to 1250°.[60,61] However, the best catalysts appear to be tin and titanium vanadates, on which the yield of benzonitrile reaches 89–90% of the theoretical based on toluene taken[71,73]. It is recommended that 6–10 moles of ammonia and 50–60 moles of oxygen (as air) should be used per mole of hydrocarbon.

The introduction of chlorine atoms into the aromatic nucleus appears to complicate the conversion of the methyl group into a nitrile group; according to Koopman[74,75], 2,6-dichlorotoluene gives the dichlorobenzonitrile in only 45–50% yield.

Tin and titanium vanadates may also be recommended for the preparation of benzonitrile from other monoalkylbenzenes. On a vanadium oxide catalyst ethylbenzene is converted into benzonitrile in only 53% yield[60,61], but on tin vanadate the reaction goes practically completely (93–96%)[71,73]. Cumene behaves in the same way; the yield of benzonitrile from it reaches 98%.[71,73] When n-propyl- and n-butyl-benzenes are used, the yield of benzonitrile is somewhat lower; phthalimide[73] in 15% yield is one of the products of oxidative ammonolysis of these hydrocarbons. Commercial mixtures of monoalkylbenzenes containing ethyl-, propyl-, and butyl-benzenes, which are difficult to separate, are also used for the preparation of benzonitrile. As a result of the oxidative ammonolysis of these so-called "polyalkyls", which are by-products of ethylbenzene and cumene production, benzonitrile is formed at the rate of 700–750 g per kilogramme of starting material[71,73]. It should be mentioned that, with other optimal conditions, the concentration of oxygen in the reaction gases has the greatest effect on the yield of benzonitrile from monoalkylbenzenes (Fig. 1)[73].

Great attention has been paid to the oxidative ammonolysis of *p*- and *m*-xylenes. Hydrogenation of the terephthalodinitrile and isophthalodinitrile formed gives *p*- and *m*-xylylenediamine[76–79], which are used as raw materials in the preparation of a variety of polyamides with melting points up to 300° and higher[80–83], and this has attracted the attention of research workers. Moreover, these aromatic dinitriles may be hydrolysed to free terephthalic and isophthalic acids or to various intermediate products with mixed functions[84,85].

A patent of Cosby and Erchak[50] shows that a mixed catalyst of oxides of vanadium, molybdenum, and phosphorus does not make the process selective enough; as a result oxidative ammonolysis of *p*-xylene on this catalyst gives *p*-toluonitrile and terephthalodinitrile at the same time, each in yield of not more than 25–26%.

By analogy with the monoalkylbenzenes the oxidative ammonolysis of *p*-xylene proceeds smoothly on fused tin vanadate[86]. It is characteristic that on this catalyst the degree of conversion of *p*-xylene can be controlled by changing the ratio of the components of the initial reaction mixture, the contact time and the reaction temperature. For example, at 330–350° with comparatively small feeds of air and ammonia the predominating reaction products are *p*-toluamide and *p*-toluonitrile, formed in yields of 15% and 55% respectively[87]. Under more drastic conditions terephthalodinitrile is obtained in 70–75% yield as the main product[56]. Still greater selectivity is shown by fused titanium vanadate and coprecipitated aluminovanadium catalyst, the use of which gives terephthalodinitrile practically free from *p*-toluonitrile and amide impurities[86]. Tin and titanium vanadates may be used not only in the fused state but also deposited on aluminium oxide[88,89].

The oxidative ammonolysis of *p*-xylene depends not only on the composition of the active phase of the catalyst, but also on the nature and method of preparation of the carrier. Hadley and coworkers, who studied the oxidative ammonolysis of alkylbenzenes on a catalyst of vanadium(V) oxide precipitated on aluminium oxide, found that the temperature used in the preliminary heating of the $Al_2O_3$ has a great effect on the yield of nitriles[61,64,90–92]. As Table 1 shows, the most satisfactory results were obtained with a catalyst the carrier of which had been roasted at 1250–1300°. Several catalysts based on aluminium oxide prepared in this way were obtained and by means of them

Fig. 1. Fig. 2. Effect of thermal treatment of catalyst on the yield of terephthalodinitrile in the oxidative ammonolysis of *p*-xylene with a catalyst of vanadium oxides on aluminium oxide[94]. *p*-Xylene : $NH_3$ : $O_2$ = 1 : 4 : 13, contact time 3 s. *A*) Yield of reaction products, %; *B*) reaction temperature, °C. Roasting temperature of catalyst: 1) without roasting; 2) 500°; 3) 600°; 4) 700°.

terephthalodinitrile could be prepared in yields of 80% and more[88,93,94]. These workers also note that the thermal treatment of the finished catalyst is of great importance[94]. For example, increasing the roasting temperature of the catalyst does not affect the yield of terephthalodinitrile, but it extends the limits of the optimum temperature range of the reaction and moves it into a region of higher temperatures (Fig. 2).

Recently several publications have appeared on the oxidative ammonolysis of *p*-xylene with the use of dust catalysts[95,96]. This variation does not materially change other parameters of the process and has little effect on the yield of reaction products, although in one of the patents it is pointed out that the use of a fluid process makes it possible to reduce the consumption of ammonia to 3 moles per mole of xylene[95].

It has been proposed that water vapour should be introduced into the reaction zone with the object of increasing the yield of terephthalodinitrile, extending the optimum temperature range, and suppressing deep oxidation processes[56,86]. The effect of changes in the water feed on the enumerated characteristics of the process is shown in Fig. 3.

In addition to *p*-xylene, other *p*-dialkylbenzenes may be used as raw materials in the synthesis of terephthalodinitrile. Investigation of the oxidative ammonolysis

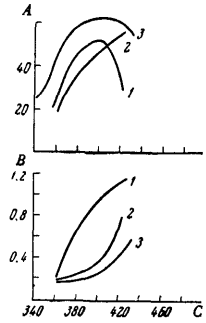

Fig. 3. Effect of quantity of water on the oxidative ammonolysis of *p*-xylene on tin vanadate[98]. $V_{hydrocarbon}$ = 50–52 g; $V_{air}$ = 2400 litres; $V_{NH_3}$ = 150–180 g per litre of catalyst per hour; contact time 0.4–0.6 s. *A*) Yield of terephthalodinitrile, %; *B*) yield of $CO_2$ in moles per mole of xylene; *C*) reaction temperature, °C. $H_2O$ (g): 1) 35; 2) 400; 3) 800 per × × litre of catalyst per hour.

of *p*-cymene[56,89], and of diethyl- and diisopropyl-benzene[59,94,97] has shown that the dinitrile may be obtained from them in 45 to 60% yield and only traces of the nitriles of the corresponding alkylbenzoic acids are formed.

In oxidative ammonolysis *m*-xylene behaves in the same way as *p*-xylene[64,98–101]. The process is usually carried out under analogous conditions with the same catalysts. The only difference is that the yield of isophthalodinitrile, and particularly of *m*-toluonitrile, is somewhat lower than in the case of the *p*-isomers. Attempts to increase the yield of these nitriles by varying the reaction conditions, or by using new types of catalysts and carriers, for example, platinum on oxides of the heavy metals and vanadium(V) oxide on silicon carbide, did not lead to the desired results[102].

The difference in the behaviour of the *p*- and *m*-isomers of xylene is explained by structural features of the *m*-xylene and of the products into which it is converted[99]. The relatively low yield of the monofunctional nitrogen derivatives of *m*-xylene is connected with the adsorption of the *m*-xylene on the catalyst by means of the two side groups, as a result of which the groups react at the same time. In contrast to *p*-xylene, the *m*-isomer is unsymmetrical and it is assumed that because of the joint orienting effect of the side groups the C–H bond at the carbon atom of the ring situated between the groups is weakened and is therefore susceptible to the action of oxygen to a greater degree than the other C–H bonds. With a high concentration of oxygen, this means destruction of the ring and the formation of aliphatic oxygen- and nitrogen-containing compounds, and combustion products.

Since the separation of *p*- and *m*-xylenes is difficult it has been proposed that commercial and other mixtures of these isomers should be used in oxidative ammonolysis with subsequent separation of the dinitriles with the aid of selective solvents. On a stationary or moving catalyst of vanadium oxides precipitated on aluminium oxide the composition of the mixture of xylenes taken does not appear to

affect the conversion of each of the components; the proportion of isomers in the starting material is the same as that in the dinitriles obtained[103,104]. The total yield of terephthalo- and isophthalo-dinitriles reaches 75% of the theoretical. On fused tin vanadate the behaviour of the isomers depends on the proportion of isomers in the starting material and the general picture of the process assumes a different character[105]. Fig. 4, which is given as an example, shows that, when the quantity of isomer in the mixture decreases, its degree of conversion increases. This applies to a great degree to *m*-xylene; in the pure state this is converted into isophthalodinitrile in 20–40% yield, but in a mixture with 9 parts of *p*-xylene the conversion of *m*-xylene is practically complete. It is noteworthy that in experiments with equimolar, or close to equimolar, mixtures deep oxidation is considerable and the yield of carbon oxides increases.

The oxidative ammonolysis of *o*-xylene proceeds in a peculiar manner. Because of the proximity of the methyl groups, the main products are usually phthalic anhydride and phthalimide, irrespective of the nature of the catalyst. With a molar ratio of ammonia : hydrocarbon of 2 : 1 and above, phthalimide begins to predominate. Under optimal conditions its yield may reach 65–70%[50,61] and even 75%,[106] based on the throughput of hydrocarbon. As a rule, only traces of *o*-toluonitrile and *o*-phthalodinitrile are formed. The formation of phthalodinitrile is promoted by a high concentration of ammonia and by the introduction of water vapour into the reaction zone[107]. With the ratio *o*-xylene: : $NH_3$ : $H_2O$ equal to 1 : (20–30) : (25–30) and an adequate supply of air, it may be obtained on tin vanadate in yields up to 45–50%. Only one worker has succeeded in obtaining phthalonitrile in a yield up to 60 wt.% with a feed containing less than 15 moles of ammonia per mole of *o*-xylene[100].

As a rule, oxidative ammonolysis of polyalkylbenzenes with three or more alkyl groups gives a mixture of aromatic nitriles. In particular, mesitylene on vanadium oxides or tin vanadates forms a mixture of mesitylenonitrile, uvitodinitrile, and trimesotrinitrile, the yields of which vary in the range 10–15, 20–25, and 20–25% respectively[60,101,108]. On dust vanadium oxide catalysts about 60% of mesitylene is converted into trimesotrinitrile[100].

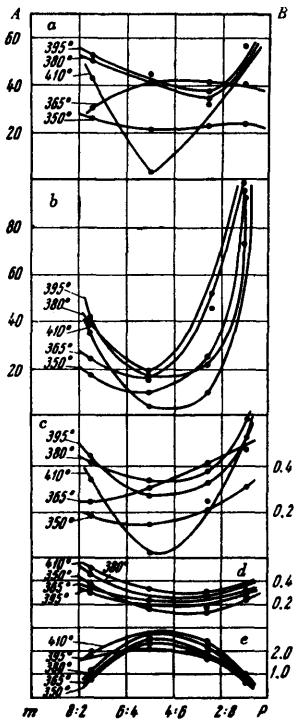

Fig. 4. Dependence of the yield of reaction products of oxidative ammonolysis on tin vanadate[105] on a mixture of *p*- and *m*-xylenes on the proportions of isomers in the mixture.
$V_{mixt}$ = 45–50 g, $V_{NH_3}$ = 130 g, $V_{H_2O}$ = 350–400 g, $V_{air}$ = 2350 litres per litre of catalyst per hour; contact time 0.5 s. *A*) Yield %; *B*) yield of HCN and $CO_2$ in moles per mole of xylene; *C*) composition of mixture of *p*- and *m*-xylenes.
*a*) Terephthalodinitrile; *b*) isophthalodinitrile; *c*) total yield of dinitriles; *d*) hydrocyanic acid; *e*) $CO_2$.

## III. OXIDATIVE AMMONOLYSIS OF CYCLOALKANES AND CYCLOALKENES

Alkyl-substituted cycloalkanes and cycloalkenes are dehydrogenated under the conditions of oxidative ammonolysis on oxide catalysts to aromatic hydrocarbons, which are then converted into the corresponding nitriles. Only nitriles of aromatic acids are found in the catalysates, which indicates that the reaction proceeds in two stages. Thus, benzonitrile was obtained from methylcyclohexane[49] and the terephthalodinitrile from dimethylcyclohexane[109]. The oxidative ammonolysis of various terpene hydrocarbons has been studied on various catalysts[110–112]. In all cases the main product was terephthalodinitrile. The yield was 48–50% from α-pinene, dipentene, and *d*-limonene, and 15–30% from menthol, borneol, terpin hydrate, [*p*-menthane-1,8-diol (Ed. of Translation)], α-terpinolene, terpinen-4-ol, and isopulegol.

## IV. OXIDATIVE AMMONOLYSIS OF ALKENES

The oxidative hydrolysis of alkenes to the nitriles of unsaturated acids is of exceptional importance. It is considered[66] that on the basis of this one of the most economic methods can be developed for the synthesis of vinyl cyanides, in particular acrylonitrile, the monomer for high-quality chemical fibres, synthetic rubber, and other polymers. Intensive work on the oxidative ammonolysis of propene is being carried on in the Soviet Union[113], the United States[66,114,115], Great Britain[64], and other countries. Several variants of the oxidative ammonolysis of propene to acrylonitrile have been described; these have been developed in the search for a more economic process and they differ mainly in the proportion of propene to ammonia. Acrylonitrile can be obtained in 65% yield, based on hydrocarbon used, or 72% based on hydrocarbon consumed, with a feed of 3 or more molecules of ammonia per mole of propene and a large excess of oxygen on cobalt, tin or antimony oxide catalysts, and also on mixed catalysts of molybdenum, tellurium, bismuth and phosphorus oxides[116–121]. Water vapour is an essential component of the reaction mixture; it is used in a molar ratio to propene of 0.25 to 10.[116] In all papers it is noted that the yield of acrylonitrile increases with increasing concentration of ammonia.

When a high concentration of ammonia is used, a considerable part of it passes through the convertor without change, and it may interact in the scrubbers with acrylonitrile to form various amino-derivatives. Cyanethylation of water also occurs in the scrubber system with the formation of hydracrylonitrile and 2,2'-oxydiacetonitrile; other secondary processes, due to the presence of unreacted ammonia, lead to the undesirable consumption of acrylonitrile. To avoid this, the ammonia coming from the reactor is preferably neutralised with sulphuric acid.

In another variant, an equimolar mixture of propene, ammonia and oxygen are passed over the catalyst, or the reaction is carried out with insufficient ammonia and air [116,120,122,123]. The conversion of ammonia is relatively high, side reactions are at a minimum, and unreacted propene is returned to the reaction. The yield of acrylonitrile, based on hydrocarbon consumed, varies between 60 and 75%. Methods of synthesising acrylonitrile from allyl chloride have also been described [124,125]; in a two-stage method propene is first oxidised in the gaseous phase by air to acrolein, after which ammonia is added to the reaction gases and they are passed over a catalyst (oxides of molybdenum, phosphorus, or other elements of variable valency) at 350–400°. [126]

## V. OXIDATIVE AMMONOLYSIS OF ALKYLPYRIDINES

In recent years a considerable amount of work has been done on the oxidative ammonolysis of alkyl derivatives of pyridine. The reaction is of interest because the cyanopyridines formed can be rapidly hydrolysed to give a good yield of free pyridinecarboxylic acids or their amides [127,128], many of which are widely used in the pharmaceutical industry [129]. According to published information the reaction conditions for 3- and 4-picolines differ little from the conditions for the oxidative ammonolysis of the alkylbenzenes. The reaction goes well with 1–3% of picoline and 3–10 vol.% of ammonia in the air feed, a contact time of 0.5–3 s, and a temperature of 350–420°. Vanadium(V) oxide [53,130–133], titanium and tin vanadates [134–137], iron [138,139], silver [138], a mixture of vanadium oxides with oxides of molybdenum and phosphorus [53,140] or with potassium sulphate [139], iron niobates [138], etc. may be used as catalyst. The catalyst may be fused or precipitated on a carrier and used as 3–5 mm granules or as a dust. As a rule, nicotinic acid and isonicotinic acid nitriles are obtained in a stable yield of 60 to 85% based on the weight of picoline taken, or 75 to 95% based on the picoline consumed. Some amides of pyridinecarboxylic acids, hydrogen cyanide, and carbon oxides are also formed. The oxidative ammonolysis of 3- and 4-ethylpyridines proceeds in the same way, although the yield of nitriles is somewhat lower (30–50%) [53]. The nitrile of picolinic acid has been obtained from 2-picoline in the same yield [132,138,141]. The presence of pyridine in the reaction products indicates that, under the given conditions, the side group in the $\alpha$-position can be eliminated and replaced by a hydrogen atom [141].

On oxidative ammonolysis the dialkyl pyridines only give the nitriles of the alkylpyridine acids and nitriloamides in small quantities. Thus, 2,6-dimethylpyridine (lutidine) gives 6-methylpyridine-2-nitrile and 2-cyanopyridine-6-carboxamide; 5-ethyl-2-methylpyridine (collidine) gives 5-methylpyridine-2-nitrile and 2-cyanopyridine-5-carboxamide [53,138,142]. By analogy with 2-picoline, in oxidative ammonolysis of 5-ethyl-2-methylpyridine a side group is eliminated from the $\alpha$-position and as a result nicotinonitrile appears amongst the reaction products. When a catalyst consisting of vanadium oxides precipitated on aluminium oxide is used, the yield of nicotinonitrile is 37%, based on the 5-ethyl-2-methylpyridine passed through [53].

Because of the difficulty of separating 3- and 4-picolines from the corresponding coal-tar fractions, attempts have been made to subject various commercial mixtures to oxidative ammonolysis. From the 3-picoline fraction, which contains ~30% of other alkylpyridines, nicotinonitrile was obtained on a dust-like vanadium-oxide catalyst in 83% yield, based on the pure isomer [143]. Commercial 4-picoline, containing ~8% of impurities, is converted into isonicotinonitrile in almost 88% yield. From a mixture of 3- and 4-picolines in close to equimolecular proportions, nitriles were obtained in practically the same ratio; the yield varied between 55 and 85%, depending on the conditions of the reaction [144,145]. Oxidative ammonolysis of a commercial product consisting of 3-picoline (33.8%), 4-picoline (35.7%), and lutidine (27.4%) gave a mixture of nitriles in 59.9% yield; the mixture consisted of 31% of nicotinonitrile, 51% of isonicitinonitrile, 11% of 6-methylpyridine-2-nitrile, and 7% of picolinonitrile [143].

## VI. SOME QUESTIONS CONNECTED WITH THE MECHANISM OF OXIDATIVE AMMONOLYSIS OF ORGANIC COMPOUNDS

A number of workers quite rightly consider that amino-compounds are the primary products of the reaction of hydrocarbons and ammonia [33,146]; these products are then dehydrogenated to nitriles:

$$R{-}CH_3 + NH_3 \rightarrow R{-}CH_2NH_2 \rightarrow R{-}CN,$$
$$R{-}CH_2{-}R' + NH_3 \rightarrow R{-}CHNH_2{-}R' \rightarrow R{-}CN.$$

With alkenes the first stages of the process are connected with the addition of ammonia to the double bond:

$$R{-}CH{=}CH{-}R' + NH_3 \rightarrow R{-}CHNH_2{-}CH_2{-}R' \rightarrow R{-}CN.$$

The orientation of the $NH_2$-group may differ according to the nature of the radicals R and R'. This question has been extensively considered in the literature, but is still not finally elucidated [26,32,33]. Moreover, in $\alpha$-alkenes the amino-group often combines, according to Markovnikov's rule, with the carbon atom attached to other carbon atoms [44,147–150]:

$$R{-}CH{=}CH_2 + NH_3 \rightarrow R{-}CHNH_2{-}CH_3 \rightarrow R{-}CN.$$

Nitriles with an unchanged carbon skeleton are formed from $\alpha$-alkenes in very small quantities; as a rule, they require special conditions, for example, high pressure [150–153]:

$$R{-}CH{=}CH_2 + NH_3 \rightarrow R{-}CH_2{-}CH_2NH_2 \rightarrow R{-}CH_2{-}CN.$$

Amino-compounds appear in fact to be the intermediate products of ammonolysis of hydrocarbons, as they have been separated in very small quantities and identified by a number of workers [16,151–154].

It is thought by some that a similar reaction also occurs in the oxidative ammonolysis of hydrocarbons [57,59,58,155]. Although the direct ammonolysis proceeds under very drastic conditions (at 500–600°) with a very small yield of nitriles, in the presence of oxygen the optimal temperature is sharply reduced and the conversion of starting material increases.

Paushkin and Osipova regard ammonolysis as a free--radical process in which both hydrocarbon and $NH_2$ radicals take part[32]. This point of view is in agreement with other results on ammonolysis, in particular those dealing with the thermal synthesis of aniline from benzene and ammonia[156], or the ammonlysis of benzene in the silent electric discharge[157], that is, in conditions under which the reactions proceed through free radicals.

In the presence of oxygen the rate of generation of hydrocarbon radicals by a catalyst surface increases[158]. The rate of formation of $NH_2$ radicals also increases[159-161]. The rate of formation of the latter may be so high that hydrazine appears in the reaction products[162]. In the presence of silver oxide at 300–400°, hydrazine can be obtained by the oxidation of ammonia in up to 20% yield[163,164]. This obviously leads to an increase in the rate of formation of amino-compounds.

Moreover, as has been noted above, amino-compounds are present in small quantities in the products of the reaction of hydrocarbons with ammonia. This is explained by the fact that at high temperature in the presence of metallic or oxide catalysts they are rapidly dehydrogenated to nitriles. Experiments on the dehydrogenation of benzylamine on a nickel catalyst have been described[165,166]. On tin and titanium vanadates, benzylamine is converted into benzonitrile in 45–50% yield[167]. The nitriles of aliphatic acids are obtained in still higher yields from various aliphatic amines on nickel, palladium, platinum[168-171], molybdenum oxide[172] chromium oxide[173], and aluminium oxide[174,175]. Oxygen to a still higher degree promotes the further conversion of amino-compounds, in particular the dehydrogenation of these compounds to nitriles. Even aniline under the action of air on thallium oxides is subjected to oxidative dehydrocondensation to azobenzene and phenazine[176]. Methallylamine with air in the presence of a silver catalyst gives 76 mole % of acrylonitrile[177,178], and on titanium vanadate, with an equimolecular quantity of oxygen and 8–10 moles of ammonia, benzylamine is converted almost quantitatively into benzonitrile[167].

If the possibility of dehydrogenating amines is excluded, they may accumulate in the reaction products. An example of this is the formation of aniline on the ammonolysis of benzene in the presence of iron, nickel, or copper catalysts[179], and cobalt or iron oxides[180].

Andrussov[181-184], Wendlandt[185], and other workers[186] have come to the conclusion that intermediate amino-compounds may also be formed in the catalytic synthesis of hydrogen cyanide from methane and ammonia in the presence of oxygen. Since the process starts with the oxidation of ammonia, they suggest that methylamine and methylenimine stages precede the formation of nitroxyl [sic (Ed. of Translation)]:

$$NH_3+O_2 \longrightarrow NH_2O_2 \xrightarrow{-H_2O} HNO \xrightarrow[-H_2O]{+CH_4} NH{=}CH_2 \xrightarrow{-H_2} HCN.$$

$$NH_3+O \longrightarrow NH_2O \xrightarrow[-H_2O]{+CH_4} H_2N{-}CH_3 \xrightarrow{-H_2} NH{=}CH_2$$

The synthesis of hydrocyanic acid is carried out at a temperature of ~1000° on metallic catalysts (platinum and alloys of platinum with rhodium, iridium, ruthenium, etc.) under specific conditions that differ substantially from oxidative ammonolysis. It may be thought that for this reason the hypothetical scheme given with the participation of nitroxyl cannot be considered as applying to the mechanism of oxidative ammonolysis of hydrocarbons.

Under conditions of oxidative ammonolysis ammonia may be oxidised to nitrogen oxides[187-190], and these could react with hydrocarbons to give carboxylic acid nitriles. Toluene and the xylenes readily react with oxides of nitrogen at 400–700° in the presence of dehydrogenating catalysts (for example, silver), to give the corresponding aromatic nitriles[191]. Isonicotinonitrile is formed from 3-picoline. There are reports of the construction of an industrial plant for the preparation of acrylonitrile from propene and nitrogen monoxide[192]. Nitro-compounds appear to be intermediate products in this reaction. In this connection, it should be noted that Wohl[47], Green[193], and also Zal'kind and Kesarev[194] observed the formation of phthalimide in the vapour-phase oxidation of nitronaphthelenes on various oxide catalysts in the absence of ammonia. The routes considered above with participation of amines and nitro-compounds are not the only ones in oxidative ammonolysis. It has been shown that with a sufficient concentration of oxygen in the presence of oxide catalysts the initial hydrocarbon may be subjected to oxidation to oxygen--containing compounds, which then participate in the formation of nitriles[57-59,72,73,86,98,99,107,155]. Later this point of view was confirmed by many workers[64,120].

It is well known that the catalytic vapour-phase oxidation of hydrocarbons leads to the formation of peroxide compounds, aldehydes, ketones, alcohols, acids, anhydrides, lactones, and other oxygen-containing products[1,11,12,15]; the products depend on the structure of the initial compound. Many of these compounds have also been found in the oxidative ammonolysis of hydrocarbons. The yield of these compounds depends on temperature, ammonia concentration, time of contact, and other parameters, but under certain conditions they may accumulate in considerable amounts (see Figs. 5-8).

At a high temperature in the presence of catalysts nearly all the oxidation products of hydrocarbons mentioned are capable of reacting at some rate or other with ammonia, giving amines, imines, amides, and acid nitriles.

The simplest route is that through an acid stage:

$$R{-}COOH \longrightarrow R{-}COONH_4 \longrightarrow R{-}CONH_2 \longrightarrow R{-}CN.$$

An extensive literature is devoted to the vapour-phase ammonolysis of acids and this method has long been considered very convenient for the synthesis of nitriles of the most varied structure. Methods of preparing nitriles from aromatic[196-199], aliphatic[200-205], and heterocyclic[206-208] acids have been described, as well as methods of preparing dinitriles from acid anhydrides[209-211] and imides[212-214], also imides from anhydrides[210], methods of dehydrating amides[200,208,215,216], etc. Ammonolysis is carried out on oxide catalysts, preferably catalysts with dehydrating activity at ~500°, and, as a rule, a large excess of ammonia is used.

On catalysts of metals of variable valency at 350–450° in the presence of air, that is, under oxidative ammonolysis conditions, the degree of conversion of acids into nitriles is low. The cause of this is connected not with the amide dehydration stage, the rate of which is sufficiently high, but with the formation of the amide group from the carboxyl[195,217,218]. The fact is that under the given conditions the acids not only react with ammonia to form amides, but they are also decarboxylated. Dilution of the reaction mixture with air, which finally leads to a reduced concentration of acid and ammonia in the reacting gases, promotes this side reaction.

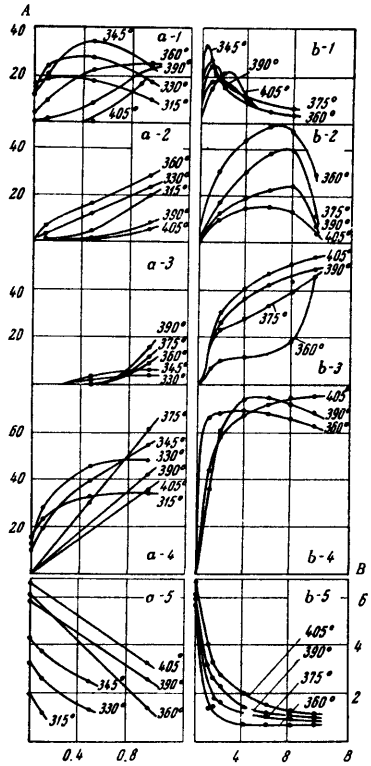

Fig. 5. The effect of ammonia additions on the yields of products of oxidative ammonolysis of *p*-xylene on tin vanadate[86].
$V_{hydrocarbon}$ = 50–52 g, $V_{air}$ = 2400 litres, $V_{H_2O}$ = 350–400 g per litre of catalyst per hour. Fig. 6. Effect of ammonia additions on the yield of products of the oxidative ammonolysis of toluene (*a*), ethylbenzene (*b*), and cumene (*c*) on tin vanadate[73].
$V_{hydrocarbon}$ = 30 g, $V_{air}$ = 2200 litres, $V_{H_2O}$ = 250 g per litre of catalyst per hour. *A*) Yield %; *B*) moles of $NH_3$ per mole of hydrocarbon. 1) Benzoic acid; 2) maleic anhydride; 3) benzonitrile.

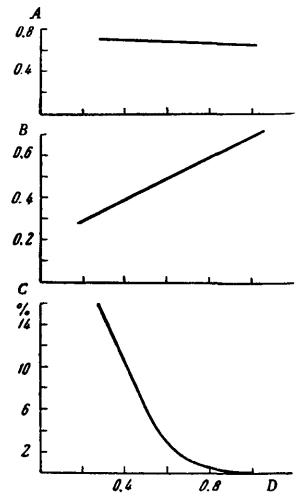

Fig. 7. The effect of the quantity of ammonia on the oxidative ammonolysis of propene in the presence of oxide catalyst[120], $C_3H_6 : O_2 : H_2O$ = = 1 : 1.5 : 1. Contact time = 2 s, $t$ = 450°. *A*) Total degree of propene conversion; *B*) degree of propene conversion into acrylonitrile; *C*) yield of aldehydes, %; *D*) moles of $NH_3$ per mole of propene.

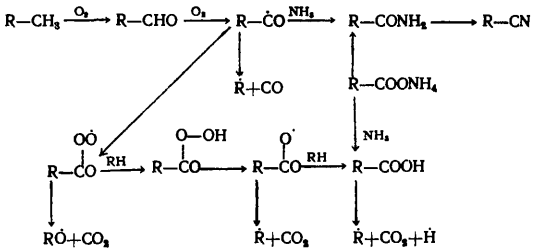

This special feature in the ammonolysis of acids has been used to prepare benzonitrile from phthalic anhydride and phthalimide; when these, mixed with ammonia and air, are passed over oxide catalysts they undergo decomposition with opening of the five-membered ring and elimination of one of the side groups[219–221]. The two-stage synthesis of benzonitrile from naphthalene described above is based on the same principle[68–69].

In the gas phase, aldehydes react with ammonia in two main directions. One of them, which was already studied by Chichibabin, is cyclisation with the formation of pyridine derivatives at a temperature of ~500°, often without a catalyst or with catalysts of the aluminium-oxide or silica type[222–227].

Ammonolysis of aldehydes on oxides of metals of variable valency gives acid nitriles. Thus benzonitrile is obtained in 40% yield from benzaldehyde and ammonia on thorium oxides[228,229]. On a copper catalyst the yield of benzonitrile was 46%,[230] and on titanium and tin vanadates nearly 90%.[231,232] On chromium and cobalt catalysts propionaldehyde is converted into propionitrile in 50–70% yield[233,235]. The preparation of methacrylonitrile[230], heptanenitrile (oenanthonitrile), 3,3,5-trimethylcapronitrile[236], acrylonitrile[237], and nitriles of a number of other carboxylic acids[238,239] by the direct ammonolysis of aldehydes on vanadium and molybdenum oxides, etc. has also been reported.

In contrast to the ammonolysis of acids, when aldehydes react with ammonia the addition of oxygen or air not only accelerates the process but also suppresses many side reactions. In the presence of air, benzonitrile, for example, is formed from benzaldehyde in 93.6% yield[62,72] and acrolein is converted into acrylonitrile (50–70% yield) on nearly all types of oxidative catalysts, including vanadium[237,240], molybdenum[241-243], chromium, manganese[126], and various mixed catalysts[244-246].

In this connection, the authors of this review concluded that when the methyl group is subjected to oxidative ammonolysis, the nitriles are formed through an amide stage, usually not from acids but from aldehydes[57-59,72,247]:

Similar interpretations on the role of aldehydes, in particular the role of acrolein in the oxidative ammonolysis of propene to acrylonitrile have been put forward by Hadley[64]. However, he considers that ammonia reacts with the carbonyl group by an aldimine mechanism:

$$R{-}CHO + NH_3 \longrightarrow R{-}CH{=}NH \longrightarrow R{-}CN.$$

Ketones as well as aldehydes may be intermediates in the oxidative ammonolysis of hydrocarbons with a side-chain having two or more carbon atoms[248-250]. The vapour-phase reaction of ketones with ammonia has been little studied. In one of the earlier papers it is reported that the ammonolysis of acetophenone and propionphenone on thorium oxide gives small amounts of the corresponding ketimines, which were isolated only as hydrochlorides[251]. On tin and titanium vanadate catalysts, acetophenone reacts with ammonia by a Chichibabin-type reaction, giving 2,4,6-triphenylpyridine in 35% yield based on ketone taken or 98% on ketone consumed[252]. Oxidative ammonolysis, even with very small air feeds, of acetophenone gives benzonitrile as the only product; the yield exceeds 70%.[72]

Therefore in oxidative ammonolysis of hydrocarbons the sequence for the conversion of the alkyl group into the nitrile group depends on the process conditions (hydrocarbon : $NH_3$ : $O_2$ ratio) and on the structure of the initial compounds. On the basis of data from the literature and experimental results, the authors of the present review have proposed a scheme of the basic probable stages in the oxidative ammonolysis of toluene, ethylbenzene, and cumene[72] (See Fig. 9).

Alcohols may also be intermediates in the catalytic vapour-phase oxidation of hydrocarbons. Ammonolysis of alcohols leads to the formation of amines or nitriles according to the conditions.

Sabatier and Mailhe were amongst the first to show the possibility of forming alkylamines by the ammonolysis of alcohols[253,254]. In the 1930's a series of papers of Shuikin and coworkers[255-257] on the study of the reaction of alcohols with ammonia in the presence of mixed oxide dehydration catalysts, began to appear. In these papers it was shown, in particular, that butylamine could be obtained in 35–40%

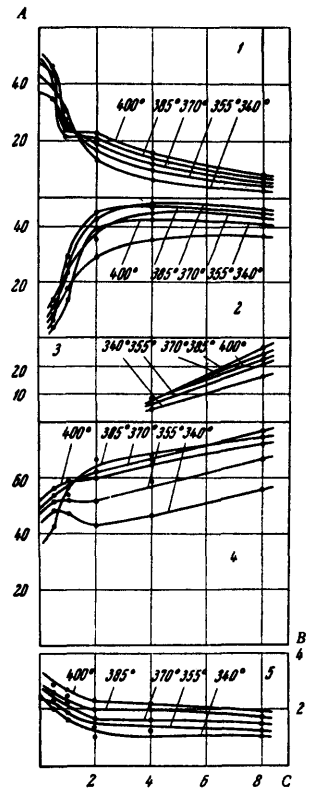

Fig. 8. Dependence of the yield of products of the oxidative ammonolysis of *o*-xylene on the reaction temperature and quantity of ammonia on a tin vanadate catalyst[107]. $V_{xylene}$ = 55–60 g, $V_{air}$ = 2500 litres, $V_{H_2O}$ = = 40 g per litre of catalyst per hour. Contact time = 0.6 s. *A*) Yield %; *B*) yield in moles per mole of xylene; *C*) moles $NH_3$ per mole of xylene. 1) Phthalic anhydride; 2) phthalimide; 3) *o*-phthalodinitrile; 4) total yield of $C_8$ reaction products, %; 5) total yield of gaseous products in moles per mole of xylene.

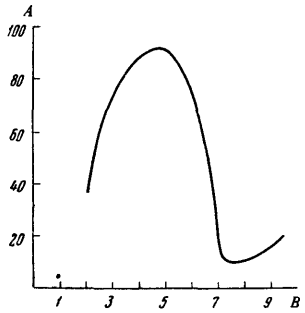

Fig. 10. Dependence of nitrile content of catalysate on the number of carbon atoms in the alcohol molecule[261]. Catalyst $Ni/Al_2O_3$, Ni content = 7.5%. *A*) Nitrile content of catalysate, %; *B*) number of carbon atoms in alcohol molecule.

yield from butanol at 380–420° on aluminium oxide. This reaction goes quite satisfactorily on catalysts of such natural materials as alumina and bauxite[258].

The position of the hydroxyl group has a great effect on the ammonolysis of alcohols[259]. Thus, in the butyl alcohol series the primary alcohol reacts fastest and the tertiary alcohol gives amines in only negligible amounts.

The use of dehydrogenating catalysts changes the direction of the reaction and nitriles become the main products of the ammonolysis of alcohols. Popov showed that, when butyl alcohols react with ammonia in the presence of platinised silica gel, butyronitrile is formed in yield up to 27%.[259] On a nickel catalyst, ethanol, propanol, butanol, and benzyl alcohol give the corresponding nitriles in 50 to 90% yield[260-262]. Similar activity is shown by copper and silver catalysts[263,264]; the sulphides of zinc, tungsten, nickel, titanium, and chromium[265]; aluminomolybdenum oxide catalyst[266]; and oxygen-free zinc salts[267].

In a study of the ammonolysis of various aliphatic alcohols Popov and Shuikin[261] found that on a nickel catalyst the greatest amount of nitrile is obtained from alcohols with four or five carbon atoms (Fig. 10).

According to available patent information[246,268], in the presence of dehydrogenating and oxidative catalysts, especially when oxygen is present in the reaction zone, the formation of nitrile from alcohol and ammonia should proceed through the intermediate aldehyde:

$$R{-}CH_2OH \xrightarrow{-H_2} R{-}CHO \xrightarrow{+NH_3} R{-}CONH_2 \xrightarrow{-H_2O} R{-}CN$$

It has been noted above that in the oxidative ammonolysis of hydrocarbons the addition of water vapour has a favourable effect on the yield of nitriles[50,86,116,242].

The introduction of water vapour into the reaction zone also promotes the formation of carbonyl and carboxylic derivatives in the vapour-phase catalytic oxidation of hydrocarbons with atmospheric oxygen[250,269-271]. It has been shown by direct experiments that toluene, benzil, and benzaldehyde on oxides of vanadium at 350–420° in the absence of air react with water to form benzoic acid and other oxygen compounds[272]. In this connection it has been suggested that the favourable action of water on the oxidative ammonolysis of hydrocarbons is also connected with the participation of water in the formation of intermediate oxygen-containing compounds[247].

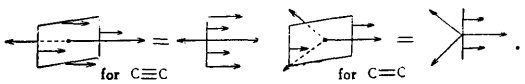
# REACTION OF ACETYLENE AND ALKYNYL COMPOUNDS WITH AMINES AND AMMONIA

I. A. Chekulaeva and L. V. Kondrat'eva

CONTENTS

1. Introduction 670
2. Reaction of acetylene with amines and ammonia 670
3. Reaction of alkyl- and aryl-alkynes with amines 672
4. Reaction of alkoxyalkynes and alkynyl sulphides with amines and ammonia 673
5. Reaction of alkynyl alcohols, their derivatives, and alkynyl oxides with amines and ammonia 674
6. Reaction of alkynyl and bisalkynyl ketones with amines and ammonia 675
7. Reaction of ethynylcarboxylic acids and their esters with amines and ammonia 675
8. Reaction of but-1-en-3-ynes and their derivatives with amines and ammonia 676
9. Reaction of buta-1,3-diyne with amines 677
10. Reaction of butenynes containing a heteroatom in the $\alpha$-position to multiple bonds, with amines 678

## 1. INTRODUCTION



In the last few decades there has been a considerable extension of the studies in the field of the chemistry of unsaturated amines. Thanks to the presence of several reaction centres in their molecules (the amino-group, multiple bonds), unsaturated amines exhibit high reactivity and can serve as starting compounds in the synthesis of more complex nitrogen-containing substances of various classes, including high-molecular-weight materials.

Many unsaturated amines and derivatives obtained from them and based on them are of interest as physiologically active substances.

One of the main methods for obtaining unsaturated amines is by the direct action of amines and ammonia on acetylene and alkyne derivatives.

Alkynes are capable of two types of reaction with amines: addition of the amines to triple bonds and replacement of the active alkynyl hydrogen by an aminomethyl group (Mannich reaction).

The addition of amines and ammonia to alkynes can be classified as a nucleophilic addition to a triple bond. Bohlmann [1] attributed the tendency of a triple bond to participate in nucleophilic addition to the asymmetry of the electron density. During the formation of each electronic bond the centre of gravity of the electron density is displaced towards the centre of the bond. The overlap integrals are a measure of this displacement to a first approximation. If the displacement is represented by vectors leaving the plane perpendicular to the bond and passing through the nucleus of the carbon atom, an almost symmetrical picture is obtained for ethylene, but there is distinct asymmetry for acetylene:

Since this also implies asymmetry of the spherical positive field of the nucleus, the carbon atoms in alkynes already possess in their ground state an approximately electrophilic character. On passing to the polyynes the electropositive character of the terminal carbon atoms increases owing to mesomerism:

$$-\overset{\delta+}{C}\equiv C-[C\equiv C]_n- \longleftrightarrow -\overset{+}{C}=C=[C=C]_n-.$$

However, these views do not explain the influence on the reactivity of the triple bond of various substituents in alkynes.

The many experimental results on the reaction of alkynes with amines show that the reactivity of the alkynyl group and the direction of the addition to it depend essentially on the electronic structure of the substituent, on the amine reacting, and on the conditions.

A possible hypothesis is that in many instances the reaction is brought about through the formation of intermediate complexes of the alkynes with the amines, the catalyst, and the solvent.

This review is intended to survey the literature on the reactions of acetylene and alkyne derivatives with amines and ammonia and to throw light on the fundamental mechanisms of these reactions.

## 2. REACTION OF ACETYLENE WITH AMINES AND AMMONIA

### (a) Reaction of Acetylene with Amines

The reaction of acetylene with amines proceeds in the presence of catalysts on heating and under pressure. Acetylene reacts with primary and secondary aliphatic amines in the presence of copper acetylide under pressure at 80–100° with formation of butynylamines [2–5]. It is thought that vinylamines are the intermediates in this reaction:

$$R_2NH + CH\equiv CH \rightarrow [R_2NCH=CH_2] \rightarrow R_2NCH(CH_3)-C\equiv CH.$$

The yields of butynylamines from secondary amines reach 60–80%; primary amines do not react so well with acetylene. Under these conditions hexamethylenediamine reacts at one amino-group.

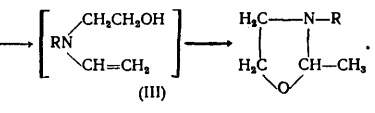
Acetylene and primary amines in the presence of zinc or cadmium acetate under pressure at 120–140° form ethylideneimines [6], and not *N*-vinylamines, as Reppe and coworkers had reported [3]:

$$RNH_2 + CH\equiv CH \rightarrow [CH_2=CHNHR] \rightarrow CH_3C(=NR)H.$$

In the presence of water at 60–70° and 20 atm, acetylene also reacts with trimethylamine to form neurine [3,7] [trimethylvinylammonium hydroxide (Ed. of Translation)] in good yield:

$$(CH_3)_3N + CH\equiv CH + H_2O \rightarrow [(CH_3)_3N^+-CH=CH_2]\,OH^-.$$

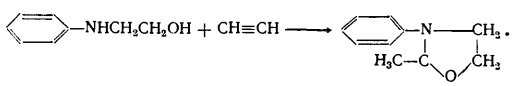
Amines of structure RNHX, in which R is an alkyl, aryl, aracyl, or ester radical, and X is a chloro-, bromo-, iodo-, cyano-, nitro-, sulpho-, or nitro-aryl group, condense with acetylene in the liquid phase in the presence of a mercury catalyst — $Hg(OAc)_2$ and $H_2SO_4$ — to give *N*-vinyl compounds of general formula $RN(CH=CH_2)X$. [8]



Amino-alcohols react with acetylene in the presence of alkaline catalysts (alkali, alkali metal alkoxides) under pressure at 120–160° to form the corresponding vinyl ethers [9–13]:

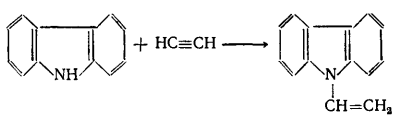
$$R_2NCH_2CH_2OH + CH\equiv CH \longrightarrow R_2NCH_2CH_2OCH=CH_2,$$

where R = H, alkyl, or aryl.



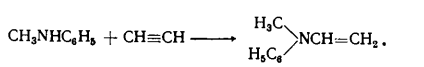
Watanabe and Conlon [14] showed that amino-alcohols with the structure $RNH(CR_2)_nOH$, where R = H or alkyl and $n$ = 2 or 3, with acetylene under pressure, at 100–200°, in the absence of traces of water give 2-methyloxazolidine ($n$ = 2) and perhydro-2-methyl-1,3-oxazine ($n$ = 3), or their derivatives (when R = alkyl) with yields of 5–75%. A vinyl ether is not formed under these conditions. The authors suggest the following mechanism for the reaction:

$$RNHCH_2CH_2OH + CH\equiv CH \longrightarrow \underset{(I)}{} \left[RN^+(CH_2CH_2OH)(CH=CH^-)\right] \underset{(II)}{} \longrightarrow \left[RN(CH_2CH_2OH)(CH=CH_2)\right] \underset{(III)}{} \longrightarrow$$



The intermediate compound (II) can be converted into the reaction product directly or through compound (III). Watanabe and Conlon did not give a convincing demonstration of the existence of (III). They represented the reaction mechanism as a special case of vinylation in which the acetylene first attacks the nitrogen of the amino-group (and not the oxygen), analogously to the reaction of aqueous tertiary amines with acetylene, as a result of which a trialkylvinylammonium hydroxide is formed. In the presence of a strongly basic catalyst at 140–150° acetylene under pressure with 2-methylaminoethanol forms a mixture of 2-methylaminoethyl vinyl ether (50%) and 2,3-dimethyloxazolidine (25%).

Aromatic amino-alcohols do not react with acetylene under these conditions. However, in the presence of cadmium acetate 2-methyl-3-phenyloxazolidine is formed from 2-anilinoethanol and acetylene[3]:



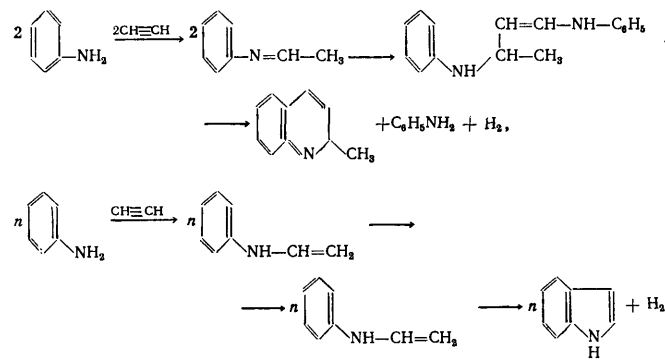
Stable *N*-vinyl compounds are obtained in the reaction of acetylene with nitrogen-containing heterocyclic compounds having a hydrogen atom on nitrogen, such as pyrrole, indole, carbazole, and imidazole[3,5]. The reaction proceeds in the presence of a strongly alkaline catalyst under pressure at 100–200° with yields up to 99%:

In the presence of alkaline catalysts at 100–200° diarylamines (diphenylamine, phenyl-α- and phenyl-β-naphthylamines) form relatively stable *N*-vinyl compounds[3]:

$$(C_6H_5)_2NH + CH{\equiv}CH \longrightarrow (C_6H_5)_2NCH{=}CH_2.$$

Vinyl derivatives and acetylene also form aralkylamines in the presence of potassium or zinc dust at 185°. *N*-methylaniline gives *N*-methyl-*N*-vinylaniline in 44% yield[4]:

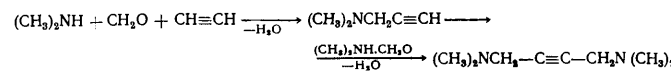
When acetylene and aniline react in the presence of copper acetylide at 20–60° under pressure, 3-anilinobutyne is obtained in 25% yield[2]:



Tertiary aralkylamines are alkylated by acetylene in the aromatic nucleus in the presence of aluminium chloride[15]:

The *p*-dimethylaminostyrene which might be expected from the scheme is not observed in the reaction products.

Kozlov and coworkers[16] showed that acetylene can condense with primary aromatic amines under pressure, and without it at room temperature, or on heating, not above 30°, in the presence of various catalysts: copper(I) chloride, mercury(II) chloride, copper acetylide, or mercury salts of organic acids. Quinaldine, indole, quinoline, and their derivatives are formed.



The authors suggest that the formation of quinaldine and indole in the reaction of aniline and acetylene in the presence of copper(I) chloride proceeds through an ethylidene--base and vinylaniline thus:

An analogous scheme was proposed for the reaction of acetylene and ethylaniline in the presence of mercury(II) chloride[17]. However, the authors did not provide convincing proof[16,17].

In the vapour phase at 400° in the presence of tetraethyl lead, aniline and acetylene give indole[18,19]. On an aluminosilicate catalyst at 450°, aniline and acetylene form quinoline in 50% yield[20].

Acetylene condenses with aliphatic amines and formaldehyde only under the influence of catalytic amounts of copper acetylide; with aqueous dimethylamine the products are *NN*-dimethylprop-2-ynylamine and a little *NNN'N'*-tetramethylbut-2-ynylenediamine[5,21,22]:

The reaction does not take place without a catalyst, even at elevated temperatures. Dimethylammonium chloride does not undergo this reaction[23].

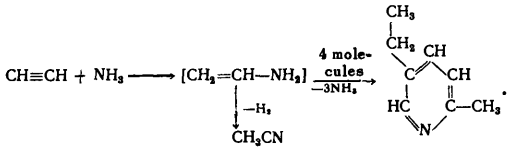
(b) Reaction of Acetylene with Ammonia

The catalytic condensation of acetylene with ammonia leads to the formation of a mixture of heterocyclic bases (piperidine bases, α- and γ-picolines, pyrrole, pyridine derivatives, aniline, benzonitrile, etc.) or acetonitrile[3,24].

Among the bases we can single out 5-ethyl-2-methylpyridine, which is formed when the catalyst employed is a nickel complex or a cobalt compound[3]. Vinylamine is probably an intermediate in the reaction of acetylene and ammonia.

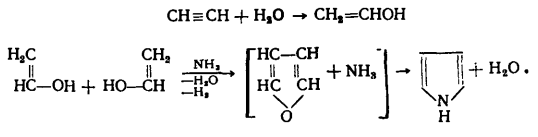
If the reaction is carried out in the presence of ammonium acetate at 170–200° and 20–30 atm, 5-ethyl-2-methylpyridine is obtained in up to 90% yield[24].

In the presence of cadmium catalysts, picolines can be obtained in good yield together with other pyridine bases[25,26].



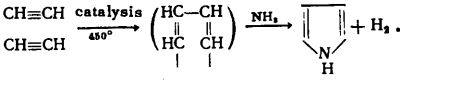
By passing mixtures of acetylene, ammonia, and hydrogen at 350° over zinc oxide and thorium oxide on

silica gel, and then over nickel on silica gel at 150°, condensates containing mainly piperidine and 2-aminoethanol are obtained. When mixtures of acetylene, hydrogen, and ammonia are heated to 650°, pyridine, pyrrole, aniline, and benzonitrile are formed as well as naphthalene and other hydrocarbons [27].



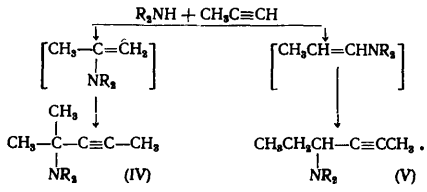
In glazed clay or quartz tubes at > 700° acetylene and ammonia form hydrogen cyanide [28].

On passing mixtures of ammonia and ethylene at 300–500° over catalysts consisting of alumina, zinc oxide, chromium(III) oxide, and 0.15% NaOH, or on using a zirconium catalyst, acetonitrile is formed in theoretical yield [29]. Other catalysts can also be used for this reaction: thorium oxide, $(ZnOH)_2CO_3$ (zinc oxide precipitated from sodium carbonate), zinc nitrate on kaolin, a mixture of sodium carbonate and alumina, carbon monoxide with hydrogen, and also molten salts ($ZnCl_2$–KCl–NaCl; $CdCl_2$–KCl–NaCl; $PbCl_2$–KCl–NaCl; $FeCl_3$–KCl–NaCl; and $SnCl_2$–KCl). [30–33] The yields of acetonitrile when these catalysts are used are 60–90%. Sometimes small quantities of MeCH=NH, pyridine bases, and hydrogen cyanide are formed.

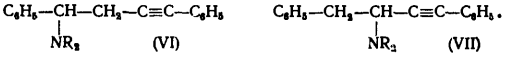


Reppe found that the reaction of acetylene and ammonia can be represented as follows [3]:

Chichibabin showed [34] that when acetylene and gaseous ammonia are passed over oxides of Al, Fe, Cr, Ti, Th, or Si on kaolin, or over aluminium phosphate at > 300°, the products are α-picoline, γ-picoline, 3-ethyl-2-methyl pyridine, pyrrole, and piperidine bases, the production of which he explained by the intermediate formation of acetaldehyde [34]. However, the formation of cyclic nitrogenous bases, for example, pyrrole, can take place in the presence of traces of moisture, as Yu'rev noted [35], by another mechanism, namely:



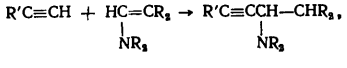
A third path of pyrrole synthesis was subsequently suggested [36]:



## 3. REACTION OF ALKYL- AND ARYL-ALKYNES WITH AMINES

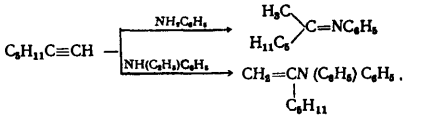
Like acetylene, alkyl- and aryl-alkynes add on aliphatic amines in the presence of catalysts and on heating [37]. The direction of the reaction is determined by the nature of the substituents on the alkyne as well as by the structure of the amine being added and the conditions of the reaction. Thus, diethylamine reacts with propyne in the presence of cadmium or zinc acetate on heating to 120°, forming *NN*-diethyl-1,1-dimethylbut-2-ynylamine in 80% yield [37].

Alkylalkynes add on amines in accordance with the Markovnikov rule. Of the two possible butynylamines, (IV) and (V), only the *NN*-dialkyl-1,1-dimethylbut-2-ynylamine (IV) was isolated:

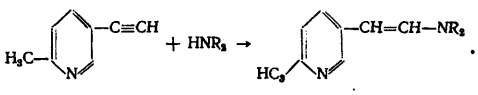


Phenylacetylene adds on secondary amines in the presence of copper(I) chloride at 100°; with morpholine, 3-morpholino-1,4-diphenylbut-1-yne and 1-morpholino-1,4-diphenylbut-3-yne are formed [38]. Compounds (VI) and (VII) were isolated from the products of the reaction between phenylacetylene and secondary alkylamines, showing that the amines add on to phenylacetylene in two ways

This suggests that, as for acetylene, when alkyl- or aryl-alkynes react with aliphatic amines, the corresponding enamines are formed as intermediates [37,38].



Brannock and coworkers [39] confirmed the formation of an intermediate enamine in the reactions of acetylene, alkyl-, and aryl-alkynes with amines. They continued the reaction of alkynes with enamines and obtained the expected alkynylamines:



where R′ = H, $C_4H_9$, $C_6H_5$, $CH_3CO_2CH_2$, etc.

The process takes place on heating, without catalysts, but catalytic amounts of copper(I) chloride accelerate the reaction so much that it sometimes becomes explosive.

Alkyl alkynes react with aromatic amines in the presence of boron trifluoride or mercury(II) oxide [40]. Under these conditions hept-1-yne gives an anil with primary aromatic amines and a vinyl derivative with secondary aromatic amines:

Pyridylacetylenes behave similarly to the alkyl- and aryl-alkynes in reactions with amines. As Kost and coworkers showed [41], the activity of the triple bond of 5-ethynyl-2-methylpyridine in these reactions is higher than that of phenylacetylene. Actually, 5-ethynyl-2-methylpyridine adds on secondary amines on heating to 180° with up to 70% yields of β-addition products:

Bromophenylacetylene reacts with secondary amines in the cold, addition and substitution taking place simultaneously [42]:

Hexafluorobut-2-yne gives addition products with primary and secondary alkylamines at 20°.[43] Thus with cyclohexylamine it forms *N*-cyclohexyl-1,1,1,4,4,4-hexafluorobut-2-enylamine:

$$F_3CC{\equiv}CCF_3 + C_6H_{11}NH_2 \rightarrow F_3CCH{=}CCF_3NHC_6H_{11}.$$

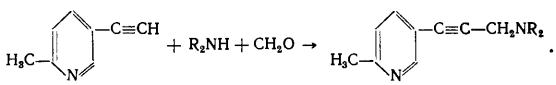
Other halogenobutynes react analogously:

$$Cl_2CHC{\equiv}CCHF_2. \quad Cl_2CHC{\equiv}CCH_3.$$

The aminomethylation of alkyl- and aryl-alkynes at the labile alkyne hydrogen takes place comparatively readily on heating, although for alkyl alkynes it would be natural to expect retardation of the process. The explanation of this behaviour must probably be sought in Arens' work on the chemistry of alkoxyalkynes (see Section 4).

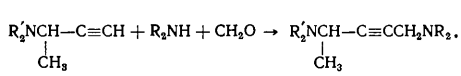
On heating to 80–100° with dialkylamines and formaldehyde, hex-1-yne forms[44,45] the corresponding alkyne derivatives in 75–81% yield:

$$C_4H_9C{\equiv}CH + R_2NH + CH_2O \rightarrow C_4H_9C{\equiv}CCH_2NR_2 + H_2O.$$



With secondary aliphatic amines and formaldehyde at 100°, phenylacetylene forms *NN*-dialkyl-3-phenylprop-2-ynylamines in yields of up to 80%:[5,46]

$$C_6H_5C{\equiv}CH + NHR_2 + CH_2O \rightarrow C_6H_5C{\equiv}CCH_2NR_2 + H_2O.$$

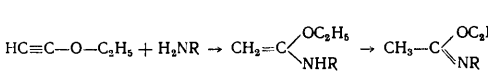


4-Phenylbut-1-yne reacts with secondary amines and paraformaldehyde in the presence of copper(II) acetate at 100° to form the corresponding compound in 76% yield[47]:

$$C_6H_5CH_2CH_2C{\equiv}CH + (CH_3)_2NH + CH_2O \xrightarrow{-H_2O} C_6H_5CH_2CH_2C{\equiv}CCH_2N(CH_3)_2.$$

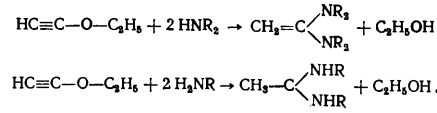
The condensation of 5-ethynyl-2-methylpyridine with secondary amines and formaldehyde proceeds in the presence of potassium hydroxide on boiling in dioxan; the yields of amino-derivatives reach 92%:[41]

Dialkylaminoalkyl alkynes react with secondary amines and formaldehyde on heating in dioxan; alkynyldiamines are formed in 55–70% yield[48]:

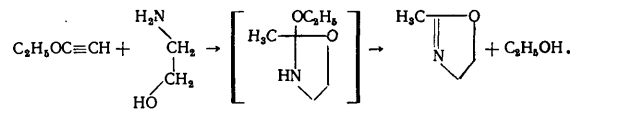


## 4. REACTION OF ALKOXYALKYNES AND ALKYNYL SULPHIDES WITH AMINES AND AMMONIA

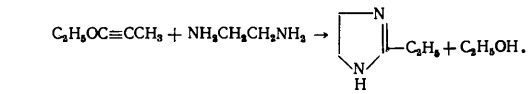
Alkoxyalkynes react slowly with aliphatic amines on heating; the reaction can be accelerated by addition of water.



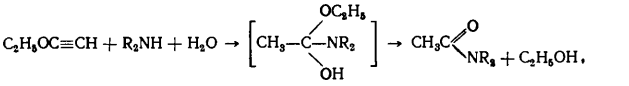
The amines add on to the $\alpha$ carbon atom in accordance with the polarisation of the alkoxyalkyne molecule. The structure of the final reaction product depends on the nature of the amine and the conditions of the reaction[49–51]. Thus secondary amines taken in equimolecular amount react to give *NN*-dialkyl-1-alkoxyvinylamines:



Under these conditions primary amines form the tautomeric iminoethers:



With an excess of the amine, nucleophilic replacement of the alkoxy-group proceeds as well as the addition:

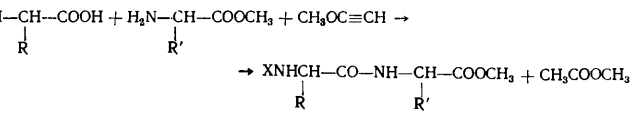


Bifunctional nucleophilic compounds, such as diamines, amino-alcohols, and amino-sulphides, give heterocyclic addition products when heated with ethoxyacetylene[49,52]:

The introduction of a methyl group into ethoxyacetylene retards the reaction with diamines and lowers the yield of addition products. The reaction is accelerated on addition of mercuric oxide. Ethylenediamine gives 2-ethyl-2-imidazoline[52,53]:

The addition of amines to alkoxyalkynes in the presence of water leads to the formation of *N*-substituted acetamides with a yield of up to 89%.[49,51,54] The authors suggest that the intermediate compound in this reaction is a derivative of orthoformic acid. When an amine of high basicity is used, the reaction is exothermic:

where R is H or alkyl.



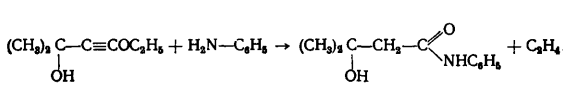
Amines of low basicity, such as aniline and diphenylamine, do not react in this way. They mainly act as catalysts for the hydration of ethoxyacetylene:

$$C_2H_5OC{\equiv}CH + H_2O \xrightarrow[\text{or } (C_6H_5)_2NH]{C_6H_5NH_2} CH_3COOC_2H_5.$$

In the presence of alkoxyalkynes, acids react smoothly (at 25–50°) with amines to form amides in quantitative yield[49,55]:

$$C_2H_5OC{\equiv}CH + RCOOH + H_2NR' \rightarrow RCONHR' + CH_3COOC_2H_5.$$

This reaction can be used for the synthesis of peptides:



Ethoxyacetylene also reacts with tertiary amines in the presence of water to form trialkyl-(1-ethoxyvinyl)ammonium hydroxides in 55–73% yields[49,56].

The reaction with higher aliphatic amines is very slow — several months are required — but with trimethylamine and triethylamine it occurs readily even at room temperature:

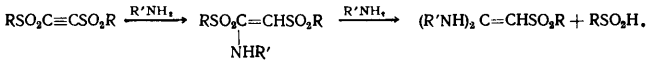
$$C_2H_5OC{\equiv}CH + N(CH_3)_3 + H_2O \rightarrow [CH_2{=}C(OC_2H_5)N(CH_3)_3]^+OH^-.$$

The compound which is formed is analogous to the vinyl derivative obtained by Reppe from acetylene, water, and a tertiary amine[3].

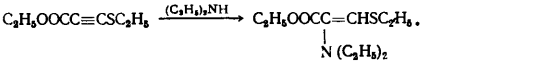
4-Ethoxy-2-methylbut-3-yn-2-ol and aniline form anilides of β-hydroxy-acids in 40% yield[49,57]:

Whereas diethylamine catalyses the decomposition of the tertiary 3-ethoxyprop-2-yn-1-ols:

nitroaniline facilitates their rearrangement into αβ-unsaturated ethers:

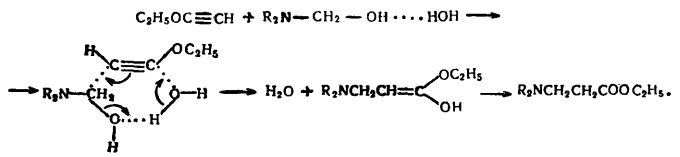


Alkynyl sulphides also react with amines on heating, to form addition products. Thus, ethyl ethynyl sulphide and diethylamine give an addition product in 65% yield[49,51].

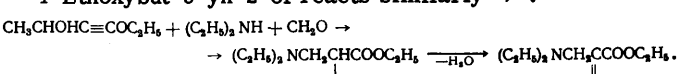


As Arens showed, the sulphide group can act as either a donor or an acceptor of electrons. A nucleophilic reagent adds on to the β carbon atom of an alkynyl sulphide in accordance with the polarisation of its multiple bond:

Alkynyl sulphones react with amines to form addition products; with an excess of the amine the sulphonyl group can be replaced by an amino-group[49,58]:



Ethyl ethylthiopropiolate adds on amines at the α carbon atom. Thus when it is heated with diethylamine an addition product is obtained in 74% yield[59]:

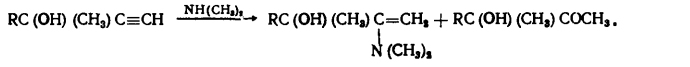


Ethylthiopropiolanilide and 1-ethylthiobut-1-yn-3-one react with amines in a similar manner[60].

Alkoxyalkynes react readily with amines and formaldehyde. Thus, ethoxyacetylene reacts with diethylamine and aqueous formaldehyde at room temperature[49,61], when ethyl 2-diethylaminopropionate is obtained instead of a Mannich base. Arens assumes that here aminomethanols are formed, which react in a hydrated form with the ethoxyalkyne. During this the hydrogen atom of the alkyne is not replaced by an aminomethyl group, but there is electrophilic addition at the triple bond, which takes place according to this scheme:

4-Ethoxybut-3-yn-2-ol reacts similarly[49,62]:

Ethoxyalkynes form bis-addition compounds with primary amines and aqueous formaldehyde[49]:



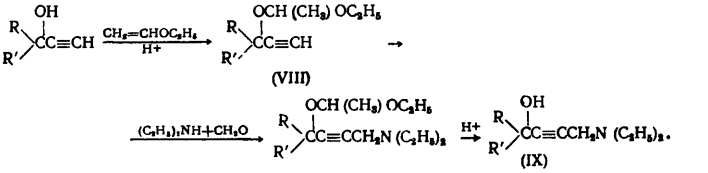
Electrophilic addition to the triple bond can probably also explain the ease of reaction of alkyl alkynes with amines and formaldehyde compared with acetylene; the decomposition of the intermediate addition product here leads to the formation of a Mannich base.

Ethylthioacetylene, unlike ethoxyacetylene, reacts with diethylamine and formaldehyde only on boiling in dioxan[63]. The product is formed by replacement of the alkynyl hydrogen by an aminomethyl group, the yield being quantitative.

## 5. REACTION OF ALKYNYL ALCOHOLS, THEIR DERIVATIVES, AND ALKYNYL OXIDES WITH AMINES AND AMMONIA

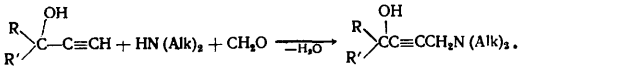
The published information on the addition of amines to the triple bond of alkynyl alcohols is restricted to the work of Vartanyan and Badanyan[64], who reported that when 2-methylbut-3-yn-2-ol or but-3-yn-2-ol are heated with aqueous dimethylamine at 100–120° vinyl amino-alcohols are formed, which are partly hydrolysed under the conditions of the experiment:

1-Ethynylcyclohexan-1-ol and 4-ethynylperhydro-2,2-dimethylpyran-4-ol react analogously.



Alkynyl alcohols and their derivatives react with amines under aminomethylation conditions at the alkynyl hydrogen atom.

Whereas α-ethynylmethanols themselves react with secondary amines and formaldehyde at 80° to form the corresponding compounds in low yields, their acetates form Mannich bases in 50–90% yields[45,65]:



However, this method of obtaining amino-alcohols is inapplicable when R and R′ are aromatic radicals, as the corresponding alkynyl alcohols are unstable in acid and alkaline media.

Shvekhgeimer[66] used an indirect path for the synthesis of the amino-derivatives of alkynyl alcohols:

The reaction of the acetals (VIII) with paraformaldehyde and diethylamine occurs when the mixture is heated in dioxan for many hours, and leads to the formation of aminoacetals (IX) with 75–97% yield.

Libman and Kuznetsov aminomethylated tertiary ethynylmethanols in the presence of copper compounds at 80–90°. The reaction is rapid and the yield 80–95%:[67]

Under these conditions amino-alcohols of the structure

are synthesised in 83–95% yield[68].

Pent-4-yn-1-ol reacts with diethylamine and formaldehyde on heating to 40–50° in the presence of copper salts, forming 6-diethylaminohex-4-yn-1-ol in 69% yield[69,70]:

$$HOCH_2CH_2CH_2C{\equiv}CH + (C_2H_5)_2NH + CH_2O \rightarrow HOCH_2CH_2CH_2C{\equiv}CCH_2N(C_2H_5)_2.$$

The following alkoxy- and acyloxy-derivatives of alkyl alkynes also undergo aminomethylation:

$C_2H_5OCH_2C{\equiv}CH$;[71] $(C_2H_5O)_2CHC{\equiv}CH$;[72] $R_1OCR_2R_3(CH_2)_nC{\equiv}CH$;[73] $CH_3(AcO)CHC{\equiv}CH$, $C_6H_5(OAc)CHC{\equiv}CH$;[74] $AcO(CH_2)_2C{\equiv}CH$;[75] $R_1R_2C(OR_3)C{\equiv}CH$.[76]

The low reactivity of the labile hydrogen of alkynyl alcohols in reactions involving substitution by the aminomethyl group is attributed by some to the electron-donor influence of the hydroxyl[67]. Displacement of the electrons of the hydroxyl group towards the side of the alkynyl hydrogen is believed to deactivate it, hindering protonation.

The addition of amines and ammonia to oxides of alkynes and but-1-en-3-ynes does not take place at the triple bond but by opening of the oxide ring according to Krasuskii's rule[77–81].

## 6. REACTION OF ALKYNYL AND BISALKYNYL KETONES WITH AMINES AND AMMONIA

Alkynyl and bisalkynyl ketones, and also alkynyl diketones readily add amines at the triple bond. The amino-group enters the $\beta$ position to the carbonyl group. The latter is a strong acceptor of electrons and intensifies the electrophilic nature of the triple bond, facilitating nucleophilic addition.

Alkynyl ketones add on primary and secondary amines and ammonia even at room temperature, forming 2-aminovinyl ketones in 36–97% yield[82–84]:

$$RCOC{\equiv}CR' + NHR_2'' \rightarrow RCOCH{=}CR'NR_2'',$$

where R is alkyl or aryl.

With conjugated ethynylene–vinylene ketones, the addition of the amine proceeds under analogous conditions at the triple bond[83]:

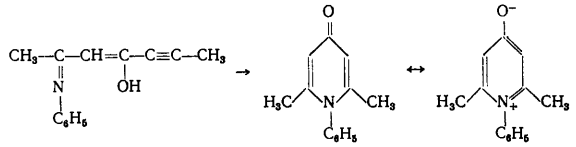
$$RCOCH{=}CH{-}C{\equiv}CH \xrightarrow{NH(C_2H_5)_2} RCOCH{=}CH{-}CH{=}CHN(C_2H_5)_2,$$

where R is alkyl.

Ketones in which the carbonyl group is between a double and triple bond also add ammonia to the triple bond[83]:

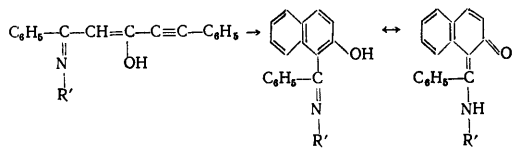
$$RCH{=}CH{-}CO{-}C{\equiv}CH \xrightarrow{NHR_2'} RCH{=}CHCOCH{=}CHNR_2'.$$

Alkynyl diketones also react readily with amines and ammonia. Dibenzoylacetylene forms the corresponding addition products with amines and ammonia[85,86]:



$$C_6H_5COC{\equiv}CCOC_6H_5 \xrightarrow{RNH_2} C_6H_5CO(RNH)C{=}CHCOC_6H_5$$
$$\xrightarrow{NH_3} C_6H_5CO(NH_2)C{=}CHCOC_6H_5,$$

where R is alkyl or aryl.



Bisalkynyl ketones readily add on ammonia and primary and secondary amines in the cold or on heating to 50°:[87–91]

$$R{-}C{\equiv}C{-}CO{-}C{\equiv}C{-}R \xrightarrow{R'NH_2} R{-}C{=}CHCOC{\equiv}C{-}R \rightleftarrows R{-}C{-}CH{=}C{-}C{\equiv}C{-}R$$
$$\underset{R'}{|}NH \qquad\qquad R{-}\underset{\|}{N} \quad \underset{OH}{|}$$
$$\xrightarrow{R_2'NH} R{-}C{=}CHCOC{\equiv}C{-}R \rightleftarrows R{-}C{=}C{=}C{-}C{\equiv}C{-}R$$
$$\underset{NR_2'}{|} \qquad\qquad \underset{NR_2'}{|}\ \underset{OH}{|}$$

The addition products of the secondary amines are thermally stable. On heating to 150° the addition products of primary amines isomerise into a 4-pyridone, when R is an alkyl radical:

When R is an aryl radical the isomerisation proceeds in two directions; in addition to a pyridone an isomeric cyclic compound is formed[87–93]:

With aniline, the reaction starts at 150° and sometimes ends with an explosion.

The ketone $CH_3C{\equiv}CCOC{\equiv}CC_6H_5$ adds on aniline at both triple bonds, forming a mixture of two substances (XI) and (XII) with a total yield of 75%:[93]

$$CH_3C{\equiv}CCOC{\equiv}CC_6H_5 \xrightarrow{C_6H_5NH_2} \begin{cases} CH_3C(NHC_6H_5){=}CHCOC{\equiv}CC_6H_5 \ (XI) \\ CH_3C{\equiv}CCOCH{=}C(NHC_6H_5)C_6H_5 \ (XII) \end{cases}$$

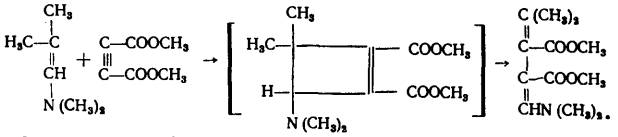
Substance (XI) preponderates in the mixture; the proportion of (XII) does not exceed 2%.

## 7. REACTION OF ETHYNYLCARBOXYLIC ACIDS AND THEIR ESTERS WITH AMINES AND AMMONIA

Like alkynyl ketones, ethynylcarboxylic acids and their esters react readily with amines, forming unsaturated compounds with the amino-group in the $\beta$-position to the carboxy-group[94–99]:

$$R{-}\overset{\beta}{C}{\equiv}\overset{\alpha}{C}{-}C\begin{matrix}=O \\ OR'\end{matrix} + HNR_2'' \rightarrow RC(NR_2'')=CH{-}COOR'.$$

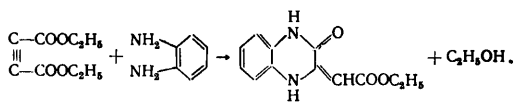
Postovskii and coworkers have shown that cyclic secondary amines add on to propiolates, tetrolates, phenylpropiolates, and ethynyldicarboxylates when cooled with ice, followed by heating to 30–60°.[98,99] Monoaddition products are formed in 16–78% yield:



$$RC{\equiv}C{-}COOR' + HN\Big\} \rightarrow R{-}C{=}CH{-}COOR',$$
$$\qquad\qquad\qquad\qquad\qquad\quad \underset{N}{|}\Big\}$$

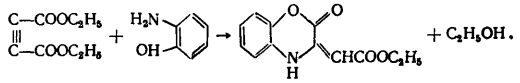
where $N\Big\}$ represents the residue of the cyclic amine.

Ethynyldicarboxylates also react readily with amines. Thus, diethyl ethynyldicarboxylate adds on benzylamine and aniline at room temperature, forming diethyl *N*-benzylaminofumarate and diethyl anilinofumarate, the yield being 63% in each instance[100]:



$$\begin{matrix} C{-}COOC_2H_5 \\ \| \\ C{-}COOC_2H_5 \end{matrix} \xrightarrow{C_6H_5CH_2NH_2} \begin{matrix} CH{-}COOC_2H_5 \\ \| \\ C(NHCH_2C_6H_5)COOC_2H_5 \end{matrix}$$
$$\xrightarrow{C_6H_5NH_2} \begin{matrix} CH{-}COOC_2H_5 \\ \| \\ C(NHC_6H_5)COOC_2H_5 \end{matrix}.$$

Brannock and coworkers [101] showed that ethynyldicarboxylates react with tertiary enamines at the double bond:



The reaction of ethynyldicarboxylic acid and its esters with bifunctional compounds, such as *o*-phenylenediamine, *o*-aminophenol, ethylenediamine, and *o*-aminobenzenethiol leads to the formation of heterocyclic compounds [102,103]. The reaction proceeds in stages: initially one amino-group reacts, forming an addition product, which then cyclises.

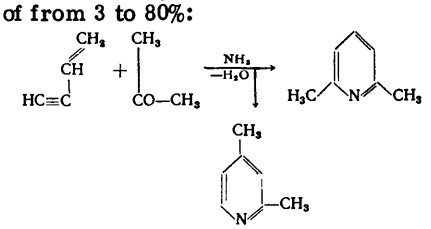
Diethyl ethynyldicarboxylate reacts at room temperature with *o*-phenylenediamine to form ethyl 1,2,3,4-tetrahydro-3-oxoquinoxalin-2-ylideneacetate:

Diethyl ethynyldicarboxylate and *o*-aminophenol give ethyl 3,4-dihydro-2-oxobenzo[*b*]-[1,4]-oxazin-3-ylideneacetate:

Acetylenedicarboxylic acid and *o*-phenylenediamine form 1,2,3,4-tetrahydro-3-oxoquinoxalin-2-ylideneacetic acid.

## 8. REACTION OF BUT-1-EN-3-YNES AND THEIR DERIVATIVES WITH AMINES AND AMMONIA

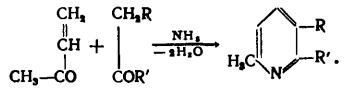
The addition of amines to but-1-en-3-yne takes place in the 1,4 position with formation of an intermediate allene derivative, which is isomerised into a diene or alkynylamine [104,105].



But-1-en-3-yne adds on secondary aliphatic amines on heating to 100° in aqueous solution under pressure, forming alleneamines. When the reaction occurs with an excess of the amine, then the alleneamine formed rearranges into an alkynylamine [104,105]:

$$CH_2{=}CH{-}C{\equiv}CH + R_2NH \rightarrow CH_2{=}C{=}CH{-}CH_2NR_2 \rightarrow CH_3C{\equiv}CCH_2NR_2.$$

Primary amines react analogously.



But-1-en-3-yne reacts with ammonia at 250° under the influence of a lead–cadmium catalyst deposited on aluminium oxide; aliphatic amines, picoline, and collidine are formed [105].

Vereshchagin showed [106-108] that but-1-en-3-yne condenses with ammonia and ketones at 350–400° in the presence of cadmium catalysts to form substituted pyridines in yields of from 3 to 80%:

The reaction mechanism is:

$$CH_2{=}CH{-}C{\equiv}CH + H_2O \rightarrow CH_2{=}CH{-}CO{-}CH_3$$

During the reaction of but-1-en-3-yne with piperidine, morpholine, and methylaniline in the presence of copper compounds, nitrogen-containing unsaturated bases used in rubber production are formed [105].

The reaction of but-1-en-3-yne with lithium dialkylamides can be used to obtain addition products which on treatment with water form amines with a terminal ethynyl group [105,109,110]:

$$CH{\equiv}C{-}CH{=}CH_2 \xrightarrow{R_2N{-}Li} H{-}C{=}C{=}CH{-}CH_2NR_2 \rightarrow$$
$$\rightarrow Li{-}C{\equiv}C{-}CH_2{-}CH_2NR_2 \xrightarrow{H_2O} CH{\equiv}C{-}CH_2CH_2NR_2.$$

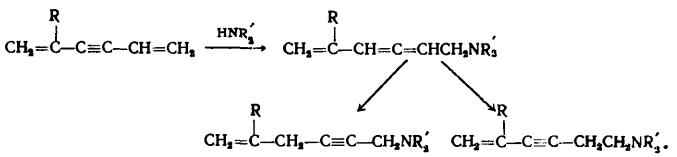
With alkyl substituted but-1-en-3-ynes the final product is an *NN*-dialkyl-4-alkylbuta-2,3-dien-1-amine:

$$R{-}C{\equiv}C{-}CH{=}CH_2 \xrightarrow{R_2N{-}Li} R{-}CLi{=}C{=}CH{-}CH_2NR_2 \xrightarrow{H_2O}$$
$$\rightarrow R{-}CH{=}C{=}CH{-}CH_2NR_2.$$

The yields of these compounds reach 45–55%. But-1-en-3-yne is an exception, which mainly forms a dimer under the conditions of this reaction.

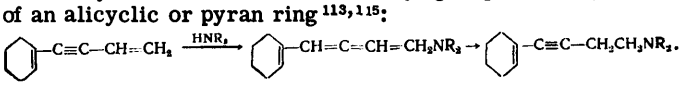
But-1-en-3-yne reacts with secondary amines and formaldehyde (in dioxan) at 100° under pressure to form the corresponding bases [111]:

$$CH_2{=}CH{-}C{\equiv}CH \xrightarrow{R_2NH,\ CH_2O} CH_2{=}CH{-}C{\equiv}C{-}CH_2NR_2 + H_2O.$$



The yield varies from 9 to 91% with various amines.

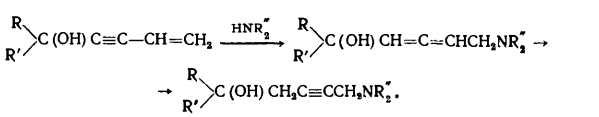
Nazarov and Mistryukov showed [112] that thoroughly purified paraformaldehyde and diethylamine hardly react with but-1-en-3-ynes. It is only when catalytic quantities of iron salts [iron(III) chloride] are added to the reaction mixture that aminomethyl derivatives are formed smoothly with yields of up to 90%:



$$-\overset{|}{C}{=}\overset{|}{C}{-}C{\equiv}CH \xrightarrow[CH_2O]{(C_2H_5)_2NH} -\overset{|}{C}{=}\overset{|}{C}{-}C{\equiv}C{-}CH_2N(C_2H_5)_2 + H_2O.$$

The reaction takes place on heating in dioxan solution.

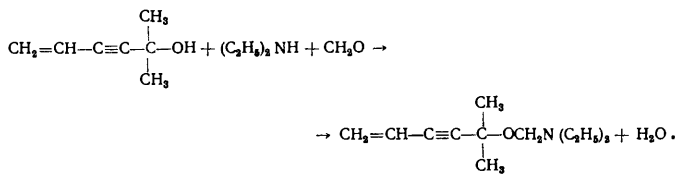
Hexa-2,5-dien-3-yne adds on secondary amines in the 1,4 position when heated in a sealed tube to 95–100°. [113,114] The triene amine formed undergoes isomerisation in two directions; as a result, hexa-5-en-2-ynyl and hexa-5-en-3-ynyl amines are obtained:



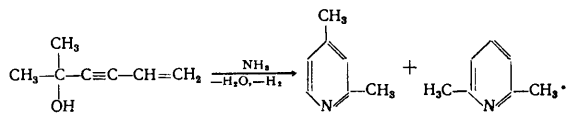
In a similar way dimethylamine adds on to hexa-1,5-dien-3-ynes in which one of the vinyl groups forms part of an alicyclic or pyran ring [113,115]:

As Vartanyan and coworkers have shown, the addition of amines to but-1-en-3-ynyl alcohols [116-118] and their esters [119] takes place in the 1,4 position on heating them with an

aqueous solution of the amine, and leads to the formation of allene amino-alcohols, which isomerise into alkynyl amino-alcohols (yield > 50%):



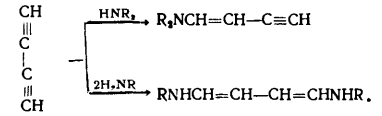
But-1-en-3-ynyl piperidols [120], tetrahydro-4-pyranols, and tetrahydro-4-thiopyranols [121], but-1-en-3-ynyl phenols and their ethers [122] behave analogously.



Dialkylaminomethylbut-1-en-3-ynes add on amines in the 1,4 position. The allene diamines formed do not isomerise into alkynyl diamines [123]:

But-1-en-3-ynyl alcohols undergo aminomethylation on boiling in dioxan or benzene, forming aminomethyl vinyl-alkynyl ethers with 43–71% yield [124]:

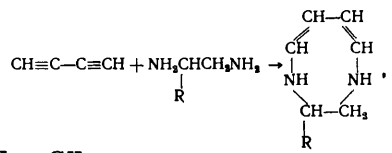
Tertiary but-1-en-3-ynyl alcohols undergo catalytic condensation with ammonia at 285–470°. Cadmium and chromium compounds are mainly used as catalysts. Pyridine bases are formed in low yield [106–108,125]:



Secondary vinylethynylmethanols on condensation with ammonia on cadmium catalysts at 400° decompose into aldehydes and but-1-en-3-ynes [126]. The aldehyde formed reacts with ammonia to form pyridine bases. Vinylacetylene does not participate in this reaction.

## 9. REACTION OF BUTA-1,3-DIYNE WITH AMINES

The first patent communication of this reaction stated that buta-1,3-diyne reacts with diethylamine at 45° in the presence of copper or silver salts to form diethylaminobutenyne [127].



Later Petrov and his coworkers showed that the reaction of buta-1,3-diyne with secondary amines is effected in the cold without a catalyst in benzene solution to form *NN*-dialkylbut-1-en-3-ynamines [128].

The results of systematic investigation of the reaction of diacetylene with amines and amino-alcohols were given by Shostakovskii and his coworkers [129–137]. They showed that buta-1,3-diyne reacts with aliphatic amines at room temperature on passing the buta-1,3-diyne through the amine. Evidently the strongly basic amines show a catalytic action on the course of this reaction. The direction of the addition of the amines to buta-1,3-diyne depends essentially on the nature of the amine. Secondary amines add on in the 1,2 position to form *NN*-dialkylbut-1-en-3-ynamines in 60–70% yield. Primary amines react with buta-1,3-diyne under analogous conditions, adding on in the 1,2 and 3,4 positions, and forming *NN'*-dialkylbuta-1,3-diene-1,4-diamines in 80% yield [130,132,135]:

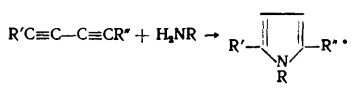
Unsaturated primary and secondary amines, such as allyl- and diallyl-amines, react similarly [137].

Buta-1,3-diyne reacts much more vigorously with bifunctional compounds (diamines and 2-aminoethanol) than with aliphatic amines [134]. The products of the reactions with propylenediamine and ethylenediamine are heterocyclic compounds: 1,2,3,4-tetrahydro-2-methyl-1,4-diazocine and 1,2,3,4-tetrahydro-1,4-diazocine respectively. The yields are 55–70%:

where R is H or $CH_3$.

Buta-1,3-diyne reacts with 2-aminoethanol at the two triple bonds, forming a linear product of addition in the 1,4 position [134].

Dialkylamino-alcohols react with buta-1,3-diyne by adding on to the triple bond in the 1,2 position [129,131]. The reaction is exothermic, without the participation of a catalyst, and leads to the formation of the corresponding ethynyl vinyl ethers with 80–90% yield:



All the above-mentioned reactions of buta-1,3-diyne with amines, amino-alcohols, and diamines proceed stereospecifically with formation of the *cis*-isomers [133–135].

These reactions show the astonishing difference in the behaviour of buta-1,3-diyne and acetylene when they react with amines, amino-alcohols, and diamines. The exceptional ease of reaction of alkylamines and 2-aminoethanols with buta-1,3-diyne is apparently due, above all, to the fact that nucleophilic addition at the triple bond of buta-1,3-diyne is activated by the second ethynyl group, which behaves in relation to the first as an electron-acceptor substituent.

But here it is impossible not to consider also the role of the second component, that is, the amino-compound, which possesses basic properties. Thus, aromatic amines (aniline, methylaniline) under analogous conditions do not react, since their basic properties are diminished owing to the delocalisation of the lone pair of $p$ electrons of the nitrogen with the $\pi$ electrons of the nucleus.

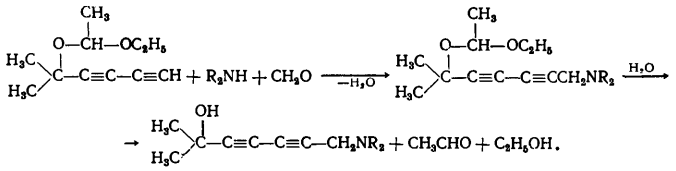
The reaction of buta-1,3-diyne with aliphatic alcohols free from amino-groups takes place only at 70–100° under the influence of an alkaline catalyst [138,139].

Disubstituted buta-1,3-diyne R'C≡C–C≡CR", where R' and R" are aliphatic, aromatic, or heterocyclic radicals, reacts with primary aliphatic and aromatic amines in the presence of small quantities of copper(I) chloride to form trisubstituted pyrroles [140]:

Buta-1,3-diyne can react with a mixture of a secondary amine and paraformaldehyde in the presence of copper or silver salts [141]. It is suggested that the reaction proceeds through the intermediate formation of an aminomethanol, leading to mono- and di-substituted products:

$$CH{\equiv}C{-}C{\equiv}CH + HOCH_2NR_2 \xrightarrow[-H_2O]{} CH{\equiv}C{-}C{\equiv}CCH_2NR_2 \rightarrow$$

$$\xrightarrow[-H_2O]{HOCH_2NR_2} R_2NCH_2{-}C{\equiv}C{-}C{\equiv}C{-}CH_2NR_2.$$



Alkadiyne compounds with isolated triple bonds react with amines and formaldehyde in dioxan solution with a copper catalyst at 80–100° and bisalkynyl ethers react at 80° to form the corresponding diamines [142–144]:

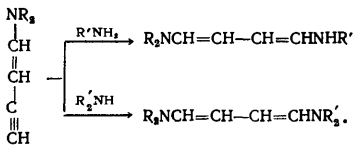
$$CH{\equiv}C{-}(CH_2)_n{-}C{\equiv}CH + 2\,R_2NH + 2\,CH_2O \rightarrow$$

$$\xrightarrow[-2H_2O]{} R_2NCH_2C{\equiv}C{-}(CH_2)_n{-}C{\equiv}CCH_2NR_2,$$

$$(CH{\equiv}CCH_2)_2O + 2\,R_2NH + 2\,CH_2O \xrightarrow[-2H_2O]{} (R_2NCH_2C{\equiv}CCH_2)_2O.$$

The acetal derivative and acetate of 2-methylhexa--3,5-diyn-2-ol react readily on heating with amines and formaldehyde at their labile hydrogen atom; diyne amino--alcohols are formed in good yield [145]:

## 10. REACTION OF BUTENYNES CONTAINING A HETEROATOM IN THE α-POSITION TO MULTIPLE BONDS, WITH AMINES



In recent years there has been an investigation of compounds of structure

$$RXCH{=}CH - C{\equiv}CH,$$

where X = O, N, or S, made in connection with the progress of work on the chemistry of buta-1,3-diyne.

The ability of these compounds to enter into nucleophilic additions is less than that of buta-1,3-diyne and approaches the reactivity of but-1-en-3-yne derivatives.

The addition of amines to butenyneamines takes place at the 3,4 position, and as a result of the reaction, 1,4-substituted dienes are formed with yields up to 80%. [132,133,135] The yield of the reaction product and the conditions of the reaction are determined by the nature of the amine being added:

The addition of amines to a triple bond of butenyneamines, despite Markovnikov's rule, does not correspond with the electron displacements in their molecules:

The displacement of the electron density in butenyneamines, due to the delocalisation of the electron pair of the nitrogen atom over the enyne system, is confirmed by the investigation of the intensities and positions of the absorption bands of the C≡C and ≡C–H stretching vibrations in these compounds and also by the determination of the dipole moment for *NN*-diethylbut-1-en-3-yne-1-amine [146–149].

These reactions can be also regarded as electrophilic additions of an ammonium ion to the position of greatest electron density [150]:

$$\overset{+}{R}NH_3 \ldots \overset{-}{H}C{\equiv}C{-}CH{=}CHNR_2 \rightarrow H(NHR)C{=}CH{-}CH{=}CHNR_2.$$

The formation of positively-charged ions is evidently explained by transfer of a proton in consequence of the autoprotolysis of the amines, which here act as amphiprotic solvents:

$$2\,RNH_2 \rightleftarrows [RNH]^- + [RNH_3]^+.$$

The formation of ammonium ions can be made possible by the presence of traces of moisture. For example, it is well known [49] that the addition of amines to alkoxyalkyne is catalysed by water.

The addition of amines to oxygen- and sulphur-containing analogues of ethynylvinylamines under analogous conditions has not been accomplished.

Whilst this review was being considered by the editors a work was published on the addition of aqueous and dry amines to dimethyldiacetylenemethanol [151].

## I. INTRODUCTION

Hot atom chemistry dates from the discovery, made by Szilard and Chalmers in the nineteen-thirties, that as a result of a nuclear reaction, radioactive atoms leave the original molecule and are found partly in a chemical form which can be separated from the initial form. Fermi showed that the reactivity of these atoms is associated with the considerable recoil impulse produced when the second particle is ejected in the nuclear process. Although the first work in the field of the chemistry of hot atoms (as atoms exhibiting appreciable kinetic energy came to be called) was devoted chiefly to the practical utilisation of the Szilard–Chalmers method for the preparation of enriched specimens of radioelements, the main attention was subsequently directed to the secondary effects associated with the chemical action of hot atoms. Here two directions have been distinguished.

Part of the work is carried out with the aim of finding an effective method for preparing labelled compounds, particularly those which are difficult to obtain by ordinary chemical synthesis or by isotopic exchange. The possibilities of the hot synthesis of organic compounds labelled with tritium and carbon have been discussed in reviews by Nesmeyanov and coworkers[1–3].

Another direction in hot atom chemistry involves the investigation of the mechanism of the elementary act of the atom–molecule collision and the subsequent reactions brought about by the transfer of the excess of energy from the atom to the molecule. Since the publication of reviews by Nesmeyanov and Borisov[4,5] in 1957 and earlier, no attempt has been made in the Soviet literature to examine the achievements made in this direction. The present paper examines the results obtained in recently published work. Particular attention is paid to the theoretical interpretation of the results. The review does not reflect completely all directions of study in hot atom chemistry: the main attention is paid to work whose results lead to definite conclusions regarding the mechanism of hot reactions.

At the present time, hot atom chemistry is attracting increasing attention as a branch of high-energy chemical kinetics. This is indicated by the two international conferences held in Prague in 1960 and in Vienna in 1964.

## II. SOME PHYSICOCHEMICAL PRINCIPLES OF HOT ATOM CHEMISTRY

### 1. The Possibility of Applying the Theory of Absolute Reaction Rates to High-Energy Chemical Processes

The first problem arising in the theoretical interpretation of the results of experiments in hot atom chemistry is the extent to which the ideas of an intermediate complex as the transition state of the reacting atom–molecule system are applicable to the reactions of high-energy atoms. The Arrhenius–Eyring equation is:

$$k \simeq z \exp[-E/RT] \simeq pz \exp[-E/RT] \simeq \chi pz \exp[-E/RT], \quad (1)$$

where $z$ is the number of active collisions, $p$ a steric factor, and $\chi$ the transmission coefficient, with $\chi = \rho\sigma$, where $\rho$ is the probability of transition between potential surfaces, and $\sigma$ the reflection coefficient (the reflection coefficient is related to the rate of deactivation in the transition state). This equation can be used to calculate reaction rate constants if the following conditions are satisfied: (1) the reaction A + BM → [AB]M → AB + M is adiabatic, that is, takes place on one potential surface; (2) the potential energy surface has a range corresponding to the existence of the activated complex; (3) equilibrium is established between the reacting substances and the complexes; and (4) the transmission coefficient is constant and close to 1.

Lack of agreement between experimental data and theoretically calculated values for the rates of chemical reactions is attributed to the fact that the intermediate and final products are formed initially with an irregular distribution of energy in the vibrational degrees of freedom. Vibrational--rotational non-equilibrium distributions may also arise as a result of inelastic collisions of the second type (extinction of electronic-excited states on collision). Deviations from "ordinary" kinetics are observed in processes accompanying the combustion of reactive fuels, rapid explosion reactions, etc.[6]

The pictorial model representation of a chemical reaction as the movement of a configurational point over a potential energy surface[7,8] is untenable in the study of reactions initiated by the collisions of fast atoms, in which the duration of the interaction is much less than the rate of energy transfer from the local point of collision to the molecule as a whole. From this it follows that conditions 1–4 can hardly be applicable to reactions initiated by the collisions of hot atoms, in view of the marked non-equilibrium character of the process of energy transfer on collision. Theoretical studies of non-equilibrium processes are at present in the development stage[9,10].

A specific feature of hot atoms is that they approach the range of the energy of chemical interaction "from above", from the direction of higher energies. On retardation, the hot atom passes successively through energy levels until it falls into an energy range below the activation energy for the reaction. In ordinary kinetics, the atoms which reach $E = E_{act}$ "from below" (that is, the active atoms) are able to take part in a chemical interaction which proceeds on a definite surface corresponding to $E = E_{act}$. The hot atom has at its disposal a set of potential surfaces (possibly with facilitated transition between them) and this makes it very difficult to calculate the probability of chemical interaction by means of a model which represents the

course of the reaction in the form of the movement of a configurational point.

Since the reaction of hot atoms with molecules leads to their stabilisation in definite chemical forms, some hot atom–molecule transition state must exist.

The aim of hot atom chemistry is to determine the nature of this transition state and the energy at which bond formation between the hot atom and the molecule takes place, and to investigate the influence of various factors on the course of hot reactions.

## 2. Reactions of Excited Molecules and Processes of Excitation Energy Transfer

As shown in Section I.1, the ideas of "ordinary" kinetics provide little basis for understanding the high reactivity of hot atoms. Irrespective of the way in which a chemical bond is formed by a hot atom on collision with a molecule, however, it is undoubtedly the case that the primary "labelled" molecule is excited. Stabilisation of this molecule can take place only with dissipation of the excitation energy. Most information on this question, particularly in recent years, has been given by radiation chemistry. The deviations, observed in a number of studies, from the law of radiation-chemical additivity in the radiolysis of binary systems can be attributed to a process involving the transfer of the excess of energy from the initially excited molecule fragments [11–15]. Analysis of experimental data on "large" and "small" deviations from additivity showed that in the first case the rate of transfer of energy is greater than the number of collisions with inhibitor by a factor of at least 10 (inhibitor concentration $< 0.01$ M). It is evident that the excitation energy is "thrown" 50–70 Å during the lifetime of the excited molecule. These processes can take place only under conditions where the excitation spectra of two components of the mixture overlap. This condition can be realised in practice by selecting substances with similar chemical structures.

If the action of radiation on a substance leads to the formation of molecular ions, the solution of the problem of energy transfer becomes possible if the following conditions are satisfied: (1) the inhibitor has a complex system of levels (an almost continuous spectrum) in the region of the excitation energy of the main component; (2) the medium is transparent, that is, the excitation levels of the molecular fragments (in particular, ions) formed during radiolysis lie below the first excitation electronic level of the main molecule. Brodskii [13] showed that the probability of inhibition is determined by the equation

$$W = kN^{2/3}\left(1 + \frac{N^{2/3}}{\omega^2} + \frac{N^{4/3}}{\omega^4}\right), \qquad (2)$$

where $N$ is the concentration of inhibitor, and $\omega$ the excitation energy. The available experimental data show good agreement with Eqn. (2) over a wide range of concentrations. Since the excitation energy cannot always be determined accurately, use is made of another equation, previously established experimentally:

$$G = k r^3 = k\left(\frac{1}{\sqrt[3]{N}}\right)^3, \qquad (3)$$

where $G$ is the radiation yield, and $r$ the mean distance between the inhibitor molecules, expressed in the number of molecules of the main substance. Eqn. (3) is a first approximation of the more general equation (2). The physical nature of the phenomenon described by Eqn. (2) is the existence of a mechanism of energy transfer analogous to sensitised fluorescence–non-radiative electromagnetic transition [15].

"Small" deviations from additivity are attributed to the direct transfer of energy through the formation of a donor–acceptor complex according to the scheme: $A^* + B \rightarrow \rightarrow [AB]^* \rightarrow A + B$, where the complex breaks down to non-excited particles.

Simple energy transfer on collision $A^* + B \rightarrow A + B^*$ either is very difficult or does not take place at all. This important experimental fact was established in an analysis of the radiation-chemical yields in the cyclohexane–benzene system and in the study of the intensity of fluorescence in the cyclohexane–terphenyl, benzene–terphenyl, and cyclohexane–benzene–terphenyl systems [11]. Since the chief primary particles in radiolysis are excited and ionised molecules, the part played by benzene in the complex $[AB]^*$ is assumed to involve the following processes: (1) the benzene brings about the conversion of the electronic excitation of the cyclohexane molecules; and (2) the benzene removes the charge from the cyclohexane molecule, since the ionisation potential of benzene is lower by 1.8 eV.

From the viewpoint of the formation of donor–acceptor complexes, it is also possible to explain the "large" deviations from additivity, observed at low concentrations of added acceptor, if we assume the existence of associates consisting of molecules of the main substance; in this case the collision of an inhibitor molecule with an associate is equivalent to a collision with an initially excited molecule.

The explanation of the results of radiolysis, however, even for a well-studied system such as the cyclohexane–benzene system, is ambiguous, since the benzene may react with thermal hydrogen atoms:

$$C_6H_6 + H^{\cdot} \rightarrow C_6H_7^{\cdot} \rightarrow \text{polymer}$$

(pyridine shows analogous behaviour in mixtures with benzene [16]).

Moreover, according to Swallow's hypothesis [17] (based on the data of Inokuti on cross-sections for the interaction of electrons with benzene molecules), radiation may be selectively absorbed in a mixture of two components, so that the concentration dependence of the yields of radiolysis products shows marked departure from linearity. Thus departure from additivity in the radiolysis of binary systems does not provide sufficient basis for concluding that energy transfer from the initially excited molecules occurs and influences the yield of radiolysis products.

If Swallow's model were applicable, the radiolysis of a cyclohexane–benzene binary mixture in the gaseous phase at low pressures should give the same effect as that given in the liquid phase. Since the gas-phase radiolysis showed differences from the regular features observed for condensed systems [18], doubt was cast on the applicability of Swallow's hypothesis.

Since the transfer of excitation energy assumes the existence of long-lived states — and this has not been proved spectroscopically — some authors suggest that the deviation from the law of radiation-chemical additivity is due to the formation of hot hydrogen atoms during radiolysis. The energy of the hydrogen atoms formed during radiolysis varies from fractions of 1 eV to 1–3 eV. These atoms are capable of detaching hydrogen from organic compounds with consequent breakdown of the primary distribution of radiolysis products [19,20].

The most appropriate viewpoint is that which allows for the principal effects observed: one of the observed (or assumed) effects may play a major part, depending on the nature of the compounds and the relative concentration of the components[21].

The processes of excited molecule stabilisation are apparently accompanied by intramolecular energy transfer. This was proved by experiments on the radiolysis of alkylbenzenes. The yield of radicals from the compounds $C_6H_5R$ (where R= alkyl) is less than that from the mixture $C_6H_6$ + RH. This indicates a process of effective energy transfer from the side chain into the phenyl ring. At the same time, analysis of the radiolysis products of alkylbenzenes indicated that the greatest tendency to undergo rupture is shown by the bond formed by the second carbon atom in the side chain, that is, the $C_6H_5CH_2^{\cdot}$ radical is formed in highest yield, irrespective of the length of the chain. This can be attributed to transfer of excitation energy from the benzene ring into the side chain, or simply to the high "vulnerability" of the $\alpha$ position in intramolecular energy migration.

The yields of the products of hot reactions also show deviation from the additivity law, suggesting that the process of energy transfer from the excited labelled products takes place.

## 3. The Retardation of Hot Atoms (Physical Interpretation)

It has recently been assumed that the retardation of hot atoms in the range of energies in which the reactions of hot atoms do not take place obeys the laws derived from the assumption of elastic particle collisions. In this case the retardation spectrum can be calculated using the equations describing the process of neutron thermalisation[22,23].

The fraction of the energy remaining on a recoil atom (m) after collision with another atom (M) is

$$E'/E = \frac{m^2 + M^2 + 2mM\cos\theta}{(m+M)^2}. \quad (4)$$

The minimum fraction is

$$\alpha = \left(\frac{m-M}{m+M}\right)^2. \quad (5)$$

The loss of energy or the fraction of the energy transferred to an atom of the medium is equal to

$$E''/E = \frac{2mM}{(m+M)^2}(1-\cos\theta). \quad (6)$$

The maximum loss is

$$\beta = \frac{4mM}{(m+M)^2}, \quad (7)$$

where $\theta$ is the scattering angle of the centre of mass in the system. The extent of the deviation from spherical scattering can be estimated from the mean value of the cosine of the angle of scattering in a laboratory system of coordinates ($\overline{\cos\varphi}$):

$$\overline{\cos\varphi} = \int_0^{\pi} \cos\varphi\,\lambda(\theta)\,d\theta = \int_0^{\pi} \frac{(M\cos\theta + m)}{\sqrt{m^2 + M^2 + 2mM\cos\theta}} \frac{1}{2}\sin\theta\,d\theta, \quad (8)$$

where $\lambda(\theta)d\theta$ is the probability of scattering.

For the case of the retardation of tritium recoil atoms in a hydrogen-containing medium, expression (8) becomes

$$\overline{\cos\varphi} = \frac{1}{2}\int_{-1}^{+1} \frac{y+3}{\sqrt{1+6y+9}}\,dy, \quad (9)$$

where $y = \cos\theta$, and $dy = -\sin\theta d\theta$.

Solution of integral (9) gives $\overline{\cos\varphi} = 0.9$, that is, the scattering of tritium recoil atoms in hydrogen-containing media is markedly anisotropic.

The number of collisions necessary for retardation of a given energy $E$ from an initial energy $E_0$ is

$$k = \frac{\ln\frac{E_0}{E}}{\xi}, \quad (10)$$

where $\xi$ is the logarithmic energy decrement

$$\xi = \overline{\ln\frac{E}{E'}} = 1 + \frac{\alpha}{1-\alpha}\ln\alpha. \quad (11)$$

For a chemical two-component compound or binary mixture of substances, the logarithmic decrement is

$$\xi = f_1\xi_1 + f_2\xi_2 = \frac{N_1\sigma_1\xi_1 + N_2\sigma_2\xi_2}{N_1\sigma_1 + N_2\sigma_2}, \quad (12)$$

where $N_1\sigma_1$ and $N_2\sigma_2$ are the macroscopic scattering cross-sections ($N\sigma = \Sigma_S$), $N_1$ and $N_2$ the mole fractions, $\sigma$ the microscopic scattering cross-section, and $f_1$ and $f_2$ the geometric probabilities of collision with the first and second components of the mixture.

The beam of hot atoms which have reached the energy level $E$ is defined by the expression

$$n(E) = \frac{q}{\xi E\Sigma_s}, \quad (13)$$

where $q$ is the number of recoil atoms generated, in $cm^3 \times s^{-1}$. Expression (13) is applicable if $E \ll E_0$, that is, if the recoil atom has undergone at least several collisions with other atoms. A more precise criterion for the applicability of Eqn. (13) is that $E < \xi^3 E_0$. If this is not so, it is necessary to make allowance for the fact that the function $n(E)$ shows discontinuities at $E = \xi^n E_0$, where $n = 1, 2, 3\ldots$ (collision density oscillations).

A more accurate hot atom distribution than that given by formula (13) can be found by the two-group approximation method (Placzek[22] and Temkin[13]). The equations obtained are extremely cumbersome, and simple expressions can be obtained only when the tracks of the hot atoms overlap. This last condition is not satisfied, however, for hot atoms obtained by nuclear reactions.

Eqn. (13) is applicable to the retardation of recoil atoms on atoms with similar masses, and also when it is desired to find the value of $n(E)$ at a distance from the initial recoil energy. These conditions are generally realised in the study of reactions brought about by hot atoms.

If the hot atoms undergo chemical reactions in the energy range from $E_2$ to $E_1$, the retarded atom spectrum loses a fraction of recoil atoms equal to

$$1 - \exp\left[-\int_{E_1}^{E_2} \frac{p(E)}{\xi}\frac{dE}{E}\right], \quad (14)$$

where the exponent expresses the probability of avoiding hot reactions in the range $E_2$–$E_1$, and $p(E)$ is the chemical reaction excitation function. The latter is dependent on

energy and apparently has resonance character. This makes it possible to apply the basic formulae from the theory of neutron retardation (4)–(14) not only to the case of retardation through collision, but also to the derivation of equations for the yields in chemical reactions of hot atoms.

The theory of neutron retardation as applied to the collisions of hot atoms was recently developed by Hsiung and Gordus[24] for isotropic and anisotropic scattering with selection of two interaction potentials (rigid-sphere collisions and Lennard-Jones potential). It was shown that isotropic scattering with respect to the centre of mass with selection of the Lennard-Jones interaction potentials is achieved only for simple atomic systems (H + $H_2$, H + He) and then naturally coincides with the isotropic scattering for the elastic scattering of particles. For more complex systems, for example, the collision H + $CH_4$, the deviation from isotropy is significant. Thus in real systems where retardation of hot atoms takes place, the loss of energy will be dependent on the energy.

If by definition $\xi = \overline{\ln \frac{E}{E'}}$, Eqn. (11), we have

$$\xi = \int_{\alpha E}^{E} \ln \frac{E}{E'} \lambda(E, E')\, dE,$$

where $\lambda(E, E')$ is the scattering function[24]. Eqn. (11) was obtained for isotropic scattering with respect to the centre of mass, when the probability of scattering is

$$\lambda(E, E') = \frac{1}{2} \sin\theta d\theta.$$

## III. CHEMICAL REACTIONS OF HOT ATOMS

The general considerations discussed in Section II naturally do not resolve the problems facing hot atom chemistry. The theory of the kinetics of the reactions of hot atoms includes many problems, each of which is still far from being solved (non-equilibrium processes of energy transfer in hot-atom collisions, the dissociation of molecules, reaction excitation function, etc.). This explains the difficulty and ambiguity of the interpretation of results in hot atom chemistry. In recent years some progress has been made in this direction. Special experiments aimed at investigating the part played by individual factors influencing the yield of hot reactions have eliminated to a considerable extent the ambiguity and indefinite nature of the results.

The greatest number of papers has been published on the chemistry of hot atoms of tritium, the halogens, and carbon in organic systems, by Rowland and coworkers[25], Wolfgang and coworkers[26], Willard and coworkers[27], Nesmeyanov and coworkers[3,28–30], and Wolf and coworkers[31].

### 1. Mechanism of the Reactions of Hot Tritium Atoms

It is now regarded as firmly established that in reactions of hot atoms no transition complex with regular energy distribution exists; this also follows from the theory of the non-equilibrium processes of kinetic energy transfer on collision between a hot atom and a molecule. An exception is those systems in which, after the primary act of collision and transfer of energy, states with lives long enough ($10^{-7}$–$10^{-8}$ s) for the even distribution of energy throughout the degrees of freedom are produced†. The substances which have been studied in this connection include cyclopropane[32], cyclobutane[33], and unsaturated compounds[34–36].

The reactions of tritium recoil atoms with molecules containing saturated carbon–carbon bonds generally take place by direct single-stage interaction between the recoil atom and individual atoms (more accurately, chemical bonds‡); this primary process does not involve other atoms. The latter merely provide the spatial limitation in the attack by the hot atom.

With this approach to the mechanism of the reactions of hot atoms, it becomes possible to compare the results of experiments with calculation. The main assumptions of the theory[37] are as follows. Of the total number of hot atoms ($N_s$) only part ($N_h$) react in the energy range $E_2$–$E_1$, in which the probability of chemical reaction on collision $p_i(E)$ differs from zero:

$$R_{ij} = N_h / N_s = \int_{E_1}^{E_2} f_j p_i(E)\, n(E)\, dE, \qquad (15)$$

where $R_{ij}$ is the yield of the $i$-product of the hot reaction from the $j$-component, $f_j$ the probability of collision with the given component, $f_j = N_j \sigma_j / \Sigma N\sigma$ ($N_j$ is the mole fraction of the $j$-component, and $\sigma_j$ the collision micro-cross-section), $n(E)dE$ the hot atom spectrum (the number of collisions between $E$ and $E + dE$), and $p_i(E)$ the probability of reaction on one collision with a molecule of the $j$-component with the formation of the $i$-labelled product. It is evident that in the range $E > E_2$, $n(E)$ is equal to the flow of hot atoms in the absence of absorption, that is, it can be calculated from formula (13): $1/\xi E$ ($\Sigma_s$ is assumed to be constant). When chemical reactions take place, the atoms taking part in the chemical reactions are "eaten out" of the spectrum in the range $E_2$–$E_1$. It is assumed that the fraction of atoms not taking part in the reaction is proportional to

$$\exp\left[-\int_{E}^{E_2} f\, p(E)\, n(E)\, dE\right] \qquad (16)$$

[see Eqn. (14)]. The flow of hot atoms when chemical reactions take place is then equal to

$$n(E) = \frac{1}{\xi E}\left\{\exp\left[-\Sigma \int_{E}^{E_2} f p(E)\, n(E)\, dE\right]\right\} \qquad (17)\S$$

(the sum with respect to all components of the mixture).

Substitution of Eqn. (17) into (15) and expansion of integral $\int_{E_1}^{E_2} \frac{p(E)}{E} dE$ into a series leads to an expression of the form

$$R = 1 - \exp\left[-\frac{f}{\xi} I\right], \qquad (18)$$

† In this case also, however, the primary act does not involve the formation of an intermediate complex. Here a "pseudo-complex" is formed, since the course of the reaction is determined by the second, slow stage of energy redistribution.

‡ See p. 685 for more details.

§ The integral in expression (17) is the resonance integral in the theory of neutron retardation[22,23]; see elsewhere[28,38] for more details.

where

$$I = \int_{E_1}^{E_2} \frac{p(E)}{E} dE. \qquad (19)$$

The quantity $R$ signifies the yield of all products containing recoil atoms and formed by hot reactions. For the yield of an individual labelled compound from a two-component system (the second component being an inert moderator), we obtain the expression

$$R_{1i} = \frac{f_1}{\xi} I - \frac{f_1^2}{\xi^2} K, \qquad (20)$$

where

$$I = \int_{E_1}^{E_2} \frac{p_i(E)}{E} dE, \qquad (21)$$

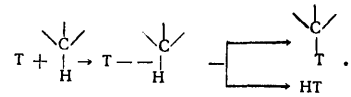
and

$$K = \int_{E_1}^{E_2} \frac{p_i(E)}{E} \left[ \int_{E}^{E_2} \frac{p(E)}{E} dE \right] dE. \qquad (22)$$

Here $p_i(E)$ is the probability of a hot reaction on one collision between a hot atom and a molecule with the formation of an $i$-labelled product, and $p(E)$ the probability of formation on collision of all labelled products. If the second component is not inert, we have

$$K = \int_{E_1}^{E_2} \frac{p_i(E)}{E} \left[ \int_{E}^{E_2} \frac{f_1 p_1(E) + f_2 p_2(E)}{E} dE \right] dE,$$

where $p_2(E)$ is the probability of chemical reaction with the formation of all labelled products on collision with a molecule of the second component.



It follows from (20) that the dependence of $(\xi/f)R_{1i}$ on $f/\xi$ should be given by a straight line. The intercept on the axis of ordinates gives the value of the integral (21), that is, the probability of chemical reaction with the formation of a definite labelled product, and the slope gives the value of integral (22) as the probability that the hot atom enters any chemical compound in general.

This model was verified for the case of hot tritium atoms in the methane–inert gas system. The mean value of the probabilities of the hot chemical reaction of tritium atoms with methane with the formation of $CH_3T$:

$$\overline{p(E)} = I/\ln\frac{E_2}{E_1}, \qquad (23)$$

was found to be 0.12. The quantities $f$ and $\xi$ were calculated from the masses and dimensions of the atoms and molecules in the approximation corresponding to elastic transfer of energy.

It was shown that the mechanism of elastic collisions is not applicable to the reactions of hot tritium atoms [39]. An important problem in this connection is the following: how does the transfer of energy from the hot atom to the molecule, leading to chemical reaction, take place? The agreement between the experimental data and calculation according to formula (20) for the yield of the product of hydrogen replacement is best [40] if it is assumed that the tritium atom collides with a mass which is smaller than the mass of the methane molecule but greater than the mass of the hydrogen atoms. If the role of this "effective mass" is assigned to the chemical bond between the atoms in organic compounds, the process of formation of compounds labelled with tritium can be represented schematically as follows.

This conclusion follows from the following experimental facts: (1) the yield of product formed by the rupture of any bond is proportional to the total number of bonds of this type; the ratio of the yields $HT/CH_3T$ in the reactions of hot tritium atoms with carboxylic acids [41] and alcohols [42] is directly proportional to the ratio: (number of C–H bonds) ÷ ÷ (number of $C-CH_3$ bonds); (2) the reactions of tritium recoil atoms are not accompanied by Walden inversion [43] and the isomeric configuration is also preserved [32,33,44]; (3) 90% of the activity of the tritium is distributed between the labelled mother compound RT and active hydrogen HT. The ratio of the yields HT/RT (hydrogen abstraction/hydrogen replacement) in the reactions of hot tritium atoms with hydrocarbons agrees with the expression

$$\frac{HT}{RT} = \frac{n}{n_1(1-\Omega) + n_2(1-\Omega)^2 + n_3(1-\Omega)^3}, \qquad (24)$$

where $n$ is the total number of hydrogen atoms in the molecule, $\Omega$ the steric hindrance in the reaction of hydrogen replacement, and $n_1$, $n_2$, and $n_3$ the numbers of primary, secondary, and tertiary hydrogen atoms.

The experimental data are compared with the results calculated from formula (24) in Table 1. [26]

These facts give grounds for concluding that hot tritium atoms react with the bonds between the C and H atoms and that attack along the C–H bond (more accurately, at small angles to this bond; in this case there is no steric hindrance so that the yield of HT is proportional to the total number of hydrogen atoms) leads to the abstraction of

TABLE 1. The part played by steric factors in the abstraction and replacement of hydrogen by hot tritium atoms.

| Substance (hydrocarbon) | Abstraction / replacement: calculated ratio | observed experimentally |
|---|---|---|
| $CH_4$ | 1 | 1 |
| $C_2H_6$ | $\frac{1}{1-\Omega} = 1.82$ | 1.82 |
|  | $\frac{1}{1-\Omega} = 1.82$ | 1.40 |
|  | $\frac{10}{9(1-\Omega)+(1-\Omega)^3} = 1.95$ | 1.95 |
|  | $\frac{4}{3(1-\Omega)+(1-\Omega)^3} = 2.05$ | 2.0 |
|  | $\frac{10}{6(1-\Omega)+4(1-\Omega)^2} = 2.2$ | 2.0 |
|  | $\frac{14}{6(1-\Omega)+8(1-\Omega)^2} = 2.4$ | 3.3 |
|  | $\frac{12}{9(1-\Omega)+2(1-\Omega)^2+(1-\Omega)^3} = 2.1$ | 2.0 |

$\Omega$ is the steric parameter in replacement reactions: $\Omega = 0.45$ is the choice made to give agreement between calculation and experiment for the case of ethane.

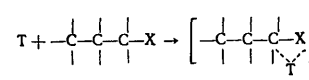
hydrogen in the form HT, whereas attack in a perpendicular direction (more accurately, at high angles to the bond; the steric hindrance increases with increase in the angle of attack and amounts to $\Omega = 0.45$ for primary hydrogen) leads to the replacement of hydrogen.

The theory whose main conclusions have been examined above has been called the "collision model" [37]. For the gaseous phase, this model was confirmed for the case of recoil halogen atoms [45-47].

It follows from the collision model that the decisive factors for reactions of hot atoms in the gaseous phase are: the steric hindrance to approach to the bond, the form of the function $p(E)$, and the hot atom spectrum in the range $E_2 - E_1$, where $p(E) > 0$. The value of the bond energy is unimportant from the viewpoint of the "collision model".

The collision model was developed by Wolfgang for multicomponent systems [48] and may now form a basis for the development of a theory of the kinetics of high-energy reactions. The case of the gas-phase reactions of tritium recoil atoms, $^3He(n,p)T$ with ethane, butane, neopentane, and hydrocarbon mixtures with the addition of a moderator has shown [49] the applicability of the Wolfgang equation — a combination of formulae (12) and (18): [48]

$$-1/\ln(1-R) = \xi_p/I + \xi_M/I\,\frac{1-f_p}{f_p}, \qquad (25)$$



where $\xi_p$ is the mean loss of energy for the collision of tritium with a molecule of the main component, and $\xi_M$ is the same for the collision with a molecule of the inert moderator, for example, helium.

These results [49] show that the ratio of the molar activity of ethane to the molar activity of neopentane for the neutron irradiation of a $^3He + C_2H_6$ + neo-$C_5H_{12}$ mixture *increases* with *decrease* in the ethane concentration, that is, the reactivity of the ethane molecules in the replacement of H by T increases (or that of neopentane decreases) with decrease in its concentration. The same effect of increase in the relative activity of tritium-substituted ethane is achieved by adding the moderator helium to the mixture being studied (at the same molar ratios). It was concluded that hot reactions are extremely sensitive to change in the spectrum of the retarding atoms, the mean energy losses for retardation in identical substances differing considerably. Data on the magnitude of the energy losses on collision of tritium with molecules of ethane, butane, and neopentane, and also the integral probabilities of chemical reaction with the formation of labelled ethane, butane, and neopentane in the reactions of hot tritium atoms, are given in Table 2 (the data were calculated relative to the value of $\xi$ He — the mean loss of energy by tritium on collision with helium, for example, $\xi$ ethane = $= 3.64\xi$ He).

TABLE 2. Mean energy loss for the collision of hot tritium atoms with ethane, n-butane, and neopentane. Integral probabilities of replacement and abstraction of hydrogen by hot tritium atoms. (Conditions [49]: 1 cm $^3He$, 2–4 cm $O_2$, 1 atm of substances, integral neutron beam $10^{15}$).

| Hydrocarbon | $\xi$ | $I_{RT}$ | $I_{HT}$ |
|---|---|---|---|
| Ethane | 3.64 | 2.1 | 0.55 |
| n-Butane | 5.05 | 2.78 | 0.79 |
| Neopentane | 5.8 | 2.93 | 0.59 |

The collision model does not reveal the nature of the phenomenon of energy transfer on collision and formation of a chemical bond, that is, a transition state leading to the hot reaction is excluded. At the same time the concept which considers the process of establishment of chemical bonds through a transition complex is more familiar to the chemist [25]. Since there is no significant difference in the yields of compounds labelled with tritium relative to change in the phase state and pressure in the gaseous phase (that is, deactivating collisions after the "marking" process do not influence the distribution of the activity), this complex should exist for a period of not more than $10^{-13}$–$10^{-14}$ s ("collision complex"), that is, for the duration of one or two vibrations of the bond:

The breakdown of the "collision complex" may be determined by the C–X bond energy, but the bond energy is apparently not so important. The reaction of hot atoms takes place in the range 15 eV–$E_{act}$, and the recoil atoms approach "from above" the energy values where the probability of reaction has maximum values. A change in the magnitude of the bond energy by several tenths of an electron volt cannot greatly influence the yield of labelled compound, since the greater part of the reactions are assumed to take place in the range 3–8 eV. Since the abstraction (of hydrogen) takes place at lower energies than substitution, as observed in experiments to find models for the collisions of atoms and molecules in the tritium + hydrocarbon system (tritium gas at $t = 1200$–$1800°$), [50] change in the C–X bond energy should be revealed as a change in the yield of the abstraction (in the form XT).

In fact, Rowland, the author of the latest theory, was able to show that the proportion of the activity of the tritium in the form HT is consistent with the energy of the C–H bond [51]; a paradoxical feature is that neopentane was not "fitted" into the relationship found for other hydrocarbons until new data were published on the energy of the C–H bond in neopentane.

It follows from the experiments of Rowland and coworkers [51] that the chemistry of hot tritium atoms gives an accuracy in the determination of the energy of the chemical bond which is no less than that given by the ordinary methods of "ordinary" chemistry.

In this connection, some doubt may be cast on the aspect of the collision theory dealing with the competing reactions of hydrogen abstraction and replacement, particularly for systems in which the hot atom spectrum contains an appreciable proportion of epithermal and "slightly hot" atoms. Such atoms in the range 0.5–3 eV have a greater tendency to take part in hydrogen abstraction, and in this range the C–H bond energy influences the yield of HT.

There are apparently no fundamental contradictions between the "collision model" [26,37] and the "collision complexes" [25]; at any rate, the experimental data can be explained equally successfully from both viewpoints. Let us take an example. Isotopic effects have been observed [39,53-58] in the reactions of tritium recoil atoms with simple dueterated compounds (Tables 3 and 4): the processes of replacement and abstraction of hydrogen by tritium ions

TABLE 3. Isotopic effect in reactions of hot tritium atoms with simple and deuterated compounds[58].

a. Abstraction of HT or DT

| Ratio of yields | Substance | | | |
|---|---|---|---|---|
| | $CH_2D_2$ | $CH_3CD_3$ | $CH_4+CD_4$ mixture | $CH_3F+CD_3F$* |
| HT/DT | 1.32±0.01 | 1.34±0.01 | 1.28±0.02 | 1.26±0.05 |

b. Replacement of H and D by T

| $CH_3T/CD_3T$ | $CH_2TF/CD_2TF$* | $C_4H_9T/C_4D_9T$** |
|---|---|---|
| 1.31±0.05 | 1.33±0.04 | 1.21±0.05 |

* Derived from experiments with mixtures of $CH_3F$ (or $CD_3F$) and cyclobutane.

** Derived from experiments with mixtures of n-$C_4H_{10}$ (or n-$C_4D_{10}$) and $CH_4$.

TABLE 4. Isotopic effect in reactions of tritium recoil atoms with simple and deuterated methyl fluoride[40].

| Replacement | Yield of products from | | H-system / D-system |
|---|---|---|---|
| | $CH_3F$ | $CD_3F$ | |
| H (D) | 12.4 | 10.1 | 1.23±0.02 |
| F | 4.2 | 3.2 | 1.30±0.02 |
| H (D), F | 2.9 | 2.1 | 1.4 ±0.06 |
| 2 H (2 D) | 1.3 | 0.9 | 1.4 ±0.09 |

(Yield given for the total absolute activity of tritium.)

For the abstraction of hydrogen (or deuterium) the isotopic effect = = 1.17 ± 0.03.

take place preferentially by 30% compared with the same processes for deuterium.

Since the loss of energy on retardation is not the same even for a homologous series of substances[49], the magnitude of the isotopic effect is investigated by carrying out experiments on the action of hot tritium atoms simultaneously in a mixture of two substances such that the spectra of the retarded atoms are the same[58]. For example, determination of the yield of $CH_2TF$ from $CH_3F$ and of $CD_2TF$ from $CD_3F$ and calculation of the ratio $CH_2TF/CD_2$. .TF (Table 3a) were carried out in a study of mixtures of $CH_3F$ and $CD_3F$ with a large quantity of cyclobutane. The yield of $CH_3T$ and $CD_3T$ from $CH_4$ + cyclobutane and $CD_4$ + + cyclobutane mixtures was determined in analogous fashion. The ratio $CH_3T/CD_3T$ was found[58] to be equal to 1.31 ± 0.05, which agrees with the ratio $\frac{CH_3T/CD_3T}{CH_4/CD_4}$ obtained from direct experiments with a $CH_4$ + $CD_4$ mixture[56].

From the viewpoint of the collision model, the isotopic effect observed in reactions of tritium recoil atoms with methane and deuteromethane can be attributed to a difference in the retarding power of the simple and deuterated compounds[40].

We are however, faced with the question of how the isotopic effect arises in the reaction of hot tritium atoms with $CH_2D_2$ $\left(\frac{HT}{DT}=1.32\right)$, with $CH_3CD_3$ $\left(\frac{HT}{DT}=1.34\right)$, and in a $CH_4$ + $CD_4$ mixture ($CH_3T/CD_3T$ = 1.26), where the recoil atom spectra are the same for the replacement and abstraction of H and D.

Some part is possibly played by a slight difference in the values of the C–H and C–D bond energies, but it is then difficult to explain the existence of the isotopic effect for the replacement of fluorine by tritium atoms in $CH_3F$ and $CD_3F$ ($CH_3T/CD_3T$ = 1.3 [40]), where the C–F bond energy is the same in both compounds.

Recent work by Rowland and coworkers[57] has shown that in the $CH_4$ + $D_2$ system the ratio of the specific activities $DT/D_2/CH_3T/CH_4$ remains unchanged with change in the ratio of the gas pressures by a factor of 15. This indicates, firstly, that the hot tritium atoms not only react with $CH_4$ in the high-energy range to give $CH_3T$, but also are effectively retarded, on collision with methane, to low energies, which are, however, higher than the activation energy for exchange with deuterium (0.5 eV); and secondly, that the $p(E)$ curve for the replacement of hydrogen in methane by hot tritium atoms lies in a higher energy range and does not overlap the range for the reaction T + + $D_2$ = TD + D. This makes possible the appearance of an "integral" isotopic effect associated with the difference in the energy dependence of the probabilities of the chemical reactions, which, like the change in the retardation parameter $\xi$, explains so successfully the difference in the yields of the products of the replacement (or abstraction) of H and D.

A pictorial representation of the dynamics of the collision of hot tritium atoms with methane molecules may be provided by the collision of "a sphere against a cushion" [57], in which an appreciable proportion of the kinetic energy of the hot atom is lost.

It has now been established that the magnitude of the mean energy loss on collision changes sharply in the range of chemical interaction[49,57]. The corresponding theoretical approach to this problem has already been mentioned (see Section II. 3).

The importance of the study of isotope effects in the reactions of hot tritium atoms is related to the fact that this may reveal the mechanism of bond formation in the reactions of highly energetic atoms with molecules. It is of interest to determine the decisive factor in the production of isotopic differences in the replacement of hydrogen and deuterium by tritium: the process of replacement on collision or the secondary process of bond formation after the ejection of hydrogen and deuterium, that is, whether the important reaction is

(1) $$T+CH_4 \rightarrow CH_3T+H,$$

or the recombination of radicals in direct proximity

(2) $$T+CH_4 \rightarrow CH_3 \,\vdots\, T+H.$$

It is suggested that the answer may be obtained by studying the yields of H and D replacement by tritium in $CH_2D_2$:

(3) $$T+CH_2D_2 \rightarrow CHTD_2+H,$$

(4) $$T+CH_2D_2 \rightarrow CH_2DT+D.$$

If the chief part is played by direct replacement, the yield of reaction (3) should be 30% greater than the yield

of reaction (4) (since the replacement of hydrogen is preferred to the replacement of deuterium to the extent of 30%). If the main part is played by the secondary isotopic effect (recombination in direct proximity), reaction (4) should be preferred to reaction (3) to the extent of 10%, since on the recombination of radicals in direct proximity to one another, an important part is played by the "inertial mechanism" of replacement, namely: the rate of recombination is greater, the smaller the mass of the fragment (see Section IV. 7). At present, however, the technical difficulties of separating the products of reactions (3) and (4) have not been overcome.

In concluding this section we may note the following feature. The magnitude of the isotopic effect, obtained in the reactions of tritium recoil atoms with simple and deuterated compounds, amounts on the average to 1.3–1.4 (H-system/D-system) and is extremely close to the ratio of the fundamental vibration frequencies of the C–H and C–D bonds (with the assumption that the force constants are equal)

$$\nu_{C-H}/\nu_{C-D} = \sqrt{\frac{f}{m_H}}\Big/\sqrt{\frac{f}{m_D}} = \sqrt{2} \simeq 1.4.$$

This ratio of the rate constants for the chemical reactions of hydrogen and deuterium replacement is obtained if in the transition complex the dimensions of the bond remain unchanged on replacement[59]. For a completely broken bond in the transition complex the kinetic isotopic effect acquires a maximum value of 18. In ordinary chemical reactions, the replacement of hydrogen by deuterium leads to a decrease in the rate of reaction by a factor of 3–8, indicating appreciable deformation of the bond during the reaction[59]. From the above comparison it may be concluded that the "transition state" in a hot reaction has the character of a local collision at the C–H bond in a period of $\sim 10^{-14}$ s, in which the lengths of the C–H and C–D bonds cannot change. Thus the kinetics of hot reactions represent an extreme case of the kinetics of ordinary chemical reactions.

Valuable information on the mechanism of the reactions of hot atoms may be given by experiments to find models for atom–molecule collisions. The first experiments in this direction with tritium atoms heated to 1800° and used to bombard a cyclopropane target[50] showed that the processes of hydrogen replacement take place in a higher energy range than the abstraction processes. This may change our ideas regarding the kinetics of hot atom reactions, particularly the conclusions regarding the mechanism of production of the isotopic effect. An increase in the retarding power of the medium should lead to an increase in the fraction of hydrogen abstraction reactions (the kinetic isotopic effect should increase).

## 2. Reactions of Hot Halogen Atoms

The energy of halogen recoil atoms obtained by an $(n,\gamma)$ reaction varies from several dozen to several hundred eV. Some of the atoms can apparently undergo chemical reaction with the medium on the first collisions. In this connection, the chemical state of the recoil atoms which have undergone the nuclear reaction is of considerable importance. The collection of recoil atoms in the gaseous phase[60] has shown that after an $(n,\gamma)$ reaction the atoms may remain in a metastable state, which leads to charged atoms after an internal conversion process. The process of charge increase takes place after the atom has left the parent molecule. The process is described in more detail as follows. The greater part of the excitation energy of the nucleus after the nuclear reaction is lost by the emission of $\gamma$-quanta (several $\gamma$-quanta with $\sim 1$–3 MeV)¶. The remaining fraction is lost by low-energy transitions accompanied by internal conversion. The lifetime of a level with $E > 1$ MeV is $10^{-14}$ s; the lifetime of transitions with low energies lies in the range $10^{-12}$–$10^{-5}$ s. After the ejection of the $\gamma$-quantum, for example, with $E \sim 1$ MeV, the atom leaves the molecule, and after $10^{-13}$ s it is stopped, after having moved a distance of several molecular diameters. Thus hot reactions initiated by part of the excitation energy of the nucleus after neutron capture take place before the start of the process of avalanche charge increase, as a result of the conversion of soft $\gamma$-quanta. These conclusions are confirmed by many experimental facts, in particular by data on the proportions of charged atoms (indium and manganese) after an $(n,\gamma)$ reaction. These proportions are independent of the original form irradiated by the neutrons and amount to 40–60%. This means that the accumulation of positive charge on the atom takes place in a time interval which is longer than that required for rupture of the bond and several first collisions. Wexler and Davies[62,63] found the proportions of charged atoms after an $(n,\gamma)$ reaction: 25% for $^{82}$Br, 12% for $^{80}$Br, 21% for $^{38}$Cl, and 50% for $^{128}$I. The mean charge of the recoil ions was found to be +10 (for $^{80}$Br). Intensive supercharging of positive $^{80}$Br recoil ions was also observed, the current strength of the resulting negative ions increasing with increase in the density of the medium.

The determination of the fraction of positively charged atoms after radiative neutron capture by the collection of recoil atoms is very imperfect. The probability of energy loss by conversion increases as $z^3$, whereas experiments with different recoil atoms give approximately the same fraction of charged atoms[60].

It follows from the foregoing that the "hot chemistry" of heavy recoil atoms should make allowance for the possibility of twofold introduction of radioactive atoms into the compounds: firstly as a result of recoil from hard capture $\gamma$-quanta, and secondly as a result of the conversion of soft capture $\gamma$-rays and the subsequent processes of charge formation on the atom: intramolecular charge transfer — formation of molecular ion — dissociation of molecular ion — formation of recoil ion — chemical reaction of recoil ion.

Suess[64] and later Libby[65] showed that the rupture of the chemical bond in a diatomic molecule uses up a fraction of the recoil energy which depends on the ratio of the masses of the recoil atom and the second atom. The excitation energy used up in the dissociation is found from the difference between the kinetic energy of the recoil atom and the kinetic energy of movement of the centre of gravity of the molecule:

$$E_{\text{excitation}} = E_m - E_M = p^2/2m - p^2/2(m+x) = E_m \frac{x}{M}, \qquad (26)$$

where $x$ is the mass of the second atom, $M$ the mass of the molecule, $M = m + x$, $m$ the mass of the recoil atom, and $p$

¶ Groshev[61] showed that the proportion of the excitation energy of the nucleus de-excited by photons with $E > 0.5$ times the binding energy of a neutron ($\alpha$) is close to 80–100% only for atoms with magic numbers of neutrons and protons. As a rule, $\alpha$ = 20–30% for heavy atoms, 30% for chlorine, 70% for sulphur, and 60% for phosphorus.

the impulse of the recoil atom. The condition for bond rupture as a result of the recoil effect has the form

$$E_{\text{recoil}}\frac{x}{M} > \nu, \qquad (27)$$

where $\nu$ is the energy of the chemical bond.

Gordus[66] obtained formulae for calculating the condition for ejection of recoil atoms from molecules in terms of the masses of the atoms, the interatomic distances, and the angles between the bonds in polyatomic molecules. In order to obtain approximate data for the case of polyatomic molecules, however, it is possible to use Eqn.(26) and the inequality (27), assuming that $x$ is equal to the mass of the molecular residue. The error amounts to 15–20%. Careful experiments to find the fractions of unbroken bonds in an $(n,\gamma)$ reaction showed that they amount to approximately 0.3–1% and show good agreement with theoretical estimates. It may therefore be assumed that after an $(n,\gamma)$ reaction the chemical bond is broken in almost all cases. Sometimes, however, marked deviations from this relationship are observed. For the rupture of the bond in the HBr molecule, according to Eqn. (27), the recoil bromine atom should have a kinetic energy of not less than 312 eV. From approximate calculation of the spectrum of bromine recoil atoms[67] it follows that 85% of all the bromine atoms have a recoil energy less than the dissociation energy. Suess's first experiments[64,68], however, and later careful experiments carried out in the gaseous phase by other workers[69] showed that only ~10% of the activity of the $^{80}$Br after an $(n,\gamma)$ reaction in the HBr + $C_2H_2$ mixture (with low HBr partial pressure) remains in the form of H$^{80}$Br, whereas we should expect a retention of H$^{80}$Br of the order of 85%. This indicates the high degree of conversion of $\gamma$-rays after the $(n,\gamma)$ reaction, one result of which is the formation of recoil ions which leave the original molecules as a result of coulombic repulsion. The discovery of the existence of recoil ions played an important part in the postulation of ion–molecular hot reactions, thanks to which it has been possible to explain certain facts, in particular the existence of isotopic effects in $(n,\gamma)$ reactions[80]. The formation of positively charged recoil ions does not always explain the experimental data, however. Thus in the isomeric transition, $^{80m}$Br → $^{80}$Br, the internal conversion coefficient is equal to 90–100%, that is, at least 90% of the $^{80}$Br atoms should leave the H$^{80m}$Br molecule as a result of isomeric transition. Experiments[70] showed that the yield of H$^{80}$Br from H$^{80m}$Br amounts to 25%. If in the $(n,\gamma)$ reaction the kinetic energy is insufficient for rupture of the bond in the HBr molecules, and the ejection of bromine atoms can be attributed to the formation of recoil ions as a result of conversion of the capture $\gamma$-rays, how are we to explain the fact that in the case of the isomeric transition in H$^{80m}$Br, where the $\gamma$-rays undergo conversion to the extent of 100%, the proportion of unbroken bonds is greater by a factor of 2.5? One possible explanation may be based on the difference in the magnitude of the charge on the ions after the $(n,\gamma)$ reaction and the isomeric transition (i.t.). In fact, the mean charge of the recoil ions of bromine-80 after the $(n,\gamma)$ reaction was found to be +10, whereas after i.t., according to Cooper's calculations[71], it amounts to +4.7. Calculations carried out by Magee[72] showed that the $HBr^{z+}$ molecules are stable up to $z$ = +4, and this may explain the fact that an appreciable proportion of the activity of $^{80}$Br after i.t. is found in the form of hydrogen bromide.

The mass-spectrometric data confirm the formation of rapidly-moving ions produced by the dissociation of highly charged molecular ions. The kinetic energy of the fragments can be estimated approximately from the difference between the ionisation potentials of the ionised molecule and the fragment ions. Cooper[71] showed that the time taken for the transfer of charge from the $K$-shell to the valency shell is $10^{-12}$ s. In this period, an atom in the molecule undergoes 10–100 vibrations, that is, there is a considerable probability of internal charge transfer with the formation of molecular ions. The relative kinetic energy of $^{80}$Br$^+$ ions from the compound $CH_3{}^{80m}$Br is 10 times greater than that from H$^{80m}$Br (on the basis of an equal distribution of charge throughout the molecule). This may explain the fact that the fraction of unbroken bonds in $CH_3{}^{80m}$Br after i.t. is much smaller than that in H$^{80m}$Br (3–7%).[70]

It may be assumed that the kinetic energy of recoil ions after i.t., and also as a result of the conversion of soft capture $\gamma$-rays, depends on the energy and degree of conversion of the $\gamma$-rays, the ratio of the masses of the recoil atom and the remainder of the molecule, and the values of the ionisation potentials of the molecular ions and fragment ions. In the gaseous phase the fraction of unbroken bonds amounts to several percent but in the liquid phase this fraction reaches about 15% (for example, the yield of $CHBr_2{}^{80}$Br from $CHBr_2{}^{80m}$Br amounted to 13% in the liquid phase in the presence of appreciable quantities of elemental bromine[73]). This can be related to the "cage" effect, which retains the recoil ion in direct proximity to the molecular residue, or to the process of intermolecular charge removal from the molecular ions, facilitating "survival" of the molecule.

Bromine and iodine recoil atoms initiated by different nuclear processes give the same distributions of activity in the products. However, the initial distributions of the atoms, after, for example, an $(n,\gamma)$ reaction and isomeric transition, are different: the $(n,\gamma)$ reaction gives the atom kinetic energy but isomeric transition gives the atom a charge. In the light of the foregoing, it may be assumed that the fact that the atoms show identical behaviour after an $(n,\gamma)$ reaction and i.t. is due to the same factors. One of these is that the conversion of $\gamma$-rays after the $(n,\gamma)$ reaction produces charged recoil atoms whose behaviour will consequently be the same as that of atoms produced in i.t., for which the coefficient of internal conversion is high. Another reason for the identical behaviour of atoms obtained by different nuclear reactions is based on the opposite assumption that the charged atoms are neutralised, as a result of which the recoil atom spectra may be the same in the range of chemical interaction. The first viewpoint leads to the postulate that an important part is played by ion–molecule reactions (see Ref. 80 for more details), whereas the second leads to the hypothesis which gives preference to the part played by kinetic energy in the hot reaction[28,74,75].

There is a third point of view regarding the source of the high activity of hot atoms. It is suggested that, irrespective of the primary processes, the atoms are obtained with an appreciable electronic excitation energy. It is then necessary to speak of the chemistry of "hot orbital electrons"[76].

Finally, a still valid viewpoint is that which concentrates attention on the radical reactions of recoil atoms with fragments formed on the path of movement and as a result of radiative breakdown produced by the Auger electrons after the conversion process[27,77]. A fundamentally new approach to the explanation of results obtained in hot atom

chemistry in organic media was put forward by Shaw[78] whose calculations showed the influence of local pressure, produced by the hot atom in the retardation zone, on the yield of labelled products. Let us examine briefly the experimental data supporting the different views on the mechanism of hot reactions.

(a) Ion-molecular mechanism. It has been established[45-47] that in the reactions of $^{80}Br$ and $^{128}I$ recoil atoms with methane in the gaseous phase in the presence of added inert gases, the yield of labelled products shows good agreement with the equations of Wolfgang's kinetic collision theory (see Section III. 1), confirming the suggestion regarding the reactions of neutral non-excited hot atoms with an excess of kinetic energy. Significant deviation from the equations of the kinetic theory were found in the study of the action of neutrons on an $I_2 + CH_4 +$ + Xe mixture and this was attributed to the transfer of charge from $^{128}I$ atoms (50% of which are obtained in the charged state after an $(n,\gamma)$ reaction) in the $^1D_2$ state to xenon, which thus exhibits a quenching action†.

The reaction of excited iodine recoil ions with xenon may compete to an appreciable extent with the ion-molecular reaction involving the introduction of iodine into methane. From this it was found that the fraction of $^{128}I$ recoil ions after the $(n,\gamma)$ reaction is 23 ± 3%. The fraction corresponding to true hot reactions (suppressed only by the moderators — inert diluents — He, Ne, and Ar) amounts to 18 ± 2%. The remaining 11% of all the reactions of iodine atoms involve interaction between methane and charged $^{128}I$ ions in $p$-states with excitation energy $E < 1.7$ eV, and these are not influenced by the addition of xenon. Study of the hot reactions of $^{80}Br$ recoil atoms in methane under the same conditions showed that only the kinetic energy influences the yield of products, despite the fact that some of the $^{80}Br$ atoms are obtained in the charged state after the $(n,\gamma)$ reaction. In isomeric transition in the $^{80m}BrBr + CH_4$ system, the yield of $CH_3{}^{80}Br$ is less than that in the $(n,\gamma)$ reaction (6.8 ± 0.8% and 12.0 ± 1% respectively)[79]. This result was attributed to the high kinetic energy after the $(n,\gamma)$ reaction. There is another possible explanation, however: if the $^{80}Br$ recoil atoms are formed in a metastable state with sufficiently long lifetime (greater than the lifetime between collisions in the gaseous phase), only some of these atoms, after their first introduction into the methane molecule, will leave the resulting molecule due to the conversion of $\gamma$-rays. These atoms apparently have the same probability of reaction with methane as $^{80}Br$ atoms from $Br^{80m}Br$. We should thus expect that the yield of $CH_3{}^{80}Br$ after the $(n,\gamma)$ reaction should be slightly greater than that for the i.t. process. An analogous process should take place with recoil atoms of the $^{82}Br$ isotope, for which a 6.2-minute isomer has been found‡[77]. This does not solve the problem of the source of the high reactivity of bromine and iodine after a nuclear $(n,\gamma)$ reaction. It is possible that the kinetic energy plays the most important role: on the production of a charge of +5 on the iodine atom in the $CH_3I$ molecule, its kinetic energy after rupture of the C-I bond is ~9 eV,[77] which is, of course, quite sufficient for the replacement of hydrogen in methane. According to calculations, however, after the replacement of hydrogen in methane by the $^{128}I$ atom, the $CH_3{}^{128}I$ molecule will have too much energy to be stabilised (see Filatov[80] for more details). Thus the ion-molecular mechanism of formation of $CH_3{}^{128}I$ in the reactions of $^{128}I$ recoil atoms with methane is to be preferred.

This was confirmed in subsequent studies of the $(n,\gamma)$ reaction in the $I_2 + CH_4$ system containing added alkyl iodides, nitric oxide, and benzene[47]. The yield of $CH_3{}^{128}I$ on irradiation of the gas-phase systems with neutrons decreased rapidly when alkyl iodides were added; this can be attributed to the transfer of charge to RI, which has a lower ionisation potential than iodine, or to the thermal ion-molecular reaction $I^+ + RI \rightarrow I_2^+ + R$, which was also observed in mass-spectrometric studies. Since iodine atoms do not react with nitrogen monoxide, the inhibition of the formation of $CH_3{}^{128}I$ by the addition of NO is due to the transfer of charge to the nitric oxide. The ion-molecular model for the reactions of hot atoms provides an explanation for the low yield (2-4%) of alkyl iodides labelled with $^{128}I$ in the neutron irradiation of the gaseous mixtures $I_2 + C_2H_6$, $I_2 + C_3H_8$, etc. Alkanes, apart from $CH_4$, can remove charge from iodine ions in the $^1D_2$, $^2P_1$, and $^3P_0$ states. In actual fact, the addition of ethane to an $I_2 + CH_4$ mixture inhibits the formation of $CH_3{}^{128}I$.[47]

The hypothesis of ion-molecular reactions of hot atoms has proved useful in the explanation of the results of a study of the chemical consequences of $\beta$-decay in the liquid-phase systems: $^{132}TeCl_4(^{132}Te \xrightarrow{\beta} {}^{132}I) + C_3H_7X + C_6H_6$ and $TeCl_4 + C_3H_7I + C_6H_5I$ (X = I, Br, or Cl). The recoil energy of the iodine atoms obtained by the $\beta$-decay of tellurium is low (0.5 eV) and cannot bring about chemical reactions. Halpern and Sokolovska[81] detected an increase in the specific activity of $C_3H_7{}^{132}I$ in the presence of benzene, which they attributed to the transfer of energy from propyl iodides to the benzene molecules. The formation of propyl iodides, however, was regarded as the reaction of $^{132}I^+$ ions with dipolar $C_3H_7X$ molecules, the yield of the product of replacement of X by $^{132}I$, as a first approximation, being proportional to the dipole moment of $C_3H_7X$. The fact that the spectra of the charged fragments formed in isomeric transition and in irradiation by X-rays with $E = 40$ keV are similar[82] suggests that not only in the chemistry of atoms obtained by i.t., but also in radiation chemistry, we are dealing with hot ions formed by the "coulombic explosion" of highly charged molecular ions.

(b) Kinetic theory of hot reactions of halogen recoil atoms. Some experimental data confirm the idea that before recoil atoms take part in chemical reactions they are neutralised and deactivated. It may thus be suggested that recoil atoms are obtained in the ground state. If we assume that the reactivity of these atoms is determined entirely by their kinetic energy, we can derive equations which permit experimental verification. Examples of such equations for reactions in the gaseous phase are those of Wolfgang, for example, Eqn. (20). Milman[74,75] and Nesmeyanov and coworkers[28] applied these equations to a condensed system. If it is assumed that for condensed systems a good approximation is provided by the elastic-collision model (since the "cage effect" facilitates rapid recombination reactions by radicals in direct proximity to one another), Eqn. (20) becomes

$$R \simeq \frac{e}{v\xi} \ln \frac{E_0}{v} f, \qquad (28)$$

† In the normal state the process of charge transfer is impossible: the ionisation potential of iodine (10.4) is less than that of xenon (12.1). The excitation energy of the $^1D_2$ level (in the ion) is 1.7 eV. The transfer of charge takes place from this level.

‡ Formed in 90% of cases of neutron capture. $E$(i.t.) = keV. Almost all $\gamma$-quanta are converted[27,77].

where $\epsilon$ is the energy of removal from the cell, $E_0$ the initial recoil energy, $\nu = \nu' M/(M-m)$, $\nu'$ is the energy of the C–Br chemical bond, $M$ the mass of the molecule, $m$ the mass of the bromine atom, and $f$, as before, the geometric probability of collision. Eqn. (28) can also be obtained by simple solution of the resonance integral from the theory of neutron retardation, assuming the mechanism of elastic transfer of energy on collision[28].

For a mixture of substances

$$R \simeq f \frac{\varepsilon}{\nu\xi} \ln \frac{E_0}{\nu} = \frac{N\sigma}{\Sigma N\sigma} \frac{\varepsilon}{\nu\xi} \ln \frac{E_0}{\nu}, \qquad (29)$$

where $N$ is the mole fraction of the original compound in the mixture with the second component. It follows from Eqn. (29) that the yield of labelled compound formed by elastic collision is linearly dependent on the mole fraction multiplied by the factor $1/\xi$. In fact, on dilution of $C_2H_5Br$ with chloromethanes, the observed values for the yield of $C_2H_5{}^{82}Br$ on irradiation of the mixtures with neutrons showed good agreement with the results obtained by calculation using formula (29):

$$R = \frac{\varepsilon}{\nu} \ln \frac{E_0}{\nu} \frac{1}{\xi} f = \text{const} \frac{4r_{Br}^2 N}{4r_{Br}^2 N + (1-N)(r_{Br}+r_{Cl})^2 n\xi_{Cl}},$$

where $\sigma$ is the collision cross-section, $\xi_{Cl}$ the logarithmic decrement for the bromine–chlorine collision, $r_{Br}$ and $r_{Cl}$ are the covalent radii of bromine and chlorine, and $n$ is the number of chlorine atoms in the chloromethane molecule. The dependence of $R$ on $f/\xi$ was found to be linear, in complete agreement with the mechanism of elastic transfer of energy[28]. Shaw and coworkers[83] showed that the results of the chemical reactions of hot bromine atoms in the liquid phase in the $RBr + Br_2$ system can be interpreted in terms of a model which assumes that the reactions involve elastic collisions.

To describe the replacement of hydrogen atoms by the hot atoms of heavy elements, it is possible to use an inelastic-collision model which assumes that the yield depends on the fraction of the energy transferred on inelastic collision through the molecule as a whole, $M/(M+m)$.[28] The threshold minimum value of the kinetic energy of the bromine recoil atom, at which replacement of hydrogen is still possible, is estimated at 6 eV. Difficulties are encountered in the estimation of the upper energy limit of the recoil atom for the replacement of a hydrogen atom in molecules. It may be estimated only approximately at ~10 eV. The minimum kinetic energy necessary to bring about reactions of elastic collision is equal to 12 eV for $C_2H_5Br$. On the basis of these considerations, it is possible to construct an approximate curve for the cross-sections of elastic and inelastic collisions leading to hot and epithermal replacement of atoms by hot $^{82}Br$ atoms (Fig. 1). Experiments on the study of the reactions of halogen recoil atoms are now being carried out with allowance for the secondary ionisation of the labelled compound formed in the first stage of the hot reaction. $^{18}F$ atoms obtained by the photonuclear $(\gamma,n)$ reaction have excitation levels of 1.13 MeV and 0.94 MeV, with lifetimes $\sim 10^{-10}$ s.[84] Since change in pressure in the $CF_4$–inert gas system did not lead to a different distribution of $^{18}F$ activity, the $^{18}F$ atoms are formed after the $(\gamma,n)$ reaction in the ground state.

Since the energy of recoil $^{18}F$ atoms after the $(\gamma,n)$ reaction amounts to $\sim 10^5$ eV, they may be ionised in the retardation process and thus still enter the range of chemical interaction in the charged state. A special study has been made of this question[84]. From the values of the energy

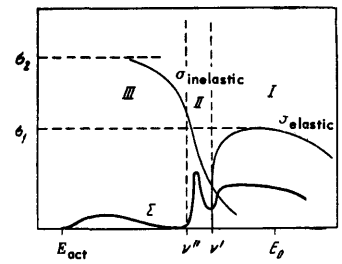


Fig. 1. Probability of chemical reactions of bromine recoil atoms with alkyl bromide molecules. $\sigma_{elastic}$ is the cross-section for elastic collision, $\sigma_{inelastic}$ the cross-section for inelastic collision, $p(E)$ the probability of reactions on one collision, and $\Sigma$ the cross-section for the hot reaction, equal to

$$p_{elastic}\sigma_{elastic} + p_{inelastic}\sigma_{inelastic},$$

($p_{elastic} = \epsilon/\nu$). In range I the reaction due to elastic transfer of energy takes place:

$$Br^* + C_2H_5Br \rightarrow [C_2H_5 + Br + Br^*]_{cell} \rightarrow C_2H_5Br^*.$$

In range II inelastic collision with the molecule as a whole leads to replacement of hydrogen:

$$Br^* + C_2H_5Br \rightarrow \left[C_2H_5\begin{matrix}Br\\ Br^*\end{matrix}\right]_{complex^*} \rightarrow C_2H_4BrBr^*.$$

In range III the reaction of "ordinary" chemistry takes place:

$$Br^* + C_2H_5Br \rightarrow C_2H_4Br + HBr^*.$$

It is possible that the paths of the cross-sections overlap in ranges II and III, and that the reactions of abstraction and replacement of hydrogen are competing reactions, differing only in the values of the probabilities

$$Br^* + C_2H_5Br \rightarrow \left[C_2H_5\begin{matrix}Br\\ Br\end{matrix}\right] \begin{matrix}\nearrow C_2H_4Br + HBr^*\\ \searrow C_2H_5Br^* + H\end{matrix}.$$

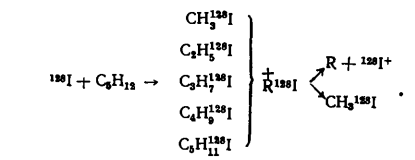
of the fluorine atoms at which the ionisation processes take place to the maximum extent, calculated from the formula

$$E = {}^1/_2 m \left(\frac{\Delta E\, a}{h}\right)^2 = 2700\,(\Delta E)^2 \text{ eV}\,\S,$$

it follows that the ionisation processes reach a maximum at energies greater than the neutralisation energies, and that at $E < 10^2$ all the atoms are neutral. The results of the chemical action of hot fluorine atoms in the $CF_4$–inert gases–radical acceptors system, treated from the viewpoint of Wolfgang's kinetic theory, showed[84] that the loss of energy for the collision of fluorine with atoms and molecules is greater than the loss calculated assuming elastic transfer of energy. The fraction of the kinetic energy lost when fluorine collides with argon should be 0.7. Experiment gives 0.94. Comparison of experiment with calculation for collision with a $CF_4$ molecule gives an even greater discrepancy: calculation gives the value $\xi = 0.36$, whereas experiment gives $1.47 \pm 0.28$ (relative to the loss of energy on collisions between fluorine and helium). The probability of chemical interaction between fluorine and $CF_4$ is small: the integral probability of formation of $CF_3{}^{18}F$

§ $\Delta E$ is the ionisation potential, $a$ the dimensions of the atom, $7 \times 10^{-8}$ cm, and $m$ the mass of the fluorine atom.

is smaller by a factor of 16 than the mean loss of energy on collision with $CF_4$ without the formation of a chemical bond. The probability of replacement of two fluorine atoms with the formation of the radical $CF_2{}^{18}F$ is the same as the probability of the replacement of one atom with the formation of $CF_3{}^{18}F$, and this cannot be explained from the energetic viewpoint, since the replacement of two atoms requires the expenditure of a further 4 eV of energy.



A considerable proportion of the studies which have now been carried out show that the equations of Wolfgang's kinetic theory assist in understanding the processes of energy loss during the retardation of hot atoms and give numerical values for the proportion of the energy lost on collisions with molecules. The retarding powers of different molecules can be compared and are found to be different even for a homologous series of substances. The equations of the kinetic theory can be used to calculate the integral probabilities of the chemical reactions of hot atoms and these are found to be greater by several orders of magnitude than those for ordinary thermal reactions. The next step in the development of reaction mechanism theory may be the determination of the analytical form of the function $p(E)$ — the probability of chemical reaction on one collision — and comparison of calculations with experiment. It is possible that valuable information on the "chemical reaction excitation function" will be provided by studies of the interaction of atoms with molecules in intersecting molecular beams.

(c) Radiative mechanism. The broad spectrum of products formed in the reactions of halogen recoil atoms enabled Willard and coworkers[85,86] to postulate that "nesters of radicals" are formed in the hot atom retardation of radicals" are formed in the hot atom retardation leads to the formation of labelled products. This approach, however, cannot explain a number of facts, including the appreciable yield of labelled products when the experiments are carried out in the gaseous phase. Thus iodine recoil atoms in methane give a 50% yield of $CH_3{}^{128}I$, bromine recoil atoms give ~14% $CH_3{}^{80}Br$, chlorine gives 27%, and tritium gives ~30% $CH_3T$. At the same time there are certain data which can be explained only from the radiative viewpoint of "random fragmentation" of molecules to form radicals. For example, it was found that the yield of $C_2H_5{}^{128}I$ after an $(n,\gamma)$ reaction in a 1.4% solution of $C_2H_5I$ in pentane amounts to 41%,[27] whereas neutron irradiation of a mixture of $I_2$ (0.25 M) with pentane gives a $C_2H_5{}^{128}I$ yield of only 18%. These data can be explained using an "autoradiative model": the distance between the $C_2H_5I$ molecules in the solution is less than the zone corresponding to breakdown brought about by the conversion electrons of soft neutron-capture $\gamma$-rays.

The energies of the electrons emitted by $^{128}I$ are different. A conversion $K$-electron apparently has an energy of several dozen keV, some of the electrons have an energy equal to the $K-L$ transition without the binding energy of the $L$-electron, that is, approximately 20 keV, and some of the electrons are emitted with an energy of several keV. The electrons bring about radiative breakdown (ionisation and excitation) among the molecules lying close to the $^{128}I$ recoil atom which has undergone retardation. The linear transfer of energy by electrons with energies (keV) of 0.1, 1, 10, and 20 is equal to (eV per Å) 3.3, 1.2, 0.23, and 0.13.[27]

Thus the $^{128}I$ recoil atom which has left the mother molecule after the emission of capture $\gamma$-quanta is found, after retardation, in the centre of the zone of breakdown produced by the conversion electrons and characteristic X-rays. The repeatedly drawn-out iodine atoms are rapidly neutralised and subsequently recombine with the surrounding radicals (including radicals of the mother compound) formed as a result of the action of Auger electrons.

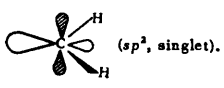
The process of $^{128}I$ marking is possibly more complex than is generally assumed. Allowance must be made for the twofold introduction of iodine atoms into the organic compounds: the iodine recoil atoms first replace hydrogen atoms and groups of atoms in pentane, after which conversion takes place with the formation of iodine recoil ions, which again take part in reaction. A scheme for reaction (5) in accordance with this suggestion is given below:

The $^{128}I$ ions may again take part in the ion–molecular reaction $^{128}I^+ + C_5H_{12} \rightarrow R^{128}I^+$, whose activation energy is 10–20 kcal lower than that of the corresponding reaction with neutral atoms.

It is at present impossible to analyse the processes of charge transfer in a condensed system. Theoretical calculation of the rate of dissociation of the linear chain of $H_2^+$ molecules, assuming the existence of intermolecular interaction, showed[87] that dissociation into atoms does not take place if the intermolecular bond is sufficiently strong. From this it follows that the intermediate molecular ions $R^{128}I^+$ may determine the direction of the subsequent reactions of $^{128}I$ atoms.

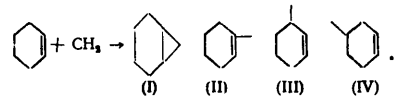
(d) Thermodynamic conception of hot reactions in condensed systems. A new approach to the study of the mechanism of hot reactions was developed by Shaw[78]. The equation for the yield of a hot reaction (28) contains the quantity $\epsilon$ — the energy of removal from the reaction cell (the energy of formation of a "hole" in the liquid, which a diffusing atom may enter). The magnitude of $\epsilon$ can be estimated from photochemical data (0.05 eV). The ratio $\epsilon/\nu$ amounts to ~0.01. If the absolute calculated yield of a hot reaction is to agree with experiment, it is necessary to assume a considerable number of collisions in the range of chemical interaction (~100) but this cannot be justified. It is suggested[78] that $\epsilon = \Delta E + p\Delta v$, where $\Delta E$ is the heat of volatilisation (formation of a "hole"), and $p\Delta v$ the work done against hydrostatic pressure in the formation of a "hole" with volume $\Delta v$. For most liquids, for example, $C_2H_5Br$, $p\Delta v = 8 \times \times 10^{-5}$ eV ($p$ = 1 atm, $\Delta v$ = 125 Å$^3$). If an atom with appreciable energy moves in the liquid, the result may be the formation of a zone with increased temperature. If the rate of formation of the zone is high, no significant change in the volume of the zone takes place during the retardation of the hot atom, so that we can examine a thermodynamic parameter $(\partial p/\partial T)v$, which, according to direct experiments[88], is found to be equal to 11.5 atm deg$^{-1}$ for ethyl bromide under normal conditions[78]. The loss of energy by hot bromine atoms was calculated by Shaw on the basis of the model of Capron and Oshima (the method

of Capron and Oshima was described by Nesmeyanov and Borisov[4]). It is suggested that the liberated energy is used up in the formation of a bubble of gas in the liquid and that this rapidly brings about retardation of the hot atom. Calculations show that after a period of $\sim 10^{-12}$ s the pressure in the bubble reaches several thousand kg cm$^{-2}$, and this alters appreciably the stability of the cell $\epsilon$. At the same time, substitution of the ratio $\epsilon/\nu$ in formula (28) gives a result which agrees with experiment. Change in temperature during the hot reaction in ethyl bromide is reflected in the magnitude of the pressure: the latter increases with decrease in temperature. An analysis carried out by Shaw shows that the magnitude of the pressure depends to a marked extent on the volume of the hot zone: the pressure increases with decrease in the volume. It may thus be assumed that the introduction of chemically inert retarding agents should increase the yield of mother compound, since in this case the kinetic energy of the hot atom decreases so that the volume of the breakdown zone also decreases.



Milman[89] recently observed a relationship between the change in the yield of labelled dibromoethane after an $(n,\gamma)$ reaction with the points of phase transformation and the change in specific heat and dielectric constant with change in temperature. This indicates a close relationship between the chemical effects of nuclear changes and the physicochemical structure of solids and certain of their properties to which attention has not been paid up to the present.

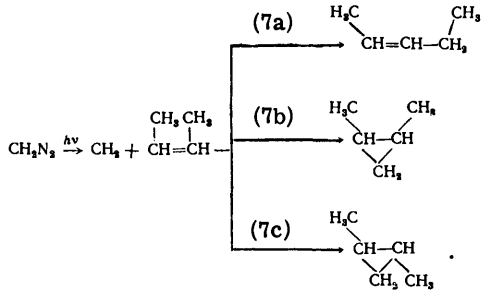
Thus several approaches have been made to the study of the mechanism of the hot reactions of atoms initiated by nuclear changes. Each approach explains only some of the experimental data, indicating that the mechanism of hot processes is complex and that it is possible to construct a theory showing satisfactory agreement with experiment only by making certain simplications and assumptions which are justified in individual specific cases.



### 3. Reactions of Hot Carbon Atoms

Unlike halogen and tritium recoil atoms, which react with molecules in the ground states, the determination of the state of carbon (including its chemical form) is more complex. The ground state of the carbon atom is a triplet state ($^3P$): $|1s^2 2s^2 2p^2|$ ↑↓ ↑↓ ↑ ↑. Conversion into other states involves a considerable expenditure of energy, thus $sp^3$ hybridisation requires 80–100 kcal. This expenditure is compensated by the energy liberated when carbon forms bonds in the $sp^3$ state. When hot carbon atoms are formed by the reactions $^{14}N(n,p)^{14}C$, $^{12}C(p,pn)^{11}C$, or $^{12}C(n,2n)^{11}C$, however, the state transition $^3P \rightarrow sp^3$ is brought about by the high kinetic energy accompanying the nuclear reaction.

Some information on the reactivity of a hot carbon atom can be obtained from photochemistry. Experiments on the photolysis of diazomethane have shown the existence of a hot $CH_2$ fragment in a ground singlet state with one free orbital and one hybridised orbital[90]:



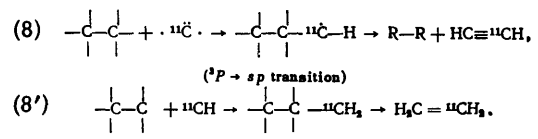
($sp^2$, singlet).

On collision with the atoms of the medium, this hot fragment undergoes a singlet–triplet transition[91,92]. The following products are obtained by the photolysis of diazomethane in cyclohexene solution:

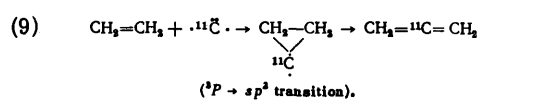
(6) 
(I) (II) (III) (IV)

The yields of the products (II), (III), and (IV) are in the ratio 2 : 4 : 4, in complete agreement with the statistical introduction of $CH_2$ at the C–H bond. The yield of norcarane (I) is much greater than that of the others[92]. The addition of $CH_2$ across a double bond can take place only if the $CH_2$ is in the triplet state, since the first excited state of the double bond — the biradical — is a triplet[93]. The formation of norcarane can be explained if we assume a change in multiplicity on the retardation of hot $CH_2$.

The reactions of hot $CH_2$ in the gaseous phase confirm the singlet–triplet transition. The photolysis of diazomethane in a medium of *cis*-but-2-ene gives the following products:



The addition of argon leads to a decrease in the yield of *cis*-pent-2-ene, formed by "insertion" at the C–H bond. The yield of reaction (7b) decreases and that of reaction (7c) increases but the sum of the yields of *cis*- and *trans*-dimethylcyclopropane remains unchanged. Collision with argon is accompanied by the singlet–triplet transition, which then brings about addition at the double bond. The isomerisation in the reactions of hot $CH_2$ with *cis*-but-2-ene is due to the fact that the products of reactions (7b) and (7c) are formed in the triplet state, for which transition to the ground singlet state is forbidden. There is a definite probability of rotation about the bond within the time corresponding to the transition, equal to $10^{-8}$–$10^{-7}$ s. The triplet state of the hot $CH_2$ obtained after several collisions is confirmed by experiments with the addition of oxygen. The ground state of oxygen is a triplet state and when added in small quantities it reacts effectively with the triplet $CH_2$ and the products of the addition of $CH_2$ across the double bond.

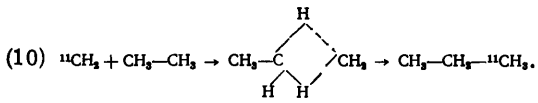


The reactions of hot carbon atoms are now being studied using the isotope $^{11}C$ obtained from carbon by $(n,2n)$, $(p,pn)$, and $(\gamma,n)$ reactions, from nitrogen by a $(p,\alpha)$ reaction, from oxygen by a $(p,pn\alpha)$ reaction, and by the reaction of neutron removal when thin targets are bombarded with $^{12}C^+$ ions.

$^{11}C$ recoil atoms, in reactions with saturated and unsaturated hydrocarbons, cyclopropane, or ethylene oxide, give labelled acetylene as chief product (~30% yield)[31,94,95]. In the reactions of $^{11}C$ recoil atoms with pentane, the chief products are acetylene (22%), ethylene (11%), butane (7%), and n-hexane (26%). If the "insertion" mechanism is

correct, the following reactions should take place in this case:

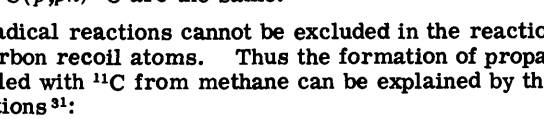
In the case of unsaturated compounds, considerable yields are obtained of alkenes containing one more carbon atom, for example, the yield of allene from ethylene amounts to 18%:



The intramolecular distribution of $^{11}C$ in allene is now being studied in order to prove the mechanism of addition across the double bond[95].

The addition of retarding agents (nitrogen) did not lead to a decrease in the yield of products. This means that the reactivity of the hot carbon atoms is not due to their kinetic energy. The yield of mother compound in the reactions of hot carbon atoms is extremely low (1.5–2%) and this is not surprising, since elastic collision reactions can hardly compete with the insertion processes. The formation of ethylene from saturated compounds apparently takes place by the insertion of a CH fragment at the C–H bond with subsequent rupture of the C–C bond (reaction 8′).

The low yield of cyclic hydrocarbons in the reactions of carbon atoms with unsaturated compounds (3%)[94,95] is due to the insertion of hot $CH_2$ at the double bond in the same way as in the reaction initiated by light. In this case, oxygen also inhibits the yield of cyclic products[31].



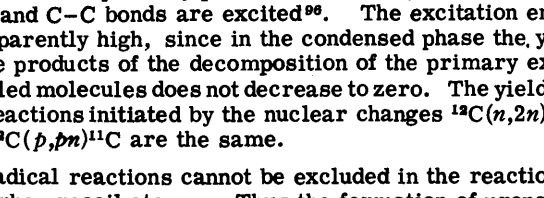
Hot $CH_2$ are formed by the retardation of carbon recoil atoms in hydrogen-containing media. The increase in chain length is due to insertion at the C–H bond:

The formation of n-hexane from pentane takes place in the same way.

Change in phase state did not lead to any significant redistribution of the activity of $^{11}C$ in the products[96]. It was found that the primary products formed by insertion at C–H and C–C bonds are excited[96]. The excitation energy is apparently high, since in the condensed phase the yield of the products of the decomposition of the primary excited labelled molecules does not decrease to zero. The yields of the reactions initiated by the nuclear changes $^{12}C(n,2n)^{11}C$ and $^{12}C(p,pn)^{11}C$ are the same.

Radical reactions cannot be excluded in the reactions of carbon recoil atoms. Thus the formation of propane labelled with $^{11}C$ from methane can be explained by the reactions[31]:

The yield of propane increases with increase in the radiation dose, confirming the radical mechanism, but the yield of ethane does not increase with increase in the dose, contradicting this suggestion.



Studies which have been carried out have shown that carbon recoil atoms take part in chemical reactions with molecules in the states C ($^3P$), CH ($sp$), and $CH_2$ ($sp^2$).

The formation of $CH_2$ does not depend on the nature of the compound; the reactions of hot carbon atoms always lead to the formation of the same proportion of $^{11}CH_2$ fragments, which undergo insertion reactions in accordance with simple statistics. Kinetic energy plays no significant part in the reactions of hot carbon atoms. The reactions of hot carbon atoms can be represented schematically as follows. Insertion reactions take place irrespective of the nature of the fragment: the insertion of a carbon atom at the C–H bond gives decomposition products, chiefly acetylene; the introduction of the CH methine group at the C–H bond leads to decomposition to ethylene or the formation of an alkene with one carbon atom more than the original molecule; the insertion of $CH_2$ at C–H and C=C bonds gives hydrocarbons with one atom more than the original molecule. The excitation energy after the insertion process is high, leading to rupture of the nearest C–C bonds. The $CH_3$ radical is apparently not formed in the retardation of a hot carbon atom. This is confirmed by the fact that no labelled methane molecules were found in the products of the stabilisation of hot $^{14}C$ atoms[97]. It is true that study of the process $^{14}N(n,p)^{14}C$ is not a sufficiently reliable method for studying the mechanism of the reactions of hot carbon atoms: the appreciable irradiation times required to obtain sufficiently high activities (200–400 h) lead to appreciable radiative decomposition not only of the original products, but also of the products of the hot reactions. Irradiation for short periods in the $NH_3 + CH_4$ system gives acetylene and ethylene, whose yields decrease with increase in the duration of irradiation[98], confirming the above model for the hot reactions of carbon atoms.

## IV. EXCITATION ENERGY TRANSFER IN REACTIONS OF HOT ATOMS AND PARAMETERS DETERMINING THE COURSE OF HOT REACTIONS

### 1. Energy Transfer on Simple Collision

In hot atom chemistry it is an experimentally established fact that the primary labelled products are in an excited state. Thus in the reactions of tritium recoil atoms with cyclopropane and cyclobutane, decomposition of the primary labelled compound is possible[32,33]:

Since change in pressure in the range 0.1–1 atm leads to an increase in the yield of labelled mother molecules, the lifetime of the excited states is estimated at $\geq 10^{-9}$ s. On going to the condensed phase, where the frequency of collision is greater by a factor of $10^3$, there is a considerable phase effect for these reactions (Table 5).

TABLE 5. Yield of tritium-labelled products obtained by reaction in cyclobutane in the gaseous $^3He(n, p)T$ and liquid $^6Li(n, \alpha)T$ phases (yield of $\square_T$ + + $C_2H_3T$ taken as 100%).

| Conditions | Products | | | | | |
|---|---|---|---|---|---|---|
| | $\square_T$ | $C_2H_3T$ | HT | $n\text{-}C_4H_9T$ | $CH_3T$ | $C_3H_6T$ |
| 9.4 cm□ 2.3 cm $O_2$ 1.4 cm $^3He$ | 50 | 50 | 151 | 3 | 0.6 | 0.2 |
| LiF + □ (liquid) | 82 | 19 | 211 | 10 | 5 | 9.7 |

Analysis of the data given in Table 5 indicates that in the reactions of tritium recoil atoms with cyclobutane, intermediate molecules in two different states are formed: with a lifetime $>10^{-9}$ s (the yield of the reaction depends on the pressure) and with a lifetime $<5\times10^{-12}$ s (since the change to the liquid phase did not block completely the decomposition of the cyclobutane molecule). The first type of state is a triplet state and the second is a singlet state. The fact that the triplet–singlet transition is forbidden is responsible for the long lifetime of the excited states, and increase in pressure decreases the probability of breakdown of the labelled excited molecules. Since the change to the liquid phase does not reduce the decomposition to zero, however, it must be assumed that there exist highly excited molecules with a short lifetime ($<5\times10^{-12}$ s, singlet), shorter than the time interval between two collisions in the liquid phase.

The removal of the excitation energy apparently takes place from the vibrational levels after the intramolecular conversion of the electronic excitation.

## 2. Parameters Determining the Course of a Hot Reaction. The Question of the Existence of a Mechanism for the Specific Transfer of Excitation Energy

Nesmeyanov and coworkers [28-30,52,99,100] suggested the existence of an excitation energy transfer depending not so much on the number of collisions as on the nature of the colliding molecules (specific transfer of energy). The deviation from additivity shown by the tritium-labelled products in the binary mixtures: benzene–cyclohexane [100], benzene–pyridine, and pyridine–cyclohexane [30], or by bromine-labelled products in the ethyl bromide–benzene [28] and methylene bromide–benzene [52] systems and by compounds labelled with $^{14}C$ in the aniline–indole system [29], can be attributed to the transfer of energy from the excited labelled molecules to molecules of an energy "acceptor", analogous to that assumed in radiation chemistry. The analogous relationship for the yields of labelled products observed for the aniline–ethanol (acetone) and acetone–water systems [101] has been examined from other angles, namely from the viewpoint that the yields of the reactions are dependent on the probability of primary interaction and the change in the spectrum of retarded atoms. This viewpoint is also similar to the concept developed in radiation chemistry. Typical curves for the yields of labelled products in binary mixtures of substances are given in Fig. 2.

The yield of labelled product when hot reactions are carried out in a mixture consisting of two components can

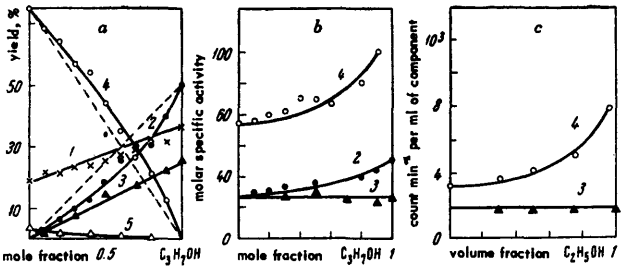


Fig. 2. Radiochemical yields and specific activities of tritium-labelled substances in the $C_6H_6$–$C_3H_7OH$ binary system: *a*) radiochemical yields: HT (1), $C_3H_7OH(T)$ (2), $C_3H_6TOH$ (3), $C_6H_5T$ (4), and cyclohexene(T) (5) for irradiation of the system: 20 mg $Li_2CO_3$ + 0.02 ml of $C_3H_7OH$ + $C_6H_6$ mixtures by a $10^{11}$ n × × $cm^{-2}$ $s^{-1}$ neutron beam for 6 h at 40°. The total activity recorded was independent of composition [42]; *b*) molar specific activity of components [42] in the $C_6H_6$–$C_3H_7OH$ binary system; *c*) absolute specific activities of the components of a binary mixture of aniline (4) and ethanol (3). The irradiation was carried out in monitored neutron beams [101].

be found by the Wolfgang–Estrup method [37] (see III. 1) or by solving the resonance integral of the theory of neutron retardation in an absorbing medium [28,38].

If we take

$$\int_{E_1}^{E_2}\frac{p_i(E)}{E}\,dE=\overline{p_i(E)}\ln\frac{E_2}{E_1}$$

[see Eqns. (20) and (22)], we have, with an accuracy up to the constant factors

$$R_{1i}\simeq\left\{\frac{f_1}{\xi}\overline{p_i(E)}-\frac{f_1}{\xi^2}-\overline{p_i(E)}\,[\overline{f_1p_1(E)+f_2p_2(E)}]\right\}\text{const}, \qquad (30)$$

where $R_{1i}=I_{1i}/\Sigma I$, $I_{1i}$ is the activity of the $i$-labelled product from the first component of the mixture, $\Sigma I$ the activity of all the labelled products in the system, $f_1$ the geometric probability of collision with the first component of the mixture, $\overline{p_i(E)}$ the mean probability of chemical reaction on collision with the formation of the $i$-labelled product from the first component, $\overline{p_1(E)}$ the mean probability of reaction on collision with the formation of all labelled products from the first component, and $\overline{p_2(E)}$ the corresponding probability for the second component. The geometric probability of collision is determined from the relationship

$$f_1=N_1\sigma_1n_1\gamma_1/(N_1\sigma_1n_1\gamma_1+N_2\sigma_2n_2\gamma_2)\quad\begin{matrix}z_1=\sigma_1n_1\gamma_1\\ z_2=\sigma_2n_2\gamma_2\end{matrix}, \qquad (31)$$

where $N_1$ and $N_2$ are the mole fractions of the first and second components of the binary mixture, $\sigma_1$ and $\sigma_2$ the collision micro-cross-sections, $n_1$ and $n_2$ the number of reactive points in the molecule at which chemical reactions are possible on collision, and $\gamma_1$ and $\gamma_2$ the steric-hindrance coefficients for attack. The logarithmic decrement for a mixture of substances can be calculated from formula (12).

Eqn. (30) was obtained [28,38,102] on the basis of the regular features observed in a study of the thermalisation of neutrons when capture processes are taking place, and is applicable if the following conditions are satisfied: (1) the

hot atoms are retarded on atoms of similar mass, or else $E < \xi\, {}^3E_0$, where $E_0$ is the initial recoil energy; (2) the function for excitation of chemical reactions, $p(E)$, has resonance character; (3) collision between an atom and a molecule is accompanied either by chemical reaction or by scattering with the loss of energy; (4) a hot atom spectrum corresponding to asymptotic collision density $1/\xi E$ can be established; (5) the mean proportion of the energy loss is independent of the energy; and (6) the collision micro-cross-section and steric-hindrance coefficient are independent of the energy. The first four conditions are evidently satisfied in the reactions of hot atoms, and the fifth and sixth conditions can be taken as extremely rough approximations necessary for the analysis of Eqn. (30).

Moreover, we assume that the mean loss of energy is independent of composition (this may be satisfied in particular cases). This facilitates the analysis of Eqn. (30).

Analysis of Eqn. (30) leads to the following conclusions[102]: (1) if $\overline{p_1(E)} > \overline{p_2(E)}$ and $z_1 > z_2$, we find that $d^2R_{1i}/dN_1^2 < 0$ and that the dependence of $R_{1i}$ on $N_1$ deviates from linearity in a positive direction; (2) if $\overline{p_1(E)} < \overline{p_2(E)}$ and $z_1 < z_2$, we find that $d^2R/dN^2 > 0$, and the dependence of $R_1$ on $N_1$ shows a deviation downwards towards the $N_1$ axis.

The derivative $d^2R_1/dN_1^2$ does not change sign throughout the whole range of concentrations $N_1$ from 0 to 1, that is, the dependence of $R_1$ on $N_1$ deviates from linearity either upwards or downwards, if $\overline{p_1(E)} > \overline{p_2(E)}$ and $z_1 > z_2$, or $\overline{p_1(E)} < \overline{p_2(E)}$ and $z_1 < z_2$¶. From this analysis it follows that the yields of the labelled products of hot reactions in a binary mixture of substances is non-linearly dependent on concentration and that the dependence may become linear only when $\overline{p_1(E)} = \overline{p_2(E)}$ and $z_1 = z_2$. From this it follows that the explanation of the deviations from additivity shown by the yields of labelled products from the viewpoint of the influence of intermolecular transfer of energy is not unambiguous, since even if the loss of energy does not change with change in concentration, the yield of a hot reaction may be non-linearly dependent on concentration because of differences in the probabilities of chemical interaction. If the retarding power of the medium also changes with change in composition, this will introduce an additional change in the yield of the reactions. The rates of change in $R/N$ at small and large values of $N$ differ by a factor of $(z_1/z_2)^2$. This means that in addition to the ratio between the probabilities of the hot reactions, the yields of labelled products are influenced to a significant extent by such parameters as the collision micro-cross-sections, the number of reactive points in the molecules, and the steric-hindrance coefficients for attack.

Solution of Eqn. (30) for small values of $N$ leads to formulae of the following type[102]:

$$\frac{R_{1i}^1}{R_{1i}^0}\frac{R_{2i}^1}{R_{2i}^0} N_1 N_2 \simeq 1, \qquad (32)$$

$$\frac{R_{1i}^1}{R_{1i}^0} N_1 = \frac{\xi_2}{\xi_1}\frac{z_2}{z_1}, \qquad (33)$$

where $R_{1i}^1$ and $R_{2i}^1$ are the yields of the labelled first and second components with the condition that their concentrations are equal to 1 (that is, the yields of labelled components from the pure substances), and $R_{1i}^0$ and $R_{2i}^0$ the yields of the first and second labelled components when their concentrations are low (that is $R_{1i}$ when $N_1 \simeq 0.1$, and $R_{2i}$ when $N_2 \simeq 0.1$). Eqn. (32) is confirmed by the experimental data for seven binary systems studied. Significant deviation was found only for the $C_6H_{12}$–$C_6H_6$ and $C_6H_6$–$C_5H_5N$ systems, possibly due to the high probability of the reactions of thermal tritium atoms with benzene and pyridine, one result of which is the formation of a polymer whose activity was not recorded in the experiments[103] (see Section II. 2).

In fact, Rowland and coworkers[104] found that the yield of polymer labelled with tritium in the benzene + + cyclohexane system amounted to 30–40%, depending on the duration of irradiation. It is assumed that the labelled polymer is formed through cyclohexadienyl radicals, whose production was noted earlier[99].

Eqn. (33) can be used to find the ratios $z_1\xi_1/z_2\xi_2$. This ratio is equal to 0.7 for the alcohol–benzene system and 0.5 for the alcohol–cyclohexane system. Thus the analogous ratio for the cyclohexane–benzene system can be found by calculation: $0.7/0.5 = 1.4$, which agrees exactly with the value found directly from experimental data on the yields of labelled compounds from a cyclohexane–benzene mixture. This indicates the possibility of using this method to treat the experimental results of studies of the yields of hot reactions in binary mixtures in the condensed phase.

Recently Rowland and coworkers[105] calculated the dependence of $R_1$ on $N_1$ by a Monte Carlo method for a number of binary mixtures in the gaseous phase. It was found that the dependence of $R_1$ on $N_1$ is determined by $p_1(E)$ and the ratios between $\sigma_1$ and $\sigma_2$, and $\xi_1$ and $\xi_2$, that is, the kinetics of hot reactions are determined by factors such as the probability of reaction, the retardation parameter, and the collision micro-cross-section.

This has a clear physical significance. Let us examine in turn the influence of the parameters determining the formation of the products in hot reactions.

### 3. The Influence of the Probability of Chemical Reaction on the Yield of the Products of Hot Reactions in a Binary Mixture of Substances

In the range $E \ll E_0$ (more accurately, $E < \xi\, {}^3E_0$) the hot atom spectrum is determined by the expression $1/\xi E$ (Fig. 3). If it is assumed that the probabilities of chemical reaction with the first and second components in the binary mixture of substances are determined in the range $E_2$–$E_1$ and depend in resonance fashion on energy (Fig. 3), the spectrum of hot atoms entering the range corresponding to determination of the function $p_{1i}(E)$ "loses" a fraction proportional to $\overline{f_1p_1(E)} + \overline{f_2p_2(E)} - \overline{p(E)}$ is subsequently denoted $p$. The fraction of hot atoms which can react with the first component with the formation of an $i$-labelled product (with probability $p_{1i}$) is equal to $1 - (f_1p_1 + f_2p_2)$. Since the probability of formation of an $i$-labelled product in the absence of competing processes is proportional to $f_1p_{1i}$, the yield $R_{1i} \simeq f_1p_{1i} \times (1 - f_1p_1 - f_2p_2)$. From this it follows that with increase in the concentration of the second component in the binary mixture of substances, the hot atom spectrum will show ever-increasing quantities of relatively low-energy atoms at the expense of "removal" of the high-energy fraction of the spectrum in the range $E_2$–$E_1'$. The effect of "selective" action of the hot atoms leads to a non-linear concentration dependence for the yields of the labelled products of the hot reactions.

¶ See Nesmeyanov and Filatov[102] for the detailed analysis.

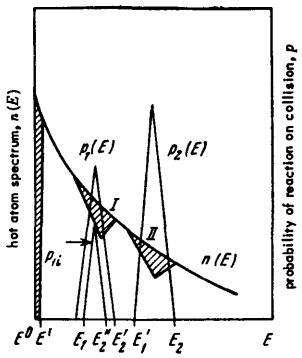

Fig. 3. Dependence of the hot atom spectrum on the probability of chemical reactions in binary mixtures of substances. $p_{1i}(E)$ is the probability of chemical reaction with the first component with the formation of the $i$-labelled product, $p_1(E)$ the same for the formation of all labelled products, and $p_2(E)$ the probability of reaction with the second component with the formation of all labelled products. The hatched regions (I and II) are the parts of the hot atom spectrum leaving the "game" as a result of chemical reactions. The fraction of hot atoms (II) is proportional to $f_2\overline{p_2(E)}$ and the fraction (I) is proportional to $f_1\overline{p_1(E)}$. The fraction of atoms $1/\xi E\{1 - [f_1p_1 + f_2p_2]\}$ (without allowance for the change in the density of collisions with change in concentration) falls in the energy range $(E_2''-E_1)$ of the function $p_{1i}(E)$. In the range of the spectrum $(E'-E^0)$ the atoms are captured by acceptors of radicals and thermal atoms $E_2 \simeq 10$ eV, $E_1 \simeq 1$ eV, $E^0 \simeq 0.03$ eV.

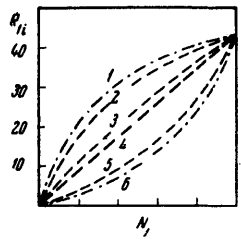

Fig. 4. Yield of labelled first component, formed by hot reactions in a binary mixture of substances, according to the kinetic equation (30), with the conditions that:

1) $p_1 > p_2$, $z_1 > z_2$; 2) $p_1 = p_2$, $z_1 > z_2$;
3) $p_1 > p_2$, $z_1 = z_2$; 4) $p_1 = p_2$, $z_1 = z_2$;
5) $p_1 > p_2$, $z_1 < z_2$; 6) $p_1 = p_2$, $z_1 < z_2$,

where $p_1$ is the probability of reaction of the hot atom on collision with the first component of the binary mixture; $p_2$ the same for the second component; $z_1$ and $z_2$ the steric parameters; $z_1 = n_1\sigma_1\gamma_1$ for the first component and $z_2 = n_2\sigma_2\gamma_2$ for the second component. $R_{1i}$ is the yield of labelled first component, and $N_1$ the mole fraction. The following values were selected for the calculation (1, 3, and 5): $p_1 = 0.3$, $p_2 = 0.2$, $z_1 = 0.3$, $z_2 = 0.1$, $p_{1i} = 0.1$, $\xi = 0.6$, and const = 5. For 2, 4, and 6: $p_1 = p_2 = 0.3$. In 3 and 4, $z_1 = z_2 = 0.3$. For $z_1 < z_2$ we took $z_1 = 0.1$ and $z_2 = 0.3$. The choice of the values of $p$, $z$, and $\xi$ is not critical. The shape of the dependence of $R_1$ on $N_1$ does not depend on the values of $p_1$, $z_1$, and $p_2$, $z_2$, but only on the relationships between $p_{1i}$, $p_1$, $z_1$ and $p_2$, $z_2$.

It is suggested[28,38,101,102] that the existence of this effect, which has been called the "integral effect", explains the *increase in specific activity of any component of the mixture with decrease in its concentration* and also the appearance of an isotopic effect in the reactions of hot tritium atoms in substances such as $CH_2D_2$, where the mean loss of energy has no influence on the result (see Section III. 1). On the other hand, since $f_1 = N_1\sigma_1n_1\gamma_1/\Sigma N\sigma n\gamma$ [see formula (31)], the rate of change in $R_{1i}$ with change in $N_1$ (and the rate of change in specific activity with change in composition) is determined by the parameters $\sigma$, $n$, and $\gamma$ (see Fig. 4).

## 4. The Influence of the Retarding Power of the Medium on the Yield of the Products of Hot Reactions

According to the kinetic equation (30), for smaller losses of energy, the hot atoms have a higher possibility of taking part in reactions, since there is an increase in the number of collisions in the energy range where $p_{1i} > 0$. On the other hand, if the probabilities of the reactions with the components are different (see Fig. 3), for low fractions of the kinetic energy lost the preferred product will be that for which the probability of formation is displaced towards higher energies (products with $p_2$). If appreciable proportions of the energy are lost on collision, the hot atom falls into the low energy range in the first collisions and then the $1i$-product will be formed with high probability. This "retardation effect" may lead to an increase in the specific activity of the component on dilution with a second substance[48]. This also follows from the relationship obtained by substituting, in place of $f/\xi$ in Eqn. (3C), the following expression:

$$f/\xi = N_1z_1/[N_1(z_1\xi_1 - z_2\xi_2) + z_2\xi_2] \qquad (34)$$

($\xi_1$ and $\xi_2$ are the mean logarithmic losses of energy on collision with the first and second components respectively)

$$R_{1i} = \frac{N_1z_1}{(N_1z_1\xi_1 + N_2z_2\xi_2)}\overline{p_{1i}(E)} - \frac{N_1z_1}{(N_1z_1\xi_1 + N_2z_2\xi_2)^2}\overline{p_{1i}(E)}\,[N_2z_1\overline{p_1(E)} + N_2z_2\overline{p_2(E)}]. \qquad (35)$$

The dependence of $R_{1i}$ on $N_1$ is non-linear.

The arguments given in Sections IV. 3 and IV. 4 are valid with the assumption that $z$ and $\xi$ are independent of $E$. If this is not the case, the analysis of the kinetic equation is more difficult.

## 5. The Loss of Energy by Hot Atoms in the Range of Chemical Interaction

As noted above, the loss of energy by a hot tritium atom on collision with a methane molecule is greater than that for collision with deuterium, despite the more favourable ratios of the masses of the tritium and deuterium for the transfer of kinetic energy. Chemical interaction apparently takes place on collision between the hot atom and a molecule even if it does not lead to stabilisation of the atom in

any chemical form, that is, "non-reactive" collisions take place with a high cross-section. This process may be called the "chemical scattering" of energy (inelastic collisions). Thus $\xi$ cannot be calculated rigorously from the ratio of the masses and dimensions of the atoms alone. The mean loss of energy on collision should be related to the collision cross-section in the range of chemical interaction energies and should depend on the energy.

According to the theory of neutron retardation, the number of collisions for retardation from $E_2$ and $E_1$ is determined by expressions (13). The loss of energy along an infinitely small section of the retardation path can be expressed by the general equation:

$$-dE/dx = LEn\sigma_p, \tag{36}$$

where $L$ is the number of molecules in unit volume, $n$ the number of scattering centres, and $\sigma_p$ the micro-cross-section of "chemical scattering". From this,

$$x = \ln\left(\frac{E_2}{E_1}\right)\Big/Ln\sigma_p. \tag{37}$$

Dividing (37) by the diameter of the molecule $\rho$, we obtain the number of collisions with molecul s in the retardation path from $E_2$ to $E_1$ (range in fractions of the molecular diameters):

$$k = \frac{\ln(E_2/E_1)}{Ln\sigma_p}\frac{1}{\rho}. \tag{38}$$

Equating (38) and (13), we obtain for $\xi$ the expression

$$\xi = Ln\sigma_p\rho. \tag{39}$$

The quantity $\xi$ should be dimensionless, as can be readily verified from (39). In the case of a binary mixture of substances we must substitute in formula (39) the "mean dimensions of the molecules" $\overline{\rho} = N_1\rho_1 + N_2\rho_2$, and the product $Ln\sigma_p$ should be replaced by the sum for both components

$$\xi = (L_1n_1\sigma_{1p} + L_2n_2\sigma_{2p})(N_1\rho_1 + N_2\rho_2). \tag{40}$$

Expression (40) gives the relationship between $\xi$ and $\sigma_p$.

This analysis shows the complexity of the processes accompanying the retardation and chemical interaction of hot atoms.

Under real conditions, some part is apparently played by several factors: the change in $\xi$ with change in composition produces a change in the density of collisions in the energy range where the probability of reaction is not equal to zero; a difference in the reaction probabilities and the steric parameters of the components of the binary mixtures leads to a change in the spectral distribution of the hot atoms with respect to energies. This change is greater, the greater the difference in the values of the probabilities and the factors $z = n\sigma\gamma$.

The fraction of the energy lost on collisions by the hot atoms $\xi$ is determined by the scattering micro-cross-sections. Since the micro-cross-section increases in the range of chemical interaction energies, the fraction of energy lost also increases.

Thus the independent quantities in formula (30) are $p(E)$, $\sigma(E)$, and, in implicit form, $\sigma_p(E)$. The functions $p(E)$, $\sigma(E)$, and $\sigma_p(E)$ alter the spectrum and density of collisions of the hot atoms, leading to a change in the yields of the hot reactions which is not proportional to the concentration of the original substances. The analytical expression for these functions, which for a given substance depend only on $E$, is unknown. At present, therefore, we cannot calculate the absolute yield of a hot reaction.

The foregoing does not exclude the possibility that transfer of excitation energy from labelled "newly-formed" molecules influences the yield of the products of hot reactions. Qualitative hypothetical conclusions regarding the existence of this mechanism[30,100] have obtained more rigorous proof. It has been shown[102] that the dependence of the change in the yield of labelled first component ($\Delta R_1$) on the addition of a second component — a hypothetical excitation energy acceptor — is linearly determined by the parameter $N_2^3$. Since $N_2^3 = 1/r_2$, where $r_2$ is the distance between the molecules of the excitation energy acceptor, the observed relationship $\Delta R_1 = \text{const} \times N_2^3$ indicates the existence of linear energy transfer throughout the molecules of the acceptor. The part of excitation energy acceptor is played by alcohol molecules in the $C_6H_6 + C_3H_7OH$ and $C_6H_{12} + C_3H_7OH$ systems and by benzene molecules in the $C_6H_{12} + C_6H_6$ system.

The experimental data show that the relationship $\Delta R_1 = CN_2^3$ applies satisfactorily for $N_2 > 0.6$ M. This indicates that the excited molecule of the first component should be surrounded by not less than six molecules of the excitation energy acceptor if the "protection" mechanism is to be effective. It is suggested[102] that at high concentrations of the energy acceptor the chief part is played by energy transfer influencing the rate of deactivation of the excited freshly-formed molecule, whereas at low concentrations the mechanism of "selective" action of the hot atoms predominates.

It may thus be assumed that at present the following parameters and processes determining the kinetics of hot reactions are known: the probability of reaction on collision, the micro-cross-sections of collision and scattering, and, possibly, the transfer of energy from "freshly-formed" labelled molecules.

## 6. The Possibility of Transfer of Hot Atoms in High-Excitation Reactions

The phenomenon of hydrogen atom transfer was observed in the nineteen-thirties[7] for exchange reactions of the type:

(14) $$H + CH_4 \rightarrow CH_3{-}H{-}H,$$

(15) $$CH_3{-}H{-}H + D \rightarrow HD + CH_4.$$

The methane molecules are hydrogen atom carriers which "catalyse" the process of deuterohydrogen formation. The activation energy of reaction (14) amounts to 10 kcal and the dissociation energy of the "fifth" hydrogen atom is ~17 kcal, that is, the compound $CH_4$–H is fairly stable.

In view of the existence of the processes of charge and excitation energy transfer, and also the above process, it may be assumed that there is a possibility of hot atom transfer from some molecules to others, for example, in the cyclohexane–benzene system after collision between tritium and a benzene molecule — the "catalytic" marking of cyclohexane: $C_6H_5$-T + $C_6H_{12} \rightarrow C_6H_{11}T + C_6H_7$ (compare Section II. 2).

In the RH + ROH system, the alcohol molecules apparently act as tritium atom carriers.

From this viewpoint it is possible to explain the change in the specific activity of certain substances in a mixture

with additives capable of transferring hot atoms. At present, however, we have no proof that such "catalytic" processes take place in hot atom chemistry.

## 7. The Stereochemistry of Hot Reactions and the Elementary Act of the Establishment of a Bond

It follows from formula (24) that the three-dimensional structure of molecules should influence primarily the replacement of atoms, since this takes place with attack by the hot atom at large angles to the direction of the bond formed by the atom being replaced. In fact, the agreement between the experimental results and calculated data assuming that the steric hindrance for attack $\Omega = 0.45$ in the replacement of a primary atom shows that steric factors play a decisive part in the competing reactions of abstraction and replacement. In attack at large angles to the bond direction, the rotational levels of the molecule are apparently excited. In this connection the mass of the molecule should apparently influence the establishment of a chemical bond following the transfer of energy. This can be readily followed by analysing the yields of the products formed by rupture of the C–C bond in different hydrocarbons. It is found that the tritium recoil atom reacts with the lighter residue of the molecule. Thus in the reaction

$$(16)\qquad T + CH_3{-}CF_3 \rightarrow \begin{cases} CH_3T \\ CF_3T \end{cases},$$

the ratio of the yields $CH_3T/CF_3T$ amounted to 15, whereas in the reaction

$$(17)\ T + CH_3{-}CH_2{-}CH_2{-}CH_2{-}CH_3 \rightarrow \begin{cases} CH_3T + R \\ CH_3{-}CH_2{-}CH_2{-}CH_2T + CH_3^{\cdot} \end{cases},$$

the ratio $CH_3T/CH_3CH_2CH_2CH_2T$ was found to be 2.8 (Table 6). For chlorinated, brominated, and fluorinated methanes, it was also found that the effect of replacement of an atom was preferred to a greater extent, the smaller the mass of the fragment with which the hot atom reacts ("the inertial effect")[106,107].

The period of rotation through an angle $\theta$ is related to the moment of inertia ($I$) by the relationship

$$\tau \simeq 2\theta\sqrt{I/2E}. \qquad (41)$$

Calculation[106] shows that the time required for the rotation of $CH_2F$ through an angle of 1 radian amounts to $\sim 5 \times \times 10^{-14}$ s if the recoil atom communicated several electron volts of kinetic energy to the $CH_2F_2$ molecule on collision at the C–F bond. This time interval is greater than the duration of the interaction between the hot atom and the C–F bond ($10^{-14}$ s). In fact, the yield of the products obtained by the replacement of fluorine by tritium atoms in $CH_2F_2$ amounted to fractions of 1%, whereas as a result of the ease of rotation of the methyl group about the centre of inertia in $CH_3F$ the yield of $CH_3T$ amounted to 4.4%.

TABLE 6. Inertial effect in the reactions of hot tritium atoms[106].

| Substance | Ratio of yield of $CH_3T$ to the yield of $R_{n-1}H_{2n-1}T$ per C–$CH_3$ bond |
|---|---|
| $C_2H_6$ | 2.7* |
| $n\text{-}C_4H_{10}$ | 1.8 |
| $n\text{-}C_5H_{12}$ | 2.8 |
| $iso\text{-}C_5H_{10}$ | 4.7 |
| $neo\text{-}C_5H_{12}$ | 8.7 |
| $n\text{-}C_6H_{14}$ | 2.2 |
| For $CH_3{-}CF_3$ | Ratio $\frac{CH_3T}{CF_3T} \simeq 15$ |

* For example, for $C_3H_8$: $CH_3T/C_2H_5T = \frac{11.0}{4.0} = 2.7$.

In the calculation it is also necessary to allow for the values of the collision cross-sections, the energy of the bonds, and the possibility of removal of the excitation energy. In the series $CH_3F$, $CH_3Cl$, and $CH_3Br$, the yield of $CH_3T$ increases systematically (4.4%, 7.1%, and 12.0%) in accordance with the increasing cross-sections of collision for tritium with the atoms on going from fluorine ($0.88 \times 10^{-16}$ cm²) to chlorine ($1.6 \times 10^{-16}$ cm²) and bromine ($1.96 \times 10^{-16}$ cm²)† – the energy of the C–X bond (X = halogen) also decreases in the above series of compounds, so that the conclusion regarding the influence of collision cross-section is ambiguous; the results show better agreement with experiment, however, for the former model. In the liquid phase the freedom of rotation of the molecules is limited. From the viewpoint of the "inertial effect", the yield of replacement products should decrease, but this is not observed (Table 7): the yield of the chlorine-replacement product increases for both $CH_3Cl$ and $CH_2Cl_2$. In the liquid phase there is apparently a sharp increase in the survival of labelled molecules as a result of the transfer of energy on collision.

The transfer of energy (non-specific) here is facilitated by the fact that the rotational energy, which is essentially kinetic, is readily converted into energy of translational movement. The rate of removal of the excitation energy is equal to the number of collisions between the atoms and molecules:

$$z = 2/\sqrt{\pi}\,\sigma\, v N_1 N_2 q, \qquad (42)$$

where $\sigma$ is the collision cross-section for the excited molecule, $v$ the velocity of the particles, $N_1$ and $N_2$ are their concentrations, and $q$ is the probability of the process,

TABLE 7. Relative yields of tritium-labelled molecules as a result of the reactions of hot tritium atoms with chloromethanes*.[108]

A

| Substance | Yield of products | | |
|---|---|---|---|
| | $CH_3T$ | $CH_2TCl$ | $CH_2TI$ |
| $CH_3Cl$ 9.1 cm, gas | 27.8 | 30.4 | 40.9 |
| Liquid | 45 | 65 | — |

B

| Substance | Yield of products | | | |
|---|---|---|---|---|
| | $CH_2TCl$ | $CHTCl_2$ | $CH_2TI$ | $CHTCII$ |
| $CH_2Cl_2$ 8.1 cm, gas | 6.9 | 13.9 | 15.3 | 6.4 |
| Liquid | 37 | 44 | — | — |

* Yield of HT taken as 100%; $^3$He pressure 1.5 cm; on irradiation in the gaseous phase the ampoules contained $I_2$.

† The covalent radii were used for the calculation[108].

equal to unity for the conversion of energy of rotation into translational energy and equal to $\sim 10^{-4}$ for the conversion of vibrational energy into translational energy.

Thus for attack at large angles to the bond direction, the rotational levels are excited. The removal of excitation energy takes place effectively on each collision with another molecule, so that increase in pressure leads to an increase in the yield of replacement product. In the case of attack along the bond, the vibrational levels of the molecule are excited. The probability of conversion of vibrational energy into translational energy is smaller by a factor of $10^4$ than that for the conversion of rotational energy into translational energy. Thus the yield of abstraction products formed as a result of this attack depends little on pressure, as confirmed by experiment[33].

It is undoubtedly true that in the establishment of a chemical bond the electronic levels of the molecule are also excited. The lifetime of excited electronic states amounts to $10^{-12}$–$10^{-13}$ s. This increases to $10^{-9}$–$10^{-7}$ s if a change in multiplicity takes place. In a period of $\sim 10^{-8}$ s the molecule is able to undergo approximately $10^5$ vibrations and approximately $10^3$ rotations. If the internal conversion of electronic excitation takes place readily, there is a definite probability of energy transfer on collision with surrounding molecules (non-specific transfer of energy). Certain substances, for example, benzene, are able to remove excitation energy directly from electronic levels (specific transfer of energy).

In the gaseous phase the time interval between two collisions is inversely proportional to pressure and is equal to $\sim 10^{-7}\, p^{-1}$ s, where $p$ is the pressure in mmHg. At a pressure of 100 mmHg the lifetime of an excited molecule should be greater than $10^{-8}$ s if deactivation is to take place on collision. In a liquid, the number of collisions per second amounts to $\sim 5 \times 10^{12}$, so that transfer of energy on collision is possible even if short-lived states are excited. The question of the specific transfer of excitation energy in reactions of hot atoms remains open. At present the main task is to establish precise experimental facts indicating that such processes take place.

The next step in the further development of the theory of the elementary acts of chemical reactions at high energies is possibly a quantum-mechanical approach, which here is facilitated by the fact that the reactions of hot atoms take place on local collision in a limited part of the molecule, so that the remaining part of the molecule can be regarded as not taking part in the primary act of establishment of the chemical bond. The first steps in this direction have already been taken[109].

# THE USE OF ELECTRON PARAMAGNETIC RESONANCE FOR THE STUDY OF CATALYSTS

V. Ya. Vol'fson and L. N. Ganyuk

## CONTENTS

I. Introduction 702

II. Reactions involving the pairing and unpairing of electrons 702

1. Deuterium exchange in molecular hydrogen 702

2. Hydrogenation–dehydrogenation reactions 705
3. The radical polymerisation of ethylene 706
III. Reactions involving electron transfer 709
1. The decomposition of hydrogen peroxide and dinitrogen oxide 710
2. The oxidation of organic substances 710
IV. Reactions involving the donation and withdrawal of an electron pair 712

## I. INTRODUCTION

The essential features of the EPR method (electron paramagnetic resonance) have been described in detail in many monographs and reviews[1-6].

The efficiency of this method in the study of catalysts is because in most cases the catalysts are paramagnetic. The nature of the paramagnetic centres may be different but they are all, in the final analysis, produced by unpaired electrons, which give EPR signals. The intensity and shape of the lines in the EPR spectrum can give information on the concentration and state of the paramagnetic centres, with which the catalytic activity of the contacts is usually associated (at any rate in reactions taking place by a radical mechanism). Here it must be borne in mind that both the bulk properties and the surface properties are reflected in the EPR. It is known that the paramagnetism of catalysts, which are most frequently studied in the isolated state at room temperature, does not reflect completely the paramagnetic state of the contacts during catalysis. Moreover, new paramagnetic centres may be produced during catalysis, so that in the comparison of the dynamic paramagnetism of the contacts with their catalytic activity, allowance must be made for the fact that the correlations will be justifiable only if the above features are taken into account.

In a number of studies it has been shown that the irradiation of catalysts by $\gamma$-rays, a neutron beam, etc., alters their catalytic activity[7]. Other work, often carried out with the same materials, has established that this irradiation generally leads to the production, in the catalyst, of defects which can be detected using the EPR method. It is convenient to compare the data obtained by different authors on the change in catalytic activity after irradiation on the one hand with the parameters of the EPR signals of the same catalyst on the other. This is particularly necessary since a simultaneous comparison of these two parameters has been made in very few studies.

In the discussion of the factual material, we have used the classification of catalytic reactions proposed by Polyakin[8], who divides all catalytic reactions into three main types: reactions involving the pairing and unpairing of electrons; reactions taking place with electron transfer (oxidation); and reactions involving the donation and withdrawal of an electron pair (acid–base reactions).

## II. REACTIONS INVOLVING THE PAIRING AND UNPAIRING OF ELECTRONS

Reactions of this type which have been studied by the EPR method include deuterium exchange in molecular hydrogen, hydrogenation, dehydrogenation, and radical polymerisation†. For these reactions to take place, it is usually necessary that the catalyst surface have paramagnetic centres ("free valencies"[12]) or, at least, that such centres be readily produced under the catalysis conditions by the influence of heat and the reaction mixture. The interaction between the surface paramagnetic centres in this case is not significant. Since the completion of the catalytic act in this type of process does not require the transfer of electrons, dielectric substances (for example, $SiO_2$ or $Al_2O_3$) with paramagnetic centres on their surface may also act as catalysts here. If the catalytic act takes place on those paramagnetic centres which are detected by the EPR method, we should expect that the intensity of these signals and the catalytic activity should change in the same sense.

### 1. Deuterium Exchange in Molecular Hydrogen

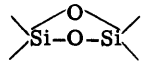
The reaction $H_2 + D_2 \rightleftharpoons 2HD$ takes place at a satisfactory rate on a number of catalysts. In recent years it has been studied on silica gel and on alumina as a model reaction for determining the influence of the irradiation of these oxides on their catalytic activity.

It has been established[13] that thoroughly dehydrated and ignited (8 h at 200–300°C in a vacuum) silica gel containing less than 0.1% Fe and Al, after irradiation at room temperature by $\gamma$-rays from $^{60}Co$ (5–10 Mrad), gives a relatively weak EPR signal [a quintet with $g$-factor equal to the $g$-factor of diphenylpicrylhydrazyl (DPPH) and splitting 22 G]. It is suggested that the observed paramagnetic centre is formed by the removal of a hydrogen atom from a surface hydroxyl group and that the hyperfine structure (HFS) is due to the interaction of the unpaired electron with the protons of neighbouring OH-groups or adsorbed water molecules. It is considered that the increased catalytic activity of irradiated silica gel in the isotopic exchange $H_2 + D_2 \rightleftharpoons 2HD$ may be associated with these paramagnetic centres. It is also suggested that the EPR spectrum after irradiation does not reveal all the paramagnetic centres produced by irradiation.

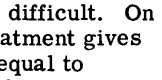
Silica gel which has been degassed at 500°C and then irradiated at room temperature with the same dose gives a narrow singlet ($g$-factor = 2.0004). In Molin and Voevodskii's opinion[14], shared by Kazanskii, this signal is due to electrons trapped in oxygen vacancies of the lattice. Kohn[15] also studied the paramagnetic resonance absorption of silica gel which had been degassed at ~500°C and then irradiated at 50°C by $\gamma$-radiation from $^{60}Co$ (dose $10^{19}$ eV$\times$ $\times g^{-1}$) or by X-rays with an energy of 50 keV. The work was carried out with silica gel in which the concentration of impurities (Fe, Al, Mg) did not exceed 0.1–0.01%. Kohn, like Kazanskii, detected an EPR signal (singlet) stable at room temperature (in a vacuum). Kohn also attributed the signal to the trapping of electrons in the oxygen vacancies of the lattice, but whereas Kazanskii and coworkers identified the paramagnetic centres observed in the EPR spectrum with the colour centres of the silica gel (the so-called $F$-centres), Kohn showed that the $F$-centres, which are also produced after irradiation, are not associated with the paramagnetic centres. Similarly the $F$-centres are not associated with the catalytic activity with respect to the reaction $H_2 + D_2 \rightleftharpoons 2HD$. In actual fact, as noted by

† The $o$-$H_2 \rightleftharpoons p$-$H_2$ process is not considered, since it takes place on all paramagnetic substances[9-11].

Taylor and Kohn[16-18], the main bulk of the hydrogen is chemisorbed on the *F*-centres so strongly that these centres cannot react further with hydrogen. Only ~ 5% of the sorbed hydrogen is capable of undergoing exchange with gaseous $H_2$ or of removal by evacuation at room temperature. Calculations show that this quantity of mobile hydrogen would be sufficient to ensure the increased catalytic activity of the irradiated silica gel. According to Taylor and Kohn's data[17], however, the rate of the exchange of this mobile fraction of the sorbed hydrogen is not sufficiently high for the exchange to be a stage in the catalytic process $H_2 + D_2 \rightleftharpoons 2HD$.



In Kazanskii's experiments, the EPR line did not become broader when oxygen was admitted, and from this it was concluded that the signal is due to bulk defects. Kohn, however, found that this signal disappears when oxygen is added ("the oxygen effect"). The accumulated data suggest that some of the paramagnetic centres are also present on the surface of the contact.



Kohn and Taylor[19] studied the change in the catalytic activity of silica gel which had been degassed at 450–600°C and subjected to $\gamma$-irradiation with a dose of approximately $10^{19}$ eV $g^{-1}$ (concentration of Fe, Al, and Mg impurities less than 0.1–0.01%) with respect to the reaction $H_2 + D_2 \rightleftharpoons 2HD$ at room temperature (static method), and established that after irradiation the silica gel is 100–2000 times more active than before irradiation. At the same time, the activation energy is reduced from 9 kcal × × $mole^{-1}$ to 2 kcal $mole^{-1}$. From this it might be concluded that the increase in the catalytic activity of the silica gel after irradiation is associated with the generation of the defects responsible for the appearance of the narrow EPR signal. In a recent paper, however, Taylor[18], referring to Kohn's results[20], points out that when the silica gel is heated at a temperature close to its melting point, its catalytic activity approaches that of the irradiated contact. The heating was carried out[20] for 16 h at 920°C. After this treatment, the rate constant for the reaction $H_2 + D_2 \rightleftharpoons 2HD$ on commercial silica gel, even at -78°C, was equal to $5 \times 10^{-7}$ $min^{-1}$ $m^{-2}$ — for comparison it should be noted that the rate constant for the reaction $H_2 + D_2 \rightleftharpoons$ $\rightleftharpoons 2HD$ at room temperature on an analogous silica gel specimen after irradiation with $\gamma$-rays from $^{60}Co$ (activity 600 c for 1 min at 35°C) is equal to $5.5 \times 10^{-5}$ $min^{-1}$ $m^{-2}$. Unfortunately, Kohn does not give the value of the rate constant at room temperature for silica gel which had been heated at 920°C, and this makes comparison difficult. On other modifications of $SiO_2$, this thermal treatment gives an even greater effect: the rate constant is equal to $10^{-3}$ $min^{-1}$ $m^{-2}$ on quartz, and $10^{-4}$ $min^{-1}$ $m^{-2}$ on quartz glass and cristobalite (these substances have a surface area of approximately 6–8 $m^2$ $g^{-1}$).

Kohn[20] also showed that the catalytic activity of silica gels is directly proportional to the concentration of aluminium present. After degassing at high temperature followed by irradiation (35°C, 600 c, $^{60}Co$ $\gamma$-radiation, 1 min), the rate constant at 25° on silica gel shown by spectroscopic analysis to contain no aluminium, was equal to $3.7 \times 10^{-6}$ $min^{-1}$ $m^{-2}$, whereas for silica gel specimens containing 0.01% $Al^{3+}$, 0.1% $Al^{3+}$, and 0.5% $Al^{3+}$, the values ($min^{-1}$ $m^{-2}$) were $3.5 \times 10^{-5}$, $5.5 \times 10^{-5}$, and $1.6 \times 10^{-4}$ respectively. An analogous direct relationship between the activity and the aluminium content is observed for silica gel specimens degassed at 500° and 625°C, but in this case the absolute values of the rate constants are smaller by 1–2 orders of magnitude. (An increase in the catalytic activity of silica gel after the introduction of additional quantities of Al was established by Kohn and Taylor[17]). It may also be noted that silica gel with maximum purity, even after extensive irradiation ($6 \times 10^{20}$ eV $g^{-1}$), adsorbs very little hydrogen, the quantity adsorbed being smaller by a factor of ~ 100 than the quantity adsorbed by irradiated commercial silica gel[16,17].

On the basis of these facts, Kohn[20] suggests that the increased catalytic activity of irradiated silica gel is due to a complex consisting of adsorbed hydrogen and a positive hole, trapped on an aluminium atom. Kohn himself, however, considers that this suggestion is only a rough approximation, since it does not explain a number of facts: the increase in activity after irradiation by ultraviolet light[16,17] or by $\gamma$-rays followed by ultraviolet light[16,17], or the poisoning of the catalyst by dry oxygen[21].

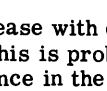
The facts indicate that the catalytically active centre in silica gel contains aluminium. In Kohn and Taylor's opinion[17], it cannot be assumed that the aluminium impurity in the silica gel forms a $\gamma$-$Al_2O_3$ phase and that it is the presence of this phase which determines the catalytic activity of the silica gel. This cannot be assumed chiefly because pure $\gamma$-$Al_2O_3$, ignited at 520°C, shows almost no change in activity after irradiation, whereas the catalytic activity of silica gel containing aluminium impurity and heated at the same temperature, increases after irradiation by a factor of 100–2000, as already noted. Kohn and Taylor[17] conclude that the aluminium must be introduced into the silica gel structure. At the same time it is undoubtedly true that heating (degassing) the silica gel increases its activity, the values of the catalytic activity after high-temperature treatment and irradiation being of the same order of magnitude. On this basis, Taylor[18] suggested that the observed changes in catalytic activity are more probably associated with the sorbed molecules (that is, with the removal of water or with the interaction of radiation with the complex catalyst — "poison"), than with the actual solid.

It is generally assumed[22] that the thermal dehydration of silica gel leads to the formation of so-called "siloxane bridges"  on its surface.

It may be suggested that the catalytically active centres of silica gel with respect to the reaction $H_2 + D_2 \rightleftharpoons 2HD$ are alumosiloxane "bridges"  , formed during the thermal or radiation dehydration of the contact. Hydrogen is probably activated on these strained energy-rich structures.

The ability of these "bridges" to activate hydrogen should naturally decrease with decrease in the temperature of catalysis. At the temperature of liquid nitrogen, these "bridges" are apparently almost inert with respect to this reaction. At the same time, the $\gamma$-irradiation of previously calcined silica gel at the temperature of liquid nitrogen will probably activate these "bridges", making them able to activate hydrogen even at -196°C. At low catalysis temperatures therefore, we should expect that previously calcined silica gel specimens will have a much lower catalytic activity than contacts which have been calcined and then irradiated. The difference in the catalytic activity of silica gel after thermal treatment, and also after thermal treatment followed by irradiation (at the

temperature of liquid nitrogen) should increase with decrease in the temperature of catalysis. This is probably the reason for the observed marked difference in the catalytic activity of silica gel at -196°C after thermal treatment on the one hand and after irradiation at the temperature of liquid nitrogen on the other hand. In fact, for example, the rate constant for deuterium exchange on silica gel containing 0.01% aluminium, after irradiation for 16 h at -196°C, is greater than $3 \times 10^{-4}$ $min^{-1}$ $m^{-2}$ (at -196°C), whereas the rate constant for the same silica gel specimen after heating at 900°C amounts to less than $3 \times 10^{-7}$ $min^{-1}$ $m^{-2}$.



The suggestion regarding the possible part played by alumosiloxane "bridges" as active centres for the reaction $H_2 + D_2 \rightleftharpoons 2HD$ on the surface of a silica gel catalyst cannot be taken as proved. It is definitely established, however, that the higher the calcining temperature, that is, the more complete the dehydration of the silica gel, the higher the catalytic activity with respect to the reaction $H_2 + D_2 \rightleftharpoons 2HD$. After thermal treatment the silica gel does not show EPR signals, so that the catalysis here is not associated with paramagnetic centres.

Analogous relationships are observed for the catalysis of the reaction $H_2 + D_2 \rightleftharpoons 2HD$ on alumina. Here also it has been established that the higher the temperature of preliminary heating (activation) of the catalyst in a vacuum, the less marked the effect of subsequent irradiation[18,23-25] (the irradiation was carried out in a vacuum for 3 min at -78°C from a $^{60}Co$ source at a rate equal to $2 \times 10^{17}$ eV × × $g^{-1}$ $min^{-1}$; the catalytic activity was also measured at -78°C). For a catalyst previously heated at 650°C, however, the activity decreased by almost one-half after irradiation. The lower the temperature of preliminary heating of the catalyst, the more rapid the decrease in the catalytic activity induced by the irradiation: the time taken amounted to 2-4 d (at room temperature) for a catalyst heated at 400°C, and to several hours, even at -78°C[23] ("annealing") for a catalyst heated at 200°. At the same time, alumina gives an intense EPR signal after irradiation (both after irradiation at the temperature of liquid nitrogen in a vacuum[26] and after irradiation by $^{60}Co$ $\gamma$-rays with an energy of 1.25 MeV at room temperature[25]).

Kazanskii[26] observed a correlation between the decrease in the intensity of one of the components of the complex EPR signal observed at -196°C and the decrease after annealing in the induced catalytic activity of catalysts previously heated at 200-500°C. On this basis it was suggested that "the additional activity of the irradiated alumina gel and the labile EPR signal are produced by the same centre".[1] It is quite probable that the irradiation of $\gamma$-$Al_2O_3$ previously heated at 650°C also leads to the appearance of EPR signals. At the same time, the catalytic activity of $\gamma$-$Al_2O_3$ decreases after this thermal treatment, as already noted. There are thus grounds for assuming that the above suggestion is erroneous.

Taylor[18] considers that the increase in catalytic activity after irradiation is associated with the removal of sorbed molecules of "poisons" (for example, water) from the surface, not only for silica gel but also for all non-metallic catalysts. This applies particularly to $\gamma$-$Al_2O_3$. Kolbanovskii and coworkers[25] also point out that the activation of $\gamma$-$Al_2O_3$ is most probably due to the removal of sufficient quantities of water from the catalyst.

It may be assumed that dehydration of the alumina gel surface leads to the formation of aloxane "bridges"

(-Al<O>Al-), which can probably act as active centres for the reaction $H_2 + D_2 \rightleftharpoons 2HD$. This assumption makes it possible to explain the regularities observed. In fact, if the preliminary heating of $\gamma$-$Al_2O_3$ is carried out at an insufficiently high temperature, this leads to the formation, on the surface of the catalyst, of a certain quantity of aloxane "bridges" and thus to the production of a definite stable catalytic activity. If this catalyst is then irradiated at low temperature (-78° or -196°C), new aloxane "bridges" are formed, accompanied by the liberation of water. In the process, the catalytic activity evidently increases. It must be assumed, however, that under these conditions the water remains in the catalyst. The aloxane "bridges" are probably less stable than alumosiloxane bridges. (For an approximate estimate of the bond strength, we may note that the energy of rupture of the Al-O- bond at 298°C is 116 kcal $mole^{-1}$, whereas that of the Si-O- bond is 193 kcal $mole^{-1}$;[27] the rate of rehydration of calcined alumina gel is greater than that of calcined alumina-silica and, more particularly, silica gel[28]). It may therefore be assumed that the aloxane "bridges" will react more readily than alumosiloxane bridges with the water remaining in the catalyst, particularly with increase in temperature (the so-called "low-temperature annealing"). If, however, the heating is continued until the water is almost completely removed and formation of the aloxane "bridges" on the surface takes place to the maximum extent, subsequent irradiation can only break down these bridges and thus decrease the catalytic activity. This interpretation explains why the effect of irradiation is greater, the lower the temperature of preliminary heating of the catalyst. On the other hand, it also explains why the irradiation of alumina gel specimens heated at 650°C leads to a decrease in catalytic activity. The phenomenon of the "annealing" of the induced catalytic activity is also explained.

It follows that the increase sometimes observed in the catalytic activity with respect to deuterium exchange in molecular hydrogen on silica gel and alumina gel after irradiation is not due to defects giving an EPR signal. The fact, observed in a number of instances, that the intensity of the signal and the catalytic activity change in the same sense, does not reflect their correlation as cause and effect but merely indicates that both these parameters are determined by the same factor (in this case radiation dehydration). It is not excluded, however, that some paramagnetic centres produced during irradiation may catalyse the isotopic exchange.

A parallelism between the intensity of the signal and the catalytic activity with respect to the reaction $H_2 + D_2 \rightleftharpoons 2HD$ is not observed on sugar carbons[29]. The maximal activity is shown by carbon heated at 905°C, for which the intensity of the EPR signal is a minimum. The maximal intensity (and minimal width) is shown by the EPR signal for carbon heated at 607°C. In Turkevich and Laroche's opinion, the high activity of carbon heated above 607°C is because treatment of the carbon in this way produces antiferromagnetic regions on which hydrogen is readily chemisorbed. Activation of hydrogen in the catalysis of the reaction $H_2 + D_2 \rightleftharpoons 2HD$ also apparently takes place on these regions.

The intensity of the EPR signal induced by irradiation is found to change in the same sense as the activity with respect to the reaction $H_2 + D_2 \rightleftharpoons 2HD$ for two catalysts: ZnO and $TiO_2$ (anatase). Thus Kohn and Taylor[30] showed that after irradiation with $^{60}Co$ $\gamma$-rays ($10^{18}$-$10^{29}$ eV $g^{-1}$,

at -78°C) the activity of pure zinc oxide for this reaction increases by a factor of 3–10, the time required for the induced activity to decrease by half being greater than one month. Terenin and coworkers[31] detected the gradual appearance of two EPR signals after the irradiation of zinc oxide with ultraviolet light (and even with visible light) at 77°K, in air: one signal had $g$-factor 1.964 and line width $\Delta H$ = 4.5 G, and the second had $g$-factor 2.018 and $\Delta H$ = = 3.0 G. Analogous signals gradually appeared after irradiation in a vacuum at the same temperature.

Schneider[32] also detected an EPR signal with a $g$-factor 1.657 and $\Delta H$ = 4.6 G after the irradiation of zinc oxide with ultraviolet light in a vacuum at room temperature.

Terenin[31] suggests that the singlet with $g$-factor 1.914 is produced by centres freed from oxygen during photodesorption — unpaired electrons in donor levels — and that the singlet with $g$-factor 2.018 is due to chemisorbed oxygen atoms. The intensity of these signals decreases rapidly when irradiation is stopped.

It can be seen that soft irradiation which does not lead to the displacement of atoms in the lattice, on the one hand increases the catalytic activity of ZnO in the reaction $H_2 + D_2 \rightleftharpoons 2HD$, and on the other induces EPR signals in the catalyst.

Mishchenko and coworkers[33] established that changes in the same sense are shown by the intensity of the EPR signal induced in titanium dioxide (anatase) by $\gamma$-irradiation with $^{60}Co$ (at -196°C in a vacuum, integral dose $1.7 \times 10^7$ r) and its catalytic activity in deuterium exchange in molecular hydrogen at -196°C. An interesting feature is that Kohn and Taylor[30] detected an increase in the catalytic activity of $TiO_2$ (rutile) with respect to this reaction, only after treatment by irradiation in a reactor. Here, however, the catalysis was carried out at -78°C, that is, a significantly higher temperature.

The above examination suggests that in pure ZnO and $TiO_2$ (anatase) the centres responsible for the EPR signals are simultaneously the centres for the activation of hydrogen in the reaction $H_2 + D_2 \rightleftharpoons 2HD$.

## 2. Hydrogenation–Dehydrogenation Reactions

A number of recent papers have compared the paramagnetic properties, influence of irradiation, and catalytic activity for platinum and palladium catalysts deposited on various carriers, and also for other catalysts, with respect to hydrogenation–dehydrogenation reactions.

(a) Hydrogenation reactions. Nicolau and coworkers[34] studied the hydrogenation of $p$-nitroanisole and crotonic acid on a catalyst consisting of 5% Pt on diamagnetic carbon, and showed that this catalyst gives a narrow EPR signal (singlet with $\Delta H$ = 2–5.4 G). Nicolau and coworkers[35] had previously established that this signal is due to the introduction of the electrons of the platinum into a so-called "pseudo-sandwich" complex with carbon. It was shown that not all of the electrons of the platinum enter complexes of this type, since the observed intensity of the signal is smaller than the calculated value by approximately four orders of magnitude.

Specimens of the catalyst were heated in air in the range 50–500°C. It was found that the higher the temperature of preliminary annealing, the lower the intensity of the EPR signal and the catalytic activity. After heating at 500°C, both quantities decrease to zero. Distinct changes in the same sense are thus shown by the catalytic activity with respect to the hydrogenation of these compounds and the concentration of unpaired electrons bound in the "pseudo-sandwich" complexes. In the hydrogenation of nitrobenzene and $p$-nitrotoluene on catalysts consisting of Ni on zeolite, 1% Pt on active carbon, and 5% Pd on carbon black, Graham[36] observed an increase in the activity of the catalysts after irradiation by X-rays, $\beta$-rays, deuterons, or neutrons. He found that the lower the melting point of the metal catalyst, the more ready its activation during irradiation and the more rapid the decrease in this induced catalytic activity. In Graham's opinion, the generation of active centres involves the creation of defects on the surface, and the decrease in catalytic activity is due to their elimination by surface diffusion and annealing. It is quite probable that under appropriate conditions these defects may be revealed in the EPR spectrum, although Graham unfortunately did not carry out these measurements.

At the same time, Minachev[37] did not observe an increase in the catalytic activity of a catalyst consisting of 0.5% Pt on alumina–silica with respect to the hydrogenation of cyclohexane, after irradiation of the contact with $^{60}Co$ $\gamma$-rays (energy of $\gamma$-quanta 0.6 MeV).

A parallelism between the appearance of a narrow EPR signal and catalytic activity with respect to hydrogenation is also observed for titanium dioxide.

According to the data of Gray and coworkers[38], $TiO_2$ with maximum purity does not catalyse the hydrogenation of benzene, and Chester[39] reports that thoroughly oxidised titanium dioxide does not give an EPR signal. $TiO_2$ which has been partly reduced by hydrogen is a satisfactory catalyst for the Fischer–Tropsch synthesis[38]. At 4.2–2.16°K, this catalyst gives an EPR spectrum consisting of 2–4 lines ($\Delta H$ = 18–30 G).[39] With increase in temperature the signal is converted into an asymmetric singlet. (It should be noted that Nicolau also detected a narrow singlet in $TiO_2$ at room temperature[40].) The nature of this signal is not clear. In Chester's opinion[39] the signal may be due to $Ti^{3+}$ ions in the interstices or at lattice sites in the Ti lattice, perturbed by adjacent oxygen vacancies. It may also be due to electrons (trapped spontaneously) in the interstices. It is not excluded that the signal is given by certain unidentified centres produced as a result of the introduction of hydrogen (but not H and OH). In any case, the signal from a catalyst with oxygen content reduced as a result of heating in a vacuum is quite different.

It was pointed out above that the catalytic activity of pure zinc oxide with respect to the reaction $H_2 + D_2 \rightleftharpoons 2HD$ increases after irradiation. At the same time, previously irradiated zinc oxide ($^{60}Co$ source, $6–10 \times 10^3$ r $min^{-1}$ in a vacuum at 15° ± 5°) shows a lower catalytic activity in the hydrogenation of ethylene at 0° than a non-irradiated specimen[41]. The probable reason for this is that the activation of the ethylene necessary for its hydrogenation does not take place on the hydrogen-activation centres induced by irradiation and revealed in the EPR spectrum.

The irradiation of zinc oxide during catalysis ($^{60}Co$ source, $2.5 \times 10^{19}$ eV $g^{-1}$ $h^{-1}$) increases its catalytic activity with respect to the synthesis of methanol from hydrogen and carbon monoxide[42]: the effect was maximal at the lowest catalysis temperature (201°C) — catalytic activity increased by a factor of 4–5.

Kohn and Taylor[17] tried to hydrogenate ethylene on irradiated industrial silica gel. Moderate activity was

detected. For example, after irradiation (1 g silica gel, dose rate $2 \times 10^{17}$ eV $g^{-1}$ $min^{-1}$) all the ethylene was hydrogenated in 4 d at room temperature (the catalytic activity was measured by a static method in a system with a volume of 30 $cm^3$, and the molar ratio of hydrogen and ethylene in the mixture was 2 : 1). There is no sense in relating this induced catalytic activity to the EPR signal induced by irradiation and observed at room temperature. It is known[43] that ethyl radicals adsorbed on the surface of irradiated silica gel are destroyed even at -70°C.

The intensity of the narrow EPR signal and the catalytic activity do not always change in the same sense. An important part is played by the chemical character of the paramagnetic centre. The intensity of the EPR signals and the catalytic activity will change in the same sense only when the paramagnetic centres are chemically capable of catalysing the hydrogenation (or dehydrogenation) of a given substance. In addition to the examples examined above where a change in the same sense does not take place, no parallelism is observed between the intensity of the narrow and broad signals for alumina–chromium oxide catalysts and their activity with respect to the hydrogenation of ethylene. The maximal activity with respect to this reaction was shown by chromium oxide which had been heated to 700°C and exhibited antiferromagnetic properties[44]. The intensity of the EPR signals of this catalyst was low, however, and its width was approximately 500 G.

(b) Dehydrogenation reactions. In the dehydrogenation of cyclohexane on silica gel, alumina, alumina–silica catalyst, $ZrO_2$, MgO, ZnO, or NiO irradiated with electrons (energy 0.8 MeV) or with $^{60}Co$ $\gamma$-radiation (dose rate 400 r $s^{-1}$), a correlation was observed between the appearance of the EPR signal and the induced catalytic activity[45]. The irradiation was carried out in ampoules containing the catalyst and cyclohexane (the ampoules were first evacuated and heated at 400°C). After this treatment, a signal due to the $C_6H_7^{\cdot}$ radical was detected in $SiO_2$, $Al_2O_3$, and $Al_2O_3$–$SiO_2$, unidentified weak signals were detected in $ZrO_2$ and MgO, and no EPR signal was detected in ZnO or NiO. From this it was concluded that $SiO_2$, $Al_2O_3$, and $Al_2O_3$–$SiO_2$ exhibit maximal catalytic activity and $ZrO_2$ lower catalytic activity, and that in ZnO and NiO there is almost no induced catalytic activity. At the same time, as the authors of the paper point out, NiO and ZnO have a high "thermal" catalytic activity (at 300°C) with respect to the dehydrogenation of cyclohexane, whereas the other oxides examined above do not catalyse this reaction at all at the same temperature.

Nicolau[46] showed that platinum, deposited on a carrier containing diamagnetic carbon (the carrier was first immersed in sugar solution and then heated for 1 h at 800°C), brings about intensive catalysis of the dehydrocyclisation of 1,1,3-trimethylcyclopentane, whereas the catalytic activity of $Pt/Al_2O_3$ and $Pt/SiO_2$ is smaller by a factor of 3.5–9. The catalytic activity of the $Pt/C + Al_2O_3$ catalyst is higher than that of $Pt/C + SiO_2$. It is significant that only catalysts containing carbon give EPR signals (concentration of paramagnetic centres $9 \times 10^{18}$ spin $g^{-1}$, $\Delta H$ = 10 G and $2.3 \times 10^{16}$ spin $g^{-1}$, $\Delta H$ = 12 G respectively). It can be seen that here also the intensity of the narrow EPR signal and the catalytic activity with respect to the dehydrogenation change in the same sense.

Summarising the results for hydrogenation–dehydrogenation reactions, it may be noted that in most cases a parallelism is observed between the intensity of the narrow EPR signals and the catalytic activity. We would emphasise again, however, that a significant part is played by the chemical character of the centre responsible for the appearance of the signal. Thus the centres responsible for the catalysis of the dehydrogenation of cyclohexane on $SiO_2$, $Al_2O_3$, and $Al_2O_3$–$SiO_2$ are evidently not identical to the centres which are responsible for the catalysis of $H_2 + D_2 \rightleftharpoons 2HD$. In actual fact, it was shown that the reaction $H_2 + D_2 \rightleftharpoons 2HD$ takes place on previously calcined silica gel and alumina gel which give no EPR signal, whereas the dehydrogenation of cyclohexane does not take place on these catalysts even at high temperature. Hydrogen and cyclohexane are apparently activated on different centres in these catalysts.

As already noted, irradiated zinc oxide is inactive with respect to the dehydrogenation of cyclohexane but effectively catalyses deuterium-exchange in molecular hydrogen (see above). In this case also the hydrogen-activation centres produced during irradiation are probably not capable of activating cyclohexane (the statement that here there is a rapid decrease in the intensity of the EPR signals of zinc oxide[45] is apparently without foundation, since the entire catalyst–hydrocarbon system is subjected to irradiation).

### 3. The Radical Polymerisation of Ethylene

The polymerisation of ethylene is catalysed by a number of catalysts containing transition metal ions[47]. Some of these catalysts have recently been studied by the EPR method. Chromium oxide catalysts have been studied in most detail in this connection. These catalysts are usually prepared by impregnating carriers (alumina or alumina–silica) with chromic acid solution with subsequent activation.

Sometimes the catalyst was activated by heating for 4 h at 350°C, followed by reduction with hydrogen at the same temperature[48,49]; sometimes the catalyst was activated by heating in air at 500°C for 4 h [50] or at 350°C [51], or in a vacuum at 350°C for 4 h [51], or at 400°C for 3 h [52]; sometimes the catalyst was treated with organic solvents[53,54]. O'Reilly and MacIver[55] prepared an alumina–chromium oxide catalyst by impregnating $\gamma$-$Al_2O_3$ with chromium nitrate, followed by roasting and reduction at 500°C. Some reduced specimens were activated by heating at 500°C. An analogous catalyst can also be obtained by coprecipitating chromium and aluminium nitrates, followed by roasting at 500–1400°C. In this work[56] some specimens were reduced by hydrogen at 500°C.

The concentration of chromium in the catalysts was varied from 0.5 wt.% to ~67 wt.%, calculated as $Cr_2O_3$. Usually, however, the total chromium concentration amounted to 2.5–3 wt.%, and then, after activation by heating in air or in a vacuum, the catalysts prepared by the impregnation method gave an EPR spectrum at room temperature containing signals of two types: a broad line ($\Delta H$ = 500–1300 G, $g$-factor 1.97–1.98) and a narrow line ($\Delta H$ = 16.7–50 G, $g$-factor 1.97–1.99)[2,48,49,51–53,55]. In a reduced alumina–chromium oxide catalyst prepared by the impregnation method (in this case the chromium concentration calculated as $Cr_2O_3$ was varied from 0.078 wt.% to 10.1 wt.%), O'Reilly and MacIver[55] detected an additional asymmetric signal, whose parameters were not given (it is merely stated that at a frequency of 9.5 Gc $s^{-1}$ this signal has a maximum close to 1500 G). The intensity of

this signal is a maximum at low chromium concentrations and changes little on oxidation. Moreover, the quantity of chromium responsible for this signal is independent of temperature in the range from -195° to +162°C.

The EPR spectrum of a coprecipitated alumina–chromium oxide catalyst[56] at $Cr_2O_3$ concentrations of 8.05–66.4 wt.%, in addition to a broad absorption line, shows another signal with parameters: $\Delta H$ = 200–750 G, $g$-factor 1.975 ± 0.01. After heating at 500–900°C, specimens with a low $Cr_2O_3$ concentration (8.05 wt.%) show only the broadest line, whereas specimens with a high $Cr_2O_3$ concentration (66.4 wt.%) show only the narrower absorption line ($\Delta H$ = 200–750 G). After roasting at 1400°C, however, at all $Cr_2O_3$ concentrations, only this last signal is observed.

Let us now consider how different authors explain the origin of the observed EPR signals. It is suggested[1,48,49,51,53] that the broad signal of the impregnated contacts is due to $Cr_2O_3$ microcrystallites. O'Reilly and MacIver[55] consider that the state of $\alpha$-$Cr_2O_3$ responsible for the broad signal corresponds more closely to $Cr_2O_3$ gel, which is paramagnetic at room temperature ($\alpha$-$Cr_2O_3$ is antiferromagnetic and has a Curie point of +30°C.[57]) In the coprecipitated catalyst, the broad signal is again, in the opinion of MacIver and coworkers[56], due to $Cr_2O_3$ microcrystallites, amorphous towards X-rays. The narrower signal ($\Delta H$ = = 200–750 G), observed only for the coprecipitated contact, is given by a solid solution of $Cr_2O_3$ in $Al_2O_3$.[56]

Finally, in the opinion of MacIver and coworkers[55,56], the asymmetric signal on both types of catalyst is due to $Cr^{3+}$ ions which are interacting weakly with one another and are situated in the lattice sites of the carrier, both on the $Al_2O_3$ surface and close to the surface.

As will be shown later, however, the narrow EPR signal is of the greatest interest from the viewpoint of the catalytic properties of deposited chromium oxide contacts, so that we shall examine its nature in more detail.

The narrow line is symmetrical on alumina gel and asymmetrical on $Al_2O_3$–$SiO_2$.[51] O'Reilly[2], and also Kossee and van Reijen[53], consider that the narrow line is due to $Cr^{5+}$ ions. O'Reilly considers that this line cannot be due to diluted $Cr^{3+}$ or $Cr^{4+}$ ions, since then the spectra should have shown a fine structure, but this was not observed. Kossee and van Reijen[53], who observed only a narrow signal with careful reduction (by boiling in organic solvents) of $CrO_3$ deposited on alumina, established that these specimens have a magnetic moment which is very close to the value corresponding to the spin of one unpaired electron. These authors therefore conclude that the narrow signal is due to quinquevalent chromium ions. Kazanskii and coworkers[51], in their latest work, also concluded that this signal is due to $Cr^{5+}$ ions. They consider, with some justification, that O'Reilly's proof is inadequate, and give additional data in support of this conclusion. A constant value for the $g$-factor at different frequencies (3.2 cm and 21.8 cm) can be observed only if the narrow signal is due to $Cr^{5+}$ ions. If the signal were due to $Cr^{4+}$ or $Cr^{3+}$ ions, the value of the $g$-factor should have increased on going from high to low magnetic fields. The detection of HFS [hyperfine structure (Ed. of Translation)] for the narrow signal on an alumina–silica catalyst[58] is also a weighty argument in support of the suggestion that the narrow line is due to $Cr^{5+}$ ions. In actual fact, the HFS indicates the absence of strong exchange interaction, so that the fine structure, if it had been observed (in this case, if the signal had been due to $Cr^{3+}$ or $Cr^{4+}$ ions), should have been clearly defined.

Further support for this conclusion regarding the origin of the narrow line in the EPR spectrum of the chromium oxide catalyst for the polymerisation of ethylene is provided by the fact, established by a number of authors, that the narrow signal is not shown by the catalysts after intensive reduction by hydrogen[50,51,55] and that this signal appears after contacts which have been previously completely reduced are oxidised[51,55]. Moreover, the narrow signal is never observed from activated $CrO_3$ in the absence of carrier, so that stabilisation of the $Cr^{5+}$ ions takes place on the surface of the carrier[51,52].

Evidence that the $Cr^{5+}$ ions are situated on the surface of the carrier is provided by the oxygen effect (for the narrow EPR signal) detected by Kazanskii and coworkers[51]. Moreover, Nicolau and Thom[59] established that at constant surface area of the carrier ($\gamma$-$Al_2O_3$) the intensity of the narrow signal remains constant with change in the chromium concentration from 1 wt.% to 20 wt.%. In their opinion, this indicates that the paramagnetic centres responsible for the signal are situated chiefly on the surface of the catalyst. There is no agreement regarding the state in which the $Cr^{5+}$ ions are present on the surface of the chromium oxide catalyst. O'Reilly[60], on the basis of the fact that the width of the narrow line remains constant with change in the concentration of chromium in the alumina–chromium oxide catalyst, suggests that the $Cr^{5+}$ ions form a phase. Kazanskii and coworkers[51] agree with this conclusion and support it with the fact that the value of the Weiss constant which they calculated for the alumina–chromium oxide catalyst is +25, that is, it is greater than zero. This means that exchange interaction takes place between the $Cr^{5+}$ ions, which therefore form a phase[51].

MacIver[55] states that $Cr^{5+}$ ions are $Cr^{6+}$ ions on which an electron is "trapped". For coprecipitated alumina–chromium oxide catalysts[56] he gives some evidence that the $Cr^{6+}$ ions are present in small $Cr_2O_3$ crystals on the surface of the carrier. The maximum intensity of the narrow signal is observed at a chromium concentration of 4.55 wt.%, which corresponds to the maximal $Cr_2O_3$ surface area. The intensity of the signal decreases at a chromium concentration greater than 7.6 wt.% $Cr_2O_3$, that is, in the range where an appreciable increase in the dimensions of the $Cr_2O_3$ granules takes place. MacIver and coworkers also established that the asymmetric signal attributed to isolated $Cr^{3+}$ ions remains unchanged under conditions in which reduction of $Cr^{5+}$ ions takes place. In their opinion, both facts indicate that the $Cr^{5+}$ ions are situated on the catalyst surface not in isolation but in small $Cr_2O_3$ crystallites. We have already noted, however, that the narrow signal has never been observed from activated $CrO_3$ in the absence of a carrier. In our opinion, this fact can be reconciled with MacIver's suggestion that the $Cr^{5+}$ ions are situated on the $Cr_2O_3$ surface only if it is assumed that the $Cr^{5+}$ ions are distributed on the interface between the $Cr_2O_3$ microcrystallites and the carrier.

Comparison of the results of statistical calculations with experimental data, in particular with data on the EPR of alumina–chromium oxide catalysts, established[56] good agreement between experiment and calculation for a model with random distribution of isolated $Cr^{5+}$ ions on the surface.

Thus MacIver's results, contrary to O'Reilly and Kazanskii's suggestion, indicate that $Cr^{5+}$ ions do not form a phase on the surface of the alumina.

As already noted[58], $Cr^{5+}$ ions on the surface of an alumina–silica carrier do not give an HFS and thus do not form a phase; the signal is anisotropic. To explain these facts it was postulated[58] that $Cr^{5+}$ ions are introduced into the alumina–silica support, in other words, that replacement of some of the $Si^{4+}$ ions by $Cr^{5+}$ ions takes place in the tetrahedra of the surface layer of the alumina–silica. The quinquevalent chromium ions form a surface compound with the alumina–silica support[54]. The quantity of $Cr^{5+}$ ions formed in an alumina–silica catalyst after its activation is small[52] and amounts to 3–4%; 85–88% of the chromium remains in the form of $Cr^{6+}$ ions.

It can thus be seen that on an alumina–silica carrier the quinquevalent chromium ions are present in the form of a dilute solid solution on the surface, whereas on alumina, in the opinion of some authors, they form a phase, while in the opinion of others a phase is not formed. The evidence in support of the suggestion that a $Cr^{5+}$ phase is not formed on the surface of an alumina–chromium oxide catalyst is more convincing.

The $Cr^{5+}$ ions may, in fact, be distributed on the surface sufficiently closely for the observed exchange interaction to take place between them[51] but at the same time at such a distance from one another that no formation of a phase takes place at this stage. The $Cr^{5+}$ ions may, for example, form a sufficiently "concentrated" two-dimensional surface solution. It is evident, moreover, that even if the appearance of HFS indicates unambigously that the $Cr^{5+}$ ions are present in the form of a dilute solid solution, the absence of HFS cannot be taken as proof that these ions form a phase.

Let us examine the relationship between the EPR signals of deposited chromium oxide catalysts and their catalytic activity with respect to the polymerisation of ethylene[53].

Kossee and van Reijen[53] were the first to suggest that the $Cr^{4+}$ or $Cr^{5+}$ ions, which give a narrow EPR signal, are the active centres of the catalyst. Recent experimental results indicate a correlation between the intensity of the narrow EPR signal of original chromium oxide–alumina–silica catalysts and their catalytic activity with respect to the polymerisation of ethylene. Kazanskii and coworkers[52] showed that the maximal catalytic activity is given by catalysts containing 2.5–4 wt.% of chromium. These are the catalysts which give the most intense narrow EPR signal (we are speaking of the original catalysts). Antuf'ev and coworkers[61] also established that the catalytic activity and intensity of the narrow EPR signal change in the same sense. In the opinion of these authors, $Cr^{5+}$ ions are the active component of chromium catalysts for the polymerisation of ethylene. This conclusion is confirmed by data on the chemisorption of the reaction components on the catalyst. Recent work by Kazanskii and coworkers[58] has shown that the $Cr^{5+}$ ions are the centres for the chemisorption of ethylene on the one hand and of water vapour — a poison which inhibits polymerisation — on the other.

It is significant that in the works cited the catalytic activity was compared with the intensity of the narrow signal of the original activated catalysts. At the same time, it can be seen from published data[52] that the intensity of the narrow signal has decreased by approximately one-half 3 h after the start of the reaction, reaching a steady value for the given experimental conditions.

It has been established that sexivalent chromium ions do not take part in the catalysis of the polymerisation of ethylene: disappearance of $Cr^{6+}$ ions from the catalyst produces almost no change in its activity[52,61]. Similarly, intermediate oxides are not the active component: their presence in the catalyst has no influence on the catalytic activity of the catalyst[52]. A catalyst without carrier, containing after activation only $Cr_2O_3$, is inactive with respect to the polymerisation of ethylene[52,61], so that chromium sesquioxide is also inert with respect to this reaction. In accordance with this, catalysts in which the narrow EPR signal disappears after reduction by hydrogen are catalytically inert[50].

The EPR method has recently been used to study deposited molybdenum catalysts for the polymerisation of ethylene[62]. It was suggested that in this case the catalytically active component consists of quinquivalent molybdenum ions formed during the reduction of the catalysts. It should be noted that here also, as in the study of the chromium catalysts, the EPR measurements were made before catalysis. During catalysis, further reduction of the catalysts takes place, but according to the published data this additional reduction is not extensive.

The formation of $Mo^{5+}$ ions is related to the reaction of the molybdenum oxides with the carrier, in the course of which these ions are stabilised. It is pointed out that the nature of the carrier has a significant influence on the shape of the absorption line: thus on alumina gel the signal (molybdenum concentration 8 wt.%) is symmetrical ($g$-factor = 1.933, $\Delta H$ = 80 G) but on an alumina–silica carrier the signal is asymmetric ($\Delta H$ = 60 G, $g_{\parallel}$ = 1.879, $g_{\perp}$ = 1.933). Asymmetric signals are also formed in catalysts based on $ZrO_2$ and $ZrO_2.SiO_2$.

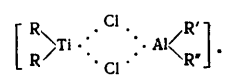
In the case of alumina–molybdenum oxide and molybdenum oxide–alumina–silica catalysts, the catalytic activity of the catalysts and the intensity of the original EPR signal change in the same sense. Both quantities reach a maximum at a concentration of 20% $MoO_3$ in the catalysts.

The correlation between the intensity of the narrow EPR signal and catalytic activity was observed not only in the case of chromium and molybdenum catalysts but also in the polymerisation of ethylene on a Ziegler catalyst [$TiCl_4$ + $Al(C_2H_5)_2Cl$].[63]

The course of the reaction between $TiCl_4$ and $Al(C_2H_5)_2Cl$ was followed continuously: the reaction mixture — $TiCl_4$ + + $Al(C_2H_5)_2Cl$ in heptane at room temperature — was circulated through the resonator. After some time, a narrow EPR signal (singlet) was detected. It was established that in this system, reduction of $TiCl_4$ to $TiCl_3$ takes place and part of the $TiCl_3$ is precipitated. This precipitate does not give an EPR signal at room temperature. The authors tried to attribute this to the possible dimerisation of $TiCl_3$ in the solid phase but it is not excluded that the absence of resonance absorption by the precipitate at room temperature may also be due to the too-rapid spin–lattice relaxation of the $Ti^{3+}$ ions. In this connection a recent paper devoted to the study of an analogous system is of interest[64]; it was established that the precipitate formed 0.5 h after the components $TiCl_4$ and $Al(C_2H_5)_2Cl$ were mixed contains no aluminium, has the composition $Ti(C_2H_5)Cl_3$, and gives no EPR signal at room temperature. At the same time, the precipitate removed 4 h after the components were mixed has the overall formula $Ti_3Cl_6Al(C_2H_5)$, contains $Ti^{3+}$, and gives an EPR signal at room temperature.

It is pointed out that "the curves giving the time dependence of the rate of polymerisation of ethylene and the time dependence of the concentration of unpaired electrons have identical shapes". The addition of 10% of water or oxygen (relative to the aluminium) increases the intensity of the signal by a factor of approximately 2. According to the data given in a patent[65], to which the authors refer, the same quantities of water and oxygen bring about maximal increase in the yield of polymer.

The nature of the signal was examined in subsequent work. A study of the $TiCl_4 + Al(C_2H_5)Cl_2$ system in heptane[66] ($[TiCl_4] = 0.108$ M, $[Al(C_2H_5)Cl_2] = 0.055$ M) established that here also an EPR signal (singlet) appears some time after the components are mixed (at room temperature). The intensity of this signal corresponds to approximately 2% of the concentration of alkylaluminium chloride. This signal consists of two superimposed singlets: a symmetrical singlet with $\Delta H = 22$ G and $g$-factor 1.925, and a weaker asymmetric signal with $\Delta H$ approximately 10 G and $g$-factor 1.933. After the components are mixed, the intensity of the signal increases, at first very rapidly, and then, after the precipitation of $TiCl_3$, which in this case gives an EPR signal, very slightly. After examining possible mechanisms, the authors concluded that the observed EPR signals are due to $Ti^{3+}$ ions which are formed as a result of complex formation by $TiCl_4$ with the alkylaluminium halides and reduction of the $TiCl_4$ in this complex to $Ti^{3+}$. The greater the strength of the alkylaluminium halide as a Lewis acid — the acid strength increases in the order $Al(C_2H_5)_2Cl$, $Al(C_2H_5)Cl_2$, $AlCl_3$ — the greater the concentration of this soluble complex and the greater the intensity of the EPR signal.



The symmetrical signal is assigned to the complex $(TiCl_3)_2.[Al(C_2H_5)Cl_2]$ and the asymmetric signal to the complex $TiCl_3.[Al(C_2H_5)Cl_2]$, obtained by the decomposition of the first complex, particularly when the ratio Al/Ti is less than unity. In a study of the closely related systems[67]

$(C_5H_5)_2TiCl_2 + Al(CH_3)_3$ [I]; $(C_5H_5)_2TiCl_2 + Al(CH_3)_2Cl$ [II];
$(C_5H_5)_2Ti(CH_3)Cl + Al(CH_3)Cl_2$ [III];
$(C_5H_5)_2TiCl_2 + Al(CH_3)Cl_2$ [IV];
$(C_5H_5)_2Ti(CH_3)Cl + AlCl_3$ [V],

however, it was shown that the analytically determined $Ti^{3+}$ ion concentration is equal to the concentration of unpaired electrons given by measurement of the signal intensity; experimental proof is thus obtained that in these systems the EPR signal is due to $Ti^{3+}$ ions. At a high concentration of the complex (not less than $1 \times 10^{-1}$ M) the spectrum shows a singlet, but at a low concentration (less than $1 \times 10^{-2}$ M) an HFS is observed (HFS in analogous systems at low concentrations of the complex was previously observed by Shilov and coworkers[68] and Maki and Rendall[69]). The conversion of the HFS into a singlet at increased concentration of the complex is accompanied by an opposite decrease in the width of the line.

An interesting phenomenon is observed in work with dilute solutions of the complex ($\leq 1 \times 10^{-2}$ M). As the Cl atoms on the aluminium are gradually replaced by $CH_3$ groups, the shape of the spectrum changes from one with a distinct HFS through a shape with an indistinct HFS to a broad singlet (the observed HFS, consisting of six components, indicates a high electron density at the aluminium nucleus, for which the spin is equal to 5/2). It may therefore be assumed that the localisation of the unpaired electrons on the aluminium decreases with decrease in the acidity of the complex, that is, the alkyl groups increase the delocalisation of the unpaired electrons in the complex.

From the fact that the $g$-factor is almost constant in the different complexes studied, it is concluded that the electron in the complex is localised to only a slight extent on R, R′, and R″, and that its density is a maximum on Ti, Al, and Cl in

A detailed investigation of the nature of the active component of the Ziegler catalyst is described by Varodi and coworkers[64], who established that the solubility in hydrocarbons shown by the above precipitates separating in the $TiCl_4 + Al(C_2H_5)_2Cl$ system is low but increases by a factor of about 1000 in the presence of $TiCl_4$. Dissolution leads to the formation of a complex of the type $(C_2H_5)TiCl_3 - Al(C_2H_5)Cl$. This complex is found in the filtrate after separation of the precipitate.

A suspension of the precipitate in heptane is catalytically inactive. The system also remains catalytically inert after the addition of $TiCl_4$. The system formed by the precipitate + $Al(C_2H_5)_2Cl$ also has a low activity. The catalytic activity increases sharply by a factor of about 3 only after the precipitate is mixed with a filtrate containing the soluble complex compound. At the same time, the catalytic activity of the filtrate itself is also low.

The catalytic activity is thus shown by the entire precipitate–soluble complex system, the presence of $TiCl_4$ in the system playing a particularly important part and leading to the maximal formation of the soluble complex compound which is the active cocatalyst.

It can be seen that on all three types of ethylene-polymerisation catalyst studied by the EPR method, it has been possible to establish that the catalytically active component of the catalysts contains $M^{n-1}$ ions, where $n$ is the highest valency of the transition metal. This is probably a general feature, although it cannot be explained at present.

## III. REACTIONS INVOLVING ELECTRON TRANSFER

Typical reactions of this group include the decomposition of hydrogen peroxide and dinitrogen oxide, and also oxidation by molecular oxygen. Catalysts for reactions of this type[70] exhibit a high electrical conductivity, which is necessary in order to ensure the possibility of electron transfer, through the catalyst, between the molecules reacting on the catalyst surface (from the molecule being oxidised to oxygen, or from one $H_2O_2$ (or $N_2O$) molecule to another). Paramagnetism (or ferromagnetism) is not, however, a necessary property of catalysts for this group of reactions. In recent years it has indeed been shown that there exists a whole class of catalysts for reactions involving oxidation — semiconductors containing no transition elements — which do not exhibit paramagnetism[71]. There are, moreover, a number of oxidation processes on transition metal oxides (in particular, on vanadium pentoxide), which take place without the reduction of $V_2O_5$, and in which paramagnetic ions (for example, $V^{4+}$ ions) play no significant part[72]. Most oxidations, however, at any rate those involving aromatic substances and alkenes, take place in the steady state on partly reduced oxides, which contain unpaired electrons and are therefore revealed in the EPR spectrum. The study of these spectra may give

some information on the structure and properties of these catalysts. For example, Nicolau and Thom[40] made a comparative study of the EPR spectra of powdered manganese oxides ($MnO_2$ and $Mn_2O_3$) and of the same oxides deposited on $\gamma$-alumina. The conductivity electrons may lead to broadening of the paramagnetic resonance absorption lines for oxide powders which are not in the highest valency state. In actual fact, the width of the absorption spectrum of $MnO_2$ powder amounts to 1600 G (the signal shows HFS containing four components); with $Mn_2O_3$ powder, $\Delta H$ is also equal to 1600 G. Deposition of these oxides on $\gamma$-$Al_2O_3$ leads to a sharp decrease in the width of the EPR signals (for $MnO_2/\gamma$-$Al_2O_3$, $\Delta H$ = 8 G and for $Mn_2O_3/\gamma$-$Al_2O_3$, $\Delta H$ = 5 G), disappearance of the HFS (for $MnO_2$), and a decrease in the intensity of the signals (from $10^{17}$ to $10^{16}$ unpaired electrons per gramme with $MnO_2$, and from $10^{17}$ to $10^{13}$ unpaired electrons per gramme with $Mn_2O_3$). This sharp change in the signal parameters was attributed to the dispersal of the paramagnetic oxides in the form of aggregates (agglomerates) over the $\gamma$-$Al_2O_3$ surface. The decrease in the width of the lines is attributed to the magnetic dilution of $MnO_2$ by the diamagnetic $\gamma$-$Al_2O_3$, and the particularly sharp decrease in the intensity of the signal with $Mn_2O_3$ is attributed primarily to the formation of a covalent bond between the $Al^{3+}$ and $Mn^{3+}$ ions.

A common feature of the signals observed by Nicolau and Thom is their asymmetry. This asymmetry was attributed to the anisotropy of the crystal and also to the influence of active oxygen. Unfortunately, a comparative study of the catalytic properties of different manganese catalysts was not carried out.

### 1. The Decomposition of Hydrogen Peroxide and Dinitrogen Oxide

Many organic polymeric materials have a low electrical conductivity activation energy, that is, they are semiconductors with a narrow forbidden zone. They thus serve as models of a semiconducting oxide. Semiconductors, however, are effective catalysts for the decomposition of hydrogen peroxide. It is thus not surprising that organic semiconductors such as polyacenequinone (PAQ), poly(acrylonitrile) (PAN), copper polyphthalocyanine (CPP), and poly(aminoquinone)s are active catalysts for the decomposition of hydrogen peroxide[73,74]. The decomposition of dinitrogen oxide also takes place on organic semiconductors[74], the maximal activity being shown by PAN, pyrolysed at 350°C in an atmosphere of argon. PAN pyrolysed in air has an extremely low activity with respect to this process. Here, therefore, oxygen has a significant influence on the catalytic properties of this semiconductor. It is probable that as this reaction proceeds, the activity should decrease as a result of the chemisorption of oxygen, which is one of the products of the decomposition of $N_2O$. An interesting feature is that in the decomposition of $H_2O_2$ there is no indication of a difference in the activities of PAN pyrolysed in air or in an atmosphere of argon. $H_2O_2$ is probably sorbed on the surface no less strongly than oxygen, so that the latter cannot displace $H_2O_2$ from the catalyst surface.

The decomposition of $N_2O$ also takes place intensively on poly(isoprenechloranil) (PICA) and poly(benzimidazole) (PBIA). All three polymers PAN, PICA, and PBIA, are semiconductors with a long system of conjugated double bonds and nitrogen atoms with a lone pair of electrons. Phthalocyanines (free phthalocyanine and CPP) and also polyacenequinone have almost no catalytic influence on the decomposition of $N_2O$. This is apparently due to the absence of a long system of conjugated double bonds in the case of phthalocyanines, and in the case of polyacenequinone to the absence of $\dot{N}$ atoms which apparently act as centres for the chemisorption of dinitrogen oxide molecules.

### 2. The Oxidation of Organic Substances

As already noted, the oxidation of hydrocarbons on the oxides of transition metals in their highest valency states is accompanied by partial reduction of the latter. The activity of the catalyst increases in the process and the concentration of paramagnetic centres also increases. Examples of this parallelism are familiar: for example, the maximal catalytic activity with respect to the oxidation of benzene (flow-circulation method) is shown by a vanadium–molybdenum catalyst containing 30% molybdenum, and the same catalyst also shows the maximal intensity and width for the EPR signal (singlet) observed at room temperature ($\Delta H$ = 190 G).[75] At a molybdenum concentration less than 30%, $MoO_3$ forms a solid solution with $V_2O_5$. To preserve electrical neutrality in the system, the $Mo^{6+}$ ions must be converted into $Mo^{5+}$ ions, or some $V^{5+}$ ions must be converted into $V^{4+}$ ions. At an Mo concentration less than 5%, the EPR spectrum of the catalyst shows an anisotropic HFS (two groups of lines with eight components in each, $g_\perp$ = 1.99, $g_\parallel$ = 1.90, $\Delta H_\perp$ = 50 G, $\Delta H_\parallel$ = 145 G), characteristic of the $V^{4+}$ ion.[76] From this it was concluded that the second mechanism is involved, that is, the addition of $Mo^{6+}$ ions to the catalyst leads to the production of $V^{4+}$ ions in an amount which, at an $MoO_3$ concentration $\leq$ 30%, is approximately equal to the quantity of added $Mo^{6+}$ ions. At a higher $MoO_3$ concentration, however, the latter react with $V_2O_5$ to form a chemical compound in which only every fifth vanadium ion is converted into $V^{4+}$. It is considered that the $V^{4+}$ ions act as impurity levels which influence the electronic properties of the semiconductor ($V_2O_5$) and hence its catalytic activity. Ioffe and coworkers[75] consider that the results provide experimental proof of "the general influence of lattice defects on the catalytic properties of semiconducting catalysts".

Ioffe considers that the addition of ions of higher valency, for example, $Mo^{6+}$ ions, to $V_2O_5$ is not necessary for the oxidation of naphthalene or *o*-xylene on $V_2O_5$, because here, as a result of the intensive reduction of the catalyst, there is spontaneous generation of defects (in the form of $V^{4+}$ ions) responsible for the increase in the catalytic activity of the vanadium oxide catalyst[77].

The $V^{4+}$ ions apparently act as centres for the activation of the molecules of the hydrocarbon being oxidised (in particular, benzene[78]). In order to bring about this activation, that is, to displace the electron density from the hydrocarbon to the catalyst, it is necessary to ensure that the Fermi level of the catalyst is sufficiently low-lying[78]. These conditions are satisfied[78] in the oxidation of benzene on a vanadium–molybdenum catalyst, which is a solid solution of $MoO_3$ in $V_2O_5$.

It is probably possible in principle, by introducing sexivalent impurity ions (for example, $Mo^{6+}$), to create such a high concentration of $V^{4+}$ ions in the $V_2O_5$ lattice that the rate of transfer of electrons from the hydrocarbon (benzene or naphthalene) to the catalyst becomes equal to the rate of transfer of electrons from the catalyst to oxygen.

The operation of the catalyst (in the oxidation of the given hydrocarbon) will thus reach a steady state and no change will take place in its chemical and phase composition. The quantity (~30 mole %) of $Mo^{6+}$ ions (and hence the equivalent quantity of $V^{4+}$ ions) which can be introduced into $V_2O_5$ without breaking down its crystal structure is insufficient to bring about this equalisation of the rates of the donor and acceptor stages in the oxidation of aromatic hydrocarbons: this is indicated by the partial reduction of the vanadium–molybdenum catalyst in the oxidation of benzene[79], naphthalene, and xylene[77]. It is for this reason that the catalytic oxidation of benzene, xylene, naphthalene, and, apparently, other aromatic hydrocarbons, takes place in the steady state on lower oxides. The latter are thus the active components of vanadium oxide catalysts for the oxidation of aromatic compounds. This is also indicated by results obtained in a study of the oxidation of naphthalene on "sodium vanadium bronze". This "bronze" has a crystal structure close to that of vanadium pentoxide, exhibits a high electrical conductivity, contains $V^{4+}$ ions[80], and gives an EPR spectrum with a signal analogous to the signal of a partly reduced vanadium oxide catalyst[81] and the optimal vanadium–molybdenum catalyst[75]. Nevertheless, the "sodium vanadium bronze" is quite inactive with respect to the oxidation of naphthalene (under the ordinary conditions of catalysis for this process) until partial reduction takes place with the formation of lower oxide phases on its surface[80]. It was also shown that the active component of the vanadium oxide catalyst is a mixture of the oxides $V_2O_4$ and $V_6O_{13}$, the $V_2O_4$ playing the leading part[82]. Of the two modifications of vanadium(IV) oxide studied — the grey crystalline form and the black form amorphous towards X-rays — the grey has the higher catalytic activity. It is the black modification, however, which exhibits intensive resonance absorption at room temperature (singlet with $\Delta H$ = = 166 G), whereas the grey modification gives no signal under analogous conditions[83]. Finally, Ioffe and coworkers[75] themselves emphasise that the line width of the EPR signal of used vanadium oxide catalysts is almost independent of the chemical composition of the catalyst. This is attributed to the fact that during catalysis, diffusion of $V^{4+}$ ions to the surface of the catalyst takes place, with the formation of lower oxide phases on the surface.

All these facts indicate that the activity of the vanadium oxide catalyst with respect to the oxidation of naphthalene is due not simply to the presence of defects in its structure, even if these defects are $V^{4+}$ ions, but to the formation, on the catalyst surface, of definite chemical compounds $V_2O_4$ and $V_6O_{13}$ for which the "defect character" of the crystal lattice is not significant for catalysis.

It appears from published data that the nature of the EPR signals (singlets) observed at room temperature for vanadium pentoxide, partially reduced vanadium oxide catalyst, vanadium(IV) oxide amorphous towards X-rays, and "vanadium bronze", has not been finally established. Ioffe and coworkers[75] attributed the EPR signal which they observed at room temperature for vanadium–molybdenum catalysts to the presence of $V^{4+}$ ions.

Ragle[84] considers that the EPR signals (singlets) observed at room temperature for commercial vanadium pentoxide, vanadium bronzes, and partly reduced vanadium catalysts, are due to an electron localised close to the vanadium. The absence of HFS is attributed to the mobility of these electrons. An analogous conclusion regarding the nature of the paramagnetic centres in $V_2O_5$ was reached by Ioffe and Patrina[85].

However, this cannot explain the difference in the behaviour of crystalline $V_2O_4$ and the form amorphous towards X-rays. This may be due to differences in the degree of dispersion of these modifications of $V_2O_4$.

Crystalline $V_2O_4$ is antiferromagnetic at room temperature[86]. In amorphous $V_2O_4$, however, because of its high degree of dispersion and the marked departure from ordering in the structure, the antiferromagnetism is probably removed to some extent and this makes it possible to observe EPR signals from $V^{4+}$ ions at room temperature.

This interpretation explains a number of other facts. During catalysis, the surface of the vanadium oxide catalyst disintegrates, becomes amorphous, and almost doubles in area[87]. The disintegration of the catalyst surface is accompanied by an increase in the intensity of the EPR signal; at the same time, the catalyst may not be chemically reduced. For example, the intensity of the signal from $V_2O_5$ after catalysis of the oxidation of phthalic anhydride increases[83] by a factor of approximately 30, but no reduction of the catalyst is observed[88]. Moreover, it was established that the intensity of the EPR signal from amorphous $V_2O_4$ increases after catalysis by a factor of approximately 2, with the simultaneous partial oxidation of the catalyst (the experiments were carried out in gradient-free conditions and measures were taken to eliminate the possible influence of inner-diffusion retardation, which might have led to oxidation of $V_2O_4$ inside the granule[89]). Special experiments showed that the intensity of the $V_2O_5$ signal decreases after remelting: by a factor of 2 for "analytical reagent" grade $V_2O_5$ and by a factor of 5 for "pure" grade $V_2O_5$. At the same time, the concentration of $V^{4+}$ ions in the oxides decreases by factors of only 1.5 and 2 respectively. Thus "annealing" of the defects takes place much more readily than the decrease in the concentration of $V^{4+}$ ions. All these facts can be explained only by relating the EPR signals observed at room temperature to the presence, in the catalyst, of defects (dislocations) which are centres for the localisation of electrons.

The fact that the signal with maximal intensity is observed from amorphous $V_2O_4$ and not from the other oxides studied can be attributed firstly to the fact that only $V_2O_4$ could be obtained in the most highly dispersed state, and secondly to the fact that this oxide contains the maximal number of mobile electrons, of which a definite proportion may be localised on the dislocations in the solid.

It should be emphasised again that the nature of the signals observed at room temperature is the subject of discussion. For us, however, it is significant that the intensity of these signals is not correlated with the activity of the vanadium oxide catalysts with respect to the oxidation of aromatic hydrocarbons.

The EPR method has also been used to study the vanadium–potassium–sulphate–silica gel (VKSS) so-called "complex" catalyst for the oxidation of naphthalene to phthalic anhydride[90]. This catalyst is prepared by impregnating coarsely-porous silica gel with an aqueous solution of vanadyl sulphate and potassium sulphate with subsequent roasting at about 400°C. It was previously considered that this treatment converted the vanadyl sulphate completely into $V_2O_5$ [91,92] and hence that in principle any soluble vanadium salt, for example, ammonium metavanadate, could be used for the preparation of the catalyst. Vanadyl sulphate was convenient simply because it penetrates more evenly into the silica gel and ensures regular formation of $V_2O_5$ throughout the whole volume of the

carrier. According to these ideas, the high selectivity of the oxidation of naphthalene to phthalic anhydride on the VKSS catalyst was due to the particularly favourable distribution of the vanadium oxides in the bulk of the carrier. The vanadyl sulphate was merely the starting material for their formation.

In the study of this type of vanadium catalyst, use was made of the fact that of all the vanadium compounds whose presence might have been expected in the VKSS catalyst — vanadyl sulphate, $V_2O_5$, $V_6O_{13}$, and $V_2O_4$ — only vanadyl sulphate gives an intense EPR signal at room temperature[76,77,83], whereas special experiments established that the vanadium oxides deposited on silica gel are not revealed in the EPR spectrum at room temperature. It was found that the catalyst prepared by impregnating silica gel with an aqueous solution of vanadyl sulphate and potassium sulphate, with composition corresponding to that used in industry, after heating at 400°C exhibits maximal selectivity with respect to phthalic anhydride and gives an EPR spectrum with HFS. The EPR signal is also preserved after the catalysis has been carried out for a prolonged period. Moreover, contacts prepared by impregnating silica gel with vanadyl sulphate solution without potassium sulphate, which after roasting do not give a signal and hence do not contain $VOSO_4$, give an intense broad EPR signal after catalysis of the oxidation of naphthalene for several minutes. The appearance of this signal can be attributed to the regeneration of vanadyl sulphate in the catalyst during catalysis. In fact, during the oxidation of the original vanadyl sulphate to $V_2O_5$ on the catalyst, $SO_3$ is liberated and may be retained by the carrier. In the reduction of $V_2O_5$ during catalysis, the $V_2O_4$ formed reacts with the sorbed $SO_3$ to form vanadyl sulphate.

It was found that a catalyst prepared by impregnating silica gel with a solution of ammonium metavanadate and potassium sulphate, that is, a catalyst not containing vanadyl sulphate and hence not giving an EPR signal at room temperature either before or after catalysis, shows extremely low selectivity. After this catalyst has been treated in $SO_3$ vapour at room temperature, however, it begins to oxidise naphthalene much more selectively, and the concentration of the products of extensive oxidation decreases sharply. This catalyst, like that with composition corresponding to that used in industry, also gives a signal with HFS‡.

The observed facts indicate that the outstanding properties of the VKSS catalyst are due chiefly to the characteristic features of its chemical composition, namely the presence of vanadyl sulphate (which gives an EPR signal detectable at room temperature).

Since in the catalysts examined the vanadyl sulphate gives a signal with HFS, it is present in the catalyst and on its surface in the form of a dilute solid solution. The operation of a VKSS catalyst which has not been heated and which, before and after catalysis, contains an appreciable quantity of the original vanadyl sulphate, revealed in the EPR spectrum by the intense singlet characteristic of the $VOSO_4$ phase, is completely analogous to that of a previously heated catalyst in the catalysis of the oxidation of naphthalene. This can be interpreted in different ways[90]. It is possible that in order to obtain the "optimum" VKSS catalyst, the form in which the $VOSO_4$ is present — as a separate phase or in the form of a dilute solid solution — is not important and that only its presence in the system is important.

It has recently been reported that the oxidation of organic substances can also be catalysed by organic semiconductors. Thus it is stated that tetralin is oxidised by a stream of oxygen bubbles in the presence of poly(acrylonitrile)[74]. It is suggested that the action of the poly(acrylonitrile) involves the catalysis of the decomposition of hydroperoxides formed during the autoxidation of the hydrocarbon.

## IV. REACTIONS INVOLVING THE DONATION AND WITHDRAWAL OF AN ELECTRON PAIR

Catalysts for this type of reaction are protonic or aprotonic acids or bases. Solid aprotonic catalysts generally show neither electrical conductivity nor paramagnetism, so that the possible applications of the EPR method in the study of catalysts of this type are extremely limited. Here also, however, its application may be useful sometimes, for example, in the examination of the influence of irradiation on the catalytic activity of silica gel and alumina–silica catalysts with respect to the reactions of cracking and isomerisation. In particular, Weisz and Swegler[93] established that pure silica gel heated for 16 h at 550°C and then irradiated with fast and slow neutrons (20 h, dose $7.5 \times 10^{18}$ cm$^{-2}$ for each type of neutron) shows no catalytic activity with respect to the cracking of isopropylbenzene (the catalytic activity was measured in a Schwab reactor at 420°C and a pressure of 1 atm). At the same time, the activity with respect to the isomerisation of hex-1-ene to hex-2-ene and hex-3-ene (measured in a flow assembly at 350°C) increases appreciably. Mikovsky and Weisz[94] also showed that irradiation with a large neutron dose ($10^{20}$ cm$^{-2}$) increases the activity of silica gel in the isomerisation of but-1-ene by a factor of approximately 50, but increases the activity of an alumina–silica catalyst by a factor of 1.5–3 (the catalytic activity was measured in a flow microreactor after storage for 6 months to ensure removal of the induced radioactivity). The heat of activation on irradiated alumina–silica is 9.7 kcal mole$^{-1}$, whereas the value for the original catalyst is 11.4 kcal × × mole$^{-1}$. The selectivity of the process remains unchanged after irradiation. It is also noted that the specific surface of the irradiated catalysts is smaller by 10–20% than that of the original catalysts.

Contrary to the results of Weisz, earlier work by Lucchesi and coworkers[95,96] established a decrease in the catalytic activity of an alumina–silica catalyst (87% $SiO_2$), previously heated at 540°C (16 h) and 675°C (3 h), in the isomerisation of the double bond in but-1-ene after electronic irradiation (fast neutron beam $8.9 \times 10^{18}$ cm$^{-2}$, slow neutron beam $6.1 \times 10^{18}$ cm$^{-2}$, $\gamma$-radiation dose $1.2 \times 10^{10}$ r). The catalytic activity measured 30 d after irradiation at 65°C.

We have already pointed out that the irradiation of anhydrous silica gel leads to the generation of an EPR signal which can be related to the appearance of defects in the structure of the catalyst. Panchenkov and coworkers[97] studied the cracking of isopropylbenzene in a flow assembly at 400°C on an irradiated alumina–silica catalyst with

‡ Treatment with $SO_3$ vapour naturally cannot alter the distribution of $V_2O_5$ in the bulk of the carrier, so that the high selectivity with respect to phthalic anhydride shown by the VKSS catalyst cannot be attributed entirely to the difference in the regularity of the distribution of $V_2O_5$ in the bulk of the carrier during its impregnation with vanadyl sulphate and metavanadate.

composition: $Al_2O_3$ 12.8, $SiO_2$ 87.1, $Fe_2O_3$ 0.07%. The catalyst was irradiated with protons (energy 1.5 MeV, intensity of beam 20 μA at the temperature of liquid nitrogen) and γ-rays (dose 48 million r) at room temperature, and it was established that an EPR signal (singlet) appears after irradiation. At the same time, judging from the degree of conversion, the catalytic activity increases by 25–40% after irradiation with protons and by 77–93% after γ-irradiation.

Comparison of the results obtained by Weisz and Panchenkov shows that irradiation generates EPR signals in these catalysts and influences their activity with respect to the reactions of cracking and isomerisation. It is known that γ-$Al_2O_3$, which is a strong aprotonic and weak protonic acid, is a comparatively poor catalyst for the cracking reaction and that alumina–silica and silicon–zirconium catalysts, which are strong protonic and aprotonic acids, are effective catalysts for this reaction[98]. It may thus be concluded that cracking takes place actively on protonated surfaces and much less readily on aprotonic catalysts. This explains the inertness of roasted irradiated silica gel (a weak protonic acid) in the cracking of isopropylbenzene. In actual fact, irradiation creates defects in the lattice (EPR signals) but it cannot create the protonated surface necessary for cracking. The increase in the activity of roasted irradiated $SiO_2$ with respect to the isomerisation of hex-1-ene and but-1-ene can probably be attributed to the fact that this reaction, unlike cracking, also takes place on an aprotonic catalyst such as $SiO_2$. Irradiation, by producing defects in the surface, naturally leads to an increase in the number of aprotonic active centres on unit surface area of the catalyst. Similarly, as we have already seen, irradiation increases the activity of a catalyst with protonic acidity — the alumina–silica catalyst — with respect to the process catalysed by protonic surfaces, that is, the cracking process.

The decomposition of the oxygen-containing compounds formic acid and propan-2-ol involves simultaneous dehydrogenation and dehydration of the starting material. Dehydrogenation is a reaction taking place by a radical mechanism, whereas dehydration involves an acid–base reaction. It is thus natural to expect that the decomposition of the above substances should take place on catalysts of the radical type[99] which exhibit acidic properties simultaneously. For example, dehydration takes place readily on silica gel, which is a relatively strong aprotonic acid. It was shown above that irradiated silica gel gives a strong EPR signal and catalyses the dehydrogenation of cyclohexane. It was thus expected that irradiated silica gel would catalyse the decomposition of the oxygen-containing compounds in two directions — with dehydrogenation and with dehydration. It was in fact shown[100] that irradiated silica gel (Xerogel R) begins to catalyse not only the dehydration of formic acid, but also its dehydrogenation.

Slinkin and coworkers[101] studied the EPR signals of alumina–chromium oxide catalysts with a wide range of compositions (1.5–93 wt.% Cr) after roasting at 450°, 600°, and 1000°C, and after catalysis had been carried out on them. In agreement with data obtained by other authors, it was found that the original catalysts at room temperature show two signals: a narrow signal with $\Delta H$ = 40–55 G, and a broad signal with $\Delta H$ = 1000 G. After catalysis, at a chromium concentration ≤ 14%, the narrow signal ($Cr^{5+}$ ions) disappears. With increase in the roasting temperature, the intensity of the broad line increases and its width decreases to 500 G. It was concluded that the active centres of the catalyst are not $Cr^{5+}$ ions but a number of centres containing $Cr^{6+}$, $Al^{3+}$, and $O^{2-}$ ions. The actual catalytic process studied is not reported, however, and an earlier paper referred to by the authors merely notes that the decomposition of propan-2-ol was studied. It is not clear from the text whether dehydrogenation, or dehydration, or both took place. It may be assumed that both processes should take place on this catalyst, which after catalysis gives an intense EPR signal and which contains a strong aprotonic acid — $Al_2O_3$.

The decomposition of propan-2-ol and cyclohexanol on certain organic semiconductors was recently studied[74]. On three of these — poly(benzimidazole), poly(acrylonitrile), and poly(isoprenebenzoquinone) — decomposition involves dehydration and dehydrogenation simultaneously; dehydration of the alcohols takes place almost exclusively only on the most "acidic" compound — polyacenequinone.

RUSSIAN CHEMICAL REVIEWS
Uspekhi Khimii

October 1965

ALEXANDR NAUMOVICH FRUMKIN

Dear Alexandr Naumovich,

Your pupils, collaborators, and the Editorial Board of the journal "Uspekhi Khimii" convey to you their warm greetings in connection with your jubilee and wish you health and many years of fruitful endeavour.

We have no doubt that the freshness and sharpness of your intellect, your energy, and outstanding capacity for work will ensure that the ideas which you have been developing will further enrich science and its practical applications with new achievements.

We all greatly value the opportunity to work with you, the leading electrochemist in the world, and are ready to assist you in every way in the further development of new and most advanced ideas of our Soviet science.

We wish you many happy days and major creative success.

# ELECTROCHEMICAL REDUCTION OF OXYGEN

V. S. Bagotskii, L. N. Nekrasov, and N. A. Shumilova

CONTENTS

1. Introduction 717
2. Reduction of oxygen at a mercury electrode 719
3. Reduction of oxygen on platinum and platinum group metals 721
4. Reduction of oxygen at a silver electrode 726

## 1. INTRODUCTION

Electrochemical (cathodic) reduction of molecular oxygen on various metallic or carbon electrodes has been the subject of numerous experimental studies in recent years. The increased interest in this reaction is due in the first place to its wide occurrence and great practical importance. The electrochemical reduction of oxygen greatly influences metal corrosion processes in aqueous media in the presence of free access of oxygen[1]. In analytical

chemistry this reaction can be used to determine the oxygen dissolved in various solutions, for example in sea water[2]. If cathodic reduction of oxygen could be achieved in practice at a sufficiently high rate and if effective oxygen electrodes could be prepared, this reaction could be used as the cathodic process in many electrochemical manufacturing processes, instead of the reaction involving the evolution of hydrogen; this would result in an appreciable saving of electrical energy. Numerous attempts have also been made to use the electrochemical reduction of oxygen for the industrial preparation of hydrogen peroxide[3].

However, perhaps the greatest interest attaches to the problem of using the electrochemical reduction of molecular oxygen in combination with the electrochemical oxidation of various types of fuel to achieve electrochemical flameless "cold" combustion[4]. This process constitutes the basis of the operation of the so-called fuel cells in which the chemical energy of the fuel is directly converted into electrical energy. Oxygen is the most readily accessible and most convenient oxidising agent for fuel cells and the complete solution of the problem of designing such cells depends greatly on the possibility of making adequately stable and effective electrodes for the reduction of oxygen.

The overall reduction of an oxygen molecule involves the participation of four electrons:

$$\text{in acid solutions } O_2 + 4H^+ + 4e \rightarrow 2H_2O, \quad (1)$$

$$\text{in alkaline solutions } O_2 + 2H_2O + 4e \rightarrow 4OH^-. \quad (1')$$

The equilibrium potentials corresponding to this reaction can be readily calculated by a thermodynamic procedure from the standard free energy of formation of water from gaseous hydrogen and oxygen. At 25° and an oxygen pressure of 1 atm this equilibrium potential is $\varphi_\gamma^{(1)} = +1.229$ V relative to the equilibrium potential of the hydrogen electrode in the same solution[5]. Since the equilibrium potentials of the hydrogen and oxygen electrodes vary in the same way with the pH of the solution, their difference is independent of the composition of the solution. The equilibrium potential of the oxygen electrode measured relative to that of the normal hydrogen electrode (in acid solution at pH 0) is $\varphi^{(1)} = +0.401$ V† in alkaline solution at pH 14 (when the pH is increased by one unit, the potential decreases by 59 mV).

A characteristic feature of the oxygen electrode is that the equilibrium potential calculated by a thermodynamic procedure is never established experimentally. When platinum, carbon, or other inert electrodes are immersed in an electrolyte in contact with gaseous oxygen; a potential $\varphi_\gamma$ between 0.8 and 1.1 V is established, i.e. 0.1–0.4 V less positive than the thermodynamic value. The potential established depends on the preliminary treatment of the electrode. In this respect the oxygen electrode greatly differs from the hydrogen electrode; as is well known, the equilibrium potential of the hydrogen electrode is relatively readily and reproducibly established at platinum and certain other metals. The difficulty in attaining the equilibrium potential of the oxygen electrode has a number of causes, in particular the possibility of the intermediate formation of hydrogen peroxide and the effect of the layers of oxygen adsorbed on the electrode surface. The only paper in which the attainment of an oxygen potential at a platinum electrode close to the equilibrium value is described is that of Bockris and Huq[6]. According to the authors, this result was achieved by very thorough purification of the solution. However, it is not entirely clear how they succeeded in eliminating effects due to the state of the surface and to what extent equilibrium between the oxygen and solution was in fact established on the electrode.

The formation of hydrogen peroxide in the cathodic reduction of oxygen was observed in the previous century, when this reaction began to be studied in connection with the investigation of the Grove oxygen–hydrogen cell[7,8].

Hydrogen peroxide can form as an intermediate in the overall four-electron reaction (1):

$$O_2 + 2H^+ + 2e \rightarrow H_2O_2, \quad (2)$$

$$O_2 + H_2O + 2e \rightarrow HO_2^- + OH^-. \quad (2')$$

Further electrochemical reduction of hydrogen peroxide to water (or hydroxide ions) proceeds according to the equations

$$H_2O_2 + 2H^+ + 2e \rightarrow 2H_2O, \quad (3)$$

$$HO_2^- + H_2O + 2e \rightarrow 3OH^-. \quad (3')$$

The normal equilibrium potentials of reactions (2) and (3) calculated from thermodynamic data are respectively $\varphi^{0(2)} = +0.713$ V and $\varphi^{0(3)} = +1.744$ V (w.r.t. normal hydrogen electrode)[5,9]. It is evident from these values that the potential corresponding to the reduction of peroxide is much more positive than the potential of its formation from oxygen. This means that hydrogen peroxide is thermodynamically more readily reducible than oxygen. Thus hydrogen peroxide is thermodynamically unstable and can appear and accumulate as an intermediate only due to kinetic factors [the low rate but not thermodynamic impossibility of reaction (3)]. As a result, hydrogen peroxide appears under certain conditions, whereas in others it cannot be detected.

The hydrogen peroxide formed by the reduction of oxygen can disappear not only as a result of its further reduction but also as a result of its catalytic decomposition under the influence of the material of the electrode:

$$2H_2O_2 \rightarrow O_2 + 2H_2O, \quad (4)$$

$$2HO_2^- \rightarrow O_2 + 2OH^-. \quad (4')$$

As will be seen below, in many cases catalytic decomposition is the main process preventing the accumulation of hydrogen peroxide.

Reaction (1) can also proceed according to a different mechanism, not associated with the formation of hydrogen peroxide as an intermediate but with the dissociation of oxygen molecules into atoms, which are adsorbed on the electrode surface:

$$O_2 \rightarrow 2O_{ads}, \quad (5)$$

$$O_{ads} + 2H^+ + 2e \rightarrow H_2O, \quad (6)$$

$$O_{ads} + H_2O + 2e \rightarrow 2OH^-. \quad (6')$$

The determination of the actual reaction pathway [via stages (2) and (3) or via stages (5) and (6)] often involves considerable difficulties; the appearance of hydrogen peroxide is a clear demonstration that the first pathway is correct, but its absence cannot be regarded by itself as an unambiguous proof that the second reaction pathway actually obtains.

† Here and henceforth $\varphi_\gamma$ will denote the potential relative to the hydrogen electrode in the same solution and $\varphi$ the potential relative to the fixed potential of a reference electrode (in solution at a specified pH), for example relative to the normal hydrogen electrode (pH 0).

Reactions (2), (3), and (6) are themselves complex and can involve a number of intermediate stages, in each of which one species is added (proton or electron). In contrast to hydrogen peroxide, the intermediate products thus formed are completely unstable and cannot be detected by the usual electrochemical or analytical means. The most likely first stage of reaction (2) is the addition of the first electron:

$$O_2 + e \rightarrow O_2^-. \quad (7)$$

The formation of the molecular $O_2^-$ ion does not require the expenditure of an unduly large amount of energy and this reaction is quite possible. Further reactions of this ion can proceed, for example, as follows:

In acid solutions

$$O_2^- + H^+ \rightarrow HO_2, \quad (8)$$

$$HO_2 + e \rightarrow HO_2^-, \quad (9)$$

$$HO_2^- + H^+ \rightarrow H_2O_2. \quad (10)$$

In alkaline solutions

$$O_2^- + H_2O \rightarrow HO_2 + OH^-, \quad (8')$$

$$HO_2 + e \rightarrow HO_2^-. \quad (9')$$

In the reduction of hydrogen peroxide by reaction (3) the possible first stage is the addition of an electron to a hydrogen peroxide molecule with simultaneous breakdown of the latter into a hydroxide ion and a hydroxyl radical:

$$H_2O_2 + e \rightarrow HO + OH^-. \quad (11)$$

However, it must be stipulated that the nature and fate of the intermediate products of this reaction cannot as yet be exactly established from the available experimental data.

It is thus seen from this by no means complete list of the possible electrochemical and chemical reactions in the system oxygen–hydrogen peroxide–water that this system is extremely complex; this greatly hinders the interpretation of the results of experimental studies. The situation is aggravated by the fact that the reduction of oxygen occurs at potentials at which the formation of adsorption-type or chemically individual oxide layers is possible on the surface of many metals. The variation of the nature and properties of these layers with potential and with experimental conditions (including the previous history of the electrode) has different effects on the possible individual stages and reactions, which makes the problem still more difficult.

In recent years experimental data have been obtained for the reduction of oxygen at a number of electrodes; these make it possible to throw at least some light on the individual aspects of the mechanism of this process. The present review deals with the results obtained for metallic electrodes.

## 2. REDUCTION OF OXYGEN AT A MERCURY ELECTRODE

The mercury electrode has proved very convenient for the investigation of the kinetics of the electrochemical reduction of oxygen and its use has led to the determination of a number of features of this reaction. The detailed investigation of this kind, at a dropping mercury electrode, was made by Heyrovský as early as 1924.[10,11] The convenience of the mercury electrode is due to the high reproducibility of the liquid mercury surface, which can be readily renewed. Furthermore, the fact that the reduction of hydrogen peroxide at the mercury electrode is very slow and occurs only at highly negative potentials is of great importance. This makes it possible to separate clearly the potentials corresponding to the reduction of oxygen and to the reduction of hydrogen peroxide, and to investigate each of these reactions separately.

Fig. 1 shows polarisation curves for the reduction of oxygen in acid (curve *a*) and alkaline (curve *b*) solutions at a dropping mercury electrode. For all the solutions the polarisation curves consist of two waves, of approximately the same height; the first wave corresponds to reaction (2) and the second to reaction (3). The limiting current densities for both waves, $i_{d_1}$ and $i_{d_2}$, correspond to the limiting diffusional flux of oxygen towards the electrode surface, allowing for the participation of two electrons in each reaction per oxygen molecule. When the partial pressure of oxygen $p_{O_2}$ is changed, and hence also the amount of dissolved oxygen, the limiting current shows a corresponding change.

Let us consider in detail the first wave [reaction (2)]. Analysis of the curve obtained in acid solutions shows that the dependence of the current density on the surface concentration of molecular oxygen $[O_2]_S$ and on the potential is of the form[12-14]

$$i = k_1 [O_2]_S \exp[-\alpha F \varphi / RT], \quad (12)$$

where the transfer coefficient $\alpha$ is 0.5. Under conditions far removed from concentration polarisation, i.e. at current densities $i \ll i_{d_1}$, the surface concentration is equal to the bulk concentration of the dissolved oxygen $[O_2]$, while the latter is in turn proportional to the partial pressure of oxygen. In this case

$$i = k_2 p_{O_2} \exp[-\alpha F \varphi / RT], \quad (13)$$

or

$$\varphi = \text{const} - b \log i + b \log p_{O_2}, \quad (14)$$

where

$$b \equiv \frac{RT}{\alpha F} 2.3 \sim 0.11 - 0.12V.$$

Experiment shows[12,15] that in acid solutions the reduction potential $\varphi$ at constant current density is independent of the pH. Fig. 2 shows an example of the variation of the half-wave potential for the first wave with the pH of the solution. Thus the kinetic equations (12) and (13) are

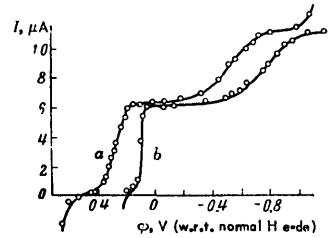

Fig. 1. Polarisation curves for the reduction of oxygen and hydrogen peroxide at a dropping mercury electrode in solutions at different pH:
1) 1.67; 2) 12.5; data of Bagotskii and Yablokova[12].

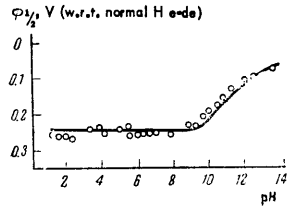

Fig. 2. Dependence of the half-wave potential for the reduction of oxygen on the pH of phosphate buffer:
circles — experimental data; continuous curve — calculated by Eqn. (16); data of Bagotskii and Yablokova [12].

independent of the pH of the solution, which in turn suggests that hydrogen ions do not participate in the slow stage which determines the rate of the overall reaction (2).

The form of the kinetic equation (12) or (13) and the independence of the reaction rate of the pH indicates that the slow stage of process (2) is reaction (7) — the formation of the oxygen molecular ion [12-14,16,17]. A change in kinetics on transition from acid to alkaline solutions is characteristic of the reduction of oxygen to hydrogen peroxide at a mercury electrode. Fig. 1 shows that in alkaline solutions the first wave is much steeper than in acid solutions. The $b$ coefficient of the kinetic equation (14) in alkaline solutions is about 0.03 V, i.e. smaller by a factor of four than in acid solutions. Furthermore, Fig. 2 shows that in alkaline solutions the reduction potential varies with the pH: with other conditions constant (current density, oxygen pressure), the potential decreases by 0.06 V per pH unit in the range between pH 9 and pH 11, and by 0.03 V at pH values greater than 11.

A similar change in the reaction on going from acid to alkaline solutions was also observed in the experiments of Krasil'shchikov [16,18,19] on the reduction of oxygen to hydrogen peroxide at a silver electrode. To explain his results, Krasil'shchikov suggested that in alkaline solutions the slow stage is the reaction involving the addition of a second electron [stage (9)] and not the stage involving the first electron [stage (7)] which determines the rate of the overall reaction in acid solutions. The theory of electrochemical kinetics shows that the $b$ coefficient in the kinetic equation (14) is $2.3\,RT/(1+\alpha)F$, which is equal to 0.04 V with $\alpha = 0.5$, i.e. close to the experimental value. Thus Krasil'shchikov's hypothesis accounts satisfactorily for the values of the kinetic coefficients in alkaline solutions, but the reason for the change in the rate-limiting step on going from acid to alkaline solutions still remains obscure.

Another hypothesis was put forward by Bagotskii et al. [12,14] concerning the mercury electrode. It was shown that in alkaline solutions the equilibrium potential for the system oxygen–hydrogen peroxide is established at the mercury electrode. The dependence of this potential on the concentration of the components (oxygen, hydrogen peroxide, hydroxide ions) is consistent with thermodynamic relations. The tabulated values of the normal equilibrium potential for this system were actually corrected on the basis of experimental measurements [9] ($\varphi^{0(2)} = +0.713$ V instead of +0.684 V given in Latimer's handbook [5]), and hence also the standard free energy of hydrogen peroxide solution ($\Delta G_{H_2O_2} = -32\,900$ cal instead of -31 470 cal).

The attainment of equilibrium between oxygen and hydrogen peroxide at a mercury electrode in alkaline solutions is also confirmed by the measurements of Koryta [20]. The attainment of this equilibrium at a porous carbon electrode was demonstrated as early as 1943 by Berl [21].

Since the potential corresponds to equilibrium, it follows that the polarisation curve in alkaline solutions is determined solely by concentration polarisation, i.e. the rate-limiting process is the diffusion-dependent stage in which the reacting oxygen molecules are brought to the electrode surface and the reaction products — hydrogen peroxide ions or molecules — are removed. On this hypothesis the $b$ coefficient in Eqn. (14) is found to be 0.03 V, which is consistent with experiment. Furthermore, this hypothesis also accounts for the observed dependence on the pH in alkaline solutions: up to pH 11 the equilibrium potential for reaction (2) changes by 0.06 V per unit pH, while at higher pH values the change in potential is smaller by a factor of two due to the ionisation of hydrogen peroxide [reaction (2′)].

On the basis of the above hypotheses, it is easy to explain the change in reaction mechanism on going from acid to alkaline solutions. In acid solutions the rate of reaction is determined by stage (7), while the remaining stages, (8)–(10), proceed fairly rapidly, so that equilibrium is set up between $O_2^-$ ions and the reaction product $H_2O_2$:

$$O_2^- + 2H^+ + e \rightleftarrows H_2O_2. \qquad (15)$$

As the pH increases, other conditions remaining the same, the concentration of $O_2^-$ rises too. This leads to an increase in the rate of the reaction which is the reverse of reaction (7), i.e. the oxidation of molecular oxygen ion $O_2^-$. At a certain pH the rate of the reverse reaction becomes comparable with that of the forward reaction, i.e. the reaction becomes reversible.

On the basis of the above hypotheses, it is possible to derive an overall kinetic equation, which expresses the dependence of the rate of reduction of oxygen on the potential over the entire range of pH: [12]

$$i = \frac{i_{d_1}}{1 + \exp[\alpha F(\varphi - \varphi_{1/2})/RT] + \dfrac{\gamma}{a_H^+ [a_{H^+} + K_d]} \exp[2F(\varphi - \varphi^{0(2)})/RT]}, \qquad (16)$$

where $\varphi_{1/2}$ is the half-wave potential (first wave) in acid solutions, $\gamma$ the solubility of oxygen in the solution, and $K_d$ the dissociation constant of hydrogen peroxide. The only quantities which cannot be determined by independent (non-electrochemical) measurements are the transfer coefficients $\alpha$ and the half-wave potential. Having determined these values from measurements in one solution, it is possible to calculate the complete polarisation curves in other solutions, both acid and alkaline. Polarisation curves calculated in this way for two solutions are compared with experiment in Fig. 3. A similar comparison is made also in Fig. 2 for the dependence of the half-wave potential on the pH. In both cases the agreement between calculation and experiment is satisfactory, which indicates the validity of the initial hypotheses.

A characteristic feature of the next stage of the overall oxygen reduction process — reduction of hydrogen peroxide to water — is a very low slope of the polarographic wave (Fig. 1). The results of kinetic measurements may be represented by the equation [12]

$$\varphi = \text{const} + b \log[H_2O_2]_S - b \log i, \qquad (17)$$

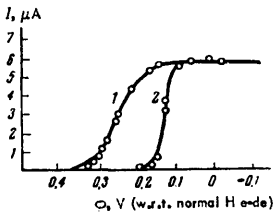

Fig. 3. Polarisation curves for the reduction of oxygen to hydrogen peroxide in solutions at different pH:
1) 3.31; 2) 11.3; circles — experimental data; continuous curve — calculated by Eqn. (16); data of Bagotskii and Yablokova [12].

where the coefficient $b = 2.3RT/\alpha F$ is 0.24–0.26 V, i.e. twice as great as for the first stage. In acid solutions the potential is independent of the pH. At pH > 11 there is a sharp decrease of the potential. This is satisfactorily explained by the hypothesis that only the hydrogen peroxide molecule and not the corresponding ion constitutes the reacting species; at pH > 11 and a constant total concentration of the peroxide, the concentration of the undissociated molecules begins to decrease.

On the basis of these data, the hypothesis was put forward [12] that the slow stage is reaction (11) involving the addition of an electron to a hydrogen peroxide molecule with its simultaneous dissociation into a hydroxide ion and a hydroxyl radical.

When a hydrogen peroxide solution is in contact with a mercury electrode, there is some, although not very rapid, catalytic decomposition of the peroxide. Comparison of the measured rate of the catalytic decomposition with the rates of the electrochemical reduction of hydrogen peroxide at the given potential [reaction (3)] and its electrochemical oxidation [the reverse reaction (2)] shows [22] that, at least in dilute solutions, these rates agree closely. Hence it follows that the catalytic decomposition of hydrogen peroxide on mercury may be regarded as coupled electrochemical oxidation and reduction (dismutation) of hydrogen peroxide, both processes occurring simultaneously. In more concentrated solutions the rate of catalytic decomposition of the peroxide is tens of times greater than the calculated value, which shows that in such solutions a non-electrochemical mechanism of the catalytic breakdown obtains (possibly a chain mechanism involving the migration of active intermediate products from the surface of the mercury electrode into the bulk of the solution).

## 3. REDUCTION OF OXYGEN ON PLATINUM AND PLATINUM GROUP METALS

In the study of the electrochemical reduction of molecular oxygen on platinum, and in general on solid electrodes, it is necessary to overcome considerable difficulties arising in the first place from the inhomogeneity of the surface of such electrodes and the effect on the kinetics of the process of the physicochemical properties of the electrode surface, which vary with potential, time, adsorption of various components of the solution, etc.

Among the large number of experimental findings concerning the ionisation of oxygen on smooth platinum in acid and alkaline solutions, the following may be regarded as established (although their interpretation is not the same in different investigations):

a. In contrast to the mercury electrode, only one oxygen reduction wave is observed at an activated smooth platinum electrode, and according to the majority of measurements the overall process involves the addition of four electrons. The appearance of a second wave, noted, for example, by Shepelin et al. [23], is probably associated with the low activity of the electrode under the experimental conditions.

b. The half-wave potential for the reduction of dissolved oxygen is close to the reduction potential of surface platinum oxides at any pH of the solution [24-27].

c. An increase in the pH of the solution by one unit causes a decrease of the oxygen reduction half-wave potential by 0.06 V. [24,28]

d. Hydrogen peroxide is formed in the reaction.

e. The kinetics of the process are appreciably affected by the degree of oxidation of the electrode surface. Surface platinum oxides have been found to both inhibit [27,29] and accelerate [24,30] the ionisation of oxygen. The dual effect of the oxidation of electrode surface on the reaction kinetics has been investigated by Müller and coworkers [31,32] and by Khrushcheva et al. [33]

Various hypotheses have been put forward concerning the mechanism of the cathodic reduction of oxygen, which may be reduced to three principal reaction mechanisms.

1. According to Krasil'shchikov and Andreeva [28], the rate-limiting stage in the process is the interaction of hydrogen atoms adsorbed on the platinum surface with molecules of dissolved oxygen. The characteristic feature of this mechanism is that it assumes the presence of adsorbed hydrogen at potentials more positive by 0.9 V than that of the reversible hydrogen electrode, which is contradicted by the results of the investigation of the surface properties of platinum [34,35], including the measurements made by Vielstich [27] by the triangular pulse method in the presence of oxygen in the solution.

2. In view of the similarity of the potentials for the reduction of oxygen and the surface platinum oxides, Sawyer and coworkers [24,36] put forward a mechanism based on the hypothesis of the electrical reduction of the oxides and their subsequent regeneration as a result of the chemical interaction of oxygen with the surface of the metal:

$$Pt(OH)_2 + 2e \rightarrow Pt + 2OH^-, \quad (18)$$

$$Pt + H_2O + \frac{1}{2}O_2 \rightarrow Pt(OH)_2. \quad (19)$$

Giner [25] and Lingane [26] have expressed similar views. According to Sawyer, two-electron reduction of oxygen to hydrogen peroxide [reaction (2)] takes place on electrodes free from chemisorbed oxygen.

3. Some investigators [21-33,37-41] have been developing the view that the electrochemical reduction of oxygen on platinum proceeds in two consecutive stages with the formation of hydrogen peroxide as an intermediate. In contrast to the reaction at the mercury electrode, hydrogen peroxide is reduced (or decomposes) at potentials corresponding to its formation, so that as a rule two separate waves are not observed. The main results of these studies are presented below.

Nekrasov and Müller [37] were the first to study the ionisation of oxygen by the method of the rotating disc electrode

with a ring, proposed by Frumkin and Nekrasov[42]. The rotating disc electrode with a ring consists of a single mechanical system comprising two electrodes — a disc and a ring — which are electrically independent. The use of this electrode yielded significant new information about the mechanism of the process which would be difficult to obtain in other ways. With this method the formation of hydrogen peroxide could be controlled directly during the reaction at the disc (smooth platinum) by oxidising at the platinised platinum ring electrode the part of the peroxide which failed to react at the disc electrode and was brought to the surface of the ring by the flow of liquid. Thereby it was possible to separate the various stages of the process and to study each of them individually.

The process in alkaline solutions was studied in greatest detail. It was found that, at fairly high rates of rotation of the electrode (for example, in excess of 700 rev $min^{-1}$), the polarisation curves for the reduction of oxygen at a smooth platinum disc electrode show a clear current maximum at a disc electrode potential $\varphi_r^{(d)} = 0.5$ V after which the current fell to a minimum at a potential of ~0.1 V (Fig. 4, curves *1–3*). Measurements at the disc electrode led to the detection of the formation of hydrogen peroxide over the entire range of oxygen reduction potentials at the disc electrode, the yield of the peroxide increasing with potential up to the value corresponding to the minimum on the cathodic curve for the disc electrode (Fig. 4, curves 1*a*–3*a*). Only at disc electrode potentials more negative than this does the observed amount of hydrogen peroxide decrease.

This form of the curves was explained by a fall of the rate of reduction of hydrogen peroxide at the smooth platinum disc electrode as the surface platinum oxides became reduced. The minimum rate of reduction is reached at a potential of 0.1 V, after which it again increases. A method has been suggested[37] for the treatment of the experimental results by plotting the so-called "corrected" polarisation curves: the current, calculated on the basis of the theory of the disc electrode with a ring[43,44], corresponding to the reduction of that part of the hydrogen peroxide which fails to react on the surface of the disc and is carried away by the liquid stream, is added to the current measured at the disc electrode. Thus the "corrected" current corresponds to the complete reduction (to water or hydroxide ions) of all the oxygen participating in the first stage of the process; the rate in this stage is equal to half the "corrected" current. The "corrected" curves (Fig. 4, curves *1′–3′*) show distinct limiting diffusion current plateaus. This result leads to the conclusion that at potentials more negative than 0.5 V, the cathodic reduction of oxygen to hydrogen peroxide is diffusion-dependent and the rate of the overall reaction is determined by the rate of reduction of hydrogen peroxide. On the other hand, in the region of the rise of the polarisation curve (at $\varphi_r > 0.6$ V) the first stage of the process becomes irreversible.

The fact that the mechanism of the reduction of oxygen involves a number of consecutive stages with intermediate formation of hydrogen peroxide is confirmed by the similarity of the polarisation curves for the reduction of oxygen and of hydrogen peroxide added to the solution. Additional evidence in favour of this hypothesis is the closeness of the values (when $\varphi_r < 0.5$ V) of the rate constant for the reduction of hydrogen peroxide calculated by the formula of Levich and Ivanov[43] on the basis of measurements with a ring-type disc electrode, and the values of the rate constant for the overall four-electron oxygen reduction process found by an independent method[32].

Study of the effect of surface platinum oxides on the electrochemical reduction of oxygen in an alkaline solution[31,32] showed that preliminary oxidation of the electrode retards the reduction of oxygen to hydrogen peroxide, and shifts the half-wave potential for the first stage of the process towards negative values (Fig. 5, curves *a* and *b*). The reduction of oxygen and the surface oxides in the same potential ranges can be explained by the fact that oxygen can be reduced only when the surface is already partially free from surface oxides, as pointed out by Vielstich[27].

The surface oxides have the opposite effect on the second stage of the process. Fig. 5 shows that, when $\varphi_r < 0.5$ V, i.e. in the potential range where the reaction kinetics are determined only by the rate of reduction of hydrogen peroxide, the current at an electrode subjected to preliminary oxidation (curve *1*) is appreciably higher than at an electrode

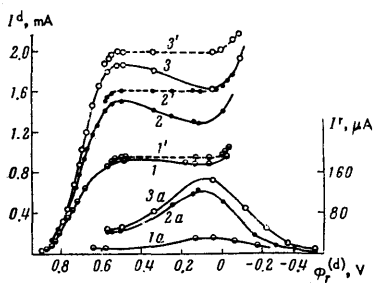

Fig. 4. Polarisation curves for the reduction of oxygen at a platinum disc electrode in 0.125 *N* KOH for different values of *m*:
1) 1040 rev $min^{-1}$; 2) 2950 rev $min^{-1}$; 3) 4560 rev × × $min^{-1}$; 1′)–3′) currents corrected for the amount of hydrogen peroxide evolved; 1*a*)–3*a*) variation of the limiting current for the oxidation of hydrogen peroxide at the ring ($I^r$) with the potential of the disc electrode; data of Nekrasov and Müller[37].

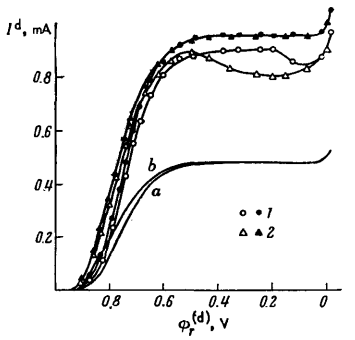

Fig. 5. Polarisation curves for the reduction of oxygen at oxidised (curve 1) and reduced (curve 2) electrodes; filled symbols — polarisation curves corrected for the amount of hydrogen peroxide evolved; *a*) and *b*) calculated polarisation curves for the reduction of oxygen to hydrogen peroxide at oxidised and reduced electrodes respectively; data of Müller and Nekrasov[31].

subjected to preliminary reduction (curve 2). The accelerating effect of surface oxides on the second reaction stage is associated with the fact that their presence ensures the occurrence of the catalytic breakdown of hydrogen peroxide on the surface of the platinum electrode. A possible mechanism for this process was put forward by Haber and Grinberg[45]:

$$Pt + HO_2^- \rightarrow PtO + OH^-, \quad (20)$$

$$PtO + HO_2^- \rightarrow Pt + O_2 + OH^- \text{ etc.} \quad (21)$$

Molecular oxygen, which is more readily reduced electrochemically than hydrogen peroxide itself, is formed during the catalytic decomposition. Direct electrochemical reduction of the peroxide has an effect on the reaction kinetics only at sufficiently negative potentials.

The occurrence of the catalytic breakdown of hydrogen peroxide on platinum and its retardation at more negative potentials was observed experimentally in alkaline and acid solutions by the method based on a rotating disc electrode with a ring[31,32,46]. The acceleration of the catalytic breakdown of hydrogen peroxide by surface platinum oxides was also observed by Bianchi et al.[47]

The doubly charged cations $Ca^{2+}$, $Sr^{2+}$, and $Ba^{2+}$ have an appreciable effect on the reduction of oxygen on platinum. This was noted for the first time in the work of Kozawa[48], who observed a lowering of the current yield of hydrogen peroxide in the presence of alkaline earth metal cations. The studies of Müller and Sobol'[40], who used the method of the rotating disc electrode with a ring, showed that the effect of the above cations is similar to that of oxygen chemisorbed on the electrode surface: their presence in solution retards the first stage of the reaction and accelerates the second stage (Fig. 6). The effect of the cations increases in the series $Ca^{2+} < Sr^{2+} < Ba^{2+}$.

The effect of cations on the electrochemical reduction of oxygen can be explained on the hypothesis that they are adsorbed on the electrode surface which results in strengthening of the bond between adsorbed oxygen and platinum. The adsorption measurements of Balashova and Kulezneva[49] confirmed the specific adsorption of $Ca^{2+}$ and $Ba^{2+}$ cations on platinum in alkaline solutions, the extent of adsorption increasing on going from $Ca^{2+}$ to $Ba^{2+}$.

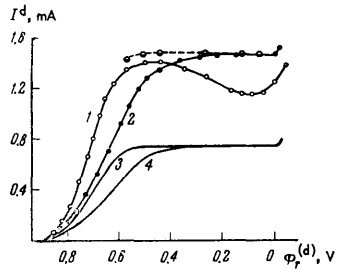

Fig. 6. Polarisation curves for the reduction of oxygen at a smooth platinum disc electrode in 0.125 *N* KOH:
1) without added doubly charged cations; 2) in the presence of $10^{-3}$ M $Ba^{2+}$; calculated polarisation curves for the first stage: 3) without added cations; 4) in the presence of $Ba^{2+}$ cations; the dashed line represents curve 1 corrected for the unreacted hydrogen peroxide; data of Müller and Sobol'[40].

The application of the method of the rotating disc electrode with a ring in the investigation of the ionisation of oxygen in acid solutions[33,38,39,46] made it possible to demonstrate the formation of hydrogen peroxide in the reduction of oxygen at a disc electrode, to observe its catalytic decomposition, and to elucidate the effect of surface platinum oxides on the first and second stages of the process. It was found that reduction of the electrode surface increases the yield of hydrogen peroxide to 70–90%. On the basis of these results, it was concluded that the mechanism of the process in acid solutions is qualitatively similar to that in alkaline solutions.

An important feature of the cathodic reduction of oxygen in acid solutions, which makes a quantitative treatment of the results difficult, is the time variation of the activity of the smooth platinum electrode, which may be due to the deactivating effect of the adsorption of anions. Polarisation measurements in solutions of various acids showed the occurrence of a pronounced shift of the half-wave potential for the reduction of oxygen towards negative values in the series $HClO_4 < H_2SO_4 < HCl < HBr$, i.e. the shift increasing with the adsorbability of the anions; this was also noted by other workers[48,50,51].

Calculation of the rate constants for the first and second stages of the reaction in 1 *N* $H_2SO_4$ on the basis of the polarisation curve measured under nearly steady-state conditions showed that in this case both reactions are inhibited, and at sufficiently positive potentials (oxidised electrode) the rate of the overall process is determined mainly by the rate of formation of hydrogen peroxide; on displacement of the potential towards negative values (reduced electrode) it is determined by the rate of reduction of hydrogen peroxide[38,39].

Interesting data on the effect of the state of electrode surface on the first and second stages of the ionisation of oxygen and also on the mechanism of the reduction of the surface oxides were obtained by the use of a rotating disc electrode with a ring, potential pulses of various amplitudes being applied to the disc. The apparatus constructed for this purpose[52] provided both periodic and single triangular and trapezoidal potential pulses, the rate of change of the applied potential ranging from 0.001 V $s^{-1}$ to 2000 V $s^{-1}$, the amplitude of the trapezoidal pulse being ±2.2 V, and the period corresponding to the upper horizontal section of the trapezium, i.e. the pause between the pulses, varying from $4 \times 10^{-5}$ to 35 s. The application of trapezoidal pulses in the investigation of the mechanism of electrode reactions makes it possible to follow not only the changes in the properties of the electrode surface but also to investigate the effect of the time during which the electrode is kept at a specified potential and the reversibility of the phenomena. Independent variation of the parameters of the trapezoidal pulses, i.e. pulse amplitude, duration of the period at a constant potential, and the rate of increase and fall of the potential increases the scope of the technique.

To investigate the effect of the state of the surface on the kinetics of the ionisation of oxygen, pulses of different amplitude are applied to the disc electrode; this produces electrodes with different degrees of oxidation. This method was used to study the effect of the degree of oxidation of the platinum electrode and the rate of reduction of

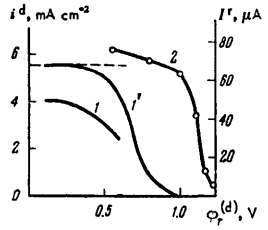

Fig. 7. Polarisation curves for the reduction of molecular oxygen in 1 *N* sulphuric acid at a rate of rotation of 2250 rev min$^{-1}$ with application of potential pulses of different amplitudes:
1) 0.1–0.6 V; 1') 0.1–1.2 V; 2) variation of the current at the ring with the amplitude of the potential pulse; data of Frumkin et al.[41]

oxygen. Fig. 7 shows the variation of the current at a ring electrode with the amplitude of triangular potential pulses applied to the platinum disc in an acid medium. It is evident that, as the amplitude increases in the anodic sense, i.e. as the degree of oxidation of the electrode increases, the current observed at the ring diminishes. On the other hand, the limiting current at the disc is higher when the anodic value of the pulse amplitude is greater, as can be seen from a comparison of the curves in Fig. 7. Thus experimental data show that the amount of hydrogen peroxide removed from the bulk of the solution falls and suggest that the second stage of the ionisation of oxygen is accelerated by surface platinum oxides.

This method also revealed the inhibiting effect of the oxides on the first stage of the ionisation of oxygen in acid solutions. Without the pulse method, the study of this effect is difficult because the adsorption of anions has a strong influence on the kinetics of the process in an acid medium.

A combination of the methods based on the rotating disc electrode with a ring and on triangular potential pulses made it possible to investigate the mechanism of the reduction of surface platinum oxides. In a number of studies it was noted that the oxidation of the electrode surface during anodic polarisation requires a greater amount of electricity than its reduction. Vetter and Berndt[53] and then Dietz and Göhr[54] explained this phenomenon by the reduction of surface platinum oxides to hydrogen peroxide. If this explanation is correct, then calculation shows that, on applying potential pulses at a high rate to the disc, in an atmosphere of nitrogen, hydrogen peroxide should be detected at the disc. Actually, when potential pulses were applied to the disc at a rate of 100 V s$^{-1}$, the limiting value of the cathodic amplitude being 0.1 V and the anodic value varying from 0.7 to 1.5 V, in an atmosphere of nitrogen in both acid and alkaline media, hydrogen peroxide was not detected. In control experiments with potential pulses applied at the same rate in an atmosphere of oxygen, where hydrogen peroxide is formed on ionisation of dissolved oxygen, the latter was detected at the ring. Thus it can be regarded as demonstrated that the reduction of oxygen chemisorbed on the surface of the platinum electrode does not result in the formation of hydrogen peroxide.

Investigation of the effect of the state of the electrode surface on the kinetics of the ionisation of oxygen includes the study of the problem of the variation of the nature of the bond between adsorbed oxygen and the electrode surface (in particular its strengthening) or the variation of the structure of the adsorbed layers of oxygen. In the experiments on these processes by the method of trapezoidal potential pulses the $i$–$\varphi$ curves shown in Fig. 8 were obtained[52]. These curves were measured with trapezoidal potential pulses applied to the electrode at a rate of change of potential of 100 V s$^{-1}$, at amplitudes between 0.01 and 1.5 V, the electrode being maintained at a potential of 1.5 V (horizontal part of the trapezium) for various times.

Fig. 8 shows that the total amount of electricity consumed during the anodic half-period of the pulse ($Q_a$) remains virtually constant regardless of the period during which the electrode is kept at a potential of 1.5 V. $Q_c$, the amount of electricity consumed during the cathodic half-period, remains virtually constant for $10^{-3}$ s, since this is commensurate with the duration of the entire potential pulse. A significant change is observed in the range 0.001–0.1 s, which is probably associated with the accumulation of oxygen during the period at the constant potential $\varphi$ = 1.5 V. The simultaneous shift of the oxygen desorption potential towards cathodic values indicates an increase in the irreversibility of the desorption process. This observation may be explained, on the one hand, by increased coverage of the electrode surface with oxygen and, on the other hand, by a strengthening of the bond between oxygen and the surface of the platinum.

In the experiments described above the electrodes used were "reduced" or "oxidised" electrochemically, i.e. by cathodic or anodic polarisation. However, although during cathodic polarisation the bulk of adsorbed oxygen atoms or surface oxides are removed, complete reduction of the surface nevertheless does not take place. Complete removal of oxygen from the surface may be achieved by reducing it with gaseous hydrogen at 400° with subsequent degassing in a vacuum at 1000°. This method of purification of the surface for electrochemical measurements was proposed by Burshtein and coworkers[55–57].

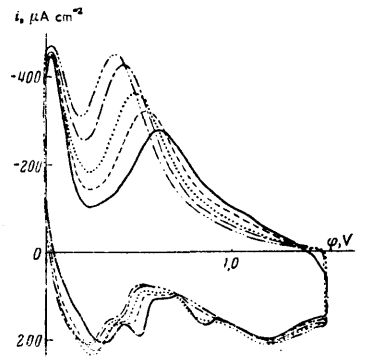

Fig. 8. $i$–$\varphi$ curves with application of potential pulses at a rate of 100 V s$^{-1}$, the potential being varied from -0.01 to 1.5 V and the electrode being maintained at $\varphi$ = 1.5 V for different periods:
1) 40 μs; 2) 10 ms; 3) 100 ms; 4) 1 s; 5) 5 s; data of Alekseev et al.[52]

In the work of Bagotskii et al.[58,60] this procedure was used to study the state of oxygen on the surface under various experimental conditions and also in experiments designed to elucidate the effect of adsorbed oxygen on the electrochemical reactions in the system oxygen–hydrogen peroxide. The data obtained showed that, when anodic charging curves are measured at thoroughly degassed platinum, the deposition of the first portion of adsorbed oxygen occurs at more cathodic potentials than in the case of a platinum surface treated in the usual way (starting with potentials $\varphi_r$ = 0.2–0.3 V). The main bulk of oxygen adsorbed exists in three forms at potentials of 0.6–0.8, 0.95–1.0, and 1.4–1.5 V respectively (Fig. 9). Thus oxygen may be present on the surface of the platinum electrode in various forms, which differ from one another in bond energy and relative stability.

The anodic and cathodic charging curves show appreciable hysteresis even at very low current densities. During the time corresponding to the cathodic section of the curve only 20% of adsorbed oxygen is removed by the time the initial potential is restored. After switching off the cathodic current, the potential again shifts towards positive values and on repeated reduction a similar amount of oxygen is again eliminated. If after removal of only part of the deposited oxygen, the anodic charging curve is again measured, an additional quantity of oxygen may be adsorbed, virtually equal to the initial amount. This type of irreversibility of the process indicates gradual penetration of oxygen into the bulk of the metal after its adsorption. The rate of penetration of oxygen into platinum (and its removal in the reverse process) depends on the potential and temperature. On degassed platinum this penetration effect is much more pronounced than on cathodically reduced platinum, in which atomic layers in the bulk of the metal are probably occupied by sorbed gases. These results, showing the penetration of anodically adsorbed oxygen into the bulk of smooth platinum, are consistent with data obtained earlier[61–63] under different experimental conditions (at higher temperatures or at higher anodic polarisations). When traces of molecular oxygen are introduced into a cell with thoroughly degassed platinum, the electrode assumes a potential $\varphi_r$ = 0.70–0.72 V, which is steadily maintained for a long time. Experiment shows[60] that equilibrium corresponding to reaction (2) is then established on the platinum electrode between oxygen and hydrogen peroxide (some of which is formed immediately after introduction of oxygen, when the electrode potential is more negative than 0.7 V). In contrast to the mercury electrode and other electrodes, the equilibrium on degassed platinum is established not only in alkaline, but also in acid solutions. However, when considerable amounts of oxygen are introduced, and also after weak anodic polarisation, the equilibrium breaks down. These data again show the strong effect of adsorbed oxygen on the mechanism of electrochemical reactions in the system oxygen–hydrogen peroxide.

Little work has been done on the study of the mechanism of the cathodic reduction of oxygen on other metals of the platinum group — palladium and rhodium. The measurements made at a palladium disc electrode with a ring[64] indicate considerable similarity in the electrochemical behaviour of palladium and platinum in the cathodic reduction of oxygen both in acid and alkaline solutions. In both cases formation of hydrogen peroxide is observed and therefore the reaction proceeds in two consecutive stages; the oxidation of the surface of the palladium electrode retards the first stage of the process and accelerates the second; the occurrence of the catalytic breakdown of hydrogen peroxide on the surface of the electrode has been established. The differences that exist are principally quantitative. In particular, it was found that both stages are faster on palladium than on platinum. The greater activity of palladium compared with platinum was also observed in other experiments[65–67].

Application of the method of the rotating disc electrode with a ring in the investigation of the ionisation of oxygen in alkaline solutions on the rhodium electrode[68] showed that this process also proceeds in two consecutive stages with the intermediate formation of hydrogen peroxide. However, it was shown that the process on rhodium is significantly different from that on platinum and palladium. Thus the polarisation curves for the ionisation of oxygen on the rhodium electrode (Fig. 10, curves *1–3*) do not show the fall of current characteristic of palladium and platinum (Fig. 4, curves *1–3*). The relative yield of hydrogen peroxide (the ratio of the current at the ring to half the "corrected" current at the disc) continuously decreases as cathodic polarisation is increased, whereas on platinum and palladium the yield passes through a maximum. Study

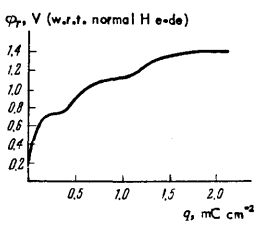

Fig. 9. Anodic charging curve for a degassed platinum electrode in 1 *N* $H_2SO_4$ at 25°; data of Luk'yanycheva and coworkers[58,59].

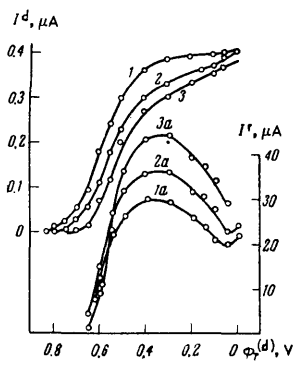

Fig. 10. Polarisation curves ($I^d$) for the ionisation of oxygen in 0.1 *N* KOH (curves 1–3) and the corresponding variation of the current at the ring ($I^r$) with the potential of the disc (curves 1*a*–3*a*) at $m$ = = 2250 rev $min^{-1}$ at reduced (curve 1), standard-activated (curve 2), and oxidised (curve 3) rhodium electrodes; data of Nekrasov et al.[68]

of the kinetics of the ionisation of oxygen as a function of the degree of oxidation of the electrode established that, as the latter increases, the half-wave potential of the polarisation curve shifts towards negative values (Fig. 10, curves *1–3*). At the same time there is an increase in the amount of hydrogen peroxide detected at the ring (Fig. 10, curves 1*a*–3*a*). In other words, an increase in the degree of surface oxidation of the rhodium electrode retards both the first and the second stages of the process.

Analysis of the experimental data leads to the conclusion that, in contrast to platinum and palladium, the second stage in the ionisation of oxygen on rhodium is electrochemical. Appreciable catalytic breakdown of hydrogen peroxide on this metal was not observed under the conditions of the experiment. Thus the results obtained for the rhodium electrode confirm the view expressed above that the acceleration of the second stage of the process on platinum and palladium by surface oxides is associated with the occurrence of the catalytic breakdown of hydrogen peroxide.

## 4. REDUCTION OF OXYGEN AT A SILVER ELECTRODE

The cathodic reduction of oxygen on silver has been investigated to a lesser extent than the reduction on mercury or platinum. In a number of experiments on the ionisation of oxygen on silver[16,69-71] it was shown that this process also is accompanied by the formation of hydrogen peroxide as an intermediate. However, the two-step polarisation curve characteristic of the mercury electrode is not as a rule observed. As with platinum, only one reduction wave is obtained in the case of silver, with a more or less distinct limiting current plateau, whose height varies between values corresponding to two-electron and four-electron processes.

As noted above, Krasil'shchikov[16,18,19] believes that in acid and neutral solutions the mechanism of the ionisation of oxygen on silver is similar to that for the process on mercury. In an acid medium the *b* coefficient is close to 0.116 and the stage involving the addition of the first electron is rate-limiting. As the alkalinity of the solution increases, the *b* coefficient falls and in fairly concentrated solutions (about 1 *N*) it is 0.04 V. In Krasil'shchikov's view, under these conditions the most likely rate-determining stage is the one involving the addition of the second electron.

On the other hand, Akopyan[72] suggested that the reduction of oxygen to hydrogen peroxide in alkaline solutions on silver is reversible (as on mercury).

In a few individual cases two polarographic waves were observed in the reduction of oxygen on silver. Such curves were obtained by Palous and Bouvet[69] for sintered silver electrodes with circulating electrolyte and for flat silver electrodes subjected to different types of treatment. Mazitov et al.[71] obtained polarograms consisting of two waves for silver electrodes which had been subjected to preliminary heat treatment in a gas flame.

Many workers believe that both two-electron [reaction (2′)] and four-electron [reaction (1′)] processes occur in the ionisation of oxygen on silver. Thus Kabanov and Siver[73], who studied the ionisation of oxygen at a silver disc electrode in a weakly acid medium, found that the reduction of oxygen at an air-oxidised electrode involves two electrons, whereas the reduction at a reduced electrode involves three electrons over the entire range of angular velocities of the electrode during the reaction, which in the authors' view can be explained by supposing that the relative contributions of the two-electron and four-electron processes are in the proportions 1 : 1.

Delahay[74], who studied the reduction of oxygen on various metals by an analytical method, also concluded that the total number of electrons involved in the ionisation of oxygen on silver changes. He established that the number of electrons participating in the ionisation on silver in a neutral solution changes from three to four in the potential range 0.05–0.0 V. He explained this result by an increase in the rate of ionisation of hydrogen peroxide with increase in electrode polarisation.

Recently, data have been obtained in a number of studies[69,71] showing that the kinetics of the ionisation of oxygen depend on the state of the electrode surface, on the preliminary activation of the electrode, and on the presence of oxides or chemisorbed oxygen on the surface. Zhutaeva et al.[75] studied the ionisation of oxygen on silver by the method of the rotating disc electrode with a ring and also its combination with the triangular pulse method. They showed that the ionisation curve (Fig. 11, curve *1′*) does not have a distinct limiting current plateau and in the potential range between 0.4 and -0.1 V there is an approximately linear increase in current with potential. The overall number of electrons participating in the reaction in this potential range increases from 3 to 3.9–4.

Over the entire range of the rotation rates of the electrode (600–5000 rev min$^{-1}$) there is a discrepancy between the experimental current $I^d_{exp}$ and the diffusion current for the four-electron process $I^d_{theor}$, the discrepancy increasing with the rate of rotation of the electrode. Over the entire range of oxygen ionisation potentials an anodic current due to the oxidation of hydrogen peroxide is observed at the ring, which indicates the formation of hydrogen peroxide as an intermediate. When the polarisation curve for the ionisation of oxygen is "corrected" for the amount of unreacted hydrogen peroxide, curve *1′* (Fig. 11) with a limiting diffusion current plateau is obtained. This shows that the observed discrepancies between the experimental current and the diffusion current are due to the low rate of reduction of hydrogen peroxide.

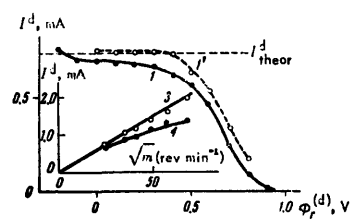

Fig. 11. 1) Polarisation curve for the reduction of oxygen at a silver disc electrode at a rate of rotation of the latter of 600 rev min$^{-1}$; 1′) currents corrected for the amount of unreacted hydrogen peroxide; 3) and 4) variation of the current at the disc electrode with $\sqrt{m}$ [3) limiting diffusion current; 4) current at $\varphi$ = 0.3 V]; open circles — corrected currents; data of Zhutaeva et al.[75]

The dependence of the currents at the ring electrode and also of the relative yield of hydrogen peroxide on the potential of the disc is presented in Fig. 12, which shows that, at a potential of 0.85 V in 1 *N* KOH, a 100% yield of hydrogen peroxide is observed, and therefore under these conditions the ionisation of oxygen proceeds by reaction (2′) with participation of two electrons. At less positive potentials there is at first a sharp and then a gradual decrease in the amount of hydrogen peroxide removed into the bulk of the solution. This is accompanied by an increase in the average number of electrons involved in the reaction. At a potential $\varphi_r$ of about 0.0 V the current corresponding to the four-electron process is attained. When the concentration of the KOH solution is varied, the region of the 100% yield of hydrogen peroxide also shifts; thus in 1 *N* KOH solution this yield is observed in the range of potentials $\varphi_r$ between 0.9 and 0.8 V, while in the solution at pH 7.2 it occurs over a wider range of potentials, $\varphi_r$ = = 1.2–0.8 V.

The polarisation curves for the ionisation of oxygen on silver show hysteresis, i.e. the reverse, anodic curves are displaced towards higher current densities. Comparison of the results obtained with a ring electrode with these data shows that the increase in current at the disc for the anodic curve is accompanied by a reduction in the amount of hydrogen peroxide detected at the ring. The observed acceleration of the ionisation of oxygen is associated with the reduction of the surface of the silver during the period corresponding to the cathodic curve. This is confirmed by the polarisation curves for the ionisation of oxygen measured at various amplitudes of triangular potential pulses applied to the silver electrode: from -0.2 V to *x* V, where *x* varies from 1 to 0 V (Fig. 13). These curves show that the degree of oxidation of the electrode increases, the current at the disc electrode falls, and the amount of hydrogen peroxide detected at the ring increases, as with the rhodium electrode. The retardation of the ionisation of oxygen when the degree of oxidation of silver increases may be due to the retardation of the reduction of hydrogen peroxide. It is also not impossible that on silver a fraction of the total current is associated with four-electron ionisation of oxygen, which takes place without intermediate formation of hydrogen peroxide [reactions (5) and (6)] and that this fraction varies with the potential.

Study of the kinetics of the ionisation of oxygen on silver in 1 *N* KOH solution showed that the *b* coefficient in

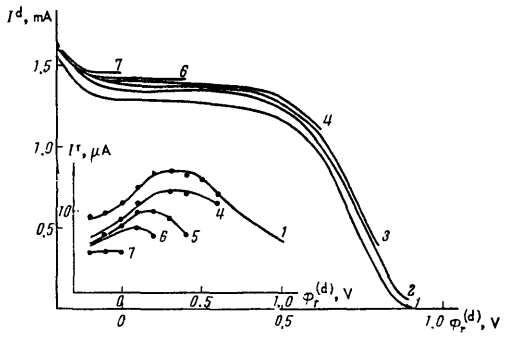

Fig. 13. Polarisation curves for the reduction of oxygen ($I^d$) and the variation of the current $I^r$ at the ring electrode with the potential of the disc electrode at $m$ = 2400 rev × ×min$^{-1}$ for different amplitudes of triangular pulses: 1) $\Delta\varphi$ between 1.0 and -0.2 V; 2) $\Delta\varphi$ between 0.9 and -0.2 V; 3) $\Delta\varphi$ between 0.8 and -0.2 V; 4) $\Delta\varphi$ between 0.6 and -0.2 V; 5) $\Delta\varphi$ between 0.4 and -0.2 V; 6) $\Delta\varphi$ between 0.2 and -0.2 V; 7) $\Delta\varphi$ between zero and -0.2 V; data of Zhutaeva et al.[75]

Eqn. (14), i.e. the slope of the polarisation curves and of the curves representing the variation of the potential with the logarithm of the partial pressure of oxygen, is 0.025–0.030 V. The value of the coefficient

$$\left(\frac{\partial\varphi}{\partial\,\mathrm{pH}}\right)_{i,\,P_{O_2}}$$

is approximately the same.

Fig. 14 presents the polarisation curve for the ionisation of oxygen and the oxidation of hydrogen peroxide in alkaline solution with added hydrogen peroxide, and shows that the cathodic and anodic branches form a single continuous curve merging into one another without an intermediate step. The continuity of the mixed polarisation curve and the displacement of the potential towards cathodic values with increase in the concentration of hydrogen peroxide show unambiguously that in the vicinity of the steady-state potential the system oxygen–hydrogen peroxide is at equilibrium. Thus the data suggest that relations similar to those observed with the mercury electrode obtain in the reduction of oxygen in an alkaline solution at potentials close to the steady-state value.

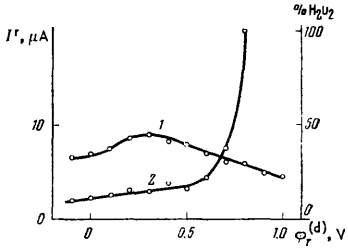

Fig. 12. Variation of the current at the ring electrode (curve 1) and of the ratio of hydrogen peroxide which failed to react at the disc electrode to $I^d_{exp}$ (curve 2) with the potential of the disc electrode at $m$ = 600 rev min$^{-1}$; data of Zhutaeva et al.[75]

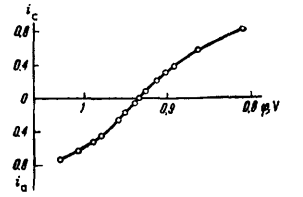

Fig. 14. Mixed anodic–cathodic polarisation curve for the reduction of oxygen and oxidation of hydrogen peroxide on silver in 1 *N* KOH solution.

The problem of different pathways for the reduction of surface silver oxides was also elucidated by a combination of the methods based on the rotating disc electrode with a ring and triangular potential pulses. It was shown that, over the entire range of rates of application of the potential, hydrogen peroxide was not detected at the ring. This suggests that oxygen adsorbed on silver during anodic polarisation is reduced directly to hydroxide ions.

The form of oxygen and the nature of its bond with the surface significantly affect the kinetics of its reduction. Silver is known to adsorb oxygen in large amounts. The presence of various forms of oxygen adsorbed on silver[77-83], with different reactivities, has a considerable effect on the kinetics of its reduction.

The effect of the form of adsorbed oxygen on its reduction on a carbon electrode was studied in detail by Frumkin and Burshtein[84]. They clearly showed that hydrogen peroxide is formed only from freshly adsorbed molecular oxygen. After the oxygen has remained for some time on the surface of the carbon, it is converted into the atomic form and is reduced to water.

It must be emphasised that many workers have concluded that at least part of the oxygen adsorbed on the surface of silver is present in the molecular form[85]. The method involving the application of trapezoidal potential pulses to the electrode can be usefully employed to characterise the strength of the bond between adsorbed oxygen and the surface of silver, which is to a large extent determined by the residence time of oxygen on the surface. In the experiments of Shumilova et al.[76] trapezoidal potential pulses were applied to a silver electrode at a rate of change of potential of 10 V $s^{-1}$, with an amplitude of 0–1.0 V, the electrode being maintained at 1.0 V for various times. At the same time $i-t$ curves were recorded at the potential corresponding to the horizontal section of the trapezium. The curves obtained show (Fig. 15) that, for periods during which the electrode is kept at a constant potential not exceeding the duration of the pulse (0.1 s), the amount of electricity passing through the electrode during the cathodic half-period of the pulse ($Q_c$) increases continuously with the period at fixed potential and the increment in $Q_c$ coincides with the value of $Q$ calculated from the $i-t$ curves. For periods exceeding 0.1 s, $Q$ remains constant while the amount of electricity passed through the electrode during this time continues to increase. The curves in Fig. 15 show that the current corresponding to the cathodic curves decreases in the potential range 1.0–0.75 V.

The observed increase of $Q_c$ when $\tau \leq 0.1$ s may be associated with the accumulation of oxygen on the surface of the electrode during the period at a constant potential. The phenomena which occur on further increase in this period (increase in the overvoltage for oxygen desorption processes and attainment of a constant value of $Q_c$) suggest that the bond between oxygen and the surface of silver becomes strengthened. The penetration of oxygen into the bulk of the metal is also possible. The latter possibility is confirmed by the observation of a current on $i-t$ curves up to $\tau = 1$ s, which indicates the occurrence of some processes on the electrode during the period when it is maintained at $\varphi = 1.0$ V.

---o0o---

The electrochemical reduction of oxygen is a complex electrochemical reaction whose mechanism can be established only by a wide variety of investigations. The present review shows that undoubted advances have been made in the study of this reaction on metallic electrodes, largely as a result of the development and application of new experimental techniques.

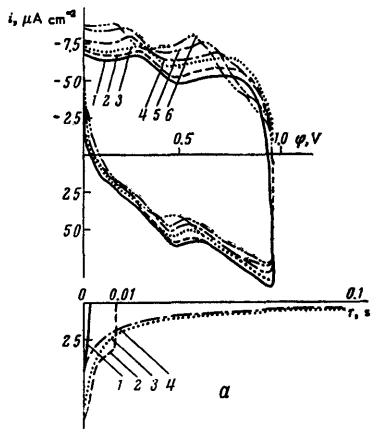

Fig. 15. $i-\varphi$ curves for silver in 1 $N$ KOH solution with pulses applied at a rate of change of potential of 10 V $s^{-1}$ and amplitude 0–1.0 V, and $i-t$ curves for the electrode maintained at $\varphi = 1.0$ V (horizontal section of the trapezium) for various times; $i-\varphi$ curves:
1) 40 μs; 2) 10 ms; 3) 100 ms; 4) 1 s; 5) 17 s; 6) 2 min;
*a*) $i-t$ curves at $\varphi = 1.0$ V:
1) 40 μs; 2) 10 ms; 3) 100 ms; 4) 300 ms; data of Shumilova et al.[76]

A large number of the experiments whose results are described in this article have been carried out in the Department of Electrochemistry in the Lomonosov Moscow State University and in the Institute of Electrochemistry of the USSR Academy of Sciences under the direction of A. N. Frumkin, who is responsible for many ideas on which the study of the electrochemical reduction of oxygen is based.

Despite these achievements, the problem of the cathodic reduction of oxygen is not exhausted. Many questions still remain unresolved. For example, the mechanism of the heterogeneous catalytic decomposition of hydrogen peroxide still remains obscure; the available data on the nature of the energy heterogeneity of the surface of solid electrodes, the nature and forms of adsorbed oxygen at various electrode potentials, etc., are inadequate.

However, bearing in mind the rapid development of the theory of electrochemical kinetics and the progress in the field of experimental techniques, there are grounds for a firm belief that many problems which are at present obscure will be successfully solved in the near future.

# STUDY OF THE STRUCTURE OF THE ELECTRICAL DOUBLE LAYER ON PLATINUM BY THE RADIOACTIVE TRACER METHOD

N. A. Balashova and V. E. Kazarinov

When a metal is immersed in a solution of an electrolyte, a layer whose structure has a powerful influence on the course of electrochemical reactions (as first pointed out by Frumkin) appears at the phase boundary.

The primary process in the formation of this surface layer is adsorption of ions, atoms, and molecules, determined by the electrical and chemical forces which operate at the interface and by the properties of the adsorbed species. The complexity of these processes and their specificity with respect to particular systems necessitate a detailed study by methods of very high accuracy and sensitivity.

The structure of the surface layer is usually investigated by a variety of electrochemical methods. These give an insight, specifically, into the very important influence of the potential drop at the electrode–electrolyte interface upon the primary process. A large number of these studies, particularly at the liquid mercury electrode, have been reported.

However, electrochemical methods cannot give direct access to the qualitative and quantitative composition of the surface layer. For this, the methods of analytical chemistry are required. Euler was the first to study the adsorption of silver ions on silver by a chemical method[1]. Frumkin and Obrucheva first demonstrated the relationship between ion adsorption and the formation of an electrical double layer on platinum by chemical titration[2]. Kolthoff and Kameda[3] studied the adsorption of electrolytes by similar methods. The determination of amounts adsorbed by chemical methods is very difficult, and sometimes even impossible, because of the minute amounts involved and of the lack of suitable analytical techniques: therefore, chemical methods have not been widely applied to these problems.

The radioactive tracer method, in which the element under study is labelled with one of its radioactive isotopes in solution or in the solid phase, has proved very fruitful in this respect. Changes in the radioactivity of the experimental system give a fast, accurate, and very reliable indication of the transfer of species across the phase boundary. This method is the most sensitive of all the existing methods for observing the behaviour of the components of a metal–electrolyte system, and has achieved increasing importance in recent years. Its earliest applications to the study of metal ion adsorption, exchange, and discharge processes are due to Hevesy and Paneth[4-7] and to Spitsyn[8], who used naturally occurring radioactive isotopes, and more recently to Joliot-Curie[9], Haissinsky[10], and Erbacher[11-13], who also used artificial radioactive isotopes. In recent years, the rate of publication of papers on the adsorption of ions on metals, using radioactive tracers, has been increasing steeply. Among the most noteworthy are those by Hackerman[14], who studied the adsorption of $SO_4^{2-}$ ions on iron, Heusler and Cartledge[15] and Iofa and Rozhdestvenskaya[16] on the adsorption of iodine on iron, Kolotyrkin and his coworkers on the adsorption of iodine on lead and silver[17,18], Schwabe and his coworkers on the adsorption of various ions on platinum[19-23], and others[24,26].

In all this work little attempt was made to measure the potentials of the adsorbents, and therefore the results cannot be used to characterise the relationship between the adsorption and the electrochemical behaviour of the metal–electrolyte system. A notable exception is the paper by Frumkin et al.[27], in which the adsorption of ions on platinum was studied by chemical titration, the change in the concentration of hydrogen ions in solution, due to the adsorption of cations and anions at different potentials, being determined. However, these changes characterise only the difference in extent of adsorption between anions and cations.

The present review discusses the results of the investigations of the double-layer structure and of the adsorption of ions on platinum, carried out in Frumkin's laboratory, using radioactive isotopes as indicators of the behaviour of the ions of interest. This work has relied on the simplest and most general radiochemical procedures, used in conjunction with electrochemical measurements — the typical approach of the Soviet workers in this field.

Concurrent measurements of adsorption and of the electrochemical parameters of the electrode provide information on the detailed structure of the surface layer, and on the direct relationship between the adsorption and the electrochemical behaviour of the layer. The radiochemical methods of identification and estimation of the amount adsorbed offer highly sensitive, simple, rapid, and specific measurements, and are therefore the most convenient. Frequently, they are the only direct method for investigating the dependence of the electrochemical behaviour of a metal upon the structure of the boundary between the metal and an electrolyte.

We shall show that this dependence is extremely important, and often determines the overall ionic adsorption at a metal surface resulting from electrostatic and also from other types of force operating at the solution boundary. In

addition to the studies of adsorption as a function of potential, work has been done on the kinetics of the adsorption of ions, their dependence on the concentration of ions in solution, the degree of irreversibility of the adsorption (as measured by desorption under various conditions and by the exchange of adsorbed ions with the ions of the electrolyte), the influence of pretreatment of the metal on the adsorption, and the possibility of penetration of adsorbed ions into the bulk of the metal.

Different variants of the procedure have been developed and used to deal with particular problems; these consist in measuring the radioactivity of the solution, or alternatively in measuring the radioactivity of the electrode still wet with a layer of solution or rinsed under specified conditions.

Great care was taken into the experiments to observe the particular conditions needed to achieve correct results. These conditions include: standard preparation of the electrode surface, radiochemical and chemical purity of the tracers, and correct choice of the ratios of area of the adsorbing surface to volume of solution and of concentration of stable ions to concentration of radioactive ions in solution.

There are now available several new methods, in a number of variants, for measuring adsorption from the change in radioactivity of a metal specimen without removing the specimen from the solution where adsorption has taken place. Many of these are developments of the method of Joliot-Curie, put forward as long ago as 1930. Modern methods of measuring adsorption by using radioactive tracers have already been reviewed[28,29]. Most of the researches discussed in this paper have made use of a method, developed at the Institute of Electrochemistry of the Academy of Sciences of the USSR, in which adsorption is measured from the change in radioactivity of the electrode, withdrawn from the solution at predetermined intervals. A correction for the activity of the wetting layer is applied.

Studies of the surface layer at a metal–solution interface become more complicated if the metal is corrodible. The platinum electrode is particularly convenient in this respect because exchange between ions in solution and the metal is practically absent, and also because its electrochemical behaviour is known in fair detail and this facilitates comparison with the adsorption behaviour. The electrochemical behaviour of the platinum electrode has been studied by a variety of methods by Frumkin and some of his students — Shlygin, Ershler, Veselovskii — and also by a number of foreign workers — Breiter, Knorr, Wicke and Weblus, Wiebe and Winkler, and others. On the basis of the experimental results[27] obtained by his school, Frumkin has developed a theory of the platinum electrode.

The results show that the electrochemical behaviour of platinum changes in the region between the hydrogen and the oxygen electrode potential, and that this can be explained by the adsorption of hydrogen, of ions from the solution, and of oxygen. Experiments with labelled ions on a platinum electrode polarised to a known potential have made possible a quantitative study of the fine details of the ion adsorption process.

If the simplest picture of the structure of the electrical double layer on metals in the absence of specific adsorption is adopted, preferential adsorption of cations and of anions should occur in the region of negative and positive potentials respectively. The adsorption of both kinds of ion should vanish at the zero-charge potential. If the adsorption of ions is not determined exclusively by the surface charge, adsorption can occur at the zero-charge potential as well as on a charged surface. Ions showing strong specific adsorption shift the point of zero charge of the metal. These predictions of the theory have been repeatedly confirmed by experiments on mercury, but for solid metals there were practically no data of this type prior to the use of radioactive tracers.

According to their adsorption behaviour on mercury, ions can be classified into two groups: the surface-active and the surface-inactive.

We shall give an account of the results which have been reported on the adsorption of sulphate and phosphate anions, considered to be surface-inactive, and on the adsorption of chloride, bromide, and iodide anions, which are typical surface-active anions. Anion adsorption has been studied either separately from or jointly with the adsorption of the surface-inactive cations of sodium, caesium, calcium, and barium in acid and in alkaline solutions, and the surface-active cadmium cations in acid solutions.

Analysis of the results on the simultaneous adsorption of cations and anions leads to a complete picture of the structure of the electrical double layer and of the position of the point of zero charge of the metal. The idea was put forward by Frumkin and developed by his school.

Different anions are adsorbed to different extents at a given potential. Plots of anion and cation adsorption against potential for platinised platinum in acid and alkaline solutions of their salts are shown in Figs. 1–6. In some experiments the change in hydrogen ion concentration in solution corresponding to the difference between anion and cation adsorption was measured in parallel with the radiochemical measurements of the adsorption of anions and cations. In Figs. 2 and 3 this change is denoted by $\Gamma_{H^+}$, and referred to 1 cm² of true surface area. Increase in hydrogen ion concentration indicates preferential adsorption of cations ($-\Gamma_{H^+}$), whereas a decrease indicates preferential adsorption of anions ($+\Gamma_{H^+}$).

In Figs. 2 and 3, taken from Kazarinov[31], the curves for the anions, obtained from measurements of hydrogen ion concentration, are shown by broken lines (curves *2*). The intersection between these curves and the adsorption curves for $Na^+$ cations (curves *1*) provides an accurate value for the zero-charge potential of platinum. In the

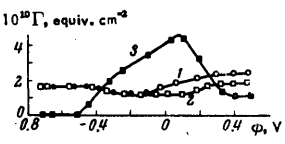

Fig.5. Variation of the extent of adsorption of $Br^-$ anions and $Na^+$ cations with platinum potential; solution $10^{-2}$ *N* NaBr + + $10^{-2}$ *N* NaOH (curve 2 for $Na^+$ and curve 3 for $Br^-$); curve 1 is for a $10^{-2}$ *N* NaOH solution; data of Kazarinov[32].

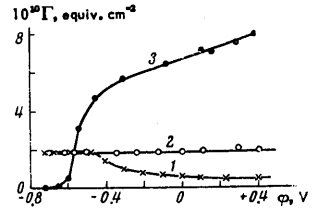

Fig.6. Variation of the extent of adsorption of $I^-$ anions and $Cs^+$ cations with potential in alkaline solution; curve 1 is for $Cs^+$ and curve 3 is for $I^-$ in $10^{-2}$ *N* CsI + $10^{-2}$ *N* CsOH; curve 2 is for $Cs^+$ in $10^{-2}$ *N* CsOH; data of Kazarinov[32].

absence of specific adsorption of ions, the charge of the ionic double layer should be zero, but it is easy to see from the Table and from the figures that such is not the case, even in a solution of sulphuric acid and caesium sulphate. The extent of adsorption at the zero-charge potential in this solution amounts to $1.50 \times 10^{-11}$ g-ion × × cm$^{-2}$, or 1/6 of the maximum extent of adsorption, corresponding to 0.01 of a monolayer. The tabulated data show that on changing from sulphate to halide anions, the extent of the superequivalent anion adsorption increases in the sequence $Cl^- < Br^- < I^-$ (since the cation remains the same). The same is true of changing from acid to alkaline solutions.

Figs. 1–6 show that the zero-charge potential in halide solutions is shifted towards more negative values as compared with its position in sulphate solutions. This shift is more marked, the higher the surface activity of the anion, i.e. it increases in the series $Cl^- < Br^- \ll I^-$. In an iodide solution and at potentials between -0.2 V and 0.06 V, in which the platinum surface carries a positive charge, $Na^+$ cations are adsorbed at the same time as iodide ions (Fig. 4). This means that iodide ions are adsorbed on the positively charged surface in greater numbers than required by the charge. The superequivalent adsorption of anions causes cation adsorption. Consequently, adsorption of iodide ions from acid solution reverses the charge of a platinum surface.

The zero-charge potentials obtained for acid solutions containing $SO_4^{2-}$, $Cl^-$, and $Br^-$ anions are in satisfactory agreement with the results given by other methods[27,33],

TABLE*.

| Solution | Zero-charge potential $\varphi_0$, V (n. hydrogen e-de) | Shift of $\varphi_0$, V | $10^{11}$ × extent of adsorption at $\varphi_0$, g-ion cm$^{-2}$ |

* All potentials are relative to the normal hydrogen electrode.

thus confirming the value of the radiochemical method in these systems. Comparative data for the other zero--charge potentials do not exist in the literature.

As Fig. 1 shows, the extent of cation adsorption in an acid solution of caesium sulphate is practically constant in the neighbourhood of the hydrogen potential. This is because the adsorption of cations depends on the number of hydrogen atoms adsorbed, which also contribute to the creation of a potential drop in this region.

In accordance with theory, the extent of anion adsorption increases and that of cation adsorption decreases as the platinum surface acquires a positive charge in acid solution, until a potential is reached where oxygen adsorption sets in (as shown by the charging curves). Oxygen and platinum form dipoles which are oriented with their negative ends towards the solution[27]. Before oxidation begins, the anions differ in extent of adsorption, in their influence on the position of the zero-charge potential, and in the degree of irreversibility of their adsorption. These differences are more marked, the greater the difference in surface activity of the anions. The $SO_4^{2-}$ anions are the least surface-active on platinum, the surface activity increasing from sulphate to phosphate and further to the chloride, bromide, and iodide anions. These differences, associated with the nature of the anion, completely determine the behaviour of platinum towards oxygen. If the surface activity of the anion is much less than that of oxygen, oxygen is readily adsorbed on the platinum and displaces previously adsorbed anions into the solution. This effect has been observed under equilibrium conditions only with the sulphate anion. In this case, changing the potential from the hydrogen potential towards more positive values produces an adsorption curve with a maximum at the potential of incipient oxygen adsorption. At this maximum, the adsorption of sulphate anions amounts to ~18% of full coverage by sulphate. Therefore, even though ~80% of the surface remains free of $SO_4^{2-}$ anions, the oxygen dislodges into the solution most of the adsorbed anions when it becomes adsorbed and forms dipoles with the platinum. The $SO_4^{2-}$ anions which are more firmly held (not by electrostatic forces) may not be fully desorbed under these conditions, as shown by the curves of Fig. 1.

In every other solution which has been examined, the previously adsorbed anions are so firmly bound to the platinum that oxygen adsorption is hindered in proportion to the stability of the anion–metal bond, i.e. in proportion to the observed irreversibility of the adsorption. These barriers to oxygen adsorption take the form of an increase in the adsorption potential, as shown by the charging curves. The effect was first reported by Ershler[34] for $Cl^-$, and later by Obrucheva[35] for $Cl^-$ and $Br^-$. Adsorption–potential curves for the anions $H_2PO_4^-$, $Cl^-$, $Br^-$, and $I^-$ on a platinum surface not previously oxidised do not show a maximum.

The adsorption maximum observed (Fig. 5) for bromide anions in alkaline solution can be explained as follows. In the potential region from -0.2 V to the potential of the adsorption maximum the whole of the charge is expended effectively upon bromine adsorption, since the electrode capacity as calculated from the adsorption curves and the charging curves has the constant value 70 $\mu F\ cm^{-2}$. Hence, oxygen adsorption does not occur in this region. It can be seen from the charging curve that oxygen adsorption sets in at the potential of the maximum on the adsorption curve. The adsorbed oxygen displaces most of the bromine from the platinum surface. The residual trace of chemisorbed bromine is probably incorporated into the oxide film which forms on the platinum. Thus, the behaviour of the strongly surface-active bromide ions in alkaline solution is reminiscent of that of the weakly surface-active $SO_4^{2-}$ anions in acid solution.

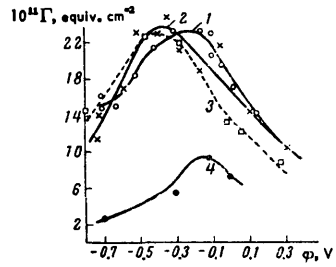

Fig. 7. Variation with potential of the extent of adsorption of cations from alkaline solution:
1) for $Ca^{2+}$ from $10^{-3}$ *N* $Ca(OH)_2$; 2) for $Ba^{2+}$ from $10^{-3}$ *N* $Ba(OH)_2$; 3) for $Ba^{2+}$ from $10^{-3}$ *N* $Ba(OH)_2$ + 1 *N* NaOH; 4) for $Ca^{2+}$ from $10^{-3}$ *N* $Ca(OH)_2$ + 1 *N* NaOH.

It is interesting to note that adsorption curves of the same general trend are observed during cation adsorption, in particular with calcium and barium on non-oxidised platinum in alkaline solutions (Fig. 7), although the maximum is entirely different in nature[36]. In the adsorption of these cations the increase of adsorption with potential up to a maximum may be due to oxygen adsorption. This is suggested, firstly, by the lack of a cation adsorption maximum on platinum which has not been carefully reduced. Secondly, it has been shown experimentally that complete desorption of calcium and barium cations requires decomposition of the oxide film (achieved by prolonged exposure to acid or, more rapidly, by cathodic polarisation of the electrode in an acid medium). Radiochemical measurements of the exchange between adsorbed $Ca^{2+}$ and $Ba^{2+}$ cations and the same cations in solution have shown that the strength of the bond between the adsorbed cations and the platinum depends on the adsorption potential. When adsorption takes place from alkaline solution at the hydrogen potential, exchange in a hydrogen atmosphere and in $Ca(OH)_2$ or $Ba(OH)_2$ solution proceeds to the extent of 26% in one minute, but after adsorption at the maximum potential or at still more positive potentials the exchange is strongly retarded. Thus, at an adsorption potential of 0.48 V exchange occurs to the extent of only ~6% in the same time. It is evident that over the whole of the potential region examined the cations are incorporated into the oxide film, but at potentials more positive than the maximum the binding of the cations to the adsorbed oxygen is weaker than at less positive potentials and some of the cations pass into the solution. This effect may be associated with the different degree of hydration of oxides formed at different potentials in alkaline solution.

The doubly charged cations $Ca^{2+}$ and $Ba^{2+}$, when adsorbed from acid solution, are more weakly bound to the platinum over the whole range of potentials than cations similarly adsorbed from alkaline solutions. Thus, $Ca^{2+}$ and $Ba^{2+}$ undergo almost complete exchange with their ions in solution (~96–100% in one minute) when adsorbed from acid solution at the hydrogen potential, at which the platinum

remains unoxidised. If the platinum is not given a preliminary reducing treatment the exchange proceeds only to the extent of 70–80%. At the potential which platinum attains in air, exchange of adsorbed cations is either undetectable or relatively small.

All these results show that cations are firmly bound to the oxide film on platinum after being adsorbed. As a result of this work, we are able to explain the mechanism of the influence of doubly charged cations on the reduction of oxygen on platinum in acid and in alkaline solutions. The phenomenon was observed in studies[37,38] of the electrochemical reduction of oxygen at a platinum electrode. It was found that small amounts ($10^{-3}$ *N* in 1 *N* NaOH) of calcium, strontium, or barium salts decrease, in that order, the current efficiency of the formation of hydrogen peroxide by oxygen reduction. Balashova and Kulezneva[36] showed that under the conditions of the electrolysis experiments these cations are adsorbed and form adsorbed compounds with oxygen and platinum which are more stable than the compounds formed in the absence of the cations. The presence of a thousandfold excess of sodium cations decreases the extent of adsorption of $Ca^{2+}$ (see curve *4* of Fig. 7), but has practically no effect on the adsorption of $Ba^{2+}$ (curve *3* of Fig. 7), which accounts for the more marked effect of the latter cation.

In acid solutions the adsorption of the doubly charged cations $Ca^{2+}$ and $Ba^{2+}$ varies with potential in much the same way as the adsorption of singly charged cations (Fig. 8); at the potentials corresponding to incipient electrochemical reduction of oxygen the extent of adsorption of the cations $Ca^{2+}$ and $Ba^{2+}$ is small, and cannot have an appreciable effect on the process.

Müller and Sobol'[38] also concluded that the oxide film is stabilised by calcium, strontium, and barium cations. Those workers studied the effect of these cations on the polarisation curves obtained at a rotating disc platinum electrode combined with a ring electrode, and were able to demonstrate by their sensitive procedure the features of the separate stages in the reduction of oxygen in the presence of doubly charged cations.

Radiochemical and electrochemical measurements of the adsorption of anions on previously oxidised platinum have shown that the greater the adsorption of oxygen and the more stable its bonding to the platinum, the slower is the adsorption of anions, even when their surface activity is quite high. Thus, for example, bromide anions are adsorbed very slowly on platinum oxidised to a potential of 1.2 V, because they are required to dislodge previously adsorbed oxygen. However, if some of the adsorbed oxygen is removed by cathodic polarisation, rapid adsorption of the anion occurs and continues until the oxygen is completely removed[39]. Desorption of the anions begins at potentials such that hydrogen already imparts a negative charge to the surface. As a result, a maximum appears on the extent of adsorption–potential curves for the adsorption of a surface-active anion on previously oxidised platinum.

The retardation of anion adsorption by previously adsorbed oxygen is easily followed by radiochemical measurements of adsorption on platinum oxidised in air for different times. Experiments of this type have shown that the adsorption of the anions $Br^-$, $H_2PO_4^-$, etc., becomes slower, the longer the oxidation time of the platinum, i.e. the greater the adsorption of oxygen and the stronger its binding to the metal surface[39,40]. The difference in time of adsorption on oxidised platinum of different anions demonstrates the higher stability of the anion–platinum bond as compared with the oxygen–platinum bond. Slow anion adsorption on platinum is observed only in the presence of oxygen adsorbed on the platinum. As Schwabe and his coworkers have shown[20], on vacuum-deposited platinum the adsorption of surface-active anions goes to completion very rapidly (in less than one minute), whereas many hours are needed when the surface has been oxidised.

Some very interesting results have been obtained by the radiochemical method on the kinetics of simultaneous adsorption of iodide anions and caesium cations from alkaline solution on platinised platinum (Fig. 9). Curves *1* and *1′* describe the adsorption kinetics of the two kinds of ion on platinum previously oxidised in air for 30 min, curves *2* and *2′* refer to platinum oxidised for 16 h. During the initial period of the adsorption process cation adsorption is significantly higher than anion adsorption. The iodide anions are adsorbed slowly because they have to dislodge the previously adsorbed oxygen, whereas the cations can attach themselves directly to the oxide film. However, the extent of anion adsorption increases with time whilst that of cation adsorption decreases. The longer the preliminary oxidation of the platinum, the more is the falling off of the extent of cation adsorption delayed. The slope of the kinetic curves for the anions varies with time, denoting a change in the rate of adsorption, which is consistent with the displacement, initially, of the less firmly bound oxygen, and afterwards of the oxygen which

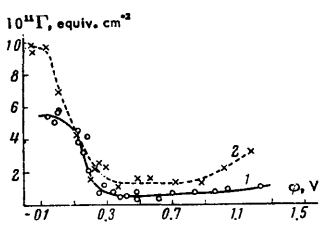

Fig. 8. Variation with potential of the extent of adsorption of the cations $Ca^{2+}$ (curve 1) and $Ba^{2+}$ (curve 2) from acid solutions [$10^{-3}$ *N* $HClO_4$ + $10^{-3}$ *N* $Ca(ClO_4)_2$ and $10^{-3}$ *N* $HClO_4$ + + $10^{-3}$ *N* $Ba(ClO_4)_2$ respectively].

1) and 1′) 30 min oxidation; 2) and 2′) 16 h oxidation.

is more firmly bound by virtue of the incorporation of cations. When the Pt–O–Cs bond is disrupted, the stable Pt–I bond can be formed.

We have recently obtained† some results on the adsorption of the surface-active $Cd^{2+}$ cations on platinised platinum which demonstrate an appreciable similarity in behaviour (and in the effect on the structure of the surface layer at the platinum–solution boundary) between cation adsorption and anion adsorption in the presence of sufficiently high surface activity. A proof of the surface activity of cadmium cations was given by Frumkin and his coworkers in a series of investigations by different methods[41–45]. In our own work, we showed with the help of the radioactive isotope $^{115}Cd$ that the adsorption of doubly charged $Cd^{2+}$ cations is very sensitive to the potential and is closely bound up with the adsorption of hydrogen and oxygen on platinum.

Fig. 10 shows the variation of the adsorption of $Cd^{2+}$ with potential: a large maximum occurs near the reversible hydrogen potential. Its origin is not entirely clear, but the maximum is evidently related to the adsorption of hydrogen atoms.

The most interesting feature of the adsorption of $Cd^{2+}$ cations is the positive shift by 700 mV of the point of zero charge as compared with its position in a solution of $Na_2SO_4$.

The extent of adsorption of $Cd^{2+}$ is greatly in excess of that of $Na^+$ cations at all potentials. At the hydrogen potential the extent of adsorption of $Cd^{2+}$ cations amounts to $3 \times 10^{-10}$ g-ion per $cm^2$ of true surface area, i.e. about ten times higher than the extent of adsorption of $Na^+$ cations. This value is unusually high for ionic adsorption: it corresponds to a ratio of 1 cadmium ion to 6 platinum atoms, as compared with 1 singly charged ion to 36 platinum atoms in the case of $Na^+$ adsorption.

Charging curves obtained under the same conditions as the experiments on ion adsorption show that cadmium cations lower the extent of adsorption of hydrogen and oxygen on platinum whilst the charging curve is being explored. $Cd^{2+}$ cations compete with these gases for adsorption on the platinum, just as in the adsorption of the surface-active anions $Br^-$ and $I^-$. The high extent of adsorption of the $Cd^{2+}$ cations, the great stability of their bonds with platinum, and the large shift of the zero-charge point of platinum all point to a chemisorptive type of adsorption for these cations. The $Cd^{2+}$ ions form dipoles with the platinum atoms, with their positive ends pointing into the solution, which should give rise to a negative potential jump at the metal–solution interface. However, the $Cd^{2+}$ ions which are adsorbed in amounts more than equivalent to the charge attract $SO_4^{2-}$ anions at potentials more negative than the zero-charge potential in $CdSO_4$ solution, and as a result the potential jump is actually positive.

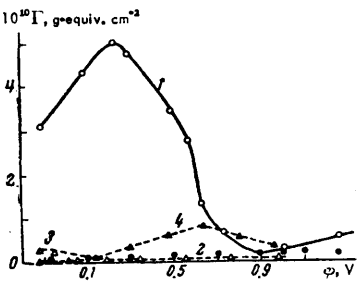

Fig. 10. Variation with potential of the extent of adsorption of cations and anions in acid solution; solutions:
1) and 2) $10^{-2}$ *N* $CdSO_4 + 10^{-2}$ *N* $H_2SO_4$; 3) and 4) $10^{-2}$ *N* $Na_2SO_4 + 10^{-2}$ *N* $H_2SO_4$.

† With the assistance of G. Mansurov.

When the electrolyte contains both surface-active $Cd^{2+}$ cations and surface-active $Br^-$ and $I^-$ anions, the resulting effects on the structure of the surface layer are very complex. Cations and anions compete for adsorption on the platinum, and the net mutual effect is a sensitive function of the surface activities, of the rate of approach to adsorption equilibrium, and of the initial state of the surface.

As an example, the Table shows the zero-charge potentials of platinum under conditions of simultaneous adsorption of surface-active $Cd^{2+}$ cations and $Br^-$ and $I^-$ anions. It is evident from these data that the anions $Br^-$ and $I^-$ have a more pronounced influence on the value of the zero-charge potential than the $Cd^{2+}$ cations under the experimental conditions described above. As a result, the zero-charge potential shifts towards more negative values than cadmium sulphate solution in both cases, but especially so in the case of $I^-$. The effect of adsorbed cadmium cations is quite appreciable, however, since the zero-charge potential is more positive in cadmium bromide or cadmium iodide solutions than in sodium bromide or sodium iodide solutions.

Thus, all the results obtained for the adsorption of cations and anions on platinised platinum from acid or alkaline solutions point to the great complexity and specificity of the phenomena occurring at the platinum–electrolyte boundary. Detailed analysis of these data and comparison with the analogous data obtained for mercury indicates that the structure of the electrical double layer on platinum has a number of specific features. It follows that the concepts of the structure of the double layer on liquid mercury are not always applicable to solid metallic electrodes.

Allowance for the effect of cation and anion adsorption from the electrolyte and for the structure of the surface layer at the platinum–electrolyte boundary is essential in studies of the kinetics of electrode processes with platinum electrodes. This has recently been discussed by Frumkin[46].

## I. INTRODUCTION

The earliest observations of properties characteristic of semiconductors in organic compounds were made with some polynuclear hydrocarbons and dyestuffs. Studies of the electrophysical properties of various compounds as a function of their structure led to the conclusion that semiconductor properties arise when a sufficiently well-developed system of conjugated double bonds is present in the molecules. This problem has been the object of many investigations, and has been discussed in a number of review articles [1-3]. It is now well established that organic polymers as well as low-molecular-weight compounds can exhibit semiconductor properties. This widens the scope of possible applications, since the synthesis of polymers with technologically desirable mechanical properties offers the advantages of controlled structure and controlled properties.

Polymeric semiconductors can be prepared either by synthesis from monomers which offer the necessary system of conjugated bonds, or by inducing polyconjugation into the complete polymers by one of several methods. In the former case the possibilities of generating polymers of different structures are almost limitless, but the resulting materials are mostly insoluble and infusible powders, and their molecular weight is not very high. It is possible also to convert a polymeric dielectric gradually into a polymeric semiconductor by radiation-induced structural changes followed by heat treatment. Many studies of the pyrolysis of polymers have been published. The electrophysical properties of the products have been most fully investigated for polyvinylbenzene [4] and polyacrylonitrile [5] for which heat treatment is clearly shown to be a very effective way of raising the conductivity.

Polyethylene is a suitable material for this purpose, because it has a stable polymeric structure and the effect of radiation on it has been studied in detail. It is well known that irradiation develops a structure in polyethylene,

forming 5–7-membered rings with the loss of a significant amount of hydrogen. The basic problem is to find the cross-linking and cyclisation conditions for the linear macromolecules which will lead to the creation of a unified structure, susceptible to subsequent heat treatment, and also to identify the mechanism giving rise to semiconductor properties.

The electrophysical and paramagnetic properties of the products of the radiation-thermal modification of polyethylene (RTMP) have been studied as a function of the dose of radiation absorbed and of the heat-treatment conditions. The following properties have been studied over a wide range of values: the conductivity in a d.c. or a.c. field, its temperature coefficient, the differential thermo-e.m.f., the structure of the products (by ESR and infrared spectroscopy), and lastly the effect of additives and the photoconductivity.

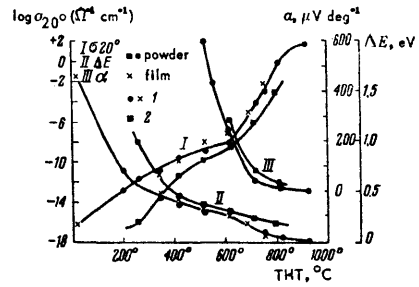

Fig. 1. Variation of electrical characteristics with dose and THT:
1) $D = 2.4 \times 10^4$ Mrad; 2) $D = 1.2 \times 10^3$ Mrad.

## II. PROCEDURE

The products of RTMP have been studied in powder form and as films. The films were deposited as already described[6] on glass or quartz substrates carrying deposited gold electrodes. The samples were irradiated in evacuated quartz bulbs (~ $10^{-5}$ mmHg) with fast electrons (5 MeV) from a U-12 accelerator. The heat treatment of the irradiated samples was by a standard procedure (brief oxidation at 260° followed by pyrolysis in a vacuum[7,8]). The d.c. electrical characteristics of specimens were studied in a vacuum (~ $10^{-5}$ mmHg).[8] Thin-film specimens were examined in surface or multilayer cells, inserted into a special holder. The electrophysical properties of the specimens in powder form were measured in a cell with platinum disc electrodes, at temperatures between 20° and 150° *in vacuo* and in air, and between 20° and -50° for the experiments on specimens with adsorbed iodine.

The d.c. measurements were made with an E6-3 teraohmmeter or with an MO-47 bridge (for low-resistance specimens). The conductivity in an alternating field was measured with an E 10-2 impedance bridge.

Iodine adsorption was measured gravimetrically on a McBain balance, with a temperature control of ±1°C.

The structural properties of the RTMP products were investigated by ESR on an RE 1301 radio-frequency spectrometer.

## III. ELECTRICAL PROPERTIES

Most of the results discussed in the present paper were obtained on RTMP films. The electrophysical properties were studied on samples of polyethylene irradiated with three distinct doses[7]: $1.2 \times 10^3$, $6.9 \times 10^3$, and $2.4 \times 10^4$ Mrad.

Conductivity measurements in the temperature range -25°–150° were in satisfactory agreement with the exponential relationship

$$\sigma = \sigma_0 \exp(-\Delta E/kT).$$

Measurements of differential thermo-e.m.f. showed that the resulting materials are *p*-type semiconductors. Between -50° and 150° the differential thermo-e.m.f. $\alpha$ is independent of the mean specimen temperature within the experimental error. Values of $\sigma_{20°}$, $\Delta E$, and $\alpha$ for specimens in powder and in film form are plotted in Fig. 1 against the temperature of heat treatment (THT) for different doses of radiation.

The figure shows that, by varying the dose and the THT, it is possible to obtain materials for which $\alpha$ varies from 1.5 $\mu$V deg$^{-1}$ to values in excess of 500 $\mu$V deg$^{-1}$, $\sigma_{20°}$ varies from $10^{-14}$ to $10^2$ $\Omega^{-1}$ cm$^{-1}$, and $\Delta E$ from 1.5 to 0 eV. The preliminary heat treatment has a profound effect on the electrophysical properties of the resulting materials. As can be seen from Fig. 1, prescribed values of $\sigma_{20°}$, $\Delta E$, and $\alpha$ are obtained at lower THT, the higher the dose of radiation absorbed by the specimens. The figure also shows that the electrical characteristics of specimens in film and in powder form are in tolerably good agreement. The electronic nature of the conductivity was demonstrated on low-resistance specimens by electrolysis.

Studies of the voltage–current characteristics of different materials have shown that Ohm's law is obeyed at fields between 1 and $2.5 \times 10^3$ V cm$^{-1}$, and that the plot of current against voltage begins to depart from linearity only at fields > $(2.5–5) \times 10^3$ V cm$^{-1}$ (see Fig. 2).

The results summarised in Fig. 1 indicate that materials of different electrophysical characteristics can be prepared by varying either the dose of radiation ($D$) or the THT. Furthermore, as we shall show below, the electrical properties of the products of RTM of polyethylene can also be altered significantly by introducing electron-acceptor impurities (oxygen, iodine). Nevertheless, it can be shown that the nature of the observed electrophysical properties is the same for all the materials, and is determined by their structural characteristics. This involves studying the electrophysical properties as a function not of the dose or the THT, which characterise the preparative conditions used, but of a parameter of the material itself, such as $\sigma_{20°}$. Fig. 3 shows the relationship between $\Delta E$, $\alpha$, and $\sigma_{20°}$ for RTM polyethylene: it is evident that the materials, whether in powder or in film form, obey a common, fairly simple functional relation between $\Delta E$ and $\sigma_{20°}$ irrespective of the dose, THT, or added impurities. This leads us to conclude that the conduction mechanism is the same for all the specimens which have been examined, and that the change in electrical characteristics is fundamentally dictated, as will be shown below, by changes in the height of the potential barriers $\Delta E$ separating regions of polyconjugation.

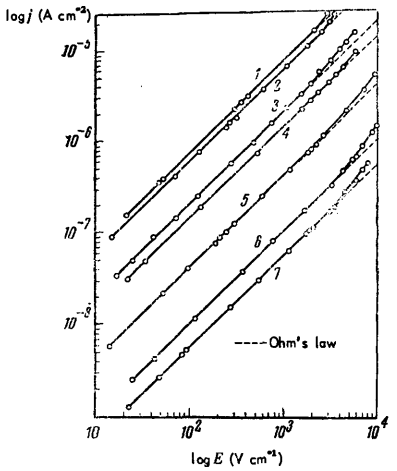

Fig. 2. Current–voltage characteristics of the specimens;
$D = 1.2 \times 10^3$ Mrad: 1) THT = 620°; 6) THT = 520°;
$D = 6.9 \times 10^3$ Mrad: 2) THT = 620°; 4) THT = 520°;
7) THT = 360°;
$D = 2.4 \times 10^4$ Mrad: 3) THT = 530°; 50 THT = 440°.

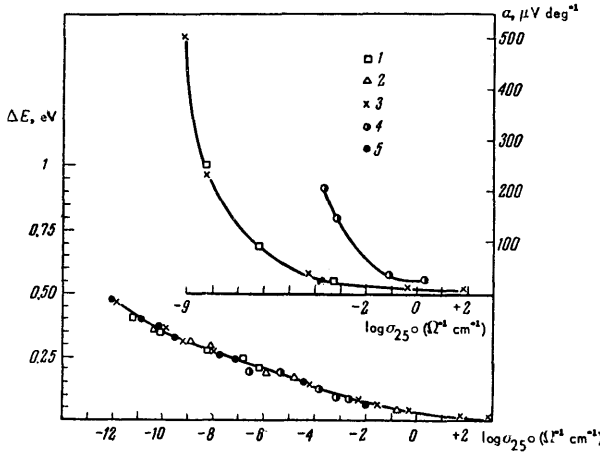

Fig. 3. Relationship between $\sigma_{20°}$, $\Delta E$, and $\alpha$.
Powders: 1) $D = 1.2 \times 10^3$ Mrad; 2) $D = 6.9 \times 10^3$ Mrad; 3) $D = 2.4 \times 10^4$ Mrad; 4) $D = 2.4 \times 10^4$ Mrad + $I_2$ at 20°.
Films: 5) $D = 2.4 \times 10^4$ Mrad.

The change in work function of the products of RTMP as a function of THT is of considerable interest. Boguslavskii's measurements[9] of contact potential difference (CPD) of RTMP films with respect to the glass electrode by the vibrating condenser method reveal a systematic lowering in work function with increasing THT. Table 1 gives the values of work function of the films, and also the activation energies for conduction, as a function of THT. The changes in work function and in activation energy for conduction of specimens prepared at different THT, relative to a specimen prepared at a THT of 720°, are also tabulated.

The agreement between the values of $\Delta E$ and $\varphi$, listed in the last two columns of Table 1, is satisfactory.

TABLE 1.

| $D = 2.4 \times 10^4$ Mrad THT, °C | Contact p.d., V | $\Delta E$, eV | $\varphi$, V | $\Delta E - \Delta E_{720°}$, eV | $\varphi - \varphi_{720°}$, V |
|---|---|---|---|---|---|
| 360 | +0.16 | 0.50 | 5.23 | 0.35 | 0.51 |
| 510 | −0.16 | 0.33 | 4.91 | 0.18 | 0.19 |
| 650 | −0.22 | 0.25 | 4.85 | 0.10 | 0.13 |
| 720 | −0.35 | 0.15 | 4.72 | 0 | 0 |

The frequency dependence (up to 30 Mc/s) of the conductivity of films prepared at different THT has also been investigated[6]: the results are shown in Fig. 4. As a rule, the conductivity increases with increase of frequency and reaches a plateau at 10–20 Mc/s, the frequency at which saturation is reached being lower for the higher THT. For a high-conductivity specimen prepared at a THT of 750°, practically no dispersion of conductivity with frequency is observed. Whereas the d.c. conductivity $\sigma_{20°}$ lies between limits 10 orders of magnitude apart, the conductivity of the same specimens in the region of the plateau ($\sigma_f$) at 10–20 Mc/s frequency spans only two orders of magnitude.

The variation of conductivity with frequency has been measured at different temperatures. Fig. 5 shows that higher measurement temperatures lower the frequency at which the conductivity plateau is reached. (These data refer to a THT of 420°.) The increase of conductivity with temperature in the region of the plateau gives an activation energy of $\Delta E_f \simeq 0.05$ eV, whereas the same specimen in a d.c. field has $\Delta E \simeq 0.5$ eV.

The effect of oxygen on the a.c. conductivity has been investigated. In contrast to the d.c. measurements, where oxygen raises the conductivity and lowers the activation

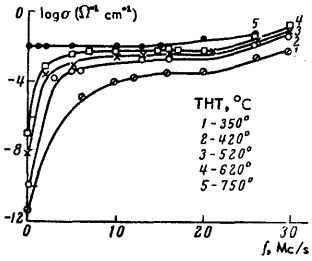

Fig. 4. Frequency dependence of the conductivity of specimens with different THT;
$D = 2.4 \times 10^4$ Mrad.

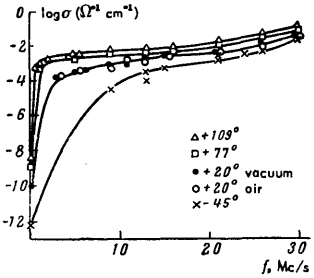

Fig. 5. Variation of conductivity with frequency at different temperatures; specimen with a THT of 440°; $D = 2.4 \times 10^4$ Mrad.

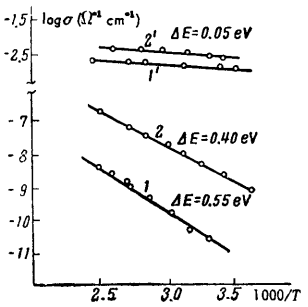

Fig. 6. Temperature dependence of conductivity:
1) and 2) d.c.; 1′) and 2′) 16 Mc/s; 1) and 1′) THT 330°; 2) and 2′) THT 460°.

energy, the conductivity in an a.c. field is quite insensitive to oxygen: Fig. 5 shows that measurements *in vacuo* and in oxygen give identical results.

Fig. 6 shows the temperature variation of the conductivity in a d.c. field and at a frequency of 16 Mc/s (i.e. in the plateau region) for two specimens. It is interesting to compare the values of $\sigma_0$ (from measurements in a d.c. field) and $\sigma_f$ (in the plateau region) for given specimens. As shown in Table 2, $\sigma_0$ and $\sigma_f$ are of the same order of magnitude for all specimens.

In the surface cell film conductivities could be studied up to the temperatures at which the specimens had been prepared, even while the heat treatment was in progress. It was found that conductivity measurements above 250° gave an activation energy for conduction well in excess of the value obtained from measurements between 20° and 150°. Thus, the activation energy calculated from the temperature dependence in the region 20–200° for polyethylene films prepared at a THT of 440° is 0.40 eV, whereas in the temperature range from 250° to 420° the value is 0.90 eV. The corresponding values for specimens with a THT of 520° are 0.30 and 0.75 eV in the low- and the high-temperature region respectively.

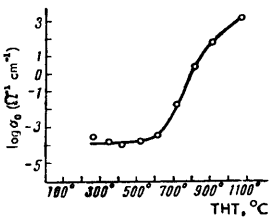

Fig. 7. Variation of $\sigma_0$ with THT.

TABLE 2*.

| THT, °C | $\sigma_0$, Ω⁻¹ cm⁻¹ | $\sigma_f$, Ω⁻¹ cm⁻¹ |
|---|---|---|
| 350 | $1 \times 10^{-3}$ | $2.5 \times 10^{-4}$ |
| 420 | $1.5 \times 10^{-3}$ | $4 \times 10^{-3}$ |
| 520 | $3 \times 10^{-3}$ | $4 \times 10^{-3}$ |
| 620 | $5 \times 10^{-3}$ | $6 \times 10^{-3}$ |
| 760 | $2 \times 10^{-2}$ | $1 \times 10^{-3}$ |

* The variation of $\sigma_0$ with THT is presented in Fig. 7.

Optical and photoelectric effects on RTMP films have been examined[10]. The long-wave absorption edge and the photoelectric sensitivity maximum are both shifted towards the infrared region as the THT is raised.

These observations on the frequency and temperature dependence of the conductivity have led to the hypothesis that the products of RTM of polyethylene have a micro-heterogeneous structure, characterised by regions of high conductivity separated by poorly conducting regions which give rise to the barrier mechanism of current flow.

## IV. ELECTRON SPIN RESONANCE

The electron spin resonance (ESR) method has been used to examine the correctness of this hypothesis. ESR studies of the products of radiation-induced and radiation--thermal modification of polyethylene rely on observations of the shape and width of the ESR line, of the saturation effect, and also of the interaction between paramagnetic centres (p.m.c.) and oxygen molecules as a function of the dose of radiation absorbed and temperature of the subsequent heat treatment. According to published results[11,12], ESR detects alkyl radicals ($-CH_2-\dot{C}H-CH_2-$) in polyethylene which has been irradiated with a dose of less than 10 Mrad, allyl radicals ($-CH_2-\dot{C}H-CH=CH-CH_2-$) for doeses of $10-10^{-2}$ Mrad, and linear polyene radicals ($-CH=CH-\dot{C}H-CH=CH-$) if the dose rises to $4 \times 10^3$ Mrad. The effect of still higher doses had not been previously investigated. We have found[13,14] that at doses in the region of $6 \times 10^3$ Mrad a new ESR line appears, with a width of 7.5 oersted, when the measurements are carried out in the presence of oxygen. The intensity of this line increases with dose.

Material prepared by irradiation of polyethylene to an absorption of $2.2 \times 10^4$ Mrad was used to study the effect of subsequent heat treatment. The variation of line-width with THT is shown in Fig. 8: it is clear that the width measured under moderate vacuum remains constant at 7.5 oersted up to a THT of 400°, and at more elevated THT the line-width initially drops to 0.5 oersted (at 720°) before rising again very steeply, reaching 50 oersted at 1100°.

Specimens prepared at temperatures below 450°, and also the original irradiated material without any heat treatment, show a characteristic saturation effect of the ESR line, which gradually vanishes as the THT is raised. It has been shown that the line width does not vary as a result of saturation. It follows that the observed line is not evenly developed, and is the envelope of a set of

separate spin packets, as shown in Figs. 9*a* and 9*b*. However, the individual spin packets are not the unresolved components of a hyperfine structure, and do not arise from the anisotropy of the *g*-factor, since the spectrum changes to a single line of Lorentz form and $\Delta H_{max}$ = 0.5 oersted when the initial products of radiation-modified polyethylene and also the products of subsequent heat treatment at 270° and 350° are subjected to prolonged vacuum treatment (up to many tens of hours) at $10^{-6}$ mmHg (see Figs. 8*b* and 9*c*). Thus, in the RTM products of polyethylene prepared at temperatures below 720° the commonly observed dependence of line-width upon THT is misleading and is due to the presence of a paramagnetic gas — oxygen — whose complete removal requires several days' vacuum treatment [15,16]. This effect is completely reversible and occurs without affecting the total concentration of paramagnetic centres. The Lorentz shape and the 0.5 oersted width of the line suggest considerable delocalisation of the paramagnetic centres. The reversible oxygen effect is easily explained by assuming the presence of separate delocalisation regions for paramagnetic centres. Molecular oxygen creates localised magnetic fields which are randomly distributed with respect to these regions. This must lead to a Gaussian distribution of very narrow lines, i.e. to a Gaussian shape for their envelope, if exchange interaction between the isolated delocalisation regions is absent. It has been shown [17,18] that in the presence of exchange the line adopts the Lorentz form in the centre, and the abscissa (*He*) of the point of transition from the Lorentz to the Gaussian form gives directly the frequency of the exchange interaction (see Fig. 10). Using the products of radiation-induced and radiation-thermal modification of polyethylene, we have analysed the shape of the line obtained both in the presence of oxygen at 150 mmHg pressure and after incomplete removal of the oxygen. In Fig. 10 the linear variation of $\log(y/I')$ with $y^2$ denotes a Gaussian shape, that between $\sqrt{y/I'}$ and $y^2$ denotes a Lorentz shape [18]. The results of the analysis are given in Table 3.

It is obvious from Table 3 that a line of mixed form is characteristic of the products obtained at temperatures below 550°: Lorentz in the middle and Gaussian at the tails. This means that in the presence of oxygen the system shows a characteristic exchange interaction between delocalisation regions. Deliberate addition of oxygen raises the frequency of the interaction. Inspection of Table 3 also shows that the exchange interaction increases as the measurement temperature is raised. It increases also on going from the deeply irradiated products to the products of subsequent heat treatment and on increasing the THT temperature, which determines the gradual loss of saturation of the ESR line with intensification of the RTM treatment. These results indicate a growth of the delocalisation regions. In the products of the modification of polyethylene discussed here these regions are thought to correspond to structural units with favourable polyconjugation, which grow at higher THT at the expense of the intervening, less structurally developed, layers. Since in the absence of oxygen all the products of RTM of polyethylene prepared below 750°, including the original specimens which have only been irradiated to an absorption of $2.2\times10^4$ Mrad, are characterised by a line of equal width (0.5 oersted) and shape (Lorentz), we may conclude that the structure of the polyconjugation regions themselves is not appreciably affected by the modification conditions. The narrow line, the independence of the line-width of measurement temperature, and the presence of line saturation in the low-temperature products all point to weak spin–orbital interaction in the system, i.e. to a low symmetry of the regions of favourable polyconjugation.

Infrared spectroscopic studies have yielded more concrete information on the nature of these regions, and have reliably demonstrated the presence of polyconjugated structures of a cyclic type in the products of RTMP. [19] The ESR and infrared data, when taken together, justify the conclusion that the polyconjugated formations detected by the ESR method correspond to these cyclic structures. As was said above, the line of width 7.5 oersted in the presence of oxygen begins to be registered by the ESR method at doses of the order of $6 \times 10^3$ Mrad. It follows that the cyclic polyconjugated structures characteristic of the products of RTMP are formed at the first stage in the modification of polyethylene, i.e. during irradiation, if the dose is high enough.

As regards the products prepared at THT > 750°, we saw in Fig. 8 that their line-width increases sharply with THT. Furthermore, the line-width in these products increases also with measurement temperature. It follows that the width of the line in these materials is determined by the spin–lattice interaction. It has been found that, in contrast to the products prepared at lower temperatures, increased duration of heat treatment transforms the line from the symmetrical Lorentz shape to an asymmetric shape, and considerably increases its width [20]. All these results point to a change in the structure of the polyconjugation regions at temperatures above 750°, in the sense of increased symmetry. Special experiments have shown that the symmetry of the polyconjugation regions increases not only with increase of the temperature of heat treatment, but also with increase of the time of heat treatment.

Thus, the structure of the RTMP products as established by the ESR method provides a complete explanation of the effects of temperature and frequency upon conductivity, listed above. Indeed, some results obtained from ESR spectra show that the polyconjugation regions are separated by narrow, structurally less perfect interlayers. These interlayers can be identified with the potential barriers opposing the drift of current carriers, whose height determines the activation energy of conduction in a d.c. field. The conductivity of the polyconjugation regions themselves is measured at high frequencies, in the region of the plateau. As shown by ESR measurements, the polyconjugation regions grow with increase of THT at the expense of the interlayers, and this leads to a decrease in the activation energy for conduction, an increase in conductivity, and a decrease in thermo-e.m.f. At the same time, the ESR data show that the structure of the polyconjugation regions themselves is practically unaffected by THT up to 750°, but begins to change appreciably with THT at higher temperatures. This is in keeping with the fact, mentioned above, that the a.c. conductivity is barely affected by changes of THT in the region between 350° and 700°.

The variation with THT of the pre-exponential term, which (as we shall show) characterises the conductivity of these regions, also suggests that changes of this type are occurring in the polyconjugation regions.

Fig. 7 shows that below 600–700° the pre-exponential term is an insensitive function of the THT, but it begins to increase sharply with THT at higher temperatures.

We have already pointed out that addition of oxygen to RTMP specimens brings about, on the one hand, a decrease in the activation energy for conduction, and, on the other hand, an intensification of the exchange interaction between polyconjugation regions. In both cases, the observed interaction occurs between the oxygen and the interlayers, and assists the transfer of electrons between regions. In accordance with this interpretation, the high-frequency conductivity in the region of the plateau should be unaffected by the presence of oxygen: this is confirmed by the experimental results (Fig. 5).

## V. INFLUENCE OF IMPURITIES ON THE ELECTRICAL PROPERTIES

The effect of adsorbed oxygen on the behaviour of RTMP products suggested that a study of the interaction of these materials with iodine would be of interest, since it could be expected to produce more clear-cut effects.

It was indeed found [21,22] that the adsorption of iodine from the gas phase has a profound effect on the electrical properties of RTMP products, raising the conductivity by several orders of magnitude and at the same time lowering the activation energy, the conductivity remaining $p$-type for iodination temperatures up to 200°. Isotherms plotted between 100° and 200° showed that the adsorption decreases with increase of the measurement temperature, has all the characteristics of physical adsorption, and increases with increase of the temperature of heat treatment of the specimens. The degree of saturation adsorption, which obtains at $p_{I_2}$ of 19 and 22 mmHg for THT of 420° and 720° respectively, is quite considerable, reaching values of ~ 0.2 and ~ 0.4 g of $I_2$ per g RTMP at an adsorption temperature of 100°. However, changes in $\sigma$ and $\Delta E$ can be detected at the very much lower extents of iodine adsorption corresponding to 20–25° (i.e. at $p \simeq 1$ mmHg). This has enabled the effect of iodine to be investigated quantitatively by comparing the iodine adsorption kinetics with the kinetics of the change in electrical characteristics. The experiments were made in the presence of air rather than in a vacuum in order to decrease the rate of adsorption of iodine.

The kinetic curves obtained for a specimen subjected to a THT of 420° are reproduced in Fig. 11. It can be seen that $\sigma$ increases by 6 orders of magnitude. The curve has a number of notable features: a threshold preceding the increase of $\sigma$, the narrow range over which $\sigma$ increases to a maximum value, and the constancy of this maximum despite the steadily increasing extent of iodine adsorption. Fig. 12 shows the variation of $\sigma$ with the extent of iodine adsorption for specimens subjected to a THT between 420°

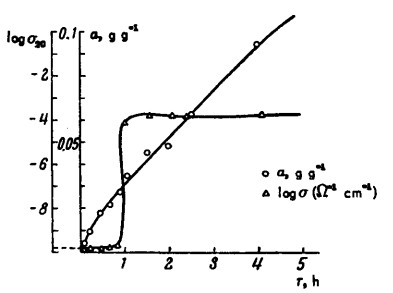

Fig. 11. Comparison of iodine adsorption kinetics and kinetics of the change of electrical conductivity for a specimen with THT = 420°.

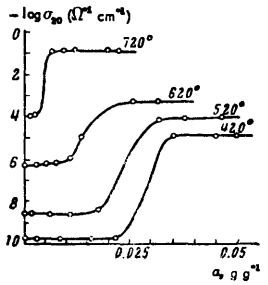

Fig. 12. Variation of $\sigma_{20}$ with amount of iodine adsorbed.

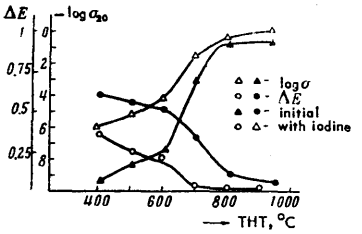

Fig. 13. Effect of THT on $\sigma_{20}$ and $\Delta E$ in the presence and in the absence of iodine.

and 720°: it is evident that the amount of adsorbed iodine needed to produce a sharp change in the values of $\sigma$ decreases with increase of THT, whilst the magnitude of the effect also decreases. The activation energy for conduction also changes sharply at a well defined degree of iodine adsorption: as might have been expected, the activation energy drops. Fig. 13 gives values of $\sigma_{20}$ and $\Delta E$ for different THT in the absence and in the presence of iodine.

These results are in complete agreement with the ideas on the structure of RTMP products derived from ESR studies, which were discussed in the previous Section. Thus, the fact that the amount of iodine necessary to shift $\sigma$ is smaller, the higher the THT, shows that iodine adsorption on the intermediate layers plays the effective role. It assists the motion of current carriers, and thus raises $\sigma$ and lowers $\Delta E$. Iodine adsorption in this case affects the potential barriers, but not the structure of the polyconjugation regions themselves, as shown by the constancy of the conductivity type. It has also been pointed out that the ESR spectra remain unchanged over the whole range of adsorption for a THT of 420°. When the polyconjugation regions become very extensive, as in the case of a THT of 720°, the ESR spectra begin to show evidence of the formation of charge-transfer complexes. This interpretation of the observed effects is also confirmed by the frequency dependence of the conductivity in the presence of adsorbed iodine. As was to be expected from the fact that potential barriers are removed, no dispersion of $\sigma$ is observed in this case.

## VI. CONDUCTION MECHANISM

We have shown above that the conductivity observed in the products of RTM of polyethylene is electronic and is determined by the concentration and mobility of free current carriers:

$$\sigma = e(n\mu_n + p\mu_p),$$

where $e$ is the electronic charge, $n$ and $p$ are the concentrations of electrons and positive holes, and $\mu_n$ and $\mu_p$ are their respective mobilities.

In the majority of cases we shall ignore the contribution of electrons to the conductivity, since the materials of interest are $p$-type semiconductors, and we shall use the expression

$$\sigma = ep\mu^*, \quad (1)$$

where $\mu^*$ is the hole mobility.

It has been shown that the conductivity in the temperature range from -25° to 150° is an exponential function of the reciprocal of temperature:

$$\sigma = \sigma_0 \exp(-\Delta E/kT). \quad (2)$$

The mechanism of electrical conductivity is determined, essentially, by whether the activation energy generates charge carriers or whether it activates mobility of the carriers in the material. Measurement of thermo-e.m.f. is a convenient method for distinguishing between the generation and the carrier transport mechanisms in organic semiconductors. For semiconductors with carriers of a single type the thermo-e.m.f. is given by the expression

$$\alpha = \frac{k}{e}\left[A + \ln \frac{2(2\pi m^* kT)^{3/2}}{h^3 P}\right],$$

where $k$ is Boltzmann's constant, $m^*$ is the effective mass of the carriers, $h$ is Planck's constant, and $A$ is a constant whose value varies from 0.5 to 4 according to the scattering mechanism. This expression can be converted to the form

$$\alpha = B + C\ln T - D\ln p,$$

where $B$, $C$, and $D$ are temperature-independent to a first approximation.

As was recently pointed out[23,24], the temperature variation of the concentration of current carriers for organic semiconductors can be derived from measurements of the thermo-e.m.f. as a function of temperature. Thus, if $p$ = const, $\alpha$ is a very insensitive function of temperature ($\alpha \propto \ln T$), and any increase of thermo-e.m.f. may be masked by the normal experimental error over small temperature intervals. If $p$ is an exponential function of $1/T$, we obtain a steeper variation of $\alpha$ with $T$, easily detected experimentally, namely $\alpha \propto 1/T$. Since $\alpha$ is independent of temperature in every sample of RTMP, we conclude that over the temperature range of the experiments

$$p = \text{const and } \mu^* = \mu \exp(-\Delta E/kT).$$

The physical significance of this expression stems from the detailed study of the structure of RTMP, based mainly on ESR spectra, which has shown that materials prepared at THT > 420° are characterised by regions with a single type of well-developed structure in which polyconjugation is prevalent, separated by narrow regions with a less well-developed structure which can be associated with the potential barriers opposing the drift of carriers.

The conductivity of the regions of polyconjugation in RTMP can be estimated from measurements at various frequencies. The observed dispersion of conductivity with frequency can be ascribed to microheterogeneity in the

specimens. The Maxwell–Wagner double-layer condenser is a classical prototype of the processes occurring in this system. Its constants $C_c$, $R_c$, $C_b$, and $R_b$ are determined by the characteristics of the regions containing conjugated bonds (dielectric constant $\epsilon_c$ and resistivity $\rho_c$) and by those of the barriers ($\epsilon_b$ and $\rho_b$). If $x$ is the ratio of barrier thickness to grain thickness and $x \ll 1$, $\epsilon_c = \epsilon_b$, and $\rho_c \ll \rho_b$ — conditions which the above arguments show to be applicable to RTMP specimens — it is possible to derive[25,26] the following limiting values for the characteristics $\rho_{sp}$ and $\epsilon_{sp}$ of the specimen:

$$\rho_{sp}^0 = \rho_c + x\rho_b, \quad \varepsilon_{sp}^0 = \varepsilon_c \frac{\rho_c^2 + x\rho_b^2}{(\rho_c + x\rho_b)^2}, \tag{3a}$$

$$\rho_{sp}^\infty = \rho_c, \qquad \varepsilon_{sp}^\infty = \varepsilon_c, \tag{3b}$$

where the superscripts 0 and ∞ refer to zero frequency and to the high frequencies at which $\rho_{sp}$ and $\epsilon_{sp}$ become independent of frequency. Thus, in the high-frequency region we measure the characteristics of the regions of polyconjugation (Figs. 4 and 5). It is evident from Fig. 4 that the lower the THT of the specimen, the higher is the frequency at which the conductivity plateau is reached. This is due to the increase in size of the polyconjugation regions, and to the decrease in barrier height, which occur as the THT is raised. For high THT, when $\Delta E \to 0$, the barriers become vanishingly small and no dispersion of conductivity with frequency can be detected. We may conclude that, when the THT is raised, the conductivity $\sigma_c = \sigma_f$ of the regions with polyconjugated bonds does not differ very much from the observed d.c. conductivity $\sigma$, and that whilst $\sigma_{20°}$ covers a range of some 10 orders of magnitude for different specimens, $\sigma_f$ for the same specimens varies only by ~ 2 orders (Fig. 4). Studies of the temperature dependence of the plateau conductivity $\sigma_f$ show an insignificant variation as compared with that of $\sigma$ (Fig. 5). Therefore, in keeping with what has already been said, the activation energy for conduction in a d.c. field can be ascribed to the potential barriers. The small activation energy for conduction $\Delta E_f$ in the polyconjugation regions is associated either with the generation of current carriers or with the motion of the carriers within these regions. No data on which to base a choice between these two processes are at present available.

It follows from our discussion that

$$\sigma_f = \sigma_c = ep\mu_c, \tag{4}$$

where $\mu_c$ is the carrier mobility in the polyconjugation regions.

The barrier mechanism of conduction is applicable to the model for the structure of the material which we have been considering[27]. To obtain an expression for the macroscopic conductivity, we ignore the resistance of the polyconjugation regions and we express the current as a function of the applied voltage across the barriers[27]:

$$j = \frac{Mp}{4}[\exp(-e\psi/kT)]\,[\exp(e\Delta V_b/kT) - 1], \tag{5}$$

where $j$ is the current density, $p$ is the average concentration of intrinsic carriers (holes) in the polyconjugation regions, $\psi$ is the height of the potential barrier, $\Delta V_b$ is the drop in potential across one barrier, and $M$ is a parameter which does not depend on $\psi$ but is a function of the specific nature of the barrier. For a barrier of 5–20 Å thickness, such as is likely to be found in our system, $M = ev_T$, where $v_T$ is the mean thermal velocity of holes. Ohm's law is obeyed up to ~ $10^3$ V cm$^{-1}$ in the products of RTMP (Fig. 2). This suggests that the potential drop at each barrier, $\Delta V_b$, is much less than $kT/e$. We can therefore re write Eqn. (5) in the form

$$j = \frac{v_T p e^2 \Delta V_b}{4kT} \exp(-e\psi/kT). \tag{6}$$

Since we are dealing with $N$ polyconjugation regions connected in series, we can evaluate $\Delta V_b$ as

$$\Delta V_b = \frac{V}{N} = \frac{V}{nl} = \frac{\varepsilon}{n}, \tag{7}$$

where $V$ is the voltage applied to the specimen, $\epsilon$ is the field strength, $l$ is the length of the specimen, and $n$ is the number of polyconjugation regions per unit length. For $\epsilon > (2.5–5) \times 10^3$ V cm$^{-1}$ the current–voltage relationship begins to depart from Ohm's law. From this figure we can make an approximate estimate of the size of the polyconjugation regions. Since the precision of the measurements is ~ 5%, deviations from Ohm's law will be detectable at $e\Delta V_b = kT/10$. (This corresponds to $2.5 \times 10^{-3}$ eV at room temperature.) Hence, from formula (6), $n \simeq (1–2) \times 10^6$ cm$^{-1}$. Ignoring the linear dimensions of the barriers in comparison to those of the polyconjugation regions, we estimate the size of the latter as $L \simeq$ (50–100) Å.

The macroscopic conductivity is given by the expression

$$\sigma = j/\varepsilon,$$

which when combined with Eqns. (6) and (7) gives

$$\sigma = \frac{v_T p e^4}{4kTn} \exp(-e\psi/kT) = ep\mu \exp(-e\psi/kT), \tag{8}$$

where

$$\mu = \frac{v_T e}{4nkT}.$$

The term $\exp(-e\psi/kT)$ is characteristic of the barriers. Eqn. (8) can be written in two forms:

$$\sigma = ep\mu^* \quad \mu^* = \exp(-e\psi/kT), \tag{9a}$$

$$\sigma = ep^*\mu \quad p^* = p\exp(-e\psi/kT). \tag{9b}$$

The macroscopic value of the Hall coefficient, $R_H$, has been found to give the value of $p$ in systems of this type. This is because the polyconjugation regions have a much lower resistance than the barriers[27], i.e. $R_H = \frac{3}{8}\frac{\pi}{ep}$, and the Hall mobility is given by

$$\mu_H = R_H\sigma = \frac{3}{8}\pi\mu^*.$$

Therefore, the Hall mobility gives a direct measure of $\mu^*$ and includes the barrier effects.

The thermo-e.m.f. in systems of this type is also determined by the more extensive system, i.e. by the polyconjugation regions, if the temperature gradient across the barriers is insignificant[4]. This measurement therefore gives the carrier concentration $p$ in the polyconjugation regions. It follows that the mobility derived from measurements of conductivity and thermo-e.m.f. is also equal to $\mu^*$, and that formula (9a) is applicable. Since the hole concentration as measured from the conductivity at high frequencies and from the thermo-e.m.f. varies only slightly, we may suggest that carriers are generated by the impurity mechanism.

On comparing the equations which describe the experimentally observed relations (2) and (9a) with those deduced from the barrier mechanism, we obtain

$$\Delta E = e\psi, \quad \mu = \frac{v_T e}{4nkT}, \quad \sigma_0 = \frac{v_T e^2 p}{4nkT}. \tag{10}$$

The expressions for $\sigma$ and $\mu^*$ enable $\mu^*$ and $p$ to be calculated for RTMP specimens of different THT. In semiconductors with a non-degenerate system of carriers

$$\frac{m^*v^2}{2} = \frac{3}{2}kT. \quad (11)$$

The effective mass $m^*$ is not known, but we can assume that in organic semiconductors the effective mass is greater than the free electron mass $m$, since many experimental and calculated results suggest that the bands are narrow. Table 4 lists the values of $\mu^*$ and $p$ calculated by formulae (8) and (11) from the experimental values of $\sigma_{20°}$ and $\Delta E$, assuming $m^*$ to be $m$ and $10m$ and making use of the size of the polyconjugation regions calculated above.

Let us consider now the expression for $\mu$ in greater detail. From (10) and (11), we have

$$\mu = \frac{3}{4}\frac{e}{m^*}\frac{L}{v_T}. \quad (12)$$

On comparing this with the expression for the mobility in the polyconjugation regions,

$$\mu_c = \frac{e}{m^*}\frac{d}{v_T} = \frac{e}{m^*}\tau, \quad (13)$$

where $d$ is the carrier mean free path, we conclude that $\sigma$ is directly determined by the conductivity of the polyconjugation regions through (12), (13), and (8):

$$\sigma = \mu_c p \frac{3}{4}\frac{L}{d}\exp(-\Delta E/kT) = \frac{3}{4}\frac{L}{d}\sigma_c \exp(-\Delta E/kT). \quad (14)$$

Thus we find that the d.c. conductivity in systems of this type is clearly determined by the conductivity of the polyconjugation regions ($\sigma_c$) and by the interlayers of structurally less perfect material ($\Delta E$).

We showed in the experimental section that the relationship

$$\sigma_0 \simeq \sigma_f = \sigma_c \quad (15)$$

holds for specimens of RTM polyethylene. Hence, $\frac{3}{4}\frac{L}{d} \simeq 1$, the mean free path $d$ is approximately equal to the dimensions ($L$) of the polyconjugation regions, and Eqn. (14) takes the following form for RTM polyethylene specimens:

$$\sigma \simeq \sigma_c \exp(-\Delta E/kT).$$

In general, $\sigma_0$ can be greater or smaller than $\sigma_c$ according to the value of the ratio $L/d$, and this ratio can be evaluated from measurements in a d.c. and an a.c. field.

TABLE 4.

| THT, °C | $D = 2.4 \times 10^4$ Mrad, $L = 100$ Å | | | |

| 420 | $2.5 \times 10^{-5}$ | $2.6 \times 10^{18}$ | $7.5 \times 10^{-4}$ | $8.4 \times 10^{18}$ |
| 520 | $3.1 \times 10^{-3}$ | $4 \times 10^{19}$ | $9 \times 10^{-2}$ | $1.3 \times 10^{14}$ |
| 620 | $1.0 \times 10^{-2}$ | $4.6 \times 10^{19}$ | $3 \times 10^{-1}$ | $1.5 \times 10^{14}$ |
| 725 | $1 \times 10^{-1}$ | $4 \times 10^{15}$ | $3.5 \times 10^{-2}$ | $1.2 \times 10^{16}$ |
| 825 | 10 | $4 \times 10^{17}$ | 3 | $1.2 \times 10^{16}$ |
| 930 | 57 | $7 \times 10^{18}$ | 17 | $2.4 \times 10^{19}$ |

The regions of bond polyconjugation are characterised by high mobility (~ 17–115 cm$^2$ V$^{-1}$ s$^{-1}$) and conductivity (~ $10^{-4}$–$10^{-2}$ $\Omega^{-1}$ cm$^{-1}$), but the effective mobility $\mu^*$ and the conductivity $\sigma_{20°}$ of RTMP specimens are very much lower, due to the presence of potential barriers.

This discussion is only approximate, because it is confined to carriers of a single kind. However, we have observed[7] an increase in positive thermo-e.m.f. in the presence of oxygen which can be explained by postulating an electronic contribution to the conductivity in addition to the hole conductivity.

## VII. NATURE OF THE PARAMAGNETISM

A limited understanding of the nature of the paramagnetism of the RTM products of polyethylene was derived from studies of the reversible oxygen effect and from comparisons of the paramagnetic and electrical properties of given specimens. As stated above, the reversible oxygen effect in products prepared at temperatures below 500° consists in the generation of localised fields and in the intensification of exchange interactions between delocalisation regions of paramagnetic centres. The latter effect indicates that overlap of electron orbitals is taking place between an oxygen molecule and the paramagnetic centres, but that the overlap is not affecting the paramagnetic centre concentration. With products obtained at temperatures in excess of 500° the delocalisation regions grow at the expense of the intervening layers to such an extent that the steric conditions leading to a more intimate overlap of the orbitals are satisfied. In these products the concentration of paramagnetic centres varies on admission of oxygen. A comparison of the reversible oxygen effect has been made on RTM products of polyethylene which had been subjected to vacuum pyrolysis with and without a preliminary oxidation: such a comparison is essential to an understanding of the role of the oxygen present in the structure of the pyrolysis products.

If the samples for irradiation are pre-oxidised, the concentration of unpaired spins in the products prepared at temperatures between 550° and 750° increases reversibly upon admission of oxygen. Measurements on a number of materials which had been heat-treated for various times at ~ 700° showed that the adsorption is physical in nature since it has a heat of 2 kcal mole$^{-1}$. It was shown that the adsorption of 1 molecule of oxygen on pre-oxidised products heated at moderate temperatures causes the loss of 2 unpaired spins. This ratio justifies the conclusion that the paramagnetism of RTM of polyethylene is due to the presence of isolated paramagnetic centres, and not to a weak interaction between strongly conjugated systems[28]. A further conclusion from the observed relationship is that the physical adsorption of oxygen on pre-oxidised products involves reversible pairing of two unpaired electrons from the specimen with two unpaired electrons from an oxygen molecule without disruption of the O=O bonds.

If the pre-oxidation stage is omitted in the preparation of these materials, the paramagnetic centre concentration in the products treated at moderately high temperatures does not increase, but rather decreases reversibly upon admission of oxygen. A similar effect is observed for many organic compounds with well developed polyconjugation systems. The effect is universally ascribed to the formation of charge-transfer surface complexes of the donor–acceptor type[13]. A comparison of the number of

adsorbed oxygen molecules with the number of the resulting paramagnetic centres has been made for RTM products prepared at 700°. The adsorption is again physical in nature, since it increases on lowering the temperature, the heat of adsorption being 2.5 kcal mole$^{-1}$. It has been shown that each oxygen molecule adsorbed causes the appearance of 1 paramagnetic centre. From this comparison of the effect of oxygen on the concentration of paramagnetic centres in RTM products of polyethylene with and without a preliminary oxidation treatment, we may conclude that oxygen-containing groups hinder the formation of charge-transfer complexes. This is probably because they compete with molecular oxygen, "drawing" the electron cloud around themselves. It has been found that the adsorption of 1 oxygen molecule induces 1 paramagnetic centre even in products prepared above 750°, whether or not the products are pre-oxidised before vacuum pyrolysis. This effect is probably associated with practically complete removal of the oxygen-containing groups from the structure of the products during high-temperature pyrolysis.

Fig. 14 shows, as a function of THT, the concentration of paramagnetic centres in vacuum-treated RTMP samples and the concentration of current carriers calculated for assumed carrier effective masses ($m^*$) of $m$ and $10m$ (lower and upper boundaries of the cross-hatched band respectively).

It is clear that the concentration of paramagnetic centres in materials prepared below 800° is higher than the carrier concentration by many orders of magnitude, and that the two concentrations vary with THT in different ways.

The conclusion to be drawn from this comparison is that the paramagnetic centres in materials of this type (including specimens subjected to irradiation only) cannot be identified directly with charge carriers. The centres are apparently caused by structural defects. As stated above, the analysis of the ESR spectra indicates that the unpaired electrons bound to structural defects are delocalised within the individual polyconjugation regions. It is obvious from Fig. 14 that for temperatures above 600° the concentration of defects decreases whilst the concentration of charge carriers increases steeply with THT. Furthermore, in the materials prepared at THT > 800° the concentration of paramagnetic centres begins to increase once again with increase of THT at much the same rate as the concentration of current carriers. Unlike the low-temperature and the intermediate-temperature products, freshly prepared high-temperature products show an increase in paramagnetic centre concentration with increase in measurement temperature. This result has led to the conclusion that current

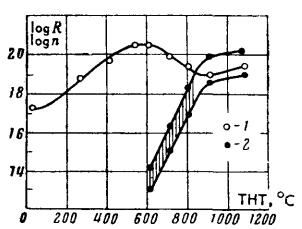

Fig. 14. Effect of THT on the concentration of paramagnetic centres (curve 1) and on the concentration of charge carriers (curves 2).

TABLE 5.

| THT | $\mu^*$, cm$^2$ V$^{-1}$ s$^{-1}$<br>$p$, cm$^{-3}$ or g$^{-1}$ | Electrical measurements | | ESR | |
|---|---|---|---|---|---|
| | | $m^* = 10m$ | $m^* = m$ | $m^* = 10m$ | $m^* = m$ |
| 930 | $\mu^*$ | 17 | 115 | 13 | 130 |
| | $p$ | $2.4\times10^{19}$ | $3.5\times10^{18}$ | $7\times10^{18}$ | |
| 1100 | $\mu^*$ | 17 | 115 | 13 | 130 |
| | $p$ | $3.6\times10^{19}$ | $5.2\times10^{18}$ | $1.5\times10^{19}$ | |

carriers are responsible for the ESR signal in this particular case. When surface oxides are formed on these products, the concentration of paramagnetic centres becomes independent of measurement temperature. The relaxation time $\tau_R$ of the carriers[30] has been obtained from the parameters of the ESR spectra — line width (Fig. 8) and the $g$-factor (2.0027) — for materials prepared at 930° by means of the formula

$$T_1 = \left(\frac{3\times10^{-8}}{\Delta H_{max}}\right) = \frac{1}{30}\,\frac{\tau}{(g-g_{free})^2},$$

given by Elliott[29]. As in the case of the electrical measurements, the numerical values of mobility were obtained from formula (13) by assuming effective masses of $1m$ and $10m$.

In this way, the mobility and carrier concentration have been calculated by independent methods: it is evident from the values obtained, which are set out in Table 5, that the agreement between the two sets of results is satisfactory. The measured conductivity of a specimen prepared at THT = = 930° is 56 $\Omega^{-1}$ cm$^{-1}$. Assuming that the density of the products is 1.5 g cm$^{-3}$, we conclude that $m^* \simeq 4m$, since the mobility is 50 cm$^2$ V$^{-1}$ s$^{-1}$ at a carrier concentration of $7 \times 10^{18}$ g$^{-1}$ (as determined by the ESR method).

These results prove that the application of the ESR method to studies of polymeric materials having semiconducting properties can assist in the identification of some of the features of the conduction mechanism in these materials as well as giving information on their structural characteristics.

In conclusion, we can say that the radiation-thermal modification of linear polymers, which we have studied in the particular case of polyethylene, offers the possibility of preparing organic semiconductors showing a wide range of properties.

# EFFECT OF CHEMISORBED GASES ON THE WORK FUNCTION OF METALS

R. Kh. Burshtein and N. A. Shurmovskaya

Most of the work on the mechanism of the adsorption and chemisorption of gases on metals has been concerned with the kinetics of these processes and with the relevant heats of adsorption. Yet, attempts were made as long ago as in the 1930's to establish a connection between the rate of interaction of gases with metals and the change in work function of the metals.

Rideal and his coworkers [1] studied the relationship between the activation energy and the work function. Langmuir [2], de Boer [3], Lukirskii [4], and others, measured the change in contact potential difference (c.p.d.) resulting from the adsorption of alkali metal atoms on tungsten, and from the adsorption of oxygen and hydrogen on alkali metals. However, the literature of that period contains various contradictory results as well as some very valuable papers: this state of affairs, which was due to the inadequacy of existing measurement techniques, was responsible for the loss of interest in this problem. In recent years, modern theories of gas–metal interactions and the development of high-vacuum and electronic measurement techniques gave new impetus to studies of the mechanism of the adsorption of gases on metals and of their influence on the work function. Recent investigations include the effect of the adsorption of hydrogen, oxygen, carbon monoxide, the noble gases, etc., on the work function of metals, and some attempts at establishing the relation between the changes in work function and in heat of adsorption under conditions of increasing surface coverage [5,6].

The results of work function measurements as a function of gas adsorption were used by several workers to calculate heats of adsorption. Eley [7] suggested the use of a semi-empirical formula, based on Pauling's equation for the energy of a covalent bond:

$$-\Delta H_0 = H_c + 23.06\,(x_m - x_a)^2, \qquad (1)$$

where $H_C$ is the initial energy of the covalent bond, and $(x_m - x_a)$ is the electronegativity difference between the adsorbent and the adsorbate.

Calculations of the heat of adsorption of hydrogen chemisorbed on tungsten, using this equation, agree satisfactorily with experimental data. However, the adsorption of oxygen, nitrogen, and also some organic molecules gave appreciable discrepancies between calculated and experimental values. Eley's calculation presupposes a linear change of contact p.d. with surface coverage, which is not always borne out by the experimental results.

The contact p.d. method has been used also to examine the mechanism of catalytic and electrochemical processes.

Work function values are of major significance [8,9] in problems involving the Volta potential, which, according to the ideas developed by Frumkin, determines the relation between the points of zero charge of metals and their work functions.

The contact potential difference in the chemisorption of gases on metals depends on the nature of both the adsorbent and the adsorbate [5,6,10]. In most cases, chemisorption of gases produces a covalent bond of partially ionic character. Under these conditions, the appearance of a surface potential is associated with the transfer of an electron from the adsorbent to the adsorbate or *vice versa*. These processes lead to an increase or a decrease in the work function respectively. According to the ideas of a number of workers [5,6,10], the sign of the surface potential of the metal, $\Delta\varphi$, is determined by the difference between the work function ($\varphi$) and the electronegativity of the adsorbate ($\psi$):

$$\Delta\varphi = \varphi - \psi. \qquad (2)$$

Hence

$$\psi = {}^1/_2(I + E), \qquad (3)$$

where $I$ is the ionisation potential and $E$ is the electron affinity.

This model predicts that chemisorption of gases having a high electron affinity, such as oxygen and the halogens, should raise the work function. Yet even some of the earlier work[11-14] showed that oxygen chemisorption on certain metals raises $\varphi$ while according to others chemisorption lowers it.

The influence of chemisorption conditions and of the nature of adsorbates of different electron affinity (fluorine, oxygen, chlorine, iodine) on the work function has been investigated as part of a detailed study of the mechanism of the chemisorption of gases on metals and of their effect on electrochemical processes such as metal passivation and corrosion.

In most of the published studies of chemisorption processes by the contact potential difference method no allowance is made for the change in surface potential of the reference electrode induced by the adsorbate.

The measurements of contact p.d. in our work were made by the vibrating condenser method and by the thermionic method (from the change in diode characteristics). For the condenser method we used an apparatus in which the reference electrode was a molybdenum sheet fused to a thin layer of glass, which protected the reference electrode from gas adsorption[15]. When the measurements were made by the thermionic method, we used an apparatus which enabled the cathode to be protected from adsorption of the experimental gases[16]. The values of contact p.d. obtained for oxygen chemisorption on iron by the condenser method[17] are in good agreement with our own results by the thermionic method under similar conditions[16,18].

The preparation of a clean metal surface is a very complicated problem. The usual procedures are either cleaning of the metal surface by reduction with carbon monoxide, followed by lengthy degassing in an ultra-high vacuum, or evaporation of the metal in an ultra-high vacuum. In the second method there is a possibility of absorption by the evaporating metal of the gases evolved from the massive metal. Furthermore, the structure of thin films is different from that of bulk metal, and this can affect the work function[19-23]. For these reasons we used the first method in our researches.

The metals were reduced at 450° and degassed at 700–900° (iron[17,18] and nickel[24]), or at 1200° (platinum[25]). Special experiments were made to check that when this procedure was used, a change in vacuum from $10^{-7}$ to $10^{-9}$ mmHg had no significant effect on the change in contact p.d. caused by oxygen chemisorption[26].

Vacuum work with halogens presents considerable difficulty. To ensure that the gases were pure, we used spherical diaphragms instead of taps[27,28].

The chemisorption of oxygen on tungsten is a classical example showing the correctness of the above ideas on the change in work function in terms of the difference in electron affinity between adsorbate and adsorbent. Both published results[29-32] and measurements in our own laboratory[16] have shown that the work function of tungsten is decreased by oxygen chemisorption over a wide range of pressures and temperatures. In most of the investigations, made by different methods, the contact p.d. $\Delta\varphi$ is found to be 1.7–1.9 V.

In order to understand the variation of the surface potential with the conditions of interaction of electronegative gases with iron, we measured the contact p.d. between a clean metal surface and a surface covered with chemisorbed gases.

To study the kinetics of oxygen chemisorption, an iron surface was exposed to small increments of oxygen pressure, and the rate of absorption of each portion was observed. The variation of the rate of oxygen absorption with surface coverage is shown in Fig. 1 (curve *1*), where the rate of the process is expressed as $\log(1/\tau)$ and $\tau$ is the time required for absorption of one-half of the aliquot of oxygen. The chemisorption of oxygen on iron occurs in two stages. The fast stage is characterised by relative insensitivity of the rate to the degree of surface coverage. This stage is completed, both for the bulk metal and for the powder, when the extent of absorption is $2 \times 10^{15}$ $O_2$ molecules per cm² of true surface area. If absorption is allowed to proceed further, the rate of chemisorption falls off sharply[33,34]. No desorption occurs upon heating iron covered with chemisorbed oxygen. However, after being heated and subsequently cooled, iron acquires the ability to absorb additional oxygen [see Fig. 1, curve *2* (100°), curve *3* (200°), curve *4* (300°)]. This activating treatment of the iron can be repeated a number of times. Thus, the increase in oxygen absorption at higher temperatures stems from disruption of the protective properties of the film formed at 20° As the temperature is increased, the limiting thickness of the film also rises, and additional chemisorption of oxygen must take place[17].

The results of our work on the interaction between iron and oxygen by the contact p.d. method are shown in Figs. 2, 3, and 4. The data of Figs. 2 and 3 were obtained by the

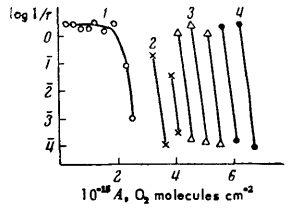

Fig. 1. Effect of temperature on the kinetics of oxygen chemisorption on iron.

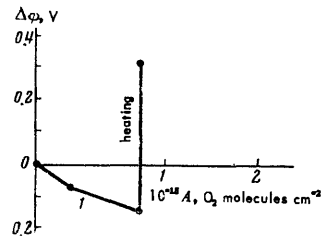

Fig. 2. Effect of oxygen, chemisorbed on iron at -120° and 100°, on the contact p.d.

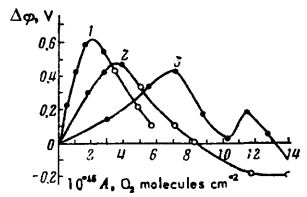

Fig. 3. Variation of contact p.d. of iron with amount of oxygen chemisorbed: 1) at 100°; 2) at 200°; 3) at 300°.

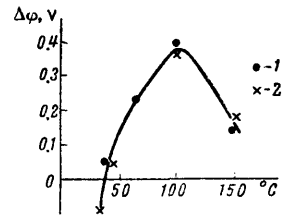

Fig. 5. Effect of temperature on the contact p.d. of nickel covered with $1.3 \times 10^{15}$ $O_2$ molecules $cm^{-2}$. Points 1 and 2 refer to different experiments.

thermionic method. Adsorption of oxygen on iron at -120° raises the work function (Fig. 2), in agreement with the ideas discussed above. However, when the temperature is increased to 100° for the same amount of chemisorbed oxygen ($0.8 \times 10^{15}$ $O_2$ molecules per $cm^2$), the work function decreases to a level 0.3 V lower than for clean iron. If the amount of chemisorbed oxygen is increased to $2 \times 10^{15}$ $O_2$ molecules per $cm^2$, the work function drops by 0.6 V. When the extent of oxygen chemisorption is very high, the work function increases (Fig. 3).

A similar variation of contact potential with amount of absorbed $O_2$ is found at 150° and 270°. However, the work function minimum shifts towards higher coverages by chemisorbed oxygen as the temperature of chemisorption is increased. As Fig. 3 shows, the work function becomes 0.2 V higher than that for reduced iron when the amount of $O_2$ exceeds $8 \times 10^{15}$ molecules per $cm^2$.

Experimental results[17] obtained by the condenser method with iron covered to the extent of $2 \times 10^{15}$ $O_2$ molecules per $cm^2$ are in quantitative agreement with the results given above. At 100° the decrease in work function goes through a maximum of 0.6 V (Fig. 4).

Since the most reliable value[35] for the work function of iron is 4.7 V, which agrees with our own measurements, the lowest work function of iron in the presence of $O_2$ absorption is 4.1 V, and the highest is 4.9 V.

Our results for the adsorption of oxygen on nickel and for the influence of chemisorbed $O_2$ on the work function show much the same features as the results for iron (Fig. 5). We again find two types of adsorption: a fast and a slow adsorption. At 20° the fast stage accounts for $1.3 \times 10^{15}$ $O_2$ molecules per $cm^2$ of true surface area. As Fig. 5 shows, at 35° the fast chemisorption stage causes an increase in work function of 0.1 V. When the temperature of oxygen absorption is raised to 45° and 100°, the work function decreases by 0.02 and 0.35 V respectively as compared with that of reduced nickel. At still higher temperatures (150°), an increase in work function is observed[24] with respect to the above value.

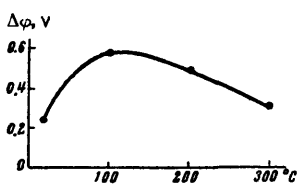

Fig. 4. Effect of temperature on the contact p.d. of iron covered with $2 \times 10^{15}$ $O_2$ molecules $cm^{-2}$.

However, there have been several reports[14,36-40] of an increase in work function following oxygen chemisorption at 20° on thin films of nickel and iron prepared by evaporation in a vacuum. This disagreement is probably due, as was suggested above, to inadequate purity of the films and to their structural peculiarities.

It should be noted that the two forms of chemisorbed oxygen affect the electrochemical properties of iron in different ways. The fast stage of oxygen chemisorption has been shown, by a vacuum-electrochemical method, to increase the rate of anodic oxidation of iron, whereas the slow stage lowers the rate of the anodic process. The absorption of $4 \times 10^{15}$ $O_2$ molecules per $cm^2$ produces complete passivation of this process[33,34,41]. Near the steady-state potential small amounts of $O_2$ ($2 \times 10^{15}$ molecules $cm^2$) chemisorbed on the surface from the gas phase cause an increase in capacitance associated with increased electrochemical adsorption[42].

Comparison of data on the influence of chemisorbed oxygen on the work function[16-18] with data on the electrochemical behaviour of iron[33,34,41] shows that the activation of the iron electrode results from absorption of oxygen under conditions leading to a decrease in work function, whereas passivation occurs when the oxygen chemisorption is accompanied by an increase in work function.

The contact p.d. method has also been used to study the mechanism of gas-phase corrosion of iron in a moist atmosphere[17].

As stated above, oxygen chemisorption at 20° lowers the work function by 0.2 V. After exposure to $H_2O$ vapour, the work function drops by a further 0.3 V. However, there is no change of $\Delta\varphi$ after complete desorption of the water vapour, whilst the iron acquires the ability to adsorb additional amounts of oxygen. This activation of the iron towards interaction with oxygen can be repeated a number of times. As Fig. 6 shows, oxygen adsorption in amounts of $2.5 \times 10^{15}$ $O_2$ molecules per $cm^2$ causes a drop of about 3 orders of magnitude in the rate of chemisorption of oxygen (curve *1*). After exposure of iron covered with an oxide film of limiting thickness to water vapour, the rate of absorption of $O_2$ increases again to its initial value. However, after further absorption of a small amount of oxygen the reaction rate decreases sharply, but it can be increased by repeated exposure to water vapour (curves *2*, *3*, *4*, and *5* of Fig. 6). The values of contact p.d. obtained for iron in the presence of oxygen and water vapour and

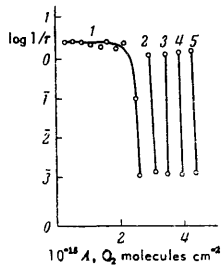

Fig. 6. Effect of water vapour on the kinetics of oxygen chemisorption by iron.

after degassing are summarised in Fig. 7. From adsorption measurements in conjunction with data on the influence of water vapour on the work function, we may conclude that the adsorption of $H_2O$ vapour facilitates migration of metal atoms. Under these conditions, an electrical double layer with its positive pole directed outwards is formed on the metal surface, as evidenced by the decrease in work function.

We shall now consider the effect of halogens on the work function of iron.

Chemisorption of the most electronegative gas, fluorine[28], produces a most striking decrease in work function. Fig. 8*a* shows the change in surface potential of iron after exposure to fluorine. The chemisorption of fluorine was studied at a pressure of $6 \times 10^{-2}$ mmHg. The results indicate that the largest decrease in work function caused by the chemisorption of fluorine on iron occurs at room temperature and amounts to 0.6–0.7 V. This value is unaffected by removal of the fluorine from the gas phase. When the iron with chemisorbed fluorine is heated in a vacuum to 100°, a slight increase in work function is observed between 20° and 100°. Further increase in temperature to 300° has practically no effect on the work function. Under these conditions, $\varphi$ is lower than the value for clean iron by 0.4 V.

The change in surface potential of iron on chemisorption of chlorine was investigated[27] in the pressure range $4 \times 10^{-4}$– $6 \times 10^{-1}$ mmHg. The results are reproduced in Figs. 8*b* and 8*c*. At all the pressures examined, chlorine chemisorption at 20° raises $\Delta\varphi$ from 0.1 to 0.27 V. As

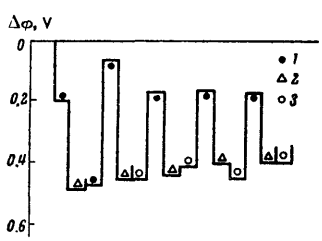

Fig. 7. Effect of oxygen, water vapour, and degassing on the contact p.d. of iron:
1) oxygen; 2) water; 3) vacuum.

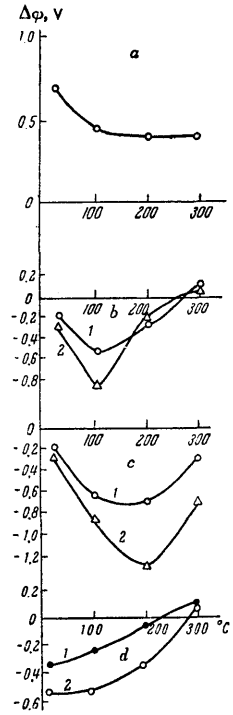

Fig. 8. Effect of halogens on the contact p.d: *a*) iron with chemisorbed fluorine heated *in vacuo* ($p_{F_2} = 6 \times 10^{-2}$ mmHg); *b*) iron with chemisorbed chlorine heated *in vacuo* [1) $p_{Cl_2} = 5 \times 10^{-2}$ mmHg; 2) $p_{Cl_2} = 6 \times 10^{-1}$ mmHg]; *c*) iron heated in the presence of chlorine in the gas phase [1) $p_{Cl_2} = 5 \times 10^{-2}$ mmHg; 2) $p_{Cl_2} = 6 \times 10^{-1}$ mmHg]; *d*) iron with chemisorbed iodine heated *in vacuo* [1) $p_{I_2} = 1 \times 10^{-2}$ mmHg; 2) $p_{I_2} = 7 \times 10^{-2}$ mmHg].

Fig. 8*b* shows, very significant changes in surface properties take place when the iron with chemisorbed chlorine is heated in a vacuum. At 100° we observe an increase in $\Delta\varphi$ from 0.1 to 0.85 V over the range of pressures stated above. With further increase of temperature the work function decreases, and reaches a value 0.1 V lower than that for a clean iron surface after heat treatment at 300°. If chlorine is present in the gas phase, a similar temperature variation is observed (see Fig. 8*c*). The only difference between these results and those of Fig. 8*b* is that the maximum contact p.d. occurs at 200° and amounts to 1.3 V.

The experiments on the effect of chemisorbed iodine on the work function[27] were done at pressures of 0.01 and 0.07 mmHg. The results are shown in Fig. 8*d*. In contrast to the behaviour of chlorine, the greatest increase in work function is found when iodine is chemisorbed on iron at 20°, and amounts to 0.3–0.5 V for the stated pressures. The chemisorption of iodine at a pressure of $7 \times 10^{-2}$ mmHg amounts to $2.7 \times 10^{15}$ $I_2$ molecules per $cm^2$ of true surface area. After heating to 300°, the work function becomes smaller by 0.1–0.15 V than the work function of a clean iron surface. In contrast to the results

obtained with chlorine, the contact p.d. decreases continuously when iron with chemisorbed iodine is heated in a vacuum.

As we have already remarked, the adsorption of gases with a high electron affinity (such as oxygen and the halogens) on a metal should be accompanied by an increase in work function, according to generally accepted principles. The results on oxygen chemisorption reported here indicate that the work function can either increase or decrease, depending on the adsorption conditions (temperature and amount of chemisorbed gas). Comparison of the results for the effect of oxygen and of the halogens at 20°, shows that the higher the electronegativity of the adsorbate the lower is the work function. The relationship between $\Delta\varphi$ and $x$ (the Pauling electronegativity) is shown by curve *1* of Fig. 9. Curve *2* of the same figure shows the variation of contact p. d. with the ionic radius of the adsorbates used in this work. These results show that the amount of positive charge on the surface increases with decreasing ionic radius of the adsorbate.

According to the view previously developed by us [16-18,24,28] and now adopted by others [43-45], the decrease in electronic work function following adsorption of an electronegative gas is due to penetration of the adsorbate below the uppermost layer of metal atoms, or to migration of the latter to the surface of the adsorption layer. In the first case the size of the adsorbed ion plays the major role in determining its penetration between the surface atoms of the metal. The experiments which we have described show that adsorption at 20° of fluorine (the gas with the smallest ionic radius) produces the greatest decrease in work function. The results also indicate that the temperature at which the greatest positive shift in potential is observed is lower, the smaller the ion of the adsorbate considered. The observed changes in contact p.d. with temperature can be explained by the following argument. The positive shift of the potential of iron and nickel is caused by penetration of the adsorbate to a certain depth. Due to the difference in ionic radius, our adsorbates achieve this depth of penetration at different temperatures (at 20° for fluorine, at 100° for oxygen, upwards of 300° for chlorine and iodine). The potential of the surface become less positive as the oxygen penetrates deeper into the metal. The penetration of chemisorbed oxygen into the bulk of the metal is confirmed also by our results for platinum [25], reported below.

When penetration of the electronegative adsorbates into iron or other metals cannot take place, as in the case of chlorine or iodine at 20°, the surface becomes negatively charged. In the chemisorption of chlorine on iron, increase of temperature from 20° to 100° causes a further increase in work function, probably due to a change in the nature of the chlorine–iron bond. At temperatures above 100° the halogen can evaporate from the surface, with loss of negative charge.

Anderson [43] studied the kinetics and the mechanism of chlorine adsorption on deposited nickel films at pressures between $5 \times 10^{-6}$ and $5 \times 10^{-3}$ mmHg and at temperatures of 20° and -122°. Under these conditions, chlorine adsorption is very fast up to monolayer coverage. At low coverages ($\theta < 0.1$) the contact potential acquires a positive value of 0.2 V. The observed decrease in work function is attributed by the author to penetration of the chemisorbed chlorine below the surface layer of metal. At high coverages the contact potential becomes negative, with a maximum value of -1.6 V. When the nickel film covered with chemisorbed chlorine is heated to 300°, the work function decreases, in complete agreement with the results of our own work [27] reported above.

Oxygen has a different effect on the work function of platinum [25]. At room temperature and at low pressure the adsorption of oxygen on platinum is negligible and has practically no effect on the contact potential difference. Between 200° and 800° platinum can absorb significant amounts of oxygen, corresponding to 600 monolayers at 800°.

When platinum absorbs oxygen in amount of $15 \times 10^{15}$–$40 \times 10^{15}$ molecules $cm^{-2}$ at 200° there is a small increase (0.2 V) of work function, which disappears if the electrode is kept for 12 h in a vacuum. The work function of the platinum is now practically the same as that of the clean metal. This can be explained by postulating that oxygen pentrates into the bulk of the platinum. The same amount of oxygen ($40 \times 10^{15}$ molecules $cm^{-2}$) has no effect at all on the work function when chemisorption occurs at 400°. This is evidently because the oxygen reaches the interior of the platinum so rapidly that $\Delta\varphi$ is not measurable.

However, as the amount of oxygen absorbed at 400° increases, the layers of platinum adjacent to the surface become saturated and the penetration of oxygen into the interior of the platinum is retarded. A larger amount of oxygen ($100 \times 10^{15}$–$200 \times 10^{15}$ $O_2$ molecules $cm^{-2}$) causes the work function to increase by 1.5 V. However, the contact potential difference decreases with time, and after 12 h the work function becomes equal to that of clean platinum, due, as before, to the penetration of the oxygen into the deeper layers of platinum (Fig. 10). Oxygen absorbed by platinum at 800° behaves quite differently. The results

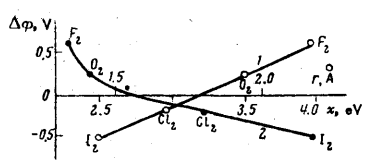

Fig. 9. Variation of the work function of iron with electronegativity $x$ (curve 1) and ionic radius $r$ (curve 2) of the adsorbate.

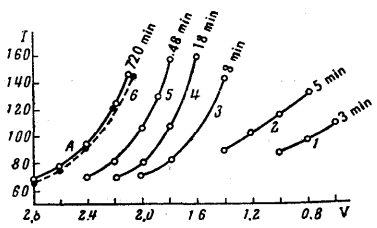

Fig. 10. Current–voltage characteristics. *A*) platinum; 1)–6) platinum covered with $125 \times 10^{15}$ $O_2$ molecules $cm^{-2}$, measured 3–720 min after completion of chemisorption.

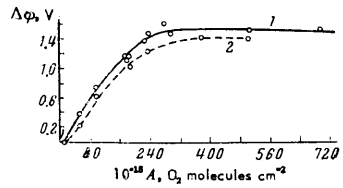

Fig. 11. Variation of contact p.d. with amount of oxygen absorbed by platinum at 800°: 1) immediately after adsorption; 2) after 12 h.

of one series of experiments are shown in Fig. 11. Increasing the amount of chemisorbed oxygen raises the work function, which remains practically constant with time and reaches 1.5 V when the extent of absorption is $233 \times 10^{15}$ $O_2$ molecules $cm^{-2}$. Further oxygen chemisorption has practically no effect on the work function. The results suggest that a relatively small proportion of the chemisorbed oxygen is firmly held at the metal surface, whereas the bulk of the oxygen penetrates into the bulk of the platinum.

These conclusions are satisfactorily confirmed by measurements of the charging curve of a platinum electrode treated with oxygen at 200–800°. Cathodic polarisation can remove only a small proportion of the oxygen, equivalent to approximately one monolayer, from the platinum surface. If the cathodic polarisation is applied again after some time, it is possible to remove an additional quantity of oxygen, originally dissolved in the metal, which has now diffused to the surface of the platinum[46].

The diffusion of large volumes of oxygen into silver at elevated temperatures was demonstrated by the work of Temkin and Kul'kova[47].

It follows from the results discussed here that with a number of metals the chemisorption of gases having a high electron affinity can be accompanied by migration of the adsorbate below the surface layer of metal atoms, which causes a positive charge to appear on the metal surface. The ionic radius of the adsorbate plays an essential part in this process. The resulting decrease in work function is responsible for the activation of the electrochemical dissolution processes of metals such as iron. Chemisorption leading to an increased work function causes passivation of iron. When oxygen can penetrate into the metal to an appreciable depth, the influence of absorbed oxygen on the surface properties of the metal is relatively small.

# ADSORPTION OF ORGANIC COMPOUNDS [AT THE MERCURY ELECTRODE-SOLUTION INTERFACE]

B. B. Damaskin

Among various direct and indirect methods for the investigation of the adsorption of organic substances on the surface of electrodes, the most widely used are those based on measurements of the interfacial tension ($\sigma$) and differential capacitance ($C$) as a function of electrode potential ($\varphi$). Most of these data have been obtained for the mercury-aqueous solution interface in the presence of small amounts of organic additives. In this connection, the theory of the adsorption or organic compounds described below is mainly based on experimental data obtained for the mercury electrode by the measurement of $\sigma-\varphi$ and $C-\varphi$ curves.

Starting with the work of Gouy [1,2] and Frumkin [3,4], the method based on the measurement of electrocapillary curves has been widely used up to the present time for the study of the adsorption on the mercury electrode of a wide variety of organic substances [5-20]. Fig. 1, taken from the paper by Gouy [1], shows that the adsorption of an organic compound (in this case pentanol) appreciably lowers the interfacial tension of mercury, the lowering being a maximum near the zero-charge point (z.c.p.) in a solution of an inorganic electrolyte, decreasing with increase in the negative or positive surface charge. In most cases, when the charge is sufficiently positive or negative, the lowering of the interfacial tension under the influence of an organic substance is not observed and the electrocapillary curve obtained in the presence of the additive coincides with the $\sigma-\varphi$ curve measured in the supporting electrolyte solution (Fig. 1). According to the Gibbs adsorption equation,

$$d\sigma = -RT\Gamma\, d\ln c, \qquad (1)$$

where $\Gamma$ and $c$ are the extent of adsorption and the concentration of the organic substance. This means that at high surface charges organic molecules are desorbed from the electrode surface. Qualitatively this effect is associated with replacement of a layer of organic molecules, having a low dielectric constant, by a layer of water molecules whose dielectric constant is much higher.

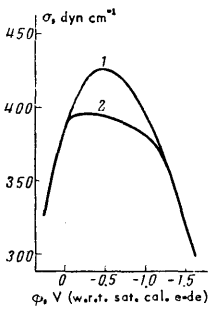

Fig. 1. Electrocapillary curves in different solutions:
1) 1 $N$ $Na_2SO_4$; 2) 1 $N$ $Na_2SO_4$ + + 0.1 M $C_5H_{11}OH$ (Gouy's data [1]).

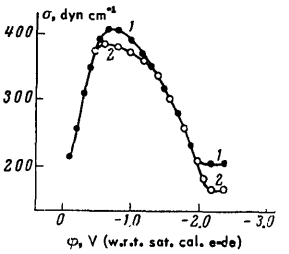

Fig. 2. Electrocapillary curves in different solutions:
1) 0.2 M NaI; 2) 0.2 M NaI + 0.1 M n-$C_5H_{11}OH$ (data of Smirnov and Demchuk [21]).

Fig. 2 shows $\sigma-\varphi$ curves measured by Smirnov and Demchuk [21] in 0.2 M aqueous solution of sodium iodide in the presence of 0.1 M n-pentanol over a wide range of potentials, up to the potential corresponding to the discharge of $Na^+$ ions with formation of sodium amalgam. In the authors' view, the divergence of the electrocapillary curves at highly negative potentials is due to the same cause as in the vicinity of the zero-charge point of mercury, i.e. it is associated with the adsorption of pentanol near the zero-charge point of the sodium amalgam.

A quantitative theory of the effect of the electric field on the adsorption of neutral molecules was developed by Frumkin [22]; according to Frumkin, when allowance is made for the attractive forces between the adsorbed molecules, the lowering of the interfacial tension ($\Delta\sigma$) and the degree of surface coverage ($\theta = \Gamma/\Gamma_\infty$) by the organic substance are related as follows:

$$\Delta\sigma = -A[\ln(1-\theta) + a\theta^2], \qquad (2)$$

where $A$ and $a$ are constants: $A = RT\Gamma_\infty$, while $a$ is a measure of the interaction between the molecules of the adsorbed species (attraction constant).

The equation for the adsorption isotherm can be readily obtained from Eqn. (2) and the Gibbs equation (1):

$$Bc = \frac{\theta}{1-\theta}\exp(-2a\theta), \qquad (3)$$

where $B$ is the adsorption equilibrium constant which determines the variation of the extent of adsorption with electrode potential. Eqn. (3) has been called the Frumkin isotherm.

In order to find the explicit relation between $B$ and $\varphi$, Frumkin suggested that the boundary between the electrode and solution may be represented by two condensers connected in parallel: the space between the plates of one of them contains only molecules of the organic substance and that between the plates of the other only the molecules of the solvent (water). The charge of the electrode ($\epsilon$) can then be represented by an equation of the following form:

$$\varepsilon = \varepsilon_0(1-\theta) + C'\theta(\varphi - \varphi_N), \qquad (4)$$

where $\epsilon_0 = \int_0^{\varphi} C_0 d\varphi$, $C_0$ and $C'$ are the double layer capacitances at $\theta = 0$ and $\theta = 1$ respectively, $\varphi$ is the potential reckoned from the zero-charge point at $\theta = 0$, and $\varphi_N$ is the shift of the zero-charge point on going from $\theta = 0$ to $\theta = 1$.

On combining Eqn. (4) with the principal equation of electrocapillarity,

$$d\sigma = -\varepsilon d\varphi - RT\Gamma d\ln c, \quad (5)$$

the following relation between $B$ and the potential is obtained:

$$B = B_0 \exp\left[-\frac{E + C'\varphi\left(\varphi_N - \frac{\varphi}{2}\right)}{A}\right], \quad (6)$$

where $E = \int_0^{\varphi} \epsilon_0 d\varphi$, i.e. the lowering of $\sigma$ under the influence of the adsorption of inorganic ions only.

Eqns. (6) and (3) permit the calculation of the dependence of the degree of coverage $\theta$ on the potential $\varphi$ and then the determination from Eqn. (2) of the lowering of the interfacial tension under the influence of the adsorption of organic molecules on the surface of the electrode. Such calculations have been made by Frumkin[22] for the adsorption of t-pentanol from 1 $N$ NaCl solution and showed satisfactory agreement with experimental $\sigma-\varphi$ curves.

However, even in these experiments a more detailed comparison of the calculated and experimental $\sigma-\varphi$ curves showed that the break in the experimental electrocapillary curves at $\epsilon > 0$ is more pronounced than would follow from theory. This result was explained[22] by a decrease in the area occupied by one adsorbed alcohol molecule as $\theta$ increases, which is equivalent to a parabolic relation between the potential and the attraction constant $a$.

In Butler's theory[23] an attempt was made to interpret electrocapillary curves on the basis of the molecular properties of the adsorbed substances, in particular by taking into account the polarisability of organic molecules. However, in Butler's theory the dipole moments of the adsorbed molecules are determined from experimental data on interfacial tension. Furthermore, this theory gives an incorrect variation of the extent of adsorption of the organic substance with its concentration in the solution, since it is based on the hypothesis that Henry's law holds.

Further development of the theory of the adsorption of organic compounds was possible on the basis of experimental measurements of the differential capacitance of the mercury electrode in the presence of organic additives, since differential capacitance is a much more sensitive function of the double-layer structure than interfacial tension[24]. On the basis of the electrocapillary data and Lippman's equation, it was to be expected that the differential capacitance curves obtained in the presence of organic additives would include a region of low capacitance (of the order of 4–5 $\mu$F cm$^{-2}$) bounded on either side by desorption peaks. Proskurnin and Frumkin[24] were able to demonstrate for the first time that $C-\varphi$ curves measured in the presence of n-octanol have indeed this shape (Fig. 3). Capacitance curves of similar shape were also obtained subsequently by a number of other investigators. Thus, starting with the work of Proskurnin and Frumkin[24], the method based on the measurement of differential capacitance has been widely used to study the adsorption of various organic substances on mercury[25–44].

However, quantitative application of these data has been limited in practice only to the range of potentials corresponding to maximum adsorption, where the $C-\varphi$ curves show a decrease in capacitance in the presence of organic

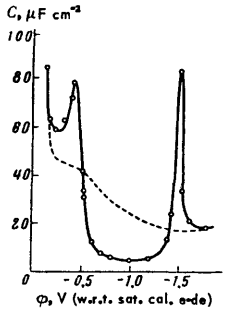

Fig. 3. Differential capacitance curves in 1 $N$ $Na_2SO_4$ solution and in 1 $N$ $Na_2SO_4$ solution saturated with n-$C_8H_{17}OH$ (data of Proskurnin and Frumkin[24]).

substances (Fig. 3) and where the following relation obtains between the capacitance and the degree of surface coverage:

$$C = C_0(1-\theta) + C'\theta. \quad (7)$$

This equation has been used[34,38,42] for the calculation of the adsorption isotherms on mercury of various organic compounds. Recently the variation of the capacitance at the potential of maximum adsorption with the degree of coverage was used by Dobren'kov to develop a theory for the simultaneous adsorption of two organic substances on the electrode surface[45,46].

In order to interpret the overall differential capacitance curve in the presence of an organic substance, it is necessary to choose an independent electrical variable and a particular equation for the adsorption isotherm. The controversy which has arisen concerning these problems[47–49] makes it necessary to examine them in greater detail.

## 1. CHOICE OF ELECTRICAL VARIABLE

Either the electrode potential[22] or the electrode charge[47] can be chosen as the electrical variable in the investigation of adsorption of organic substances on electrodes. It will be assumed initially that the experimental variation of the extent of adsorption of an organic substance $\Gamma$ with its bulk concentration and the potential may be written thus:

$$Bc = f(\Gamma), \quad (8)$$

where $B$ is a function of $\varphi$ only and $f(\Gamma)$ a function of $\Gamma$ only. It is evident that under these conditions it is useful to choose the potential as the independent electrical variable, since the shape of the isotherm [Eqn. (8)] in dimensionless coordinates is then independent of $\varphi$. It follows from Eqn. (8) that

$$\frac{d\ln B}{d\varphi} = -\left(\frac{\partial \ln c}{\partial \varphi}\right)_{\Gamma} = \frac{1}{RT}\left(\frac{\partial \varepsilon}{\partial \Gamma}\right)_{\varphi}, \quad (9)$$

where the second equality is a consequence of the basic equation of electrocapillarity [Eqn. (5)]. On integrating Eqn. (9), we find

$$\varepsilon = RT\left(\frac{d\ln B}{d\varphi}\right)\Gamma + \varepsilon_0 = A\left(\frac{d\ln B}{d\varphi}\right)\theta + \varepsilon_0, \quad (10)$$

where, as before, $A = RT\Gamma_\infty$.

Let the charge at $\theta = 1$ and the given potential be $\epsilon'$, so that

$$\varepsilon' = A\left(\frac{d\ln B}{d\varphi}\right) + \varepsilon_0. \quad (11)$$

It follows from Eqns. (10) and (11) that

$$\varepsilon = \varepsilon_0(1-\theta) + \varepsilon'\theta. \quad (12)$$

On differentiating Eqn. (12) with respect to the potential at $\theta$ = const, we obtain Eqn. (7). Thus representation of the sorption isotherm by Eqn. (8) and hence the choice of the electrode potential as the independent electrical variable are consistent with the model of the electrical double layer previously proposed by Frumkin [22].

If it is assumed as a first approximation that the capacitance $C_0$ is independent of $\varphi$, then evidently $\epsilon_0 = C_0\varphi$ and for $\epsilon = 0$ Eqn. (4) yields

$$\varphi_{\varepsilon=0} = \frac{\varphi_N 0}{\frac{C_0}{C'}(1-\theta)+\theta}, \quad (13)$$

where $\varphi_{\epsilon=0}$ is the difference between the zero-charge point at a given $\theta$ and the zero-charge point at $\theta = 0$, i.e. the jump in potential due to adsorption. Eqn. (13) shows that the variation of $\varphi_{\epsilon=0}$ with $\theta$ (or $\Gamma$) is not linear when the potential is chosen as the electrical variable, and deviates from linearity to a greater extent the higher the value of $C_0/C'$.

It will be assumed first that the experimental data can be described by an equation of the type

$$Gc = f(\Gamma), \quad (14)$$

where $G$ is a function of $\epsilon$ only and $f(\Gamma)$ a function of $\Gamma$ only. In this case it is reasonable to choose the electrode charge as the independent electrical variable, since the shape of the isotherm defined by Eqn. (14), in dimensionless coordinates, is then independent of $\epsilon$. It follows from Eqn. (14) that

$$\frac{d\ln G}{d\varepsilon} = -\left(\frac{\partial \ln c}{\partial \varepsilon}\right)_\Gamma = -\frac{1}{RT}\left(\frac{\partial\varphi}{\partial\Gamma}\right)_\varepsilon, \quad (15)$$

where the second equality is due to the basic equation of electrocapillarity corresponding to $\epsilon$ = const. [50] On integrating Eqn. (15), we obtain

$$\varphi = -RT\left(\frac{d\ln G}{d\varepsilon}\right)\Gamma + \varphi_0 = -A\left(\frac{d\ln G}{d\varepsilon}\right)\theta + \varphi_0, \quad (16)$$

where $\varphi_0$ is the value of $\varphi$, when $\theta = 0$, corresponding to the given value of $\epsilon$.

If the potential at a given $\epsilon$ and $\theta = 1$ is denoted by $\varphi'$, then

$$\varphi' = -A\left(\frac{d\ln G}{d\varepsilon}\right) + \varphi_0. \quad (17)$$

Eqns. (16) and (17) show that

$$\varphi = \varphi_0(1-\theta) + \varphi'\theta. \quad (18)$$

On differentiating Eqn. (18) with respect to $\epsilon$ for $\theta$ = const, we obtain

$$\frac{1}{C} = \frac{1-\theta}{C_0} + \frac{\theta}{C'}. \quad (19)$$

Thus when the adsorption isotherm is represented by Eqn. (14), and therefore when the electrode charge is chosen as the electrical variable, we have a model corresponding to two condensers with capacitances $C_0/(1-\theta)$ and $C'/\theta$ connected in series. The physical interpretation of this model appears to be difficult.

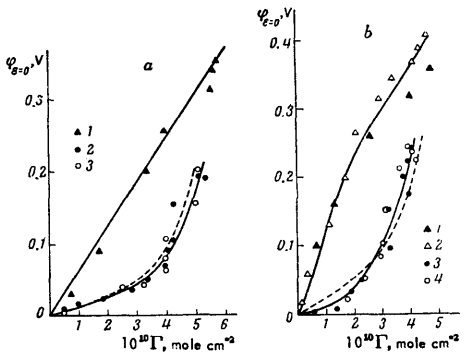

Fig. 4. Variation of the adsorption-induced potential jump with the extent of adsorption of the organic substance: *a*) adsorption of n-$C_4H_9COOH$; 1) at the solution/air interface, supporting electrolyte 0.01 *N* $H_2SO_4$; 2) and 3) at the mercury/solution interface [2] supporting electrolyte 0.01 *N* $H_2SO_4$; 3) supporting electrolyte 1 *N* $Na_2SO_4$ + 0.01 *N* $H_2SO_4$]; dashed line — calculated by Eqn. (13) for $\varphi_N$ = 0.02 V, $\Gamma_\infty = 5\times10^{-10}$ mole cm$^{-2}$, and $C_0/C' = 5$; *b*) adsorption of n-$C_5H_{11}NH_2$: 1) and 2) at the solution/air interface [1] supporting electrolyte 0.05 *N* KOH; 2) supporting electrolyte 1 *N* $Na_2SO_4$ + 0.05 *N* KOH]; 3) and 4) at the mercury/solution interface [3] supporting electrolyte 0.05 *N* KOH; 4) supporting electrolyte 1 *N* $Na_2SO_4$ + 0.05 *N* KOH]; dashed line — calculated by Eqn. (13) for $\varphi_N$ = 0.4 V, $\Gamma_\infty = 5\times10^{-10}$ mole cm$^{-2}$, and $C_0/C' = 5$.

On the other hand, if the capacitances $C_0$ and $C'$ are independent of $\epsilon$, then evidently $\varphi_0 = \epsilon/C_0$ and $\varphi' = \epsilon/C' + \varphi$. In this case Eqn. (18) can be rewritten thus:

$$\varepsilon = \frac{\varphi - \theta\varphi_N}{\frac{1-\theta}{C_0} + \frac{\theta}{C'}}. \quad (20)$$

Putting $\epsilon = 0$ in Eqn. (20), we obtain a linear variation of the adsorption-induced potential jump with $\theta$ (or $\Gamma$):

$$\varphi_{\varepsilon=0} = \theta\varphi_N. \quad (21)$$

Thus the variation of the adsorption-induced potential jump with $\Gamma$ makes it possible to decide whether condition (8) or condition (14) holds, and hence which choice of the electrical variable ($\varphi$ or $\epsilon$) is more reasonable in the investigation of the adsorption of an organic substance at the interface.

Fig. 4 shows the variation of $\varphi_{\epsilon=0}$ with $\Gamma$ for the adsorption of n-butyric acid and n-pentylamine at the mercury/solution and solution/air interfaces [51]. It is evident that the relation between $\varphi_{\epsilon=0}$ and $\Gamma$ at the mercury/solution interface is satisfactorily consistent with Eqn. (13), regardless of the concentration of the supporting electrolyte, and sharply deviates from the linear variation predicted by Eqn. (21). At the same time at the solution/air interface the relation is approximately consistent with Eqn. (21)†. Similar results were obtained by the present author also for the adsorption of n-propanol and n-butanol at both interfaces.

† Certain deviations of the $\varphi_{\epsilon=0}$–$\Gamma$ plot from linearity for the solution/air interface may be associated with a change in the orientation of the adsorbed molecules as $\Gamma$ increases.

It follows from these results that both the physical interpretation of the model of the double layer and the experimental variation of the adsorption-induced potential jump with the extent of adsorption suggest that the electrode potential and not the electrode charge be chosen as the electrical variable in the investigation of the adsorption of organic compounds at the mercury/solution interface.

## 2. CHOICE OF ADSORPTION ISOTHERM

Since experimental adsorption isotherms for organic compounds can have both the form of a logarithmic curve and the characteristic S-shape (Fig. 5), in choosing the equation for the adsorption isotherm it is reasonable to consider only those equations which can represent various shapes of the experimental isotherms, depending on the quantity $a$ (the attraction constant). This condition is satisfied by the following equations for adsorption isotherms:

(1) Frumkin's isotherm — Eqn. (3).

(2) de Boer's isotherm [52]:

$$Bc = \frac{\theta}{1-\theta}\exp\left(\frac{\theta}{1-\theta}\right)\exp(-2a\theta), \qquad (22)$$

(3) Parsons' isotherm [47]:

$$Bc = \frac{\theta}{1-\theta}\exp\left[\frac{2-\theta}{(1-\theta)^2}\right]\exp(-2a\theta), \qquad (23)$$

(4) The general equation of Frumkin's isotherm:

$$Bc = \frac{\theta}{(1-\theta)^n}\exp(-2a\theta), \qquad (24)$$

obtained by the present author [53] and taking into account both the forces of interaction between the adsorbed molecules and the organic substance (via the quantity $a$), and the displacement by the adsorbed species of $n$ molecules of the solvent (water).

Apart from the theoretical justification of a particular type of equation for the adsorption isotherm [47,48], it appears that experimental criteria must be the deciding factor. Such criteria were proposed by Parsons [47] and Tedoradze [54], but, as shown by the present author [55], they do not allow a choice among the four equations for adsorption isotherms given above. Let us therefore consider another criterion which does permit such a choice.

It is readily seen that the above equations are all of the form

$$Bc = F(\theta)\exp(-2a\theta), \qquad (25)$$

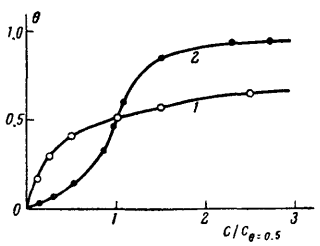

Fig. 5. Adsorption isotherms on mercury: 1) triethylammonium cations; 2) t-pentanol (data of Lorenz and coworkers [42,43]).

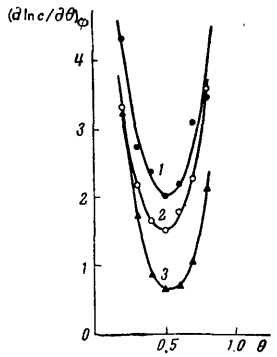

Fig. 6. Variation of $(\partial \ln c/\partial\theta)_\varphi$ with $\theta$ obtained from experimental adsorption isotherms:
1) aniline; 2) n-$C_5H_{11}NH_2$; 3) t-$C_5H_{11}OH$.

where $F(\theta)$ is a function of $\theta$ independent of $a$. On taking logarithms in Eqn. (25) and then differentiating it with respect to $\theta$ with $\varphi$ = const, we obtain

$$\left(\frac{\partial \ln c}{\partial\theta}\right)_\varphi = \frac{d\ln F(\theta)}{d\theta} - 2a. \qquad (26)$$

Analysis shows that at a certain value $\theta = \theta^*$, determined by the condition

$$\frac{d^2 \ln F(\theta)}{d\theta^2} = 0, \qquad (27)$$

the relation between $(\partial \ln c/\partial\theta)_\varphi$ and $\theta$ passes through a minimum whose position is determined only by the function $F(\theta)$ and is independent of the attraction constant $a$.

As shown elsewhere [55], the values of $\theta^*$ for Eqns. (3), (22), (23), and (24) are respectively 0.500, 0.333, 0.215, and $1/(1+\sqrt{n})$. Thus the position of the minimum on the experimental curve for the variation of $(\partial \ln c/\partial\theta)_\varphi$ with $\theta$ may serve as a convenient criterion for choosing one of the four isotherms. When this method is used, only de Boer's equation [Eqn. (22)] and Eqn. (24) with $n = 4$ are virtually indistinguishable.

Experimental $(\partial \ln c/\partial\theta)_\varphi - \theta$ curves can be obtained as follows. Initially, using the value of the capacitance at the minimum on the $C-\varphi$ curves, the $\theta - c$ adsorption isotherm is plotted in terms of Eqn. (7), which, as we have seen, is valid for any isotherm of the type represented by Eqn. (8) or (25). Since $d\ln c/d\theta = dc/cd\theta$, the values of $(\partial \ln c/\partial\theta)_\varphi$ can be found from the slope of this isotherm for various $\theta$, and the $(\partial \ln c/\partial\theta) - \theta$ curve can be plotted.

The characteristic curves obtained for the adsorption of aniline, n-pentylamine, and t-pentanol on the mercury electrode are presented in Fig. 6, which shows that the minimum on these curves corresponds to $\theta^* \simeq 0.5$ and therefore the adsorption of these compounds follows Frumkin's isotherm [Eqn. (3)]. Similar $(\partial \ln c/\partial\theta)_\varphi - \theta$ curves were obtained also for n-propanol, n-pentanol, isopentanol, isopentylamine, phenol, and tetrabutylammonium cations. For all these compounds the experimental values of $\theta^*$ are in the range between 0.45 and 0.55. [55]

Thus the adsorption on mercury of most organic compounds which lower the double-layer capacitance follows the equation of Frumkin's isotherm [Eqn. (3)]. Recently

Dobren'kov and Golovin[56] showed that this equation is also valid for the adsorption of dibutylnaphthalenesulphonic acid and isopentanol on the cadmium electrode‡. Therefore the equation of Frumkin's isotherm [Eqn. (3)] should be used as a basis for the theory of differential capacitance curves in the presence of organic substances.

## 3. QUANTITATIVE THEORY OF DIFFERENTIAL CAPACITANCE CURVES IN THE PRESENCE OF ORGANIC ADDITIVES

The fact that experimental data suggest the choice of the electrode potential as the electrical variable and of Frumkin's equation (3) as the equation of the adsorption isotherm means that the theoretical relations obtained by Lorenz and coworkers[42,43] and Parsons[47] and also the Devanathan[60] and Bockris–Devanathan–Müller[61] theories must be rejected, particularly as the last two theories have a number of significant disadvantages, which are discussed in detail in Ref. 62.

If the potential is chosen as the independent electrical variable, then under the condition that the adsorption of the organic substance on the electrode surface is not complicated by the formation of multilayers and micellar films, the electrode charge is a function of electrode potential and degree of coverage only:

$$\varepsilon = \varepsilon(\varphi, \theta). \tag{28}$$

Thus the overall expression for the differential capacitance can be put in the following form:

$$C = \frac{d\varepsilon}{d\varphi} = \left(\frac{\partial \varepsilon}{\partial \varphi}\right)_\theta + \left(\frac{\partial \varepsilon}{\partial \theta}\right)_\varphi \frac{d\theta}{d\varphi}. \tag{29}$$

The quantities $(\partial\epsilon/\partial\varphi)_\theta$ and $(\partial\epsilon/\partial\theta)_\varphi$ in this equation can be found immediately from Eqn. (4):

$$\left(\frac{\partial \varepsilon}{\partial \varphi}\right)_\theta = C_0(1-\theta) + C'\theta, \tag{30}$$

$$\left(\frac{\partial \varepsilon}{\partial \theta}\right)_\varphi = -[\varepsilon_0 + C'(\varphi_N - \varphi)]. \tag{31}$$

The derivative $d\theta/d\varphi$ is found from Eqn. (3). On taking logarithms in this equation and then differentiating it with respect to $\varphi$, we obtain after algebraic rearrangement,

$$\frac{d\theta}{d\varphi} = \frac{d\ln B}{d\varphi} \frac{\theta(1-\theta)}{1-2a\theta(1-\theta)}. \tag{32}$$

It follows from Eqn. (6) that

$$\frac{d\ln B}{d\varphi} = -\frac{\varepsilon_0 + C'(\varphi_N - \varphi)}{A} \tag{33}$$

and therefore

$$\frac{d\theta}{d\varphi} = -\frac{\varepsilon_0 + C'(\varphi_N - \varphi)}{A} \frac{\theta(1-0)}{1-2a\theta(1-\theta)}. \tag{34}$$

On substituting the values of the derivatives from Eqns. (30), (31), and (34) in Eqn. (29), we obtain the final expression for the differential capacitance in the presence of an organic substance:

$$C = C_0(1-\theta) + C'\theta + \frac{[\varepsilon_0 + C'(\varphi_N - \varphi)]^2}{A} \frac{\theta(1-\theta)}{1-2a\theta(1-\theta)}. \tag{35}$$

This equation was obtained for the first time by Hansen and coworkers[28].

As already pointed out above, Eqns. (3) and (6) make it possible to calculate the variation of $\theta$ with $\varphi$ at a given concentration of the organic substance. Once this variation has been found, and the constants $C'$, $A$, $a$, and $\varphi_N$ are known, the total differential capacitance curve in the presence of an organic substance may be calculated by Eqn. (35). Such calculations, made by Hansen and coworkers[28] and by the present author[63], show that, despite the qualitative agreement between the calculated and experimental $C-\varphi$ curves, there is a very significant quantitative discrepancy between them. Analysis shows that the discrepancy is evidence of a change with potential of the attraction constant in the equation of Frumkin's isotherm [Eqn. (3)]. Furthermore, in contrast to Frumkin's hypothesis[22], the variation of $a$ with $\varphi$ for most organic compounds is linear and not parabolic.

Thus it is of interest to develop a theory assuming an arbitrary variation of $a$ with $\varphi$ [$a = a(\varphi)$].

In this case on taking logarithms in Eqn. (3) and differentiating with respect to the potential, we obtain, after rearrangement, the following expression instead of Eqn. (32):

$$\frac{d\theta}{d\varphi} = \left(\frac{d\ln B}{d\varphi} + 2\theta\frac{da}{d\varphi}\right) \frac{\theta(1-\theta)}{1-2a\theta(1-\theta)}. \tag{36}$$

At the same time differentiation with respect to $\varphi$ when $\theta$ = const gives

$$\left(\frac{\partial \ln c}{\partial \varphi}\right)_\theta = -\left(\frac{d\ln B}{d\varphi} + 2\theta\frac{da}{d\varphi}\right). \tag{37}$$

Taking into account the second equality in Eqn. (9), we obtain

$$\frac{1}{A}\left(\frac{\partial \varepsilon}{\partial \theta}\right)_\varphi = \frac{d\ln B}{d\varphi} + 2\theta\frac{da}{d\varphi}. \tag{38}$$

On integrating this equation and remembering that the integration constant is $\epsilon_0$, we obtain

$$\varepsilon = \varepsilon_0 + A\frac{d\ln B}{d\varphi}\theta + A\theta^2\frac{da}{d\varphi}. \tag{39}$$

Since $\epsilon = \epsilon' = C'(\varphi - \varphi_N)$ when $\theta = 1$, it follows from Eqn. (39) that

$$\frac{d\ln B}{d\varphi} = -\frac{\varepsilon_0 + C'(\varphi_N - \varphi)}{A} - \frac{da}{d\varphi}. \tag{40}$$

After integrating this equation from 0 to $\varphi$ and taking antilogarithms, we have

$$B = B_0 \exp\left[-\frac{E + C'\varphi\left(\varphi_N - \frac{\varphi}{2}\right)}{A}\right] \exp(a_0 - a), \tag{41}$$

where $a_0$ is the value of $a$ when $\varphi = 0$.

Eqn. (41) represents the variation of the adsorption equilibrium constant with potential for any relation between $a$ and $\varphi$. It is readily seen that it becomes identical with Eqn. (6) when $a$ = const.

On substituting Eqn. (40) in Eqn. (39), we obtain the equation for the electrode charge in the general case, when $a = a(\varphi)$:

$$\varepsilon = \varepsilon_0(1-\theta) + C'\theta(\varphi - \varphi_N) - A\frac{da}{d\varphi}\theta(1-\theta). \tag{42}$$

‡ The satisfactory agreement of Eqn. (3) with experimental data implies that in the more general equation (24) $n = 1$ and therefore one adsorption site on the surface of the electrode is occupied by a group of several water molecules[53]. When allowance is made for the considerable attractive interaction between the $H_2O$ molecules adsorbed on mercury[57-59], this result may be explained by the fact that the work associated with the transfer of this group of molecules, taken as a whole, from the surface into the bulk of the solution is smaller than the overall work of transfer of each of these molecules separately.

As was to be expected, Eqn. (42) becomes identical with Eqn. (4) when $a$ = const.

Finally, we shall find an expression for the differential capacitance in the presence of an organic substance under the condition that $a = a(\varphi)$. From Eqn. (42), we have

$$\left(\frac{d\varepsilon}{\partial\varphi}\right)_\theta = C_0(1-\theta) + C'\theta - A\frac{d^2a}{d\varphi^2}\theta(1-\theta), \quad (43)$$

$$\left(\frac{\partial\varepsilon}{\partial\theta}\right)_\varphi = -\varepsilon_0 + C'(\varphi-\varphi_N) - A\frac{da}{d\varphi}(1-2\theta). \quad (44)$$

On substituting Eqn. (40) in Eqn. (36), we find

$$\frac{d\theta}{d\varphi} = -\left[\varepsilon_0 - C'(\varphi-\varphi_N) + A\frac{da}{d\varphi}(1-2\theta)\right]\frac{1}{A}\frac{\theta(1-\theta)}{1-2a\theta(1-\theta)}. \quad (45)$$

If we now substitute the values of the derivatives from Eqns. (43), (44), and (45) in Eqn. (29), we obtain the final expression for the differential capacitance:

$$C = C_0(1-\theta) + C'\theta - A\frac{d^2a}{d\varphi^2}\theta(1-\theta) + \frac{1}{A}\left[\varepsilon_0 + C'(\varphi_N-\varphi) + A\frac{da}{d\varphi}(1-2\theta)\right]^2\frac{\theta(1-\theta)}{1-2a\theta(1-\theta)}. \quad (46)$$

Evidently Eqn. (46) becomes identical with Eqn. (35) when $a$ = const.

Earlier the present author obtained expressions for the adsorption equilibrium constant $B$, the electrode charge $\epsilon$, and the differential capacitance $C$ under the condition that the attraction constant is a linear function of electrode potential:

$$a = a_0 + \beta\varphi. \quad (47)$$

In the expressions for $B$, $\epsilon$, and $C$ the variation of $a$ with $\varphi$ was allowed for by introducing a new constant:

$$\varphi_N^0 = \varphi_N + \frac{\beta A}{C'}. \quad (48)$$

Eqns. (41), (42), and (46) obtained in this work are free from the limitations imposed by condition (47), and are valid for any relation between the attraction constant and the electrode potential. Since the experimental variation of the attraction constant with potential satisfied condition (47) in most cases, the formulae obtained in Ref. 64 led to satisfactory agreement between calculated and experimental $C-\varphi$ curves[63,65-68]. Fig. 7 illustrates this result using as an example the adsorption of n-valeric acid on mercury[68]. Similar satisfactory agreement between calculation and experiment was observed by the author for the adsorption on mercury of n-propanol, n-butanol, n-pentanol, isopentanol, t-pentanol, n-butylamine, n-pentylamine, isopentylamine, and diethyl ketone.

The calculated and experimental $C-\varphi$ curves for the adsorption of aniline[69] and pyridine[70] on mercury coincide only in the range of negative surface charges (Fig. 8). On going from $\epsilon < 0$ to $\epsilon > 0$, there is a change in the orientation accompanied by partial desorption of aniline or pyridine molecules due to their $\pi$-electron interaction with the positive charges on the surface of mercury. It is this process and not total desorption of the molecules of the organic substance from the electrode surface which corresponds to the anodic maxima on the $C-\varphi$ curves in the presence of aniline or pyridine. Clearly, under these conditions when $\epsilon > 0$ theoretical $C-\varphi$ curves, which do not take account of the above anomalies in the adsorption of an organic substance, cannot coincide with the experimental differential capacitance curves.

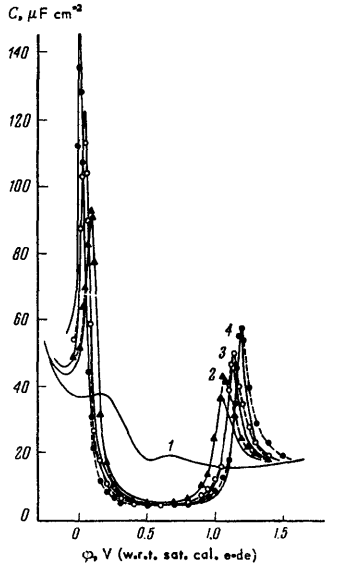

Fig. 7. Differential capacitance curves for 0.05 $N$ $Na_2SO_4$ solution with different concentrations of added n-$C_4H_9COOH$ (M): 1) 0; 2) 0.05; 3) 0.08; 4) 0.12; continuous lines — experimental data for 400 c/s; symbols and dashed lines — calculated values.

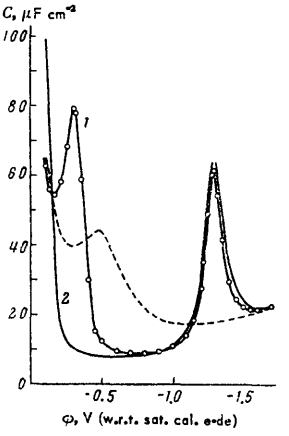

Fig. 8. Differential capacitance curves for 0.1 $N$ KCl solution alone (dashed curve) and in the presence of 0.1 M aniline: 1) experimental data; 2) calculated curve.

Finally, in the adsorption of phenol on mercury[71] the planar disposition of molecules, associated with strong $\pi$-electron interaction, is characteristic of the entire range of its adsorption potentials. In this case the constants which enter into the equations for the quantity $B$ [Eqn. (41)] and the differential capacitance [Eqn. (46)] characterise the planar configuration of the phenol molecules in the adsorbed state, so that the calculated and experimental $C-\varphi$ curves agree with one another over the entire range of potentials (Fig. 9). However, the effect of the $\pi$-electron interaction

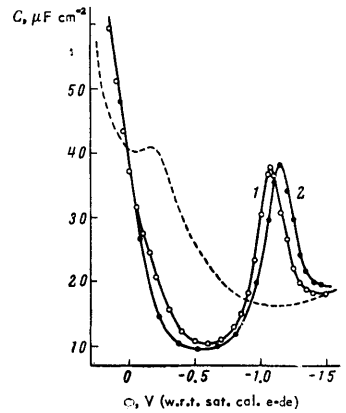

Fig. 9. Differential capacitance curves for 1 $N$ $Na_2SO_4$ solution alone (dashed curve) and in the presence of 0.05 M phenol: 1) experimental data; 2) calculated curve.

leads nevertheless to less satisfactory agreement between calculation and experiment for phenol than for the adsorption of aliphatic compounds (Fig. 7).

Apart from the quantitative interpretation of the differential capacitance curves in the presence of an organic substance, Eqns. (3), (41), and (46) make it possible to investigate certain general features of equilibrium (i.e. extrapolated to zero frequency) and non-equilibrium $C-\varphi$ curves, in particular the dependence of the potentials corresponding to the peaks on the $C-\varphi$ curves and the height of these peaks on the concentration of the organic substance. Study of these relations is very important, since it leads to methods for the determination of the principal constants in Eqns. (41) and (46) and the relations between $a$ and $\varphi$ from experimental differential capacitance curves. Recently the present author and Tedoradze [72-76] considered the problems involved in the determination of such general relations, which are of independent scientific interest.

I should like to take this opportunity to express my profound gratitude to A. N. Frumkin for continued interest in this work and discussion of the results obtained.

## I. INTRODUCTION

The theory of electronic processes in liquids occupies a very specific place in the general theory of chemical kinetics. A comparison of various electronic processes occurring in the liquid phase and in solids reveals a great similarity of physical mechanisms. Yet, no such analogy is normally found between gas-phase and liquid-phase reactions. For example, we may consider the electron exchange reaction between ions of the same sign. If we compare the rate of charge transfer between ions in gases with the rate of analogous oxidation–reduction reactions in water, we find that charge transfer in gases not only occurs significantly faster than in solutions, but also, and this is less trivial, that the phenomenon of resonance charge transfer is in general absent in solutions. It is well known that charge transfer between similar ions differing only in valence state proceeds much faster in the gas phase than reactions between unlike ions[1]. At the same time, the reaction $Fe^{2+} + Fe^{*3+} \rightarrow Fe^{3+} + Fe^{*2+}$ is much slower, in solutions, than a reaction like $Fe^{2+} + FeOH^{2+} \rightarrow \rightarrow Fe^{3+} + FeOH^{+}$. On the other hand, it has been possible[2-7] to apply the theory of $F$-centres and polarons, which was developed for crystals[4], in the study of the absorption spectra and of the conductivity of solutions of metals in liquid ammonia.

The lack of similarity between gas-phase reactions and electronic processes in liquids makes it very difficult to apply the transition state theory effectively to the latter processes. Indeed, this is easily verified by noting that the potential energy surfaces for electronic reactions in a condensed phase must be multidimensional, since we assume that the electron interacts strongly with a very large number of solvent molecules. This does not mean, of course, that the rate of the process will not show activational features: the situation involves, on the one hand, the Franck–Condon principle (i.e. the quasi-classical motion of heavy atoms), and, on the other hand, fluctuation theory (the Boltzmann formula). We are only considering the actual calculation of activation energies by means of the transition state theory. Furthermore, in the case of non-adiabatic reactions with multidimensional electronic energy levels (i.e. potential energy surfaces) there is no method of calculating the pre-exponential factor (the so-called transmission coefficient) similar to the Landau–Zener method for one-dimensional levels, used to calculate the rates of gas reactions. In this sense, the transition state theory hardly justifies its name of theory of absolute reaction rates.

Lastly, we have one further reason for renouncing the formal use of the transition state theory: it is the absence of any criterion whatsoever for its applicability, which has the effect of creating the illusion that the method is of universal applicability. Yet, we know from the most general considerations that such criteria must exist. We shall show below, using a concrete example (see Sections II, 2 and II, 3), that the absolute reaction rate theory is applicable only at high enough temperatures. Formally, this shortcoming stems from the absence of a sufficiently rigorous method of deriving the formulae of the transition state theory. We are not only concerned with the need for a quantitative criterion of the exactness of a theoretical discussion: such a criterion, in conjunction with experimental data, would also throw light on the mechanism of various reactions.

The physical analogy between various electronic processes in liquids and in solids suggests the possibility of applying to electronic processes in liquids the mathematical formalism which has been developed to deal with kinetic phenomena in solids (polar crystals, impurity semiconductors, alloys, etc.). A very wide range of contemporary problems in chemistry, electrochemistry, and biochemistry could be solved by the application of some of the techniques of the quantum theory of irreversible processes. There are a number of problems, however, in which the difference between a liquid and an ordered crystal can prove to be a fundamental one (see, for example, Section II, 5). This is especially true of the calculation of mobilities. In an ideal crystal, the electrical conductivity is infinitely high in the absence of thermal vibrations, whereas in liquids (as in any disordered system) the electronic electrical conductivity remains finite even if the thermal motion of the atoms is ignored. We shall show in Section II, 5 that in this case it is possible to apply (in a slightly modified form) the quantum statistics used to describe disordered solids (alloys, or impurity semiconductors).

In compiling the present article, we have relied mainly on our earlier theoretical results, which we have compared with the results of other workers. This restriction is due to the fact that the method presented here differs very considerably from the theoretical approach of other workers, so that an attempt at unification would not be expedient. However, the list of references includes a selection of reviews[5-8] and original papers by both experimental and theoretical workers.

## II. THEORY OF HOMOGENEOUS REACTIONS

### 1. Model of a Liquid

Since the present review will be concerned mostly with polar liquids, this Section is devoted exclusively to liquids of this type. Non-polar liquids will be discussed to some extent in Section II, 5 in connection with the study of electronic spectra.

A polar liquid can be completely described by specifying the coordinates of all the dipoles in the medium. To simplify the discussion, we shall adopt the following scheme: let the position of the dipole be characterised by the coordinate of the centre of gravity $R_i(t)$ and by the angle $\theta_i(t)$ which defines the orientation of the dipole. The subscript $i$ denotes the number of the dipole, and $t$ indicates that both $R_i$ and $\theta_i$ are time-dependent. In accordance with modern ideas on the liquid state, the variation of $R_i$ and $\theta_i$ with time can be visualised as follows: the dipole resides in a certain temporary equilibrium position $R_i^0$, $\theta_i^0$, about which it executes small oscillations. The average time interval between sudden changes of $R_i^0$ and $\theta_i^0$, $\tau_g$, can be calculated from diffusion data. Thus, for water $\tau_g \simeq 10^{-9}$ s, whereas the libration frequency of the dipole (describing changes of the angle $\theta_i$ in the neighbourhood of $\theta_i^0$) is of the order of $10^{11}$ s$^{-1}$. One of the most important postulates of the theory states that the most fundamental dynamic role is played by the librational oscillations of the dipole, and not by its diffusional jumps. This assumption can be explained as follows. A fairly accurate description would be obtained if the desired physical quantity (say, the probability of electron transfer) could be calculated for fixed values of $R_i^0$ and $\theta_i^0$, and the result averaged over all $R_i^0$ and $\theta_i^0$. Unfortunately, this procedure is far from being generally possible. For example, in the presence of strong interaction between the electron and the solution the distribution function of $R_i^0$ and $\theta_i^0$, i.e. the probability of finding the dipole in the position $R_i^0$, $\theta_i^0$, is itself, obviously, a function of the distribution of the electronic charge density or of the quantum state of the electron. In practice, this means that if we are interested only in the probability of an electronic transition from some initial state to a final state, we should first calculate the probability for the conditions $R_i^0 = (R_i^0)_{\text{init}}$ at the beginning of the transition and $R_i^0 = (R_i^0)_{\text{fin}}$ at the end of the transition, and we should then sum the probabilities over all possible $(R_i^0)_{\text{fin}}$ and average over $(R_i^0)_{\text{init}}$. We shall assume that the transition from an arbitrary state $R_i^0$ to a state of thermodynamic equilibrium occurs faster than the time $\tau_e$ between electronic transitions. In this case it is no longer necessary to average over $R_i^0$. Thus, for $\tau_e \gg \tau_g$ we can ignore the effect of discontinuous changes in the coordinates $R_i^0$ and $\theta_i^0$, and consider only the librational oscillations of the dipole as the total or intramolecular vibrations of the liquid. Lastly, we shall make one further observation, of which we shall make use in what follows. If the static dielectric constant $\epsilon_s$ is calculated for a system of oscillating dipoles, it is found to be independent of temperature. Thus, yet another criterion for the applicability of our model is that $\epsilon_s$ should be an insensitive function of temperature. In particular, for water $\epsilon_s = a/T$, so that the relative change

of $\epsilon_s$, $\left(\left|\frac{\Delta\epsilon_s}{\epsilon_s}\right| = \left|\frac{\Delta T}{T}\right|\right)$, is not large at ordinary temperatures. As for our fundamental criterion $\tau_e \gg \tau_g$, we shall merely state at this point that it is always satisfied in practice by the systems of interest, and that a more detailed discussion (from a somewhat different viewpoint) will be given in Section II, 3.

Strictly speaking, the oscillations of dipoles in a liquid are not of the harmonic type. However, the problem of electronic processes is susceptible to fully quantitative treatment and can be solved quantum-mechanically only in the harmonic approximation. In this approximation the model of the liquid takes the form of an assembly of harmonic oscillators (phonons) whose Hamiltonian expressed in normal coordinates is

$$H_s = \frac{1}{2}\sum_k \hbar\omega_k \left(q_k^2 - \frac{\partial^2}{\partial q_k^2}\right). \qquad (2.1)$$

In this formula the normal frequencies $\omega_k$ should be treated as empirical. In general, the electron can interact both with optical and with acoustic phonons, but in polar systems only longitudinal phonons of the optical type[4] of low dispersion (i.e. $\omega_k \simeq \omega_0$) play a really important role. Physically, either intramolecular vibrations of the dipoles or librational oscillations can correspond to these types. For example, for water we have the vibrations of the O–H bond or of the H–H hydrogen bond, and also the librational oscillations of the molecule as a whole. As will be evident from what follows, it is most rational to choose the latter (librational) type of oscillation for water, with $\omega_0 \simeq \simeq 10^{11}$ s$^{-1}$. If complex or hydrated ions are relevant to the problem, it becomes necessary to consider several optical vibration types. The presence of a small dispersion in the optical type does not affect the final results in any way, but for purely computational reasons[9] it is convenient to introduce a finite dispersion at an intermediate stage and make this tend to zero in the final result.

The theory becomes particularly revealing if the model used to describe the liquid is a continuum with macroscopic specific polarisation $\vec{P}$. Strictly speaking, such a model can describe a real system satisfactorily only some distance away from the electron (or ion), but the formulae obtained from this model offer some valuable though approximate numerical results. The Hamiltonian for this system was first obtained by Pekar[4] and Fröhlich[10], and we shall not derive it here (see also Ref. 6). We shall only point out that it is of the same form as Eqn. (2.1), but we must set $\omega_k = \omega_0$, and the normal coordinates $q$ are found to be related to the Fourier amplitudes of $\vec{P}$ by the expression

$$\vec{P}(\vec{r}) = \left(\frac{c\hbar\omega_0}{4\pi V}\right)^{1/2} \sum_k \vec{Q}_k e^{i\vec{k}\vec{r}}; \quad q_k = \frac{1}{2}\begin{cases} i(Q_k - Q_k^*), & k > 0; \\ Q_k + Q_k^*, & k \leqslant 0, \end{cases} \qquad (2.2)$$

where $V(\to\infty)$ is the volume of the fundamental region of periodicity of $\vec{P}$, and

$$c = \frac{1}{\varepsilon_0} - \frac{1}{\varepsilon_s}. \qquad (2.3)$$

$\epsilon_0$ denotes the optical dielectric constant (equal, for example, to 1.78 for water). The parameter $c$ plays a fundamental role in the polarisation model. Its function can be illustrated as follows. When expressing the potential energy of a liquid, one should consider only that part which concerns the motion of heavy particles, since the electronic part of the polarisation follows their motion without inertia and contributes a constant term to the energy. On the other hand, the interaction between a slow electron in homogeneous reactions and the electronic part of the polarisation can also be assumed constant if one considers that the electrons of the liquid molecule are moving immeasurably faster than the outer electron which is taking part in the reaction. Therefore, this term also can be omitted if the electron does not leave the liquid. The case of heterogeneous reactions, when the electron passes from the liquid into the electrode, will be considered separately (see Section III, 1). The notion of calculating the potential energy of the inertial part of the non-equilibrium polarisation, $\vec{P}_{\text{inert}}$, amounts to a calculation of the work needed to form $\vec{P}_{\text{inert}}$ by slowly applying a fictitious electrical induction $\vec{D}$ and then removing it instantaneously:

$$U_{P_{\text{inert}}} = -\frac{1}{4\pi}\int_0^D DdE - \frac{1}{4\pi}\int_D^0 DdE = -\frac{1}{4\pi\varepsilon_s}\int_0^D DdD - \frac{1}{4\pi\varepsilon_0}\int_D^0 DdD = \frac{c}{8\pi}D^2. \qquad (2.4)$$

The value of $D$ must, of course, be chosen so that the polarisation in the final state is equal to $P_{\text{inert}}$. Since the first stage (application of the induction) was carried out slowly, we can use the equilibrium formula

$$\vec{P}_{\text{inert}} = \vec{P} - \vec{P}_{\text{electr}} = \frac{\varepsilon_s - 1}{4\pi\varepsilon_s}\vec{D} - \frac{\varepsilon_0 - 1}{4\pi\varepsilon_0}\vec{D} = \frac{c}{4\pi}\vec{D}. \qquad (2.5)$$

On inserting formula (2.5) into (2.4), we find

$$U_{P_{\text{inert}}} = \frac{2\pi}{c}P^2_{\text{inert}}. \qquad (2.6)$$

This expression was first obtained by Pekar[4], and also by Marcus[11], who used an independent and somewhat more complicated method. This deduction, based on non-equilibrium thermodynamics, has one major shortcoming: the quantum-mechanical Hamiltonian is found to depend on temperature through $\epsilon_s(T)$. In practice, this means that, instead of a single statistical averaging of the final results, we have performed a partial averaging at the Hamiltonian stage. This procedure can be justified by using the concepts expressed at the beginning of this Section. Indeed, the condition that $D$ should be applied slowly implies that a preliminary averaging with respect to $R_i^0$ and $\theta_i^0$ is permissible. Hence it is evident that formula (2.6) is also correct only if the condition $\tau_e \gg \tau_g$ is satisfied. In other words, in all formal thermodynamic calculations $\epsilon_s$ is to be treated as a parameter which does not depend on temperature.

## 2. Adiabatic Perturbation Theory

As was pointed out above, the characteristic feature of a polar medium is that the interaction between an electron and the medium (i.e. the phonons) is not a weak one. Therefore, the familiar methods of the theory of small perturbations are not suitable in this case for calculating the probability of electron transfer, if the solution is wanted in the form of a power series of the electron–phonon interaction constant. Physically, this means that several phonons are emitted during the electron transfer process rather than a single phonon. One of the methods of calculation used in problems of this type relies on the so-called adiabatic perturbation theory. We shall now describe the physical concepts underlying this theory.

It is convenient to set up the Hamiltonian for the total system in the form

$$H(x, q) = H_e(x) + H_s(q) + V(x, q) + H'(x, q) = H(x, q) + H'(x, q). \qquad (2.7)$$

Here $H_e(x)$ is the total energy of an electron interacting with a given external field (for example, with ions, with

light, etc.); $H_S(q)$ is the total energy of the liquid (in the phonon model assumed here); $V(x,q)$ is the electron–phonon interaction energy. To make the treatment more general, we have introduced the term $H'(x,q)$, which is small in comparison with $H(x,q)$, as required by perturbation theory. In a sense, this term can describe the effect of, for example, neighbouring ions on an electron situated close to some specific ion. Since the calculation of $H'(x,q)$ does not present particular difficulty, we shall consider for the time being the Hamiltonian $H(x,q)$. The basic concept which we intend to use is that the rate of motion of the electron is very much higher than that of the heavy atoms of the liquid, i.e. of the phonons. Hence, as "seen from" the fast electron, the atoms of the liquid can be treated as immobile, and the problem becomes that of an electron in a given field:

$$\{H_e(x)+V(x,q)\}\psi_\alpha(x,q)=\varepsilon_\alpha(q)\psi_\alpha(x,q), \tag{2.8}$$

where $\alpha$ is the number of the electronic level, and the energy $\epsilon_\alpha(q)$ and the electron function $\psi$ depend on $q$ as a parameter. If $H_S(q)$ were to vanish, i.e. if the atoms of the liquid were immobile, $\psi_\alpha(x,q)$ would be an exact solution of the problem. However, allowance for the slow motion of the atoms introduces the possibility of electron transfer from one state $\alpha$ to another state $\alpha'$. Therefore, the exact solution of the problem takes the form of a superposition of all states $\psi_\alpha(x,q)$, with some "weighting" factors $\chi_\alpha(q)$ which are, of course, a function of $q$. Mathematically speaking, we have expanded an exact $\psi$-function into a series as a full set of orthogonalised functions $\psi_\alpha(x,q)$:

$$\psi(x,q)=\sum_\alpha \chi_\alpha(q)\psi_\alpha(x,q). \tag{2.9}$$

On substituting this expression into the wave equation for $H(x,q)$, after multiplying the left-hand side by $\psi^*_\beta(x,q)$ and integrating with respect to $x$, we obtain the following equation for $\chi_\alpha(q)$:

$$\{H_s(q)+\varepsilon_\beta(q)-E\}\chi_\beta(q)=\sum_\alpha L_{\beta\alpha}(q)\chi_\alpha(q), \tag{2.10}$$

where

$$L_{\beta\alpha}(q)=\frac{1}{2}\sum_k \hbar\omega_k\left\{\int\psi^*_\beta\frac{\partial\psi_\alpha}{\partial q_k}dx\cdot\frac{\partial}{\partial q_k}+\int\psi^*_\beta\frac{\partial^2\psi_\alpha}{\partial q_k^2}dx\right\}. \tag{2.11}$$

Since $\frac{\hbar}{i}\frac{\partial}{\partial q_k}$ is an operator for the rate of motion of heavy particles, the first term in (2.11) can be interpreted, in a sense, as a mean velocity, and the second term as a mean square velocity. Therefore, the operator $L$ must be treated as small in the adiabatic approximation (this operator is sometimes called the non-adiabaticity operator). If we use the quasi-classical approximation for the electron, we can show that $L\simeq\sqrt{m/M}$, where $m$ is the mass of the electron and $M$ the mass of the heavy particles. In the zeroth approximation, assuming $L=0$, we obtain

$$\left\{-\frac{1}{2}\sum_k\hbar\omega_k\frac{\partial^2}{\partial q_k^2}+\frac{1}{2}\sum_k\hbar\omega_k q_k^2+\varepsilon_\beta(q)\right\}\chi_{\beta n}(q)=E_n\chi_{\beta n}(q), \tag{2.12}$$

where the subscript $n$ identifies the various quantum levels of the slow subsystem. If the electron is initially in the state $\alpha$, $\chi_{\beta n}(q)\simeq\delta_{\beta\alpha}$, i.e. the electronic state $\alpha$ with $L=H'=0$ will not suffer any changes. The quantity

$$U_\beta(q)=\frac{1}{2}\sum_k\hbar\omega_k q_k^2+\varepsilon_\beta(q) \tag{2.13}$$

plays the role of potential energy for the heavy subsystem, and admits of the following simple interpretation: the first term represents the direct interaction of the heavy particles; the second term represents the interaction of the heavy particles with the blurred electron cloud (i.e. the heavy particles "perceive" the fast-moving electron only in a smeared out form). Therefore, the latter must evidently depend on the electronic state $\beta$. $U_\beta(q)$ is called the electronic energy level, or the potential energy surface.

If $L$ or $H'$ is finite, transitions can occur between the different states $\Psi_{\alpha,n}=\psi_\alpha\chi_{\alpha n}$ and $\Psi_{\alpha' n'}$ with probability $w_{\alpha n\to\alpha' n'}$. Therefore, if we are interested only in the change of electronic state, $w_{\alpha n\to\alpha' n'}$ must be summed over $n'$ and statistically averaged over $n$ (we assume that the heavy subsystem is initially in statistical equilibrium):

$$w_{\alpha\to\alpha'}=\sum_{n'}\langle w_{\alpha n\to\alpha' n'}\rangle_n. \tag{2.14}$$

To calculate $w$ it is necessary to know $\chi_{\alpha n}$, i.e. to be able to solve Eqn. (2.12). An approximate solution can be obtained by expanding $\epsilon_\alpha(q)$ in a power series of $q$ around the equilibrium value $q_0^\alpha$ and retaining only the first two terms:

$$\varepsilon_\alpha(q)\simeq\varepsilon_\alpha(q_0^\alpha)+\sum_k u^\alpha(q_k-q_{k0}^\alpha). \tag{2.15}$$

The electronic energy level then has the form

$$U_\alpha(q)=\varepsilon_\alpha(q_0^\alpha)-\sum_k u_k^\alpha\left(q_{k0}^\alpha+\frac{u_k^\alpha}{2\hbar\omega_k}\right)+\frac{1}{2}\sum_k\hbar\omega_k\left(q_k+\frac{u_k^\alpha}{\hbar\omega_k}\right)^2.$$

Since by definition $q_0^\alpha$ corresponds to a minimum value of $U_\alpha(q)$, it follows that $q_{k0}^\alpha=-\frac{u_k^\alpha}{\hbar\omega_k}$ and

$$U_\alpha(q)=\varepsilon_\alpha(q_0^\alpha)+\frac{1}{2}\sum_k\hbar\omega_k q_{k0}^2+\frac{1}{2}\sum_k\hbar\omega_k(q_k-q_{k0}^\alpha)^2=J_\alpha+$$
$$+\frac{1}{2}\sum_k\hbar\omega_k(q_k-q_{k0}^\alpha)^2. \tag{2.16}$$

This expression allows a simple physical interpretation: before the electron is introduced, the liquid executes small oscillations close to the unpolarised state $q=0$ (see curve $a$ of Fig. 1); after introduction of an electron into the state $\alpha$, the liquid becomes polarised to the value $q_0^\alpha$, and the total potential energy of the system is made up of the polarisation energy of the liquid $-\frac{1}{2}\sum_k\hbar\omega_k q_{k0}^2$, the energy of the electron in the polarised liquid $\epsilon_\alpha(q_0^\alpha)$, and the energy of the oscillatory motion of the liquid close to its equilibrium state $\frac{1}{2}\sum_k\hbar\omega_k(q_k-q_{k0}^\alpha)^2$. It is evident from this picture that the approximation (2.15) adopted here corresponds to the case where it is permissible to ignore the changes in vibrational frequency of the dipoles caused by the interaction between the electron and the liquid.

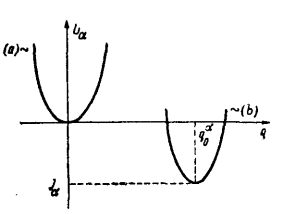

Fig. 1.

In order to apply the perturbation theory to the continuous spectrum, we shall assume that $\omega_k = p_k\Omega_0$, where $p_k$ are integers and $\Omega_0 \to 0$. Without reproducing the lengthy calculations[12-14], we shall quote the expression for the probability of electronic transition per unit time:

$$w_{\alpha\to\alpha'} = \frac{2\pi}{\hbar}|V_{\alpha'\alpha}|^2 e^{\frac{J_\alpha - J_{\alpha'}}{2kT} - \sum_k z_k \coth\frac{\hbar\omega_k}{2kT}} \sum_{m=-\infty}^{+\infty} \frac{\sin m\Omega_0 t}{\pi\hbar m\Omega_0} e^{-\frac{m\hbar\Omega_0}{2kT}} \sum_{l_k}' \prod_k I_{l_k}(z_k). \tag{2.17}$$

We have introduced the following terminology: $V_{\alpha'\alpha}$ is a matrix element of the perturbation, i.e. either $L_{\alpha'\alpha}$ or $H'_{\alpha'\alpha}$, according to which of the two is the most significant; $z_k = \frac{1}{2}(q^{\alpha}_{k0} - q^{\alpha'}_{k0})^2 \operatorname{cosech}\frac{\hbar\omega_k}{2kT}$; $I_l(z)$ is a Bessel function of imaginary argument of order $l$; lastly, the prime in the summation denotes the choice of values of $l_k$ among all possible integral values such that $\sum_k \hbar\omega_k l_k = J_{\alpha'} - J_\alpha + m\hbar\Omega_0$. The only assumption made in the derivation of this formula was $t < \frac{1}{\Omega_0} \to \infty$. The physical significance of this condition is that the times considered are small enough to make (according to the uncertainty principle) $\Delta E \sim \frac{\hbar}{t} \gg \hbar\Omega_0$, i.e. such that there is no noticeable dispersion of the energy spectrum. From the exact formula (2.17) we can obtain an asymptotic expression for the case of very small dispersion of the frequency spectrum ($p_k \simeq p_0 = \frac{\omega_k}{\Omega_0} \to \infty$). Since we are assuming that the type of dispersion plays no part, we shall choose $p_{k_1} = p_0$ and $p_{k_2} = p_0 + 1$ ($k_1 \neq k_2$). Under these conditions, division of all $k$ by $k_1$ and $k_2$ is arbitrary. Using the asymptotic properties of $I_m(z)$, it is possible to show that

$$w'_{\alpha\to\alpha'} \simeq \frac{2\pi|V_{\alpha'\alpha}|^2}{\hbar^2\omega_0} e^{\frac{J_\alpha - J_{\alpha'}}{2kT} - \frac{E_s}{\hbar\omega_e}\coth\frac{\hbar\omega_e}{2kT}} I_{m_0}\left(\frac{E_s}{\hbar\omega_0}\operatorname{cosech}\frac{\hbar\omega_0}{2kT}\right); \quad \hbar\omega_e \ll \sqrt{kTE_s}. \tag{2.18}$$

The parameter $E_S = \frac{1}{2}\sum_k \hbar\omega_0(q^{\alpha}_{k0} - q^{\alpha'}_{k0})^2$ has the significance of a "reorganisation" energy (or "transpolarisation" energy) for the liquid as a result of the electronic transition and $m_0 = \frac{J_\alpha - J_{\alpha'}}{\hbar\omega_0}$.

This formula assumes a particularly simple form at high temperatures, when $\hbar\omega_0 < kT$:

$$w_{\alpha\to\alpha'} = \left(\frac{\pi}{\hbar^2 kTE_s}\right)^{1/2}|V_{\alpha'\alpha}|^2 e^{-\frac{E_a}{kT}}; \quad kT > \hbar\omega_0, \tag{2.19}$$

where the activation energy $E_a$ is given by

$$E_a = \frac{(J_{\alpha'} - J_\alpha + E_s)^2}{4E_s}. \tag{2.20}$$

Thus, we have in fact arrived at a formula of the same type as that of the transition state theory, but only in the particular case of $kT > \hbar\omega_0$.

The advantage of the $\omega_k = \omega_0$ model, i.e. the model in which the motion of the dipoles can be characterised by a single frequency, is that a single effective coordinate $q$ can be introduced in place of the many coordinates $q_k$. (One of us[15] has given a strict mathematical proof of this.) In this case we are in fact dealing with one-dimensional potential curves $U_\alpha(q)$, and we can therefore use the Landau–Zener theory of adiabatic electronic transitions if the motion of heavy particles (dipoles) is described classically. Omitting the straightforward mathematical derivations, we shall describe the physical results obtained in the case of interest. The broken lines in Fig. 2 denote two electronic energy levels, corresponding to two electronic states $\alpha$ and $\alpha'$, between which the transition occurs. At the intersection ($q^*$) of the two levels the electronic state is doubly degenerate, i.e. the same energy $\epsilon_\alpha(q^*) = \epsilon_{\alpha'}(q^*)$ corresponds to two distinct states $\alpha$ and $\alpha'$ [this follows from Eqn. (2.13)]. However, when allowance is made for the perturbation $V_{\alpha'\alpha}$, this degeneracy is removed and resonance splitting of the levels arises at the point $q^*$. (See the solid line in Fig. 2.) If the perturbation $|V_{\alpha'\alpha}|^2$ is smaller than some critical value $|V_{cr}|^2 = \hbar\omega_0\left(\frac{kTE_s}{\pi^3}\right)^{1/2}$, we can suppose that the system, initially at the level $U_\alpha$, jumps non-adiabatically to the level $U_{\alpha'}$, but only after several passages through the intersection point. If, however, $|V_{\alpha'\alpha}| \gg |V_{cr}|$, the separation of the levels at the point $q^*$ will be large, and transitions from the level $U_\alpha$ to the level $U_{\alpha'}$ will occur in such a way that the system remains always at the lowest level: these transitions are called adiabatic transitions. Calculations of the probability of transition per unit time by the quasi-classical Landau–Zener method lead to the high-temperature approximation formula (2.19) for non-adiabatic transitions; in the case of adiabatic transitions we obtain the formula

$$w_{\alpha\to\alpha'} = \frac{\omega_0}{2\pi} e^{-\frac{E_a}{kT}}, \tag{2.21}$$

where the activation energy $E_a$ is approximately the same as in Eqn. (2.20), i.e. it equals the distance from the point of "intersection" of the levels to the minimum of the initial level (Fig. 2).

In the discussion which follows we shall make use of the above theory to investigate various concrete problems.

## 3. Theory of Oxidation–Reduction Reactions

This section deals with oxidation–reduction reactions occurring in a liquid by an electronic mechanism, i.e. a mechanism whose fundamental step does not involve either breaking or forming chemical bonds. Such a reaction can be represented schematically in the form

$$A^{z_1} + B^{z_2} \to A^{z_1+1} + B^{z_2-1}. \tag{2.22}$$

We shall classify all reactions into fast and slow. To clarify the meaning of this classification, we shall consider two ions taking part in a reaction of the type of (2.22).

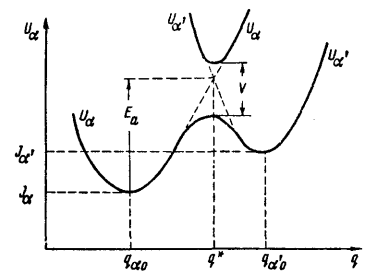

Fig. 2.

First of all, we introduce the concept of a reaction volume, this being the region within which the ions $A^{z_1}$ and $B^{z_2}$ must be to enable electron transfer to proceed from $A^{z_1}$ to $B^{z_2}$. If the residence time of the ions in the reaction volume ($\tau_g$) is much greater than the time between electronic transitions ($\tau_e$), the reaction should be called fast or proceeding by a diffusion mechanism. Since electronic equilibrium between the ions can be established at each "collision" (i.e. each time the ions fall into the reaction volume), diffusion must be the rate-determining step. We are assuming that the reaction volume is so small that the residence time of the ions in this volume is of the same order as the time between diffusional jumps ($\tau_g$).

In this review we shall be concerned only with slow reactions, i.e. with the case $\tau_e \gg \tau_g$. These reactions are characterised by the fact that electron transfer occurs only after several "collisions" between the ions. On the other hand, this is just the case where we can apply the formulae of perturbation theory, which are correct at times $t \ll \frac{1}{w_{\alpha\alpha'}} = \tau_e$. Indeed, since the ions remain in the reaction volume for a time $\tau_g \ll \tau_e$, it can be assumed that the probability of an electronic transition is directly proportional to time, which is equivalent to ignoring reverse transitions during the interval $\tau_g$. It can be shown[16] that the specific rate constant of the bimolecular reaction (2.22) is of the form

$$K_{AB} = \int w_e(R)\, w_{AB}(R)\, dv, \qquad (2.23)$$

where $w_{AB}(R)$ is the probability of finding the ions $A^{z_1}$ and $B^{z_2}$ at a distance $R$ apart, $w_e(R)$ is the probability of an electronic transition from $A^{z_1}$ to $B^{z_2}$. In view of the assumption that $\tau_g \ll \tau_e$, we can use the equilibrium distribution function of the ions (which at small distances has the form $e^{-\frac{z_1 z_2 e^2}{\varepsilon_s kTR}}$) in place of $w_{AB}$. It is surprising to find that the condition for a slow reaction obtained here corresponds to the assumption $\tau_g \ll \tau_e$, which was made in Section II.1, if the diffusion coefficients of the ions $A^{z_1}$ and $B^{z_2}$ are of the same order of magnitude as the self-diffusion coefficients of the liquid molecules.

All slow reactions can be divided into two classes: adiabatic and non-adiabatic. For the former, the quantity $w_e$ should be expressed by formula (2.21), when the resulting rate constant takes the form

$$K_{AB} = \frac{kT}{h} e^{-\frac{\Delta F^{\neq}}{kT}} v_r, \qquad (2.24)$$

where $v_r$ is the volume of the reaction region, and $\Delta F^{\neq}$ is the free energy of activation, which is related to the activation energy by the expression

$$\Delta F^{\neq} = \Delta E^{\neq} - T\Delta S^{\neq}, \qquad (2.25)$$

$$\Delta E^{\neq} = E_a + \frac{z_1 z_2 e^2}{\varepsilon_s R_r}, \qquad (2.26)$$

$$\Delta S^{\neq} = k \ln \frac{\hbar\omega_0}{kT}. \qquad (2.27)$$

Here $E_a$ is given by formula (2.20), and $R_r$ is the mean distance between the ions in the reaction region.

For non-adiabatic reactions, expression (2.19) must be used in place of $w_e$, and $V_{\alpha'\alpha}$ should be interpreted as an exchange integral[13]. The result is the following formula for $K_{AB}$:

$$K_{AB} = \varkappa \frac{kT}{h} e^{-\frac{\Delta F^{\neq}}{kT}} V_r, \qquad (2.28)$$

where the transmission coefficient $\varkappa$ is of the form

$$\varkappa = |V_{\alpha'\alpha}|^2 \left(\frac{4\pi^3}{\hbar^2\omega_0^2 kTE_s}\right)^{1/2} = \frac{|V_{\alpha'\alpha}|^2}{|V_{cr}|^2}. \qquad (2.29)$$

Experimental data for the specific rate constants of different reactions, computed by means of formula (2.28), are given in the Table together with calculated values of the corresponding transmission coefficients $\varkappa$. The Table shows that most of the reactions are non-adiabatic, with $\varkappa \sim 10^{-3}$. Only four of the reactions are exceptional, and proceed by an adiabatic mechanism.

We have recently attempted[15] a numerical evaluation of $K_{AB}$ for the $Fe^{2+}/Fe^{3+}$ system. For $R_r$ we used the value[17] 6.8 Å, and $\omega_0$ was assumed to be $10^{11}$ $s^{-1}$, whilst $E_s$ was calculated from the Born model. On the assumption that the reaction is adiabatic, we obtained $K_{AB}$ = = 50 litre $mole^{-1}$ $s^{-1}$, $\Delta F^{\neq}$ = 15.1 kcal $mole^{-1}$, and $\Delta E^{\neq}$ = = 11.5 kcal $mole^{-1}$. By comparing these with the experimental results, we find that the values obtained are in reasonable agreement with experiment, despite the coarseness of the approximation.

To conclude this Section, we shall give the quantitative formulation of the criterion for a slow reaction. From (2.23) and (2.28), the rate constant can be related to $\tau_e = 1/w_e$:

$$K_{AB} = \frac{1}{\tau_e} v_r e^{-\frac{z_1 z_2 e^2}{\varepsilon_s R_r kT}} \qquad (2.30)$$

The condition $\tau_g \ll \tau_e$ leads to the inequality

$$K_{AB} \ll \tau_g^{-1} v_r e^{-\frac{z_1 z_2 e^2}{\varepsilon_s R_r kT}}. \qquad (2.31)$$

Knowing the radius of the reacting ions, the radius $v_r$ of the reaction volume can be readily evaluated. In particular, if we adopt a value of 7 Å for $R_r$, and insert $10^{-9}$ s for $\tau_g$ in Eqn. (2.31), we obtain $K_{AB} \ll 2 \times 10^6$ litre $\times$ $\times$ $mole^{-1}$ $s^{-1}$.

## 4. Absorption of Light by Anions

The theory developed above can be applied to the study of the absorption of light by halide ions. According to the Franck–Condon principle, the light energy absorbed

TABLE.

| System | Ratio constant, litre $mole^{-1}$ $s^{-1}$ | Activation energy $E^{\neq}$, kcal $mole^{-1}$ | Temperature, °C | Transmission coefficient, $\varkappa$ |
|---|---|---|---|---|

$\hbar\omega_a$ is equal to the distance between energy levels at fixed polarisation. To calculate the average value of $\hbar\omega_a$, it is necessary to average out $U_\beta(q) - U_\alpha(q)$ by means of the quantum distribution function for a one-dimensional oscillator[18]:

$$dw(q) = \left(\frac{1}{\pi}\tanh\frac{\hbar\omega_0}{2kT}\right)^{1/2} e^{-q^2\tanh\frac{\hbar\omega_0}{2kT}}\,dq. \qquad (2.32)$$

The result is

$$\hbar\bar{\omega}_\beta = J_\beta - J_\alpha + E_s = \varepsilon_\beta(q_0^\alpha) - \varepsilon_\alpha(q_0^\alpha). \qquad (2.33)$$

Physically this means that, to find $\hbar\bar{\omega}_a$, we must know the ground level and the first excited level of the electron at fixed initial equilibrium polarisation, defined by the coordinate $q_0^\alpha$. The difference between these energies gives the mean energy of the light absorbed by a halide ion. The mean energy of the emitted light is found by an analogous procedure:

$$\hbar\bar{\omega}_e = J_\beta - J_\alpha - E_s = \varepsilon_\beta(q_0^\beta) - \varepsilon_\alpha(q_0^\beta). \qquad (2.34)$$

In addition to $\hbar\bar{\omega}_a$, it is interesting to calculate also the width of the absorption band, i.e. the standard deviation of the light energy absorbed:

$$D^2 = (\hbar\omega_a)^2 - (\hbar\bar{\omega}_a)^2 = \hbar\omega_0\coth\frac{\hbar\omega_0}{2kT}E_s, \qquad (2.35)$$

or in the high-temperature approximation

$$D^2 = (2kTE_s)^{1/2}. \qquad (2.36)$$

The width of the absorption band varies with temperature as $T^{1/2}$. On changing the temperature from 10° to 50°, the width of the band increases, according to Eqn. (2.36), by 7%, which agrees tolerably well with the experimental value[19] of 5%.

## 5. Theory of Electron Mobility

The problem of slow electrons in various liquids has attracted considerable attention in recent literature. In particular, the problem has been discussed extensively in radiation chemistry[27] and biological investigations[28]. Some electrochemical papers which consider the possible kinetic role of solvated electrons are beginning to appear. Not surprisingly, systems in which the liquid is water present the greatest interest. We shall therefore consider the case of a polar medium in the first part of the present subsection, and we shall report a number of results for non-polar media in the second part.

The basic problem facing us when considering polar liquids is the calculation of mobility. In order to throw some light on the physical mechanism of electrical conduction in liquids, we shall begin by stating the theory of electron mobility in polar crystals.

There is a large number of semiconductors whose properties cannot be described by the conventional band theory They show a characteristic, activational dependence of mobility upon temperature:

$$u \sim e^{-\frac{E_a}{kT}}.$$

This phenomenon cannot be explained within the framework of the normal band theory, since the thermal motion of the crystal lattice increases the probability of scattering of carriers, and should therefore lower the mobility. A mobility which increases with temperature is observed in substances with very small mobility values. For example, for $Fe_2O_3$ and NiO, $u \simeq 4\times10^{-3}$ cm$^2$ V$^{-1}$ s$^{-1}$, and the mean free path $\lambda$ of current carriers is found to be much smaller than the lattice constant. Contrary to the band theory, according to which the electrical conductivity depends on the changes in the velocity of the free electron as a result of scattering by lattice vibrations, Ioffe suggested[20] that the transport process in semiconductors of this type should be treated as the transition of an electron from a given cell of the crystal to a neighbouring one. Since we know that the theory developed in Section II, 2 is applicable in this case, it is obvious that the desired temperature dependence can be obtained from formula (2.19) at high enough temperatures. The difficulty, however, is that "band" solutions are found because of the translational symmetry of the crystal, which persists even in the semiconductors under discussion. A great deal of work[9,21-26] has been devoted to the problem of the change in the mechanism of electrical conduction, i.e. to the manner in which electrons in bands (or delocalised) can be correctly assigned to localised states. Unfortunately, lack of space prevents us from giving rigorous derivation of the results of the theory: we shall only point out that the criteria for the applicability of the band and of the transfer mechanism of conduction have been obtained from the above work. Calculation shows that at low enough temperatures the mobility decreases with increase of temperature, but begins to rise again exponentially with further increase of temperature: we know that this corresponds to a change from the band mechanism to the barrier (or "jump") mechanism. The model we have described is correct only for the case of strong binding, when the electron interacts strongly just with the atom in whose neighbourhood it happens to be at a given moment. In other words, the exchange integral for two nearest-neighbour atoms is fairly small. This is why the overall theory has been called the theory of small polarons. (We are using the term polaron in its usual meaning of an electron surrounded by a "coat" due to the polarisation of the dipoles.) However, in the case of weak interaction between the electrons and all the atoms of the crystal (but strong interaction with the polarisation) we must apply the theory of large polarons, developed by Pekar[4].

In polar liquids the situation is much more complex; the following cases are possible.

1. The mobility arises by the large polaron mechanism, i.e. the electron has a weak interaction with one solvent molecule. Since the radius of the large polaron is much greater than the average distance between neighbouring liquid molecules, we can apply the continuum model of the liquid, so that Pekar's original theory can be used without any modification.

2. The mobility is determined by a band polaron of small radius. This situation can arise when the correlation length between liquid molecules (i.e. the distance of short-range order) is greater than the mean free path of the polaron.

3. Lastly, one more variant is possible, in which the jump mechanism applies to polarons of small radius. In this case the difference between liquids and crystals disappears. To simplify the discussion, we shall quote the expression for the mobility:

$$u = \frac{ea^2|V|^2}{\hbar kT}\left(\frac{\pi}{kTE_s}\right)^{1/2} e^{-\frac{E_s}{4kT}}, \qquad (2.37)$$

where $a$ is the average distance between liquid molecules,

$V$ is the exchange integral, and as before $E_S$ denotes the energy of "transpolarisation". If the electron jump takes place adiabatically, we can write

$$u = \frac{ea^2}{kT}\frac{\omega_0}{2\pi}e^{-\frac{E_s}{4kT}}. \quad (2.38)$$

Formulae (2.37) and (2.38) are readily integrated using the Einstein relation $u = eD/kT$ if we introduce the diffusion coefficient of the electron:

$$D_{\text{adiab}} = \frac{a_0}{\tau_e}; \quad D_{\text{non-adiab}} = \varkappa\frac{a^2}{\tau_e}. \quad (2.39)$$

It is interesting to note that oxidation–reduction reactions in liquids can give rise to an electronic contribution to the electrical conductivity (in parallel with the ionic component). This was first pointed out by Frumkin. Since we have considered only slow reactions ($\tau_e \ll \tau_g$) in Section II,3, it is obvious that the contribution of the electronic component to the total electrical conductivity will be small. Simple calculation shows that the electrical conductivity is given by

$$\sigma_e = \frac{e^2c^2R_i^2K_{AB}}{6\,kT}. \quad (2.40)$$

To conclude this Section, we shall discuss the behaviour of electrons in non-polar liquids. The calculation of mobility in this system presents considerable difficulty, and we shall therefore confine ourselves to a study of the energy spectrum of the electron. As will be shown below, a knowledge of the spectrum offers also a qualitative understanding of the mechanism of electrical conduction in non-polar liquids.

To simplify the calculation, we shall examine the one-dimensional model of a liquid[29], i.e. a chain of identical atoms distributed in a practically random fashion. Since the concentration of electrons is assumed to be very small, the calculation can be made by the one-electron approximation. The Hamiltonian for this problem is of the form

$$H(x) = -\frac{\hbar^2}{2m}\Delta_x + \sum_i u(x - R_i), \quad (2.41)$$

where the first term is the kinetic energy of the electron, and $u(x - R_i)$ is the interaction energy between the electron and the $i$th atom of the liquid. The values of $R_i$ can be treated as random, but determined by a known distribution function $\Phi(R_1, \ldots, R_N)$. In practice, of course, the form of $\Phi$ is not known, since there is no theory of the liquid state at present. We shall therefore, in what follows, confine ourselves to a consideration of some plausible models of the liquid state which offer a basis for discussion. Thus, our problem is to determine the spectrum of the Hamiltonian (2.41), averaged with respect to $\Phi$, with arbitrary values of the parameter $R$. The most convenient mathematical approach to this problem is the method of Green functions, well known in quantum field theory and in statistics. The mean density of levels is related to a Green function by the expression[30]

$$\left\langle \frac{dn}{dE} \right\rangle = \frac{1}{\pi} Jm Sp\langle G\rangle. \quad (2.42)$$

Here $Jm$ denotes the imaginary part of the spur of $\langle G\rangle$, where the angular brackets are used to indicate averaging with respect to random values of $R_i$. The Hamiltonian (2.41) is conveniently written in the form $H = \langle H\rangle + V$, where $V = H - \langle H\rangle$ is the departure of $H$ from the value $\langle H\rangle$. Under certain conditions $V$ can be assumed to be small, so that the problem can be solved by perturbation theory. The zeroth approximation for $V$ gives the usual spectrum of a one-dimensional crystal in the strong binding approximation:

$$E_0(p) = \varepsilon_0 + 2\langle J\rangle\cos p, \quad (2.43)$$

where $\epsilon_0$ is the energy of the electron in an isolated atom of the liquid, $\langle J\rangle$ is the mean value of the exchange integral, and $p$ is the quasi-momentum of the electron. The function $E_0(p)$ is shown in Fig. 3 as a broken line. Allowance for the perturbation $V$ produces two effects in the first approximation. First, it alters the form of the spectrum within the previous band (see Fig. 3, full line):

$$E(p) \simeq \varepsilon_0 + 2\langle J\rangle\left(1 - \frac{\langle I^2\rangle}{2\langle J\rangle^2}\right)\cos p, \quad (2.44)$$

where $\langle I^2\rangle = \langle (J - \langle J\rangle)^2\rangle$ is the dispersion of the exchange integral. Secondly, the state of quasi-momentum $p$ begins to relax in time, the relaxation time $\tau$ being given by the formula

$$\tau_p^{-1} = \nu_p = \frac{\langle I^2\rangle}{|\langle J\rangle \sin p|}(1 + \cos^2 p). \quad (2.45)$$

Analysis of formula (2.45) shows that the results obtained from the perturbation theory are correct at sufficiently low dispersions:

$$\langle I^2\rangle \ll \langle J\rangle^2. \quad (2.46)$$

To give more real significance to the condition (2.46), we can attempt a calculation, assuming that $J(R) \sim e^{-R/R_0}$. We shall also assume that correlation operates only between the positions of the two nearest atoms in the liquid. Without explicitly stating the form of $\Phi(R)$, we shall assume that the deviation of $R$ from its average value is small and of the order of $l$. Condition (2.46) then reduces to the requirement that

$$l \ll R_0. \quad (2.47)$$

In practice, the following condition must also be satisfied:

$$p^2 \gg \frac{\langle I^2\rangle}{\langle J\rangle^2}. \quad (2.48)$$

The inequality (2.48) follows directly from (2.43) and (2.45). This condition means that the theory of perturbations is not applicable near the band edge[30]. Using an improved form of the perturbation theory, it can be shown that a shift of the old band edge in the direction of expansion does in fact occur, and that the form of the spectrum in the region of the new band edge is as shown in Fig. 3 (dotted line close to the new band edge):

$$E(p) \simeq \varepsilon_0 + 2\langle J\rangle\left\{1 + \left(\frac{\langle I^2\rangle}{\sqrt{2}\langle J\rangle^2}\right)^{2/3} - \frac{p^2}{3}\right\}, \quad p^2 \ll \frac{\langle I^2\rangle}{\langle J\rangle^2}. \quad (2.49)$$

It follows from this formula that the average width of the band increases, due to the presence of dispersion, by an amount of the order of $(\langle I^2\rangle/\langle J\rangle^2)^{2/3}$, and that the

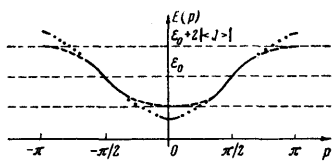

Fig. 3.

effective mass in the new band differs from the mass calculated for the old band by formula (2.43):

$$m_{\text{eff}} = \frac{3}{2} m^0_{\text{eff}}. \qquad (2.50)$$

The factor 3/2 in this formula appears because of the non-analytical variation of $E(p)$ with the small parameter $\epsilon = \langle I^2\rangle/\langle J\rangle^2$ [$E(p) \sim \epsilon^{2/3}$].

The most interesting case is, of course, that of large dispersion of the exchange integral [see Eqn. (2.47)]:

$$l \gg R_0. \qquad (2.51)$$

In this case perturbation theory is already inapplicable, but it has been possible to carry out a partial summation in the expression for the Green function. Retaining the most significant terms, the following equation for the electron spectrum was obtained:

$$E(p) - \varepsilon_0 = 2(E(p) - \varepsilon_0)\left\langle \frac{J^2(R)}{(E(p)-\varepsilon_0)^2 - J^2(R)} \right\rangle + 2(E(p) - \varepsilon_0)^2 \left\langle \frac{J(R)}{(E(p)-\varepsilon_0)^2 - J^2(R)} \right\rangle \cos p. \qquad (2.52)$$

This equation also was derived on the assumption that all the exchange integrals are uncorrelated, but the parameter $\epsilon = \langle I^2\rangle/\langle J\rangle^2$ was treated as much larger than unity. Eqn. (2.52) can be solved only if the binary distribution function of the atoms of the liquid is known. To arrive at the final expressions, we have used the simple model

$$\Phi(R) = \begin{cases} 0, & |R-a| > l, \\ \dfrac{1}{2l}, & |R-a| < l, \end{cases}$$

where $a$ is the average distance between the atoms of the liquid. The result was the following formula for the spectrum:

$$E_u(p) = \varepsilon_0 + |J_m|\left(1 \pm e^{-\frac{R_0}{2l(1-\cos p)}}\right),$$
$$E_l(p) = \varepsilon_0 - |J_m|\left(1 \pm e^{-\frac{R_0}{2l(1+\cos p)}}\right), \qquad (2.53)$$

where $E_u$ and $E_l$ apply to the upper and the lower band (see full line in Fig. 4), and $J_m$ denotes the maximum value of the exchange integral, corresponding to the minimum distance between the atoms, $R_{\min} = a - l$. In the derivation of (2.53) it was assumed that $J(R) \sim e^{-R/R_0}$.

It follows from (2.53) that the distance between the centres of the upper and the lower band is $2|J_m|$, and the width of both bands is $2|J(a)|$, i.e. the value of the exchange integral calculated for an average distance $a$. To make clear the physical significance of the result, we can compare formulae (2.53) with the spectrum calculated for the periodic chain shown in Fig. 5. This problem can be solved exactly, and the resulting form of the spectrum is (see broken curve in Fig. 4):

$$E^0_u = \varepsilon_0 + \sqrt{(J_1 + J_0)^2 - 4J_1J_0\cos^2 p},$$
$$E^0 = \varepsilon_0 - \sqrt{(J_1 + J_0)^2 - 4J_1J_0\cos^2 p}. \qquad (2.54)$$

Here $J_1$ is the exchange integral for particles 1 and 2, $J_0$ for particles 2 and 3 (see Fig. 5). The distance between the centres of the bands $E^0_u$ and $E^0_l$ is $2\sqrt{J_1^2 + J_0^2} \simeq 2|J_1|$, since $|J_1| \gg |J_0|$, and the width of each of the bands is $2|J_0|$. We see by inspection of formulae (2.53) and (2.54) that the major contribution to the average spectrum of the electron at high dispersions is given by the

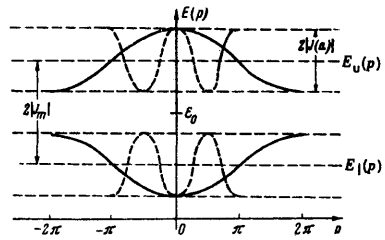

Fig. 4.

Fig. 5.

configurations of the atoms in which the closest approach of two atoms of the liquid occurs. This situation is reminiscent of the fact that in the calculation of mobility it is just these configurations which are the most important. This somehow corresponds to an electronic jump between two atoms. It is not hard to see that the temperature dependence of the mobility is also in qualitative agreement with the case of small polarons, discussed earlier in this Section. Thus (2.45) requires that a low temperatures the dispersion increases with increase of temperature, whilst $\tau_p$ decreases; consequently, the mobility $u \sim e\tau_p/m_{\text{eff}}$ also decreases. On the other hand, at high dispersions an increase in temperature must obviously increase the frequency of the jumps, and therefore the mobility.

## III. THEORY OF OXIDATION-REDUCTION REACTIONS

The simplest electrode reactions from the point of view of a theoretical study are of the form

$$A^z + e\,(\text{in the electrode}) \rightarrow A^{z-1}, \qquad (*)$$

where $A^z$ and $A^{z-1}$ are ions of charge $z$ and $z$ - 1 respectively

An electrode process involves several steps. In what follows, we shall be concerned exclusively with processes in which the slow (and therefore the rate-determining) step is discharge of the ion at the electrode. The phenomenological theory of slow discharge for reactions of the type (*) at a metal electrode was developed by Frumkin[31].

In the work of Levich, Vdovin, and Myamlin[32,33], the phenomenological slow discharge theory is extended to cover reactions at semiconductor electrodes. The earliest attempts at deriving a microscopic theory of oxidation-reduction reactions of the type (*) are due to Randles[35] and Hush[36]. Gerischer[37] had discussed heterogeneous reactions involving negligible changes in the inner coordination sphere of the ion. In his studies of oxidation-reduction reactions at metal and semiconductor electrodes, Gerischer has suggested that the activation energy arises mainly from the displacement of the atoms in the first coordination sphere of the ion. This approach gives the correct physical picture, but it failed to provide quantitative results.

Many more quantitative results were obtained by examining heterogeneous oxidation–reduction reactions not involving adsorption of reagents, formation or breaking of chemical bonds, and proceeding without any changes in the first coordination sphere of the ion. This review will deal exclusively with reactions of this type. The theory of these reactions has been developed in papers by Marcus[38-40], and Dogonadze, Chizmadzhev, and Kuznetsov[41-49]. As was stated at the beginning of this article, Marcus used the thermodynamic method, which offers several advantages coupled with the disadvantage of not allowing calculation of the exchange current.

In our previous papers[41-49] we have used the approach followed in the discussion of homogeneous reactions (see Section II). The main results of this work will now be described.

## 1. Calculation of the Fundamental Ion-Discharge Step at an Electrode and General Kinetic Relations

We shall consider a system consisting of an electrode, a polar solvent, an ion $A^z$, and an electron which can be associated either with the electrode or with the ion. The probability of electron transfer in this problem is determined by formula (2.19), in which $V$ is to be intepreted as an exchange integral and $J_s$ and $J_f$ are given by the following expressions

$$J_s = \varepsilon_{z-1} - e\varphi(R) - \frac{\varepsilon_s - 1}{8\pi\varepsilon_s}\int D^2_{0z-1}\,dv, \tag{3.1}$$

$$J_f = \varepsilon_f - e\varphi_e - U_0 - \frac{\varepsilon_s - 1}{8\pi\varepsilon_s}\int D^2_{0z}\,dv, \tag{3.2}$$

where $\epsilon_{z-1}$ is the energy of the electron in the isolated ion $A^{z-1}$, $\varphi(R)$ is the potential at the point where the ion undergoing discharge is located, $\varphi_e$ is the potential of the electrode, $U_0$ is the depth of the potential well for the electron in the electrode (see Fig. 6), $J_f$ is the level of the electron in the electrode, and $D_{0z}$ ($D_{0z-1}$) are the inductions of the ions $A^z$ ($A^{z-1}$). The quantities $\epsilon_s$ and $J_f$ have the same meaning as in the case of homogeneous reactions (Section II), but when dealing with heterogeneous reactions we must include in $J_s$ the energy of the interaction of the electron with the electronic polarisation of the solvent, since this is not included in $J_f$ and is not retained in the electron transfer process. In Eqns. (3.1) and (3.2) the subscript $s$ indicates that the electron is in the solution whilst $f$ indicates that the electron is in the electrode at the energy level $\epsilon_f$.

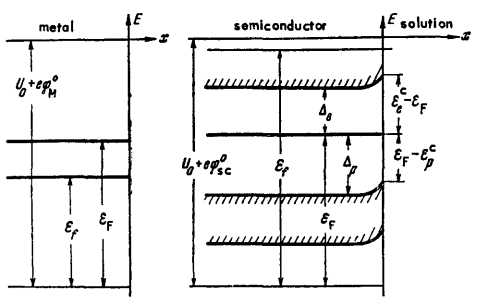

Fig. 6.

These expressions for the probability of electron transfer allow us to calculate the current flowing in the electrode–solution system. The current density can be expressed in the form

$$i = i_a - i_c,$$

where $i_a$ is the anodic current, generated by the passage of the electron from the solution into the electrode, and $i_c$ is the cathodic current. We shall invariably assume that all the ions are discharged at the electrode independently of each other. This implies that an expression for (say) the anodic current can be obtained as follows. The probability of electron transfer from the solution to the energy level $\epsilon_f$ of the electrode is multiplied by the concentration of the appropriate ions, $c_{z-1}(x)$, at the particular point in the solution, and by the probability of finding the energy level of the electrode unoccupied, $1 - n(\epsilon_f)$. The resulting expression must then be integrated over all possible states of the electron in the electrode and with respect to all the coordinates of the ion in the solution. An expression for $i_c$ can be obtained by a similar procedure:

$$i_a = e\int_0^\infty c_{z-1}(x)\,dx \int w_{sf}(x)\,[1 - n(\varepsilon_f)]\,\rho_f\,d\varepsilon_f, \tag{3.3}$$

$$i_c = e\int_0^\infty c_z(x)\,dx \int w_{fs}\,n(\varepsilon_f)\,\rho_f d\varepsilon_f, \tag{3.4}$$

where $n(\epsilon_f)$ is the distribution function of the electrons over the energy levels in the electrode, and $\rho_f$ is the density of energy states in the electrode. It must be noted that the problem of calculating the current really consists of two separate problems: the first problem is to find the probability of an ion being at a distance $x$ from the electrode, i.e. to evaluate $c_z(x)$ and $c_{z-1}(x)$; the second problem is to find $w_{sf}$ ($w_{fs}$). The solution of the second problem has been discussed in the previous paragraph. To find the probability that an ion approaches to a given distance from the electrode is a complex statistical problem which is still not finally solved. We shall therefore have to resort to one of the approximate theories, such as the Gouy–Stern theory. Within the framework of the theory developed in Section II, 2 it can be shown that the probability of the forward transition is related to the probability of the reverse transition by the expression $w_{sf} = w_{fs}\exp[(J_s - J_f)/kT]$. By using this expression, the resulting current can be written in the form[44]

$$i = e\int_0^\infty dx \int d\varepsilon_f \rho_f n(\varepsilon_f)\, c_z w_{fs}(x)\left\{\frac{c_{z-1}(x)}{c_z(x)}\,\frac{1 - n(\varepsilon_f)}{n(\varepsilon_f)}\,e^{\frac{J_s - J_f}{kT}} - 1\right\} \tag{3.5}$$

To simplify the subsequent calculations, we shall assume that the currents are not large, so that the Boltzmann equilibrium distribution can be used to express $c_{z-1}$ and $c_z$. For the same reason, we shall ignore departures from equilibrium within the electrode and use the normal Fermi distribution function for $n(\epsilon_f)$. This procedure is always justifiable for metals and intrinsic semiconductors at low current densities, and it can also be applied to impurity semiconductors if the current of minority carriers through the semiconductor interface is smaller than the limiting diffusion current of minority carriers. The formulae can be easily generalised to allow for departures from equilibrium in a semiconductor[45,49], which can be quite large at high currents and especially if

the semiconductor is illuminated (see also III, 5). In the light of these assumptions, Eqn. (3.5) can be rewritten

$$i = i_c\left(\exp\left\{\frac{e\varphi_e - (\alpha_{z-1}-\alpha_z) + \varepsilon_{z-1} - (\varepsilon_F - U_0) - kT\ln\frac{c_z}{c_{z-1}}}{kT}\right\} - 1\right), \quad (3.6)$$

where $\epsilon_F$ is the Fermi level in the electrode and $c_z$ and $c_{z-1}$ are the concentrations of the ions $A^z$ and $A^{z-1}$ respectively in the bulk of the solution at $x \to \infty$; the potential of the solution is taken to be zero. The quantity $\alpha_{z,z-1} = \frac{\epsilon_S - 1}{8\pi\epsilon_S}\int D^2_{0z,z-1}dv$ is the hydration energy of the ions $A^{z,z-1}$ in the Born approximation[50].

Using (3.6), it is easy to derive an expression for the equilibrium Galvani potential difference at the semiconductor–solution interface[44] from the condition that the total current must vanish:

$$e\varphi^0_e = (\alpha_{z-1}-\alpha_z) - \varepsilon_{z-1} + (\varepsilon_F - U_0) + kT\ln\frac{c_z}{c_{z-1}}. \quad (3.7)$$

It is evident from (3.7) that the equilibrium Galvani potential depends on properties of the electrode ($\epsilon_F - U_0$), on properties of the ions ($\epsilon_{z-1}$, $\Delta\alpha$), on the concentration of the ions, and on the properties of the solvent ($\Delta\alpha$).

An expression for $\varphi^0_e$ can be obtained also by using a thermodynamic cycle[42]. The various stages of the cycle are shown in Fig. 7. Under equilibrium conditions the work done in stages 1, 5, and 7 is zero. The work done in stages 2 and 4 is

$$\bar{\mu}_{z-1} = \psi_{z-1} + kT\ln c_{z-1};\quad \bar{\mu}_z = \psi_z + kT\ln c_z, \quad (3.8)$$

where $\psi_{z-1} = kT\ln N + \alpha_{z-1}$; $\psi_z = kT\ln N + \alpha_z$; $N$ is the number of solvent particles.

Denoting by $\alpha^e_m = e_e\varphi_0 + U_0 - \epsilon_F$ the work of extraction of the electron from the electrode, and equating to zero the work expended in the entire cycle, we obtain

$$-\bar{\mu}_{z-1} - \varepsilon_{z-1} + \bar{\mu}_z - e\varphi^0_V - \alpha^e_m = 0, \quad (3.9)$$

where $_e\varphi_0$ is the potential jump at the electrode–gas boundary and $\varphi^0_V$ is the equilibrium Volta potential of the electrode. The equilibrium Galvani potential at the electrode–solution interface is

$$\varphi^0_e = \varphi^0_V - {}_e\varphi_0. \quad (3.10)$$

Formulae (3.8), (3.9), and (3.10) lead to the expression (3.7).

We now introduce the overvoltage $\eta$ defined as

$$\eta = \varphi_e - \varphi^0_e. \quad (3.11)$$

Eqn. (3.6) can therefore be rewritten

$$i = i_c(e^{\frac{e\eta}{kT}} - 1). \quad (3.12)$$

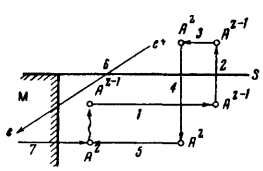

Fig. 7.

Furthermore, it follows from (3.12) that

$$i_a = i_c e^{\frac{e\eta}{kT}}. \quad (3.13)$$

It is obvious from the derivation of formulae (3.7), (3.12), and (3.13) that these expressions are applicable both to metal and to semiconductor electrodes.

The formulae derived here are quite general. To obtain more concrete expressions, we make the following approximation: the transition probability decreases very steeply as the distance from the ion to the electrode increases. The concept of an effective reaction region of thickness $l$, within which discharge occurs, thus arises quite naturally. The integral with respect to distance in formulae (3.3) and (3.4) can then be approximated by the product of $l$ by the value of the integrand function at some intermediate point $x = \delta$, which can be thought of as the most probable distance over which discharge occurs. In practice, the quantity $\delta$ can, of course, be identified with the thickness of the Helmholtz layer.

## 2. Kinetics at Metal Electrodes

To obtain concrete expressions for the current at a metallic electrode, it is necessary to carry out the integration with respect to the electronic states in the metal in expressions (3.3) and (3.4). Since in a metal all the states lying below the Fermi level are occupied, and all those lying above the Fermi level are empty, the integration in (3.3) must be performed between the limits $\epsilon_F$ and $U_0$, and that in (3.4) between 0 and $\epsilon_F$. Calculation leads[42] to the following expression for the anodic current

$$i_a = \left(\frac{\pi e^2 kT}{\hbar^2 E_s}\right)^{1/2}\cdot \rho_f c_{z-1}(\delta)\, l\,|V|^2 \exp\left\{-\frac{\left(e\varphi(\delta) + kT\ln\frac{c_{z-1}}{c_z} + E_s - e\eta\right)^2}{4E_s kT}\right\}, \quad (3.14)$$

where $\varphi(\delta)$ is the potential in the solution at the point $\delta$ (in practice, the $\psi_1$-potential). A similar calculation gives $i_c$.

Eqn. (3.14) shows that the variation of $\ln i_a$ with $\eta$ is not, in general, of the Tafel form. However, if $e\eta$ is small compared with $E_S$, the squared expression in brackets can be expanded and small terms of the second order can be ignored (the quantity $e\varphi'(\delta) + kT\ln\frac{c_{z-1}}{c_z}$ is usually much smaller than $E_S$). The expression for the total current then takes the Tafel form (provided that the potential jump $\varphi'(\delta)$ has its equilibrium value):

$$i = i_0(e^{\frac{e\eta}{2kT}} - e^{-\frac{e\eta}{2kT}}), \quad (3.15)$$

where the exchange current is equal to

$$i_0 = \left(\frac{\pi e^2 kT}{\hbar^2 E_s}\right)^{1/2}\rho_f l\,|V|^2\sqrt{c_{z-1}(\infty)\,c_z(\infty)}\,e^{-\frac{E_s}{4kT} - \frac{(2z-1)e\varphi'(\delta)}{2kT}} \quad (3.16)$$

In this case the transfer coefficient $\alpha$, defined by the expression

$$\alpha = -\frac{kT}{e}\frac{d\ln i_c}{d\eta}, \quad (3.17)$$

equals 1/2.

Brønsted's rule. The Tafel formula is usually derived by invoking a semi-empirical rule due to Brønsted[31], according to which

$$E^{\neq}(\eta) - E^{\neq}(\eta = 0) = -\beta[\Delta J(\eta) - \Delta J(\eta = 0)]$$

where $E^{\neq}$ is the activation energy and $\Delta J$ is the heat of the reaction (in our case $\Delta J$ is the difference between the minima of the potential energy curves of the system in its initial and final states). This expression is the equivalent of Polanyi's rule;[34], formulated for gas-phase reactions. In the theory discussed here, Brønsted's rule applies[44,47,49] for $e\eta < \sqrt{4E_S kT}$, the constant $\beta$ having the value 1/2 for a metallic electrode. It must be noted, however, that Brønsted's rule is obeyed by our system only at low enough overvoltages. When the overvoltage is appreciable, the rule ceases to apply, because the current–voltage characteristic deviates from the Tafel relation.

It is interesting to compare these theoretical results with experimental data obtained relatively recently by Frumkin and his coworkers[63]. Those workers investigated the electrolytic reduction of anions at metallic electrodes, and observed departures from the Tafel relation. Of all the reactions investigated, only the reduction of $Fe(CN)_6^{3-}$ behaves as required by the theory, but the qualitative nature of the agreement is evident from Fig. 8. The theoretical curve is smoother than the experimental curve. The greatest discrepancy between the two curves occurs in the region of potentials where other effects can become appreciable (for example, ion-pair formation). The particular feature of this reaction is that the $Fe(CN)_6^{3-}$ ion is fairly large, whereas $E_S$ is relatively small. Therefore, according to the theoretical predictions, deviations from Tafel's formula should set in at not very high overvoltages, as is indeed found to be the case in practice.

We must stress that the equilibrium potential does not appear in the expressions for the current which have been obtained: only departures from the equilibrium potential. In other words, the formulae for the current do not include quantities depending on the work function of the metal, and therefore the reaction rate in this sense is independent of the work function of the metal. Different electrodes are characterised by their density of states and by the exchange integral $V$ rather than by their work function.

The expressions (3.14)–(3.16) for the current are derived for reactions proceeding non-adiabatically. The study of adiabatic electrode reactions involves a number of difficulties arising from the presence of a continuous spectrum of states in the solid. However, we may suggest (without as yet any real proof) that these formulae will be applicable to the adiabatic case with the usual substitution of $V$ by $V_\sigma$ [see for example Eqn. (2.21)].

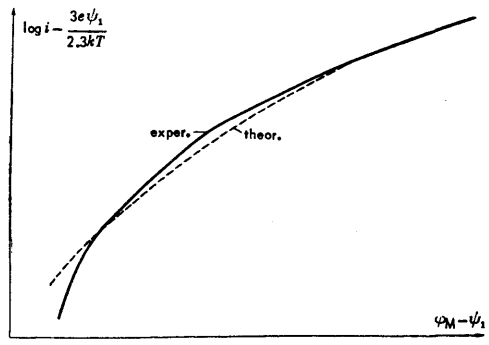

Fig. 8.

## 3. Kinetics at Semiconductor Electrodes

The basic physical mechanism of current flow at a semiconductor electrode is the same as for a metallic electrode. The most characteristic features of semiconductor electrodes are that the Fermi level in a semiconductor is situated in the forbidden gap, and that the filling of energy levels by electrons is a sensitive function of temperature and of the distribution of potential in the system. A consequence of the first characteristic is that the integration in (3.3) and (3.4) must be carried out over both the conduction and the valence band of the semiconductor. The resulting expressions will be called the electron current ($i^e$) and the hole current ($i^p$) respectively. From the second characteristic, it follows that in a semiconductor the variation of current with potential and with temperature will be determined not exclusively (or even mainly) by the effect of these parameters on the transition probability, but rather by their effect on the concentration of free carriers.

We can point out immediately that the procedure used to derive formulae (3.12) and (3.13) makes it obvious that the formulae are applicable to each of the components (electrons and holes) of the total current[44,49]. We shall therefore quote only the expressions for cathodic currents. The expressions for anodic currents are easily obtained by using the formulae given above.

Semiconductor with non-degenerate surface. We shall assume that the Fermi level does not extend into either band, i.e. that the following condition is satisfied (see Fig. 6):

$$\Delta_{e,p} - e|\varphi_{sc} - \varphi_c| > 4\,kT. \tag{3.18}$$

In this case the integration in (3.4) gives[47,49]

$$i_c^p = i_0^p \exp\left\{-\beta_p \frac{e(\eta_c - \eta_d)}{kT}\right\} \exp\left\{-\frac{ze\eta_d}{kT}\right\}; \tag{3.19}$$

$$i_c^e = i_0^e \exp\left\{-\beta_e \frac{e(\eta_c - \eta_d)}{kT}\right\} \exp\left\{-\frac{ze\eta_d}{kT}\right\} \exp\left\{-\frac{e(\eta - \eta_c)}{kT}\right\}. \tag{3.20}$$

where $i_0^e$ and $i_0^p$ are the electron and hole exchange currents,

$$\beta_p = \frac{1}{2} - \frac{\varepsilon_p^c - \varepsilon_F}{2E_s};\ \varepsilon_p^c - \varepsilon_F = -(\Delta_p - e(\varphi_{sc}^0 - \varphi_c^0)); \tag{3.21}$$

$$\beta_e = \frac{1}{2} - \frac{\varepsilon_e^c - \varepsilon_F}{2E_s};\ \varepsilon_e^c - \varepsilon_F = \Delta_e + e(\varphi_{sc}^0 - \varphi_c^0). \tag{3.22}$$

The remaining symbols are illustrated in Figs. 6 and 9.

The second terms in (3.19) and (3.20) give the potential dependence of the probability of electronic transition. Of course, this quantity depends only on the difference in potential between the electrode surface and the point where the ion undergoing discharge is situated. The third terms describe the potential dependence of the concentration of ions in the reaction region ($\psi_1$-effect). Lastly, the third term in (3.20) describes the potential variation of the concentration of electrons close to the semiconductor surface.

Brønsted's rule. It can be shown[44,47,49] that with semiconductor electrodes Brønsted's rule can only be

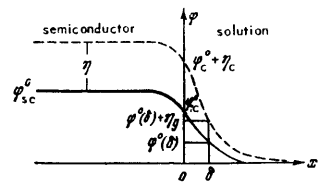

Fig. 9.

applied, generally speaking, to the electron and the hole current separately. The $\beta$ coefficients are given by formulae (3.21) and (3.22), and are not usually the same. In a semiconductor with a non-degenerate surface, the inequalities $\beta_e \leqslant \frac{1}{2} \leqslant \beta_p$ are always satisfied. Only when $E_S$ is large enough do we find $\beta_e = \beta_p = \frac{1}{2}$ (i.e. just as in the case of a metal electrode).

It is interesting to note that, in principle, the values $\beta_p \geqslant 1$ and $\beta_e \leqslant 0$ are possible. The cases of strict inequality correspond to the distribution of energy levels shown in Fig. 10). The cases of equality denote that the corresponding level is non-activated. These situations can evidently be realised in the discharge of large ions, for which the transpolarisation energy $E_S$ is relatively small, and when the equilibrium bending of the bands is large. Let us examine in greater detail the expressions for the currents $i^e$ and $i^p$. To simplify matters, we shall ignore the $\psi_1$-effect and assume that $\eta_g = 0$. The quantity $\eta_k$ is determined by the properties of the semiconductor surface. However, if the concentration of surface states is large, we find[44,50] that $\eta_k \simeq \eta$. This is precisely the case of interest when the situation $\beta_p > 1$ and $\beta_e < 0$ occurs, because an unusual current–voltage relation is observed. Thus, for $\eta_k = \eta$, say, the expression for $i^p$ takes the form

$$i^p = i_0^p \left\{ e^{\frac{e(1-\beta_p)\eta}{kT}} - e^{-\frac{e\beta_p\eta}{kT}} \right\}, \qquad (3.23)$$

and if $\beta_p > 1$ the current $i^p$ initially increases with increase of $\eta$, but reaches a maximum and then begins to fall off. It should be noted, however, that a curve of this type, showing a maximum, can only be obtained if for any reason the electron current vanishes or is very small. In the opposite case the electron current can mask the effect, since it will usually show a normal potential variation (it is very unlikely that the inequalities $\beta_p > 1$ and $\beta_e < 0$ can both be satisfied at the same time). A similar effect can take place for $\beta_e < 0$. The possibility of a maximum in the electron or the hole current was envisaged in a qualitative argument by Gerischer[51]. However, Gerischer considers that this can occur only if the semiconductor surface is degenerate. He gives[51] only a qualitative discussion, and does not derive the $\beta$ coefficients.

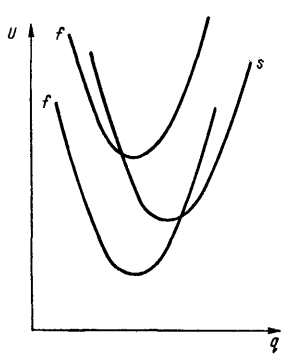

Fig. 10.

Transfer coefficients. The coefficient $\alpha$, introduced by formula (3.17), is indistinguishable from $\beta$ for a metallic electrode (in the absence of the $\psi_1$-effect). Such is not the case with a semiconductor. When the system comprises a semiconductor electrode, the following relations apply:

$$\alpha^e = 1 - (1 - \beta_e)\, d\eta_k/d\eta, \qquad (3.24)$$

$$\alpha^p = \beta_p\, d\eta_k/d\eta. \qquad (3.25)$$

In the absence of surface states, $d\eta_k/d\eta \ll 1$ and $\alpha^e$ and $\alpha^p$ are equal to 1 and 0 respectively[43,44]. Surface states can, on the one hand, affect the potential distribution in the system and thus influence the electron exchange between the solution and the bands of the semiconductor, and, on the other hand, they can themselves exchange electrons with the solution and thus contribute to the current. The former effect can make the transfer coefficients differ appreciably from 1 and 0, and be a function of the overvoltage, which should lead to departures from the Tafel relation[47,49]. The latter effect leads to a change in the nature of the current–potential relationship[47,49] (from electronic to hole current) as the surface states become gradually filled, if the concentration of surface states is high.

Exchange currents. The general expressions for the exchange currents are extremely cumbersome[44,47,49], and there is no simple relation, in general, between $i_0^p$ and $i_0^e$. However, if the condition $|\Delta_p, e \pm e(\varphi_{sc} - \varphi_c)| \ll E_S$ is satisfied, the two exchange currents are related by the simple expression[47]

$$i_0^e = i_0^p \exp\left\{ -(1 + \Delta_0/E_s)\, \frac{e\,(\varphi_{sc}^0 - \varphi_c^0) - (\Delta_p - \Delta e)/2}{kT} \right\}, \qquad (3.26)$$

where $\Delta_0$ is the half-width of the forbidden gap. This expression coincides with the formula given by Dewald[52]. It is evident from (3.26) that, in the absence of surface states, the ratio of exchange currents is independent of the impurity concentration in the semiconductor over a wide range. If a large density of surface states is present, the quantity $\varphi_{sc}^0 - \varphi_c^0$ is practically constant, and the ratio of currents becomes a function of impurity concentration.

Degenerate surface. If the Fermi level intersects either of the bands, the surface of the semiconductor assumes metallic properties. In this case the expression for the current is similar to the analogous expression for a metallic electrode, and the major part of the current is carried by electrons located close to the Fermi level[44,49].

In conclusion, we should stress the fact that the use of semiconductors as electrodes in the study of electron transfer processes between an electrode and a solution offers some definite advantages over metallic electrodes. The current at a semiconductor electrode is a function of semiconductor parameters such as the position of the Fermi level in the forbidden gap, the equilibrium bending of the bands, and the width of the forbidden gap. These parameters can be varied over wide limits, either by working with different semiconductors or by controlling the bending

of the bands for the same semiconductors. Therefore, a semiconductor offers very wide possibilities for research in this field. However, one serious disadvantage of semiconductors in this respect is that it is not always possible to determine unambiguously some of the semiconductor characteristics, and this can make the interpretation of experimental results very difficult.

## 4. Kinetics of Electrochemical Reactions in the Metal–Semiconducting Film–Electrolyte Solution System

In the study of various processes at metal surfaces one often has to deal with metals whose surface is covered with a natural oxide film. A considerable number of experimental and theoretical papers[53-59] have been devoted to oxide films on metal surfaces. The interest in studies of this type springs from the profound effect of oxide films on the course of many catalytic, corrosion, and electrochemical processes. Most contemporary workers consider that the semiconductor nature of oxide films must be taken into account when discussing the effect of these films on the above processes. Since we share this view, we have examined[46,49] a number of electrochemical processes in the metal–semiconducting film–electrolyte solution system.

In our discussion of the kinetics at a clean metallic electrode (III, 2) and at a clean semiconductor electrode (III, 3), we showed that there is an essential difference between these systems as regards their electrochemical behaviour. In a mixed metal–semiconductor–solution system we can expect to find properties both of the metallic and of the semiconductor electrode. Real oxide films are very complex structures, and are difficult to discuss theoretically. We have therefore considered[46,49] a highly idealised model, which, however, allows a qualitative study of some of the properties of these systems.

The film is treated as a uniform semiconductor to which the normal band theory can be applied. This limitation excludes very thin films from our discussion. An oxidation–reduction reaction of the type (*), satisfying all the conditions laid down at the beginning of this chapter, is proceeding at the surface of the film. It is assumed that the composition of the film does not change during the reaction, i.e. that the material of the film does not take part in the reaction.

A direct study of the kinetics of reaction (*) has shown[46] that the expressions obtained for a semiconductor electrode are quite general and can be modified for the present system by allowing for the difference between the energy diagram of this system (Fig. 11) and that of the semiconductor–solution system. The potential distribution in the two systems is also different, so that different quantitative results can be expected.

The expressions for the hole and the electron current are given, as before, by formulae (3.19) and (3.20), with the proviso that the values of $\epsilon_F - \epsilon_p^s$ and $\epsilon_e^c - \epsilon_F$ now take the form

$$\varepsilon_F - \varepsilon_p^c = \Delta_p - e(\varphi_M^0 - \varphi_c^0) + \chi_{sc}^0 - \chi_M^0, \qquad (3.27)$$

$$\varepsilon_e^c - \varepsilon_F = \Delta_e + e(\varphi_M^0 - \varphi_c^0) - \chi^0 + \chi_M^0, \qquad (3.28)$$

where $\chi_{sc}^0$ and $\chi_M^0$ are the work functions of the isolated semiconductor and metal respectively, and $\varphi_c^0$ is the equilibrium potential at the film–solution interface.

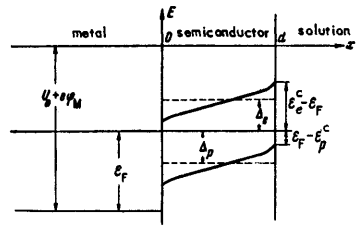

Fig. 11.

It follows from (3.27) and (3.28) that the properties of the system depend on the potential distribution (values of $\varphi_M^0 - \varphi_c^0$, $\eta_c$, $\eta_g$) and on the work function of the metal and the semiconductor ($\chi_M^0$ and $\chi_{sc}^0$). The whole of the above treatment is applicable to a uniform semiconductor under conditions of small departures from equilibrium in the semiconductor. The formulae can be generalised to include significant departures from equilibrium[48,49]. With weakly non-uniform semiconductors the general expressions remain valid, but the position of the bands at the interface with the solution with respect to the Fermi level ($\epsilon_{p,e}^s - \epsilon_F$) ceases to be defined by formulae (3.27) and (3.28), and becomes a function of the physical structure of the film.

The most significant feature of this system is that the parameters which determine the current–voltage characteristic (exchange currents and transfer coefficients) depend on the thickness of the film. In fact, the transfer coefficients [see Eqns. (3.21) and (3.22)] and the exchange currents depend on $\epsilon_{p,e}^s - \epsilon_F$. The latter quantity is a function of the potential distribution in the system and therefore of the thickness of the film. For a uniform semiconductor, it is possible to investigate in a general way the variation of the exchange currents with film thickness[46,49]. The expressions obtained[46,49] for the exchange currents show that the hole exchange current decreases and the electron exchange current increases with increase of $\varphi_c^0$ potential. Therefore, the problem becomes one of determining the variation of $\varphi_c^0$ with film thickness at a fixed value of $\varphi_M^0$. This relationship was investigated in Ref. 53, where the potential distribution in the film is examined under different conditions.

1. Consider the case of a uniform potential gradient in the film, with $\varphi_c^0 < \varphi_M^0$. As the thickness of the film decreases, $\varphi_c^0$ increases and approaches the value of $\varphi_M^0$, so that the hole exchange current decreases while the electron current increases. If $\varphi_c^0 > \varphi_M^0$, the reverse is true.

2. If the fall of potential in the film is not monotonic, the variation of $\varphi_c^0$ (and therefore also of $i_0^p$ and of $i_0^e$) with film thickness may or may not be monotonic[49]. Not surprisingly, the behaviour of the total exchange current $i_0 = i_0^p + i_0^e$ will be very complex, depending on the relative values of the individual exchange currents. We must stress that all the above effects will be appreciable only with film thicknesses smaller than the Debye length in the semiconductor.

The variation of the exchange currents and of the transfer coefficients with film thickness becomes particularly simple if the fall of potential in the film is linear. To make the problem concrete, let $\varphi_M > \varphi_c$, and also

$|\epsilon_{p,e}^{c} - \epsilon_F| \ll 2\sqrt{E_S kT}$. The exchange currents and the transfer coefficients are then given by[46]

$$\ln i_0^{p,e} = (\text{const})^{p,e} \mp (\chi_{sc}^0 - \chi_M^0) \pm e\varphi_M^0 \frac{1}{1 + \frac{\delta}{d}\frac{\epsilon_{sc}}{\epsilon_H}}, \quad (3.29)$$

$$\alpha_p = \frac{1}{2}\frac{1}{1 + \frac{d}{\delta}\frac{\epsilon_H}{\epsilon_{sc}}}; \alpha_e = 1 - \alpha_p, \quad (3.30)$$

where $d$ is the film thickness, $\delta$ is the thickness of the Helmholtz layer, $\epsilon_{sc}$ and $\epsilon_H$ are the dielectric constants of the semiconductor and of the Helmholtz layer. It is obvious that for large film thicknesses ($d \gg \delta\epsilon_{sc}/\epsilon_H$) $\alpha_p$ and $\alpha_e$ will approach 0 and 1 respectively, i.e. the film behaves as an ordinary semiconductor. As the thickness decreases, $\alpha_p$ increases and $\alpha_e$ decreases. In the limit of $d = 0$ we obtain $\alpha_{p,e} = 1/2$, i.e. the same result as for a metallic electrode. The condition of linear potential gradient in the film for small values of $\varphi_M$ ($e\varphi_M \ll kT$) leads to $\varkappa d \ll 1$, where $\varkappa$ is the Debye screening length in the semiconductor. If $\varphi_M$ is large, this condition becomes insufficient, and one must proceed with some care.

It follows from what has been said that the current–voltage characteristics of these systems are determined by the energy diagram of the system and by the potential distribution. Therefore, to obtain the variation of current with voltage for any system we must know the energy diagram and the potential distribution for the system. On the other hand, it is possible to form an opinion of the electronic structure of the film by comparing the theoretical relations derived from a definite model of the system with experimental results.

## 5. Stationary Photoeffect in the Semiconductor–Electrolyte Solution System

Methods relying on illumination of the electrode are widely used in studies of electrochemical processes at the semiconductor–solution interface. There are also theoretical papers devoted to the photoeffect at the semiconductor–solution interface. The influence of illumination on the potential of a semiconductor electrode has been examined[60,61] by a combination of a thermodynamic argument and of the Tafel formula. This method leads to a number of relationships containing experimentally determinable parameters. The stationary photoeffect, considered in the light of the above adiabatic theory of electron transfer reactions, is of interest in this context.

Consider a reaction of the type of (*), proceeding at a semiconductor electrode. In the absence of illumination, both the net current in the external circuit and the individual hole and electron currents must be equal to zero at equilibrium. When the semiconductor is illuminated, the latter requirement ceases to apply. The increase in electron and hole concentration in the semiconductor resulting from illumination produces an increase in the currents of both electron and hole transfer into the solution at a given potential. Therefore the potentials $\varphi_p^0$ and $\varphi_e^0$ at which the hole and the electron current respectively vanish are not equal to each other or to the equilibrium potential of the system $\varphi_{sc}^0$. When the semiconductor is illuminated, a steady state which we shall call a quasi-equilibrium state is established: in other words, we assume that the quasi-Fermi levels for electrons ($\Phi_e$) and for holes ($\Phi_p$) are constant over the entire space-charge region. Proceeding as in the derivation of formula (3.12), it is possible to obtain[45,47,49] the following expressions for the currents in a semiconductor with a non-degenerate surface not at equilibrium:

$$i^{e,p} = i_c^{e,p}\left[\exp\left\{\frac{e(\varphi - \varphi_{sc}^0) + \varepsilon_F - \Phi_{e,p}}{kT}\right\} - 1\right]. \quad (3.31)$$

It follows that the potentials $\varphi_p^0$ and $\varphi_e^0$ are related to the quasi-Fermi levels by the expressions

$$e\varphi_{p,e}^0 = e\varphi_{sc}^0 + \Phi_{p,e} - \varepsilon_F. \quad (3.32)$$

This result agrees with that obtained thermodynamically by Brattain and Garrett[60]. When there is no net current in the system (open circuit), a potential $\varphi_{st}$ is set up for which (see Fig. 12).

$$i^p = -i^e. \quad (3.33)$$

Since the quasi-Fermi level for electrons lies above the Fermi level when the semiconductor is illuminated, we have $\varphi_e^0 > \varphi_{sc}^0$. For holes, $\varphi_p^0 < \varphi_{sc}^0$. The quasi-Fermi levels for electrons and holes are related by the expression[62]

$$\left[\exp\left(\frac{\varepsilon_F - \Phi_p}{kT}\right) - 1\right]\left[\exp\left(-\frac{\varepsilon_F - \Phi_e}{kT}\right) - 1\right]^{-1} = n_0/p_0, \quad (3.34)$$

where $n_0$ and $p_0$ are the electron and hole concentrations in the bulk of the semiconductor.

The solution of the electrostatic problem taking account of Eqns. (3.33) and (3.34) determines the deviation of the potential from its equilibrium value in terms of the positions of the quasi-Fermi levels for electrons and holes. To find the variation of the steady-state potential $\varphi_{st}$ with the intensity of illumination $S$, we have to introduce an expression relating the position of the quasi-Fermi level to $S$. We shall assume that the semiconductor is illuminated with light in the fundamental absorption region and that the light is absorbed over a distance which is small compared with the diffusion length of minority carriers but not necessarily smaller than the Debye length: we assume, in other words, that the diffusion length of minority carriers is much greater than the Debye length. Taking an $n$-type semiconductor as a concrete example, we can write[62]

$$I - i_r^p = I_s^p\left[\exp\left(\frac{\varepsilon_F - \Phi_p}{kT}\right) - 1\right], \quad (3.35)$$

where $I$ is the number of hole–electron pairs generated by the light in unit time and per cm² of semiconductor surface ( a quantity proportional to $S$), $I_S^p = ep_0[D_p/L_p + v_S^p]$, $D_p$ and $L_p$ are the diffusion coefficient and diffusion length of holes, and $v_S^p$ is the surface recombination velocity.

At small departures from equilibrium, solution of Eqn. (3.33) gives

$$\frac{e(\varphi_{st} - \varphi_{sc}^0)}{kT} \simeq \frac{I}{I_s^p}\left[\frac{p_0}{n_0} - \exp\left\{\left(1 + \frac{\Delta_0}{E_s}\right)\frac{e(\varphi_{sc}^0 - \varphi_c^0) - (\Delta_p - \Delta_e)/2}{kT}\right\}\right] \text{ for } i_0^p \ll I_s^p. \quad (3.36)$$

It is evident from Eqn. (3.36) that the photoeffect can have either sign, according to the relative values of $\varphi_{sc}^0 - \varphi_c^0$ and $\Delta_p - \Delta_e$. In particular, the photoeffect vanishes at $e(\varphi_{sc}^0 - \varphi_c^0) \simeq (\Delta_e - \Delta_p)/2$ (since $\Delta_0 \ll E_S$). If $e(\varphi_{sc}^0 - \varphi_c^0) < (\Delta_e - \Delta_p)/2$, the photoeffect is positive. If the opposite is true, the photoeffect is negative. Analogous expressions can be written for a $p$-type semiconductor.

If the potential drop in the solution is ignored, expressions for $\varphi_{st}$ can be obtained also for the case of high illumination intensities[48,49] ($I \simeq I_S^p$). To simplify the problem, we shall assume that the condition $i^p \ll I_S^p$ holds true. Several different cases are possible.

1. $(i_0^p/i_0^e)^{1/2} \gg 1$.

$$e(\varphi_{st} - \varphi_{sc}^0)/kT \simeq -\ln(1 + I/I_s^p) = (\Phi_p - \varepsilon_F)/kT, \qquad (3.37)$$

i.e. the potential is shifted by the same amount as the quasi-Fermi level $\Phi_p$.

2. $(i_0^p/i_0^e)^{1/2} \ll 1$.

$$e(\varphi_{st} - \varphi_{sc}^0)/kT \simeq \ln(1 + p_0 I/n_0 I_s^p) \simeq (\Phi_e - \varepsilon_F)/kT, \qquad (3.38)$$

i.e. the potential shifts by the same amount at $\Phi_e$.

3. $i_0^p \simeq i_0^e$.

$$e(\varphi_{st} - \varphi_{sc}^0) \simeq [\Phi_e - \varepsilon_F + \Phi_p - \varepsilon_F]/2. \qquad (3.39)$$

These results are readily understood by reference to Fig. 12. The exchange currents determine the slope of the lines with respect to the $\varphi$ axis. In case 1 the left-hand line is very steep and the right-hand line is shallow. Thus their intersection is close to $\varphi_p^0$. In the second case the opposite situation occurs and the straight lines intersect close to $\varphi_e^0$. In the third case the picture is symmetrical and the lines intersect in the middle.

Let us now consider, in a sense, the opposite problem. We shall examine the variation of the current in the system under illumination at a given potential. It is easy to show that, for small light intensities [$e(\varphi_{st} - \varphi_{sc}^0) \ll kT$] and small values of $\varphi - \varphi_{st}$, the current varies linearly with $\varphi - \varphi_{st}$, and the exchange current is equal to its dark value. For appreciable intensities of illumination ($I \simeq I_S^p$), the expression for the total current is of the form[48,49]

$$i = i_0^{eff}[\exp\{e(\varphi - \varphi_{st})/kT\} - \exp\{-e(\varphi - \varphi_{st})/kT\}]. \qquad (3.40)$$

This expression is correct only for small deviations of the potential from $\varphi_{st}$. The effective exchange current is

$$i_0^{eff} = \sqrt{i_0^p i_0^e}\,\exp[e(\Phi_e - \Phi_p)/2kT]. \qquad (3.41)$$

It is evident from (3.41) that at high light intensities the exchange current is greater than the dark exchange current. This is not surprising, since the effective exchange current is the current flowing in one direction in the absence of net current in the external circuit. Under illumination this current can be very significantly higher than the dark exchange current.

The stationary photoeffect shows a distinct similarity to other steady-state processes: two oxidation–reduction reactions occur simultaneously at the semiconductor electrode under conditions such that the concentrations of the oxidised and the reduced form of both the first and the second species remain constant in the bulk of the solution. When the semiconductor is illuminated, the potentials $\varphi_p^0$ and $\varphi_e^0$ (at which the electron and the hole currents vanish) take on different values because the quasi-Fermi levels for electrons and holes no longer coincide. As a result, a steady state in which the total current is zero but the individual hole and electron currents are finite is established in the system. In a similar way, in a two-reaction system the potentials $\varphi_1^0$ and $\varphi_2^0$ ($\varphi_1^0 > \varphi_2^0$, say) at which the currents of the first and the second reaction go through zero do not coincide. (Of course, this difference does not arise from the difference in quasi-Fermi levels in the semiconductor, but is due to differences in the concentration and in the nature of the ions.) Therefore, we can again observe a state of zero net current but finite currents of the first and the second reaction:

$$i_1 = -i_2.$$

The solution of this equation defines the stationary potential $\varphi_{st}$ of the system. We shall not reproduce all the equations (see Refs. 48 and 49); they are similar to the corresponding equations for the stationary photoeffect. For small values of $\varphi_1^0 - \varphi_2^0$ and $\varphi - \varphi_{st}$, the variation of the current with $\varphi - \varphi_{st}$ is linear, and the exchange current equals the sum of the exchange currents of the first and the second reaction. If $\varphi_1^0 - \varphi_2^0$ is large, the expressions obtained are similar to (3.40) and (3.41) except for the replacement of $\Phi_e$ by $\varphi_1^0$, $\Phi_p$ by $\varphi_2^0$, and $\sqrt{i_0^p i_0^e}$ by $\sqrt{i_{20}^p i_{10}^e}$.

# ELECTROCHEMICAL IMPLANTATION OF ALKALI METALS

B. N. Kabanov, I. I. Astakhov, and I. G. Kiseleva

## CONTENTS

I. Introduction 775

II. Thermodynamic possibility of discharging alkali metal ions 776

III. Explanation of some obscure phenomena by means of the implantation concept 776

IV. Experimental study of implantation 778

V. Mechanism of implantation 781

1. Implantation overvoltage 781

2. Loosening and disintegration of cathodes 782

## I. INTRODUCTION

The alkali metals are deposited on cathodes at potentials so negative that hydrogen evolution makes them inaccessible in aqueous solutions, even when the electrodes consist of metals with a high hydrogen overvoltage such as lead or mercury. The highest potentials attainable under ordinary experimental conditions are more positive than the equilibrium potentials of the alkali metals by about 1 V. However, if liquid mercury is used as cathode, the alkali metals can be discharged at not too negative potentials because the discharge potential is shifted towards more positive values. This phenomenon is well known, and has been used in industry for a long time and has been investigated by physical chemists for over a hundred years. The cause of this shift is the strong chemical interaction between the alkali metals and mercury, with formation of amalgams. Electrolysis of aqueous solutions has produced amalgams not only of the alkali and alkaline earth metals, but also of ammonium and of some organic cations such as tetramethylammonium [1,2].

The large free energy change accompanying amalgam formation is the basic factor which enables alkali metal ions to be discharged on mercury from aqueous solutions. The high hydrogen overvoltage of mercury, which increases the fraction of the current carried by alkali metal deposition, and the rapid convective transport of the alkali metal towards the deeper layers of the liquid cathode (coupled with the high rate of formation of the amalgam), favour the discharge of alkali metal cations and enable the process to be used in practice. For this reason, the process has effectively been studied only at a liquid mercury cathode.

Numerous experimental studies have shown that the rate of discharge of alkali metal ions on mercury is very high[3-9]. Only recently have such measurements been made possible by the use of the Faradaic impedance[10] and the Faradaic rectification method[11]. Exchange current densities of the alkali metal ions have been found to be of the order of 0.1–0.2 A $cm^{-2}$ on these amalgams.

## II. THERMODYNAMIC POSSIBILITY OF DISCHARGING ALKALI METAL IONS

Strong chemical interactions with alkali metals are not an exclusive property of mercury. It is well known that the alkali metals, which occupy the first subgroup of the Periodic Table, react energetically with many elements, the reactivity increasing with increasing non-metallic character of the elements in question. We must remember that the overriding factor in the formation of intermetallic compounds is not, in general, the energy of interaction between the atoms involved in compound formation, but other factors such as the dimensional relationship between the reacting atoms or the concentration of free electrons in the resulting metallic compound. However, if the atoms from which the compound is formed show a strong interaction (as in the case of gold and an alkali metal) this interaction is found, as a rule, to be the major factor which determines the structure and properties of the intermetallic compound[12]. This accounts for the formation of stable intermetallic compounds, similar to amalgams in their properties, between the alkali metals and many other metals.

The behaviour of atoms towards compound formation can be characterised, for example, by the Pauling electronegativity concept[13]. The greater the electronegativity difference between two atoms, the more strongly the atoms will interact, and the greater the percentage ionicity of the resulting bond. Electronegativity values, taken from Ref. 14, are listed in Table 1. Most of these values were obtained by thermochemical methods.

It is evident from the table that the electronegativity of mercury is no greater than that of many other metals. Therefore, these metals should interact with the alkali metals at least as strongly as mercury.

TABLE 1.

| Elements | Li | Na | K | Rb | Cs | Cu | Ag | Au | Zn | Cd |
|---|---|---|---|---|---|---|---|---|---|---|
| Electronegativity | 0.95 | 0.9 | 0.8 | 0.8 | 0.75 | 1.8 | 1.9 | 2.3 | 1.6 | 1.7 |
| Elements | Hg | $Sn^{2+}$ | $Sn^{4+}$ | $Pb^{2+}$ | $Pb^{4+}$ | Bi | | | | |
| Electronegativity | 1.8 | 1.7 | 1.8 | 1.6 | 1.8 | 1.8 | | | | |

TABLE 2.

| | Cd | Sn | Pb | Zn |
|---|---|---|---|---|
| Na | 1.4 | 1.2 | 1.5 | 1 |
| K | 1.8 | 1.2 | 1.5 | 1.1 |

Many experimental investigations have been aimed at the interactions between alkali metals and other metals. They include measurements of the e.m.f. of a cell consisting of an alloy of the alkali metal and of one of the components of this alloy. However, this work was done mostly at high temperatures, above the melting point of the alloys. Hauffe and Vierk[15,16], and also Alabyshev, Morachevskii, and others[17-20], examined a large group of metals (Cd, Tl, Hg, Sn, Pb, etc.). Their experimental results indicate that at temperatures of 300–600° some of the metals (e.g. Cd, Tl) react with the alkali metals more strongly than does mercury, whilst others (e.g. Sn, Pb) show an interaction comparable to that of mercury or somewhat weaker. In order to extrapolate from these experimental data to the interaction at room temperature, we must know the temperature variation of the specific heats of the alloys. No such data are available at the present time. It must also be remembered that compounds which would form at room temperature may dissociate at higher temperatures. Hence, no firm conclusions as to the likely value of the interaction energy between these metals at room temperature can be drawn from these and other similar investigations.

Two series of relatively old papers (by the schools of Haber[21,22] and Kremann[23-29]) are concerned with studies of the potentials of alloys of the alkali metals. The work was carried out in solutions of electrolytes in organic solvents at room temperature and below. The results of these two series of papers are in good agreement, but the measurements of Kremann and his coworkers are the more accurate, and include a greater variety of metals. Some of the results obtained by Kremann's school are reproduced in Table 2, which lists the potentials of the most noble of the intermetallic compounds examined by those workers. The potentials are referred to the pure alkali metal, and are therefore equivalent to the maximum positive shift of the potential for cathodic deposition of the alkali metal on the particular electrode.

The table shows that the discharge potential of Na and K on Sn, Pb, Zn, and Cd electrodes is lowered by more than 1 V, which suggests that the deposition of alkali metals from aqueous solutions on these electrodes is apparently quite feasible.

Thus, we may conclude from these data that mercury has no thermodynamic advantage over a number of other metals. The discharge of alkali metal ions from aqueous solutions can be expected to occur also on other metals under suitable conditions.

## III. EXPLANATION OF SOME OBSCURE PHENOMENA BY MEANS OF THE IMPLANTATION CONCEPT

Until quite recently, there had been no experimental papers giving a direct demonstration of the possibility of discharging alkali metal ions on solid electrodes from aqueous solutions. There was some indirect evidence, however, that the process should be possible. Some

remarkable electrochemical phenomena have been observed during cathodic polarisation of solid electrodes in aqueous solutions containing alkali metal ions. A satisfactory explanation of these phenomena necessitates the assumption that the alkali atoms can be implanted into solid electrodes. The deposition of alkali metals on solid metal electrodes with formation of intermetallic compounds accompanied by penetration of the alkali metal into the bulk of the electrode has been termed[30] electrochemical implantation of alkali metals.

At the turn of the century Bredig and Haber[31,32] discovered and investigated the cathodic disintegration of lead, tin, mercury, thallium, and bismuth. They showed that the process can be reproduced satisfactorily only if the electrolyte contains alkali metal ions. In all cases, loosening of the electrode occurs before disintegration. The cathodic disintegration of lead and tin was later examined in more detail by Haber and Sack[21], and by Sack[22]. These workers explained the phenomenon by postulating the possibility of discharge of alkali metal ions at the electrode, but their discussion of the mechanism of this process is rather superficial.

After the work of Haber and Sack, not a single paper on the cathodic disintegration of lead appeared for almost half a century, and it was not until 1953 that Salzberg[33-35] again investigated the features of this process. He also found that cathodic disintegration proceeds stably and reproducibly only when alkali metal cations are present in solution, but he was unable to give the correct explanation of the phenomenon. Angerstein[36] showed that the disintegration of lead in acids, observed in some experiments both by Haber's school and by Salzberg, is due to the presence of alkali metal impurities in the solution.

Kabanov and his coworkers[37-39] observed the cathodic superactivation of aluminium and magnesium in alkalis, and explained it by assuming cathodic formation of a surface compound of Al or Mg with an alkali metal. This hypothesis was based on the dependence of superactivation upon the nature of the cation (from lithium to tetramethylammonium). In their study of the electrolytic reduction of acetone in alkaline solutions, Antropov and his coworkers[40] observed anomalous current yields on a number of solid cathodes. The anomalies were similar to those resulting from the use of amalgam cathodes. To explain their results, the authors suggested that intermetallic compounds are formed between an alkali metal and the cathode metal when lead, tin, zinc, and cadmium electrodes are cathodically polarised.

Turomshina and Stender[41] studied the electrodeposition of zinc from sulphuric acid solutions, and found that the current efficiency of zinc deposition drops when alkali metal ions are present in solution. They ascribe this behaviour to incipient co-deposition of alkali metal ion with the zinc ions†, with formation of the appropriate intermetallic compounds.

There are many reports of unexplained phenomena, noticed during measurements of the hydrogen overvoltage of various metals: slow changes in overvoltage with time, hysteresis, abnormally high slopes of the linear plots of overvoltage against the logarithm of current density[42-45]. The absolute values of the overvoltage (or the rates of hydrogen evolution at a given potential) in alkaline solutions are often very sensitive to elusive differences in experimental conditions. These surprising phenomena have not always been described in the published papers (unless of course they had a direct bearing on the main topic of the paper) because they were thought to arise from trivial, random causes. In some cases these phenomena are explicitly ascribed to the influence of random factors[43-45]. Thus, Kaptsan and Iofa have retracted the electrochemical mechanism of decomposition of amalgams[46] put forward in their previous papers, believing it to be due to random factors, and early measurements of the hydrogen overvoltage of mercury and of dilute amalgams in alkaline solutions have recently been re-examined[47-49], but no explanation has been given why the difficulties encountered in alkalis do not arise to the same extent when working in acid solutions. In some cases the change of overvoltage with time is explained by postulating the formation of surface hydrides.

The idea of alkali metal implantation was first put forward a few years ago[30] to explain the very startling hydrogen overvoltage curves obtained for zinc in alkalis. The explanation was later extended to other cases of hydrogen evolution on solid metals in alkaline solutions.

The shape of the plot of hydrogen evolution potential against the logarithm of current density is very sensitive to the conditions of measurement. Under certain conditions we find satisfactorily reproducible linear plots with a slope of 0.11–0.12 V. The requirements are that the cathodic potential of the electrode is not allowed to exceed a certain value, and that the measurements are made in a sufficiently short time. When the curve is plotted slowly, the potential begins to increase with time upon reaching a certain value (Fig. 1). After a few tens of minutes the electrode potential has shifted by 0.2–0.3 V in the negative direction. After this cathodic polarisation the slope of the curve is very much higher, and hysteresis is observed. If the curve is now plotted in the reverse direction (from high towards low polarisations), the potential is found to decrease with time at constant current when the polarisation of the electrode has been reduced by a sufficient amount.

We put forward the hypothesis that the time variation of the hydrogen evolution potential is associated with the formation (by implantation) or with the decomposition at the cathode surface of intermetallic compounds formed by the cathode metal with alkali metal atoms. The hydrogen overvoltage at the surface of these compounds is higher, as a rule, than on the pure metal (probably because of the lower hydrogen adsorption energy). The properties of the intermetallic compounds formed depend on the nature of the cation. Thus, the hydrogen overvoltage in alkalis is a

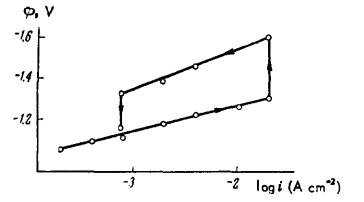

Fig. 1. Polarisation curves for hydrogen evolution on silver in 1 *N* NaOH.

† Since co-deposition of alkali metal ions with zinc ions is involved, rather than penetration of the alkali metal into the zinc cathode, this phenomenon is of minor relevance to our problem.

function of the nature of the alkali metal cation. The overvoltage increases with increasing ionic radius of the non-hydrated cation. After strong cathodic prepolarisation, the potential of the silver electrode at a current density of $10^{-2}$ A $cm^{-2}$ corresponds to -1.42, -1.54, -1.56, -1.68, and -1.72 V for the cations $Li^+$, $Na^+$, $K^+$, $Cs^+$, and $(CH_3)_4N^+$ respectively.

The observed dependence of hydrogen overvoltage upon the nature of the cation can be explained in terms of the variation of the adsorption properties of the intermetallic compounds towards hydrogen atoms when the cation is varied.

On the other hand, the implantation of the alkali metal is easier and faster, the smaller the intrinsic ionic radius, i.e. the faster the diffusion of the cation into the electrode metal. For this reason, lithium is implanted faster than any other alkali metal, and the lithium intermetallic compounds decompose more rapidly than others. This conclusion was drawn from measurements of the time needed to establish a constant electrode potential in hydrogen evolution experiments. The time was found to be shorter for the cations of smaller radius.

Recently, the structural changes of the surface of silver and zinc electrodes have been examined by electron microscopy after cathodic polarisation in solutions containing alkali metal ions[30,50]. Fig. 2 shows the structure of a silver electrode surface after weak polarisation lasting 3 h, Fig. 3 shows the same surface after strong polarisation. It is easy to see that strong polarisation causes loosening of the electrode surface. Similar changes take place on the surface of strongly polarised zinc electrodes. It was interesting to find that silver electrodes are embrittled only when their surface is etched in concentrated $HNO_3$ before polarisation. Electrodes whose surface has been cleaned with glass powder or mechanically polished before polarisation are not loosened under these conditions.

To detect structural changes in the deeper layers of the electrode, electron diffraction studies were made on silver films prepared by vacuum evaporation and cathodically polarised in a solution of sodium sulphate. It was found

that weakly polarised films give a fairly sharp electron diffraction pattern with narrow lines (Fig. 4). After strong cathodic polarisation the lines become diffuse (Fig. 5), showing that the films tend towards an amorphous structure as a result of polarisation.

Thus the implantation of alkali metals causes both loosening of the electrode surface and also, in some cases, a structural change in a layer adjacent to the surface. This phenomenon should no longer be ignored by electrochemists working with alkaline solutions.

However, none of these explanations was entirely satisfactory, because the implantation process itself was not understood owing to the many and serious contradictions. The most important one is the sharp difference between the small experimentally observed rate of penetration of the alkali metal and the large rates expected from various theoretical considerations and obtained experimentally for the amalgam formation process. Before attempting to explain this difference, we shall deal with the methods for investigating the implantation of alkali metals into solid metallic electrodes, and with the experiments on which was based the assertion that alkali metal implantation is possible.

## IV. EXPERIMENTAL STUDY OF IMPLANTATION

The electrochemical membrane method[50] is one of the techniques which have been applied to the study of alkali metal implantation into electrodes.

In this method the alkali metal is passed through a zinc foil membrane, polarised on one side. Double electrochemical cells are used, similar to the cells used in electrochemical studies of hydrogen diffusion through a metallic membrane (Fig. 6). On one side of the membrane the alkaline solution is placed, and cathodic polarisation is applied for a long time at various current densities, and on the other side is placed a dilute solution of $K_2SO_4$, and the pH of this solution is monitored. The results of diffusion measurements of lithium, potassium, caesium, and tetramethylammonium ions through a membrane 30 $\mu$m thick indicate that the rate of implantation of the first two ions is in inverse proportion to the crystallographic radius of the ions, whereas caesium and tetramethylammonium ions

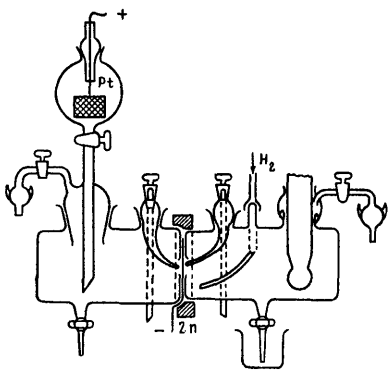

Fig. 6. Cell for measuring the diffusion of an alkali metal through a zinc membrane.

do not in fact diffuse through the membrane. These results are in qualitative agreement with the measurements of the rate of implantation of various ions from the time needed to establish a constant hydrogen evolution potential[42].

The diffusion coefficient of potassium through the zinc membrane was evaluated from the measured time dependence of the rate of diffusion, and found to be of the same order of magnitude as the coefficient for the self-diffusion of zinc along crystal grain boundaries.

The variation of the rate of implantation with electrode potential was investigated in the particular case of penetration of potassium into zinc. In Fig. 7 the polarisation potential of the membrane is plotted horizontally, and the logarithm of the amount of potassium diffusing through the membrane in 22 h is plotted vertically. The membrane thickness was 20 $\mu$m. It can be seen that the rate of implantation increases exponentially with increasing membrane potential. A negative shift in membrane potential of 0.35 V raises the implantation rate by nearly a factor of 100.

Implantation is a complicated, inadequately investigated type of diffusion: it involves reactive diffusion, during which the diffusing substance interacts with the medium. In particular, nothing is known about the difference between bulk and grain-boundary reactive diffusion of the alkali metals in other metals. It is known, however,[51,52]

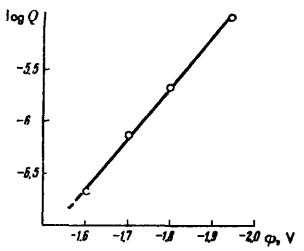

Fig. 7. Variation of the amount ($Q$) of potassium diffusing in 22 h through a zinc membrane 20 $\mu$m thick with polarisation potential of the membrane in 1 $N$ KOH.

that the rate of bulk self-diffusion in zinc at room temperature is smaller by a factor of about $5 \times 10^5$ than the rate of boundary self-diffusion. Most often, the bulk and boundary heterodiffusion rates differ by at least as much as the rates of self-diffusion, since the difference is caused primarily by the difference in structure between the crystal grain boundaries and the bulk phase. Therefore, the transport of the alkali metal through the membrane at room temperature can be expected to occur exclusively along crystal grain boundaries. Thus, when comparing measurements of the rate of implantation by diffusion of alkali metal ions through a membrane with measurements based on the time needed to reach a steady potential during hydrogen evolution, it is important to remember that diffusion measurements characterise only the rate of penetration at the outcrop of grain boundaries on the electrode surface. Since the grain boundaries occupy only a small fraction of the electrode surface, clearly, this process cannot give rise to a significant increase in hydrogen overvoltage. The coverage of the whole surface of the electrode by the intermetallic compound and the consequent establishment of a high hydrogen overvoltage arise from penetration of the alkali metal into the surface of the crystal grains (albeit to a very small depth). The rates of these two penetration processes are expected to be vastly different.

The experiments show that loosening of the surface takes place during the actual polarisation. This makes it very difficult to analyse the results of hydrogen overvoltage measurements on solid electrodes, if the solutions contain alkali metal cations, since at least two opposing factors are always operative. On the one hand, the formation of an intermetallic compound raises the electrode potential at constant current density, and, on the other hand, the loosening of the electrode surface lowers the hydrogen overvoltage. There have been reports of a decrease (rather than an increase) of potential resulting from implantation, and the process responsible for this change in potential could not be unambiguously identified. In any case, we cannot exclude the possibility of the hydrogen overvoltage at some intermetallic compounds being lower (rather than higher) than at the pure metal.

The direct study of the implantation process and the study of the properties of the resulting intermetallic compounds meet with a host of difficulties. We must first of all point out that cathodic implantation of an alkali metal in aqueous solutions is invariably accompanied by hydrogen evolution, the rate of the latter process being higher than that of the former by several orders of magnitude. Yet another difficulty attending the study of these systems is the fact that the compounds which are formed are often unstable, and are rapidly attacked by water when the electrode polarisation is removed. For this reason, they cannot be studied by conventional analytical methods. The most appropriate method for the purpose has been found to be one based on oscillographic recording of $\varphi-t$ (potential–time) curves, or charging curves[53].

The $\varphi-t$ curve allows the change in electrode potential to be monitored after an interruption or a reversal of the current. From the type of curve obtained, one can deduce whether or not a certain process operates at the electrode in a given potential region.

It was found that, when a $\varphi-t$ curve is measured without preliminary cathodic polarisation of the electrode in alkaline solutions, the potential suffers a steep, monotonic change, and the electrode capacity calculated from

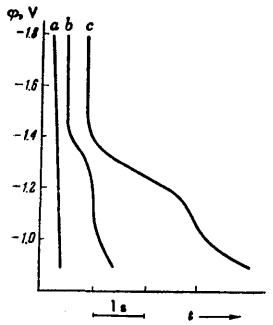

Fig. 8. Anodic potential–time curves for Pb in 1 *N* NaOH; $i_a = 5 \times 10^{-5}$ A cm$^{-2}$: *a*) $t_c$ = 1 min; *b*) $t_c$ = 15 min; *c*) $t_c$ = 30 min

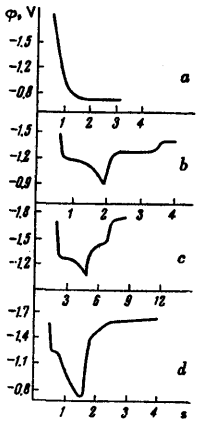

Fig. 9. Anodic and cathodic potential–time curves in 1 *N* LiOH after polarisation at $\varphi_c$ = -1.6 V: *a*) Cd, $t_c$ = 1 min; *b*), *c*), and *d*) Ag, Cd, Pb, $t_c$ = 30 min.

this curve is equal to the double-layer capacity. If, however, the electrode is cathodically polarised during 30 min in the alkaline solution at a potential of, say, -1.6 V, before plotting the $\varphi$–$t$ curve, an arrest is observed on the anodic $\varphi$–$t$ curve (Fig. 8). If the cathodic polarisation is once again applied, it is possible to observe a curve for the growth of cathodic polarisation which also has a plateau (potential arrest). Typical anodic and cathodic $\varphi$–$t$ curves are shown in Fig. 9: the arrests in the fall and in the growth of potential are clearly visible. Arrests on the cathodic $\varphi$–$t$ curves are normally ascribed to the formation of intermetallic compounds, whereas arrests on the anodic curves are ascribed to their decomposition. From the position of the arrests, we can determine an important characteristic of the intermetallic compounds: their equilibrium potential. The equilibrium potential values are intermediate between those corresponding to the onset of the anodic and of the cathodic arrests. Table 3 lists the measured potentials of the arrests, and the equilibrium potentials of the intermetallic compounds of silver, cadmium, lead, and zinc with lithium[53].

TABLE 3.

| Potential | Ag | Cb | Pb | Zn |
|---|---|---|---|---|
| Cathodic arrest | −1.30 | −1.40 | −1.40 | −1.45 |
| Anodic arrest | −1.28 | −1.27 | −1.28 | (−1.35) |
| Equilibrium | −1.29 | −1.33 | −1.34 | (−1.40) |

The presence of arrests on the $\varphi$–$t$ curves is indisputable evidence that electrochemical processes occur at the electrode when these potentials are reached. It remains to be proved, however, that these processes are in fact the formation and decomposition of intermetallic compounds, and that the equilibrium potentials observed are those of the intermetallic compounds. Charging curves alone are not enough to justify this assertion. Cathodic polarisation may be expected to give rise also to compound formation between the electrode metal and hydrogen (hydrides)[54].

On metals (such as iron and nickel) which show a strong tendency to adsorb hydrogen, electrochemical formation of surface hydrides is a definite possibility. However, zinc, cadmium, and lead are metals for which no hydrides are known. Metals from which hydrogen is evolved with a large overvoltage, such as mercury, are known to adsorb very small amounts of atomic hydrogen on their surface[55]. Cathodic formation of hydrides in appreciable quantities is unlikely in this case, and amounts of the order of a monolayer are out of the question. Conversely, intermetallic compounds of lead, zinc, cadmium, and silver with alkali metals are well known, and can be prepared chemically or by electrolysis in molten salts with liquid cathodes.

A direct proof that these arrests are associated with the formation and decomposition of intermetallic compounds was obtained by comparing the equilibrium potentials calculated from the arrests with the potentials of genuine intermetallic compounds, prepared by fusing the elements together. This test was applied to a number of compounds, both in aqueous and in non-aqueous solutions. It was found, for example, that the equilibrium potential of $NaPb_3$ prepared by fusing lead with sodium is the same as the equilibrium potential read off the charging curve of lead in a solution of NaOH. Thus the identity of intermetallic compounds obtained by thermal synthesis with those formed by cathodic polarisation was demonstrated.

Anodic curves sometimes show two or three arrests instead of a single one. This indicates that several intermetallic compounds of different composition can be obtained on the electrode under cathodic polarisation.

Assuming that each molecule of the resulting intermetallic compound contains one alkali metal atom, and knowing the standard potentials of the compounds, we can calculate their standard free energies $\Delta G^\circ$ of formation by the implantation reaction

$$nM + Li^+ + e = LiM_n$$

and the free energy of these compounds.

TABLE 4.

| Composition | $\varphi^\circ$ | $\Delta G^\circ$ | $G^\circ_{LiM_n}$ | Composition | $\varphi^\circ$ | $\Delta G^\circ$ | $G^\circ_{LiM_n}$ |
|---|---|---|---|---|---|---|---|
| $LiAg_n$ | −1.29 | 30 | −40 | $LiZn_n$ | (−1.4) | (32) | −38 |
| $LiCd_n$ | −1.33 | 30.5 | −39.5 | $NaHg_8$ | −1.92 | 44.2 | −18.35 |
| $LiPb_n$ | −1.34 | 31 | −39 | $NaHg_8$ | −2.0 | 46 | −16.48 |

Table 4 lists the free energies of the lithium compounds calculated in this way; for comparison, the values for $NaHg_6$ and $NaHg_2$ are also given.

## V. MECHANISM OF IMPLANTATION

### 1. Implantation Overvoltage

Despite the conclusive evidence discussed above for the existence of alkali metal implantation into solid electrodes in aqueous solutions, all attempts at explaining the behaviour of electrodes in alkalis in terms of implantation failed until the inconsistencies mentioned above (mostly concerning the high implantation overvoltage) were overcome. It was difficult to visualise the cause of the high overvoltage for the deposition of alkali metals, since these metals are deposited on mercury cathodes in alkaline chloride solutions with negligible overvoltage, and they are deposited even more readily in melts. Table 4 shows that implantation into solid metals gives rise to compounds which are more stable than the alkali metal amalgams. Thus we can expect the electrochemical stage of the implantation reaction to proceed at least as fast as the electrochemical amalgam formation reaction. But if implantation into solid metals is fast and exceeds (as in the case of mercury) the rate of hydrogen evolution, we would expect not one monolayer but $10^5$ or more monolayers to form in 30–60 min. Furthermore, when the cathodic polarisation is lowered the compound decomposes very rapidly (hundreds of thousands of times faster than implantation into the pure metal).

Using the observed increase of hydrogen overvoltage with time, we can obtain some information on the rate of the cathodic implantation reaction. If we assume that the achievement of a limiting hydrogen overvoltage denotes the completion of a monolayer of the compound, we can evaluate the mean rate of implantation on a fresh electrode. Clearly, this calculation can give no more than the order of magnitude of the reaction rate. The hydrogen overvoltage of lead in 1 *N* CsOH reaches a limiting value after 60 min cathodic polarisation (Fig. 10). The extrapolated mean current density of alkali metal implantation into pure lead at $\varphi$ = -1.3 V is of the order of $10^{-10}$ A cm$^{-2}$. This means that implantation proceeds with an extremely high overvoltage. The fact that, after brief cathodic polarisation of the electrode, the anodic oscillographic charging curve does not show an arrest is further evidence of the slowness of implantation. An anodic arrest can be observed only after lengthy cathodic polarisation (30 min, say)[53,56].

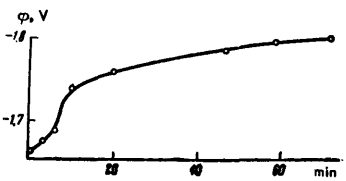

Fig. 10. Growth of the hydrogen overvoltage of lead in 1 *N* CsOH at constant current density $i_c = 3 \times 10^{-3}$ A cm$^{-2}$.

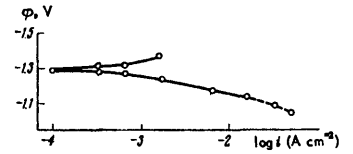

Fig. 11. Polarisation curve for the decomposition of an intermetallic compound, measured for a prepared alloy in 1 *N* NaOH.

The plot of overvoltage curves ($\varphi$–log $i$) is one of the methods used in electrochemistry to measure reaction rates. For the alkali metal implantation reaction, these curves were plotted using the lead–sodium compound obtained by thermal synthesis (Fig. 11). The exchange current of sodium over the alloy was found to be of the order of $10^{-3}$ A cm$^{-2}$.

For an electrode of pure metallic cadmium, the variation with potential of the rate of the anodic decomposition of the intermetallic compound produced by previous cathodic polarisation was measured from a series of anodic charging curves, taken over a range of anodic current densities between $10^{-4}$ and $10^{-2}$ A cm$^{-2}$. The potential of the anodic arrest varied with anodic current density. These results were used to construct a $\varphi$–log $i$ curve for the reaction at a cadmium electrode (Fig. 12). The exchange current was again found to be $\sim 10^{-3}$ A cm$^{-2}$.

Thus, even allowing for the very rough approximation made in the estimation of the rate of the implantation reaction on lead, we can say that the rates of implantation into a fresh lead electrode and into cathodically polarised lead or an alloy of lead with sodium differ very substantially (by approximately seven orders of magnitude).

We concluded earlier, on the basis of published data, that from the point of view of thermodynamics and of electrochemical kinetics mercury should be in no way superior to a number of other metals. It seems reasonable to suppose that the major obstacle to the rapid deposition of alkali metals on solid electrodes is the structural difference between liquid and solid metals. Thus, when alkali metal ions are discharged at a liquid mercury cathode the free volume which exists between atoms in the liquid ensures that the penetration of the alkali metal ions into the cathode is unhindered. Solid metals (lead, silver, zinc, etc.) are composed of closely packed atoms. All the intermetallic compounds which they form with alkali metals are of the substitutional type. Diffusion in these metals and in the intermetallic compounds occurs by exchange between a metal atom and a vacancy in the crystal lattice.

Fig. 12. Polarisation curve for the decomposition of an intermetallic compound, measured for cadmium in 1 *N* NaOH.

Therefore, the diffusion of an alkali metal into the bulk of a solid electrode can only occur by the vacancy mechanism [56].

On the other hand, if we assume, as is often done, that the interaction energy of an ion in the metal with its surroundings is proportional to the coordination number of the ion, it turns out that the most energetically favourable process is the transition of the alkali metal ion undergoing discharge to a vacancy on the electrode surface, since its coordination number then takes the value 9. For comparison we might point out that the coordination number of an ion falling on the plane surface of the electrode is 3, and the coordination number of an ion falling onto the edge of a step (incomplete crystal plane) or of a screw dislocation is 5 or 6. Since the equilibrium potentials of the alkali metals are approximately 1.5 V more negative than the electrode potential during implantation of alkali metals, it is evident that any alkali metal ion falling on the plane surface of the solid electrode will have a higher probability of going back into the solution than of remaining on the electrode surface or of diffusing along the surface until it meets a site where the number of bonds between the ion and the atoms of the electrode is a maximum. Such a site, as was said above, is a surface vacancy. Of course, there is a finite probability that an alkali metal ion falling on a vacancy will also go back into the solution, but the average residence time of the ion on the electrode will be greater the stronger the binding to the electrode. Therefore, an ion falling on a vacancy has the highest probability of exchanging places with another vacancy diffusing outwards from the bulk of the electrode, thus penetrating further into the electrode, instead of going back into the solution.

We have already remarked that the electrochemical stage of the implantation reaction should be a fast one, and cannot therefore determine the rate of the overall reaction. It follows that, even at potentials slightly more negative than the equilibrium potential of the intermetallic compound, all the vacancies present at the electrode surface should be occupied by the alkali metal. Hence, the phenomena taking place at a solid electrode undergoing alkali metal ion implantation are determined by the interplay of two factors. On the one hand, we have the increased concentration of the alkali metal in the surface layer of the electrode due to ion implantation. The rate of this process is determined by the number of vacancies at the electrode surface, which may depend (as we shall see below) on the potential of the electrode. On the other hand, we have the diffusion of alkali metal to the interior of the electrode at a rate which can be very sensitive to the structure of the electrode. Therefore, the course of the overall process of alkali metal implantation is determined (unlike the course of the majority of electrochemical reactions) not only by processes taking place at the electrode surface itself but also (and to a considerable extent) by the structural peculiarities of the electrode metal. As long as the rate of diffusion of the alkali metal towards the interior of the electrode remains smaller than the rate of implantation into the surface, the concentration of alkali metal in the surface layer of the electrode will increase. At first, a solid solution of the intermetallic compound in the electrode metal is formed, and later, when the concentration of alkali metal reaches a value corresponding to the composition of the intermetallic compound, reorganisation of the crystal lattice occurs at a definite rate. With further increase in concentration, a solid solution of the alkali metal (or of a compound richer in the alkali metal) in the intermetallic compound first formed is obtained. In time, the alkali metal diffuses to the interior of the electrode, and the thickness of the layer of intermetallic compound increases [50].

## 2. Loosening and Disintegration of Cathodes

The well-known phenomenon of cathodic loosening and disintegration of metals is intimately associated with diffusion of an alkali metal into the bulk of the electrode. The mechanism responsible for surface loosening of electrodes during implantation is not completely understood. Some authors believe the loosening to result from decomposition of an intermetallic compound formed at the surface [21,22,30,36,50]. Decomposition of the compound present in intercrystalline layers probably plays an important part. It is possible that the compound decomposes as a result of changing polarisation conditions at a given locality on the electrode, for example, by the formation of a hydrogen bubble which screens the surface. A significant accumulation of alkali metal must obviously be present in the surface layer of the electrode to produce loosening. This can happen if the alkali metal penetrating into the electrode cannot reach the interior rapidly enough. Disintegration is possibly connected with the fact that implantation occurs mainly along grain boundaries. If the rapid penetration of alkali metal gives rise to stresses tending to weaken the mutual binding of the grains, separate grains of the metal can break loose and float away with hydrogen bubbles.

Silver electrodes which have been mechanically polished or cleaned with glass powder have a surface layer of heavily deformed metal (cold working) showing enhanced permeability towards diffusion processes. The alkali metal rapidly penetrates to the interior of the electrode, the surface layer cannot become supersaturated with alkali metal, and as a result the electrode does not disintegrate. Etching the electrode in $HNO_3$ dissolves the cold-worked layer, and the electrode disintegrates upon subsequent cathodic polarisation.

Since all the surface vacancies are occupied by the alkali metal even at potentials very little different from the equilibrium potential for the implantation reaction, the observed relationship between the rate of implantation and potential suggests that the concentration of vacancies at the electrode surface increases with increasing potential. Polukarov [57] tried to explain the dependence of the structural peculiarities of the metallic electrode on the electrode potential by suggesting that the change in surface tension of the metal with potential is responsible for the variation with potential of the rate of disappearance of defects in the electrolytic deposit. Similar ideas were used to explain the implantation process [50]. The energy of formation of vacancies depends on the surface tension of the metal, and the relationship can be taken to be linear to a first approximation. The lower the surface tension, the lower will be the energy of formation of vacancies. According to the laws of electrocapillarity, an increase in cathodic potential lowers the surface tension of the electrode metal, lowers the energy of formation of vacancies, raises the surface concentration of vacancies, and therefore increases the rate of implantation. This explanation of the potential dependence of the rate of implantation cannot, of course, be advanced as the only possible one, since it must be remembered that in aqueous solutions a much more intensive process — hydrogen evolution — occurs

in parallel with the implantation of alkali metal and can also affect the energy of formation of vacancies.

The conversion of deposited silver films into an amorphous state by cathodic polarisation in a solution containing alkali metal ions, mentioned above, can be ascribed to the excess of vacancies left behind when alkali metal is implanted and subsequently diffuses outwards.

The number of vacancies at the surface is a function of their rate of formation and of their rate of arrival from the underlying layers of the metal. Lead, unlike silver, has a low melting point and a relatively large self-diffusion coefficient, which allows recrystallisation to occur at room temperature. A concentration of vacancies in excess of the thermodynamic equilibrium value is therefore unlikely to exist at room temperature within the crystal grains of a lead electrode. The main sources of vacancies in this case are the surface, the grain boundaries, and the dislocations.

As we have already pointed out, progressive coverage of the electrode surface by a layer of intermetallic compound is accompanied by an increase in hydrogen overvoltage. The overvoltage reaches its limiting value, in all probability, when the surface is completely covered. Upon further polarisation the layer of intermetallic compound on the electrode surface gradually thickens, whilst at the same time the compound penetrates more rapidly into the core of the electrode along grain boundaries. If during cathodic polarisation the intermetallic compound was formed not merely as a surface monatomic layer, but was allowed to penetrate to the adjacent layer of the metal, and was then decomposed at the surface by passing anodic current, a vastly increased number of vacancies will appear not only at the surface, but also in a small volume immediately below the surface (mainly along grain boundaries and near the intermetallic phase remaining undecomposed below the surface). Such an electrode is said to be "worked". Its high vacancy concentration facilitates the discharge of alkali metal cations with formation of an intermetallic compound, and increases the rate of diffusion. As a result, the overall rate of the process is increased by several orders of magnitude [56].

The electrode can retain its "worked" condition for only a limited time, until the excess vacancies have diffused to the sites which act as sinks for vacancies. Thereafter, the electrode regains the properties characteristic of the pure metal rather than of the compound, and the rate of the process once again becomes very small.

The following experiments confirm the mechanism described for the implantation process. An electrode was polarised for 90 min, and its anodic $\varphi$–$t$ curve was recorded. Without delay, the electrode was again cathodically polarised for 0.5 s and the anodic polarisation curve was again recorded, followed by further brief cathodic polarisation and so on. It was found that after the 90 min polarisation it was possible to plot a number of anodic curves in succession, showing a gradual decrease in the length of the potential arrest, by applying brief periods of cathodic polarisation. The explanation of this is that the rate of diffusion of sodium from the bulk of the electrode is not high enough to give rise to a single large arrest at $\varphi$ = = -1.3 V for the particular anodic current density employed. However, the layer of compound on the surface can become partly reduced after 0.5 s cathodic polarisation, due to the discharge of sodium ions and to the diffusion of sodium from the interior. After 20 min cathodic polarisation, only one anodic arrest can be detected, and the next anodic charging curve does not show any potential arrest. This indicates that even after 20 min a sufficiently thick layer of intermetallic compound has not had time to form.

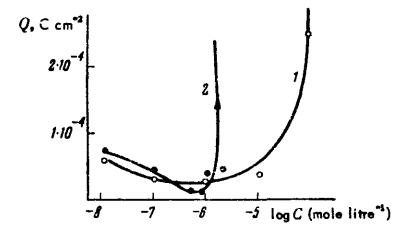

Fig. 13. Variation of the length of the anodic arrest with concentration of $As_2O_3$ (1) and HgO (2) in 1 *N* NaOH.

The anodic decomposition of the resulting intermetallic compound is characterised by the diffusion of sodium atoms from the interior of the electrode to the surface through a layer of intermetallic compound, both for a "worked" lead electrode and for an electrode of the intermetallic compound, prepared by alloying in a separate experiment. We have already pointed out that this type of diffusion should be much faster than the diffusion of the same atoms in the pure electrode metal. The experimental results show that, in fact, on a fresh lead electrode (but not on the alloy) the cathodic formation of intermetallic compound is slower by several orders of magnitude than the anodic decomposition of the intermetallic compound formed by cathodic polarisation. Similar results have been obtained with other electrode metals and other alkali metals [56].

These experiments made it clear that "equilibrium" vacancies, generated at the surface of a metallic electrode or diffusing from the bulk, can give rise to implantation but only at extremely low rates, typically $10^{-10}$ A cm$^{-2}$ for the case of lead. Implantation can occur at appreciable rates only in the presence of a number of vacancies greatly in excess of the "equilibrium" concentration, supplied to the surface from the deeper layers of the electrode. Hence, the essential characteristic of the implantation process is rate control by the state of the metal in the bulk (but close to the surface), a situation not often found in electrochemistry. Of course, factors affecting only the state of the surface can play a part in this case also. However, their effect is incomparably smaller than the effect of structural changes in the bulk of the electrode. Anodic polishing and etching activate the surface and significantly assist implantation. The rate is affected also by the presence of arsenic, mercury, and tellurium on the electrode surface, the effect being a function of the concentration of these elements in solution. At concentrations of $10^{-8}$–$10^{-6}$ M, these impurities inhibit implantation, but when present in greater amounts they assist the process by being co-deposited with the alkali metal (Fig. 13).

Thus, the rate of implantation of an alkali metal into an electrode is determined by the concentration of defects in the bulk of the cathode metal, whilst factors affecting only the electrode surface, such as adsorption of poisons, polishing, and etching, have a vastly smaller effect on the rate of the process [56].

---oOo---

We may conclude as follows. Electrochemists working at the turn of the century suggested that implantation of alkali metals into electrode metals can occur in aqueous solutions, but they were unable to demonstrate the phenomenon experimentally, and the majority of electrochemists rejected the suggestion. In later years there were occasional indications of the reality of alkali metal implantation, since a number of phenomena observed during cathodic polarisation with alkali metal cations in the solution could not otherwise be explained. These included the cathodic disintegration of metals, the cathodic superactivation of aluminium and magnesium in alkalis, the anomalous behaviour of lead, tin, zinc, and cadmium electrodes during cathodic reduction of acetone, anomalies in hydrogen overvoltage in alkalis, certain phenomena in electroplating, and others. Many departures from the expected behaviour for cathodic processes in alkaline and in neutral solutions were disguised by introducing empirical coefficients, and practical methods of preparation of electrodes failed to attract the attention of electrochemical analysts, for example. Of course, a related phenomenon can often accompany implantation in analytical electrochemistry, in electro-hydrometallurgy, and in electroplating; the co-deposition of alkali metals with other metals such as Zn, Pb, Cd, Ag, and others. However, the most striking feature of implantation — an extremely high initial overvoltage — does not manifest itself. This overvoltage is responsible for the apparent lack of reproducibility of the phenomenon, which compelled most electrochemists of the first half of the present century to abandon their attempts to substantiate the idea of cathodic formation of intermetallic compounds between alkali metals and various electrode metals, and to establish its mechanism. Haber and others tried to investigate this phenomenon 60 years ago, but they did not progress far towards an explanation of the mechanism. In very recent years considerable progress has been made in this direction, and the remarkable features of alkali metal implantation into electrodes have been revealed and explained to some extent; we owe this to the rapid developments in electrochemistry, to the very high level reached by the theory of electrochemistry and of electrochemical methods (due in large measure to the fundamental researches of A. N. Frumkin), and lastly to progress in solid state physics.

It now remains to develop in more detail and to substantiate the theory of electrochemical implantation, and to broaden its experimental foundations.

We cannot exclude the possibility that this process takes place also on metals of Group VIII, say, although hardly any intermetallic compounds have so far been reported between these metals and alkali or alkaline-earth metals.

# BARRIERLESS ELECTRODE PROCESSES

L. I. Krishtalik

The slow discharge theory, developed and substantiated by the work of Frumkin and his school, satisfactorily describes the basic features of a large number of electrochemical processes (see, for example, Ref. 1). The concepts which had been originally used to describe the discharge of hydrogen ions were shown to be widely applicable to all types of reaction, such as the electrochemical desorption of adsorbed hydrogen, the reduction of anions and neutral molecules, etc. In recent years it has been shown that the basic ideas of the slow discharge theory imply the existence (in a few limiting cases) of new types of electrode reactions showing a number of interesting features [2-4]. The present review article aims to discuss these limiting cases.

The most distinguishing feature of electrochemical reactions is the variation of their activation energy with potential: as the electrode departs from its equilibrium potential in the cathodic (or the anodic) direction, the activation energy of the corresponding electrode process decreases. This behaviour is most conveniently described by the relation

$$A = A_0 - \alpha\eta F, \qquad (1)$$

where $A$ is the activation energy at an overvoltage $\eta$ (real activation energy values [5] will be used throughout), and $A_0$ is the activation energy at the equilibrium potential. The transfer coefficient $\alpha$ is found experimentally to be constant over a range of potentials, and its value is often close to 1/2.

If the activation energy of the forward reaction decreases with increase of overvoltage, the activation energy for the reverse reaction must increase

$$A' = A_0' + \beta\eta F. \qquad (2)$$

It can be shown thermodynamically† that at a given potential $\alpha + \beta = 1$.

Relationships involving activation energy values are conveniently visualised with the help of a potential energy diagram. Fig. 1 shows a cross-section of the potential energy surface along the reaction coordinate. Curve *2* corresponds to a higher potential than curve *1*. Since the energy of the activated transition state increases more slowly with potential than does the energy of the initial state, the difference between the two, i.e. the activation energy, decreases.

Consider a discharge reaction (cathodic, say). Since its activation energy is finite at any given potential, and since it decreases with increase of overvoltage, it must ultimately tend to zero at a high enough overvoltage. Under these conditions the reaction rate will be a maximum, and further increase in potential will not affect the current. In other words, for a non-activated process such as this we can write $\alpha = 0$. But for the reverse ionisation reaction we find $\beta = 1$ at these potentials. The potential curves for this case are shown in Fig. 1 as curves *3* and *4* .

Imagine now that the overvoltage is decreased. This raises the activation energy for discharge, but at the same time the activation energy for ionisation is lowered. At a sufficiently low cathodic (i.e. at a sufficiently high anodic) potential the activation energy vanishes. Under these conditions $\beta = 0$ and $\alpha = 1$. The shape of the corresponding potential energy diagram is shown by curves *5* and *6* of Fig. 1.

Unlike non-activated processes, the processes for which $\alpha = 1$ (or $\beta = 1$) require a considerable activation energy. However, and in contrast to normal discharge processes, this activation energy is equal to the heat of the fundamental reaction step, and the activation energy for the reverse processes is zero‡. On a potential diagram this process does not show the familiar hump of the

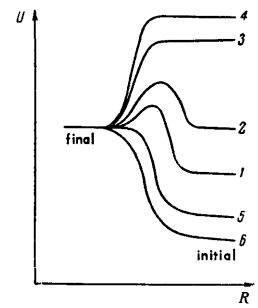

Fig. 1. Potential energy diagram for normal (curves 1 and 2), non-activated (curves 3 and 4), and barrierless discharge (curves 5 and 6).

† We are confining the discussion to one-electron processes.

‡ We must stress once again that we are considering the real activation energy, so that the heat of the fundamental step is a real heat, i.e. a quantity which does not include the latent equilibrium heat of the overall electrode process. We could have based the whole discussion on ideal activation energies, but this would not affect the results.

# BARRIERLESS ELECTRODE PROCESSES

L. I. Krishtalik

The slow discharge theory, developed and substantiated by the work of Frumkin and his school, satisfactorily describes the basic features of a large number of electrochemical processes (see, for example, Ref. 1). The concepts which had been originally used to describe the discharge of hydrogen ions were shown to be widely applicable to all types of reaction, such as the electrochemical desorption of adsorbed hydrogen, the reduction of anions and neutral molecules, etc. In recent years it has been shown that the basic ideas of the slow discharge theory imply the existence (in a few limiting cases) of new types of electrode reactions showing a number of interesting features [2-4]. The present review article aims to discuss these limiting cases.

The most distinguishing feature of electrochemical reactions is the variation of their activation energy with potential: as the electrode departs from its equilibrium potential in the cathodic (or the anodic) direction, the activation energy of the corresponding electrode process decreases. This behaviour is most conveniently described by the relation

$$A = A_0 - \alpha\eta F, \qquad (1)$$

where $A$ is the activation energy at an overvoltage $\eta$ (real activation energy values [5] will be used throughout), and $A_0$ is the activation energy at the equilibrium potential. The transfer coefficient $\alpha$ is found experimentally to be constant over a range of potentials, and its value is often close to 1/2.

If the activation energy of the forward reaction decreases with increase of overvoltage, the activation energy for the reverse reaction must increase

$$A' = A_0' + \beta\eta F. \qquad (2)$$

It can be shown thermodynamically† that at a given potential $\alpha + \beta = 1$.

Relationships involving activation energy values are conveniently visualised with the help of a potential energy diagram. Fig. 1 shows a cross-section of the potential energy surface along the reaction coordinate. Curve *2* corresponds to a higher potential than curve *1*. Since the energy of the activated transition state increases more slowly with potential than does the energy of the initial state, the difference between the two, i.e. the activation energy, decreases.

Consider a discharge reaction (cathodic, say). Since its activation energy is finite at any given potential, and since it decreases with increase of overvoltage, it must ultimately tend to zero at a high enough overvoltage. Under these conditions the reaction rate will be a maximum, and further increase in potential will not affect the current. In other words, for a non-activated process such as this we can write $\alpha = 0$. But for the reverse ionisation reaction we find $\beta = 1$ at these potentials. The potential curves for this case are shown in Fig. 1 as curves *3* and *4* .

Imagine now that the overvoltage is decreased. This raises the activation energy for discharge, but at the same time the activation energy for ionisation is lowered. At a sufficiently low cathodic (i.e. at a sufficiently high anodic) potential the activation energy vanishes. Under these conditions $\beta = 0$ and $\alpha = 1$. The shape of the corresponding potential energy diagram is shown by curves *5* and *6* of Fig. 1.

Unlike non-activated processes, the processes for which $\alpha = 1$ (or $\beta = 1$) require a considerable activation energy. However, and in contrast to normal discharge processes, this activation energy is equal to the heat of the fundamental reaction step, and the activation energy for the reverse processes is zero‡. On a potential diagram this process does not show the familiar hump of the

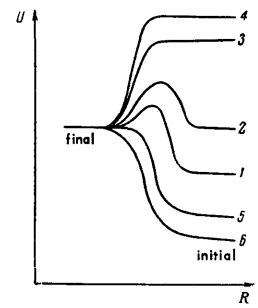

Fig. 1. Potential energy diagram for normal (curves 1 and 2), non-activated (curves 3 and 4), and barrierless discharge (curves 5 and 6).

† We are confining the discussion to one-electron processes.

‡ We must stress once again that we are considering the real activation energy, so that the heat of the fundamental step is a real heat, i.e. a quantity which does not include the latent equilibrium heat of the overall electrode process. We could have based the whole discussion on ideal activation energies, but this would not affect the results.

activational barrier, and therefore we have introduced the term "barrierless" to describe processes of this type[2].

Thus, every electrode process can be expected, in principle, to occur in three forms: barrierless, normal, and non-activated. The polarisation curve, ignoring complications resulting from other stages of the reaction, should have the shape shown in Fig. 2.

Whether or not a current–voltage relation of this form can be observed in practice depends first and foremost on the position of the curve in Fig. 2 with respect to the equilibrium potential. Thus, if the transition from $\alpha = 1$ to $\alpha = 1/2$ occurs below the equilibrium potential (the case denoted by the letter *a* in Fig. 2), barrierless discharge cannot be observed since the reverse (ionisation) reaction predominates below the equilibrium potential. This case appears to be a very common one. However, if the break in the polarisation curve occurs above the equilibrium potential (case *b* of Fig. 2) barrierless discharge becomes accessible to direct observation.

To carry out a barrierless process it is essential that the fundamental reaction step be accompanied by heat absorption, because an activation energy is essentially a positive quantity. In other words, the energy level of the final state must lie above that of the initial state.

It follows that for the slow discharge of hydrogen ions, say, a barrierless process can in principle be observed only with metals which adsorb hydrogen poorly. This is because for these cathodes the energy level of the final state of the slow step — adsorbed hydrogen and a water molecule on the electrode surface — lies well above the energy level corresponding to molecular $H_2$ in the gas phase and water in the bulk. At the equilibrium potential this latter state is practically at the same level as the initial state — $H_3O^+$ ions in the double layer. (As before, we are ignoring the latent equilibrium heat of the process.) These energy relations are illustrated in Fig. 3.

On the other hand, for the slow electrochemical desorption of hydrogen the barrierless process is possible in principle only if the energy of the metal–hydrogen bond is large. In this case the final state is a physically adsorbed $H_2$ molecule, whose energy level is close to that of gaseous hydrogen, and the energy of the initial state (which includes an adsorbed H atom) is lower, the higher the heat of adsorption of hydrogen.

In addition to the above criterion for the realisation of a barrierless process, it is essential that the activation barrier in the normal discharge region should not be too

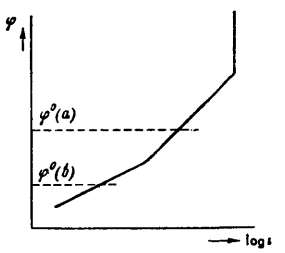

Fig. 2. Idealised polarisation curve (the current corresponding to reaction in one direction only is plotted as abscissa).

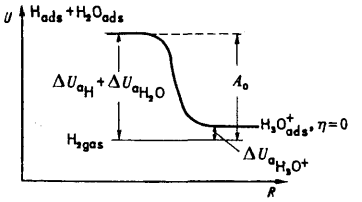

Fig. 3. Potential energy profile for barrierless discharge of $H_3O^+$ ions at the equilibrium potential; $\Delta U_a$ is the adsorption energy of the species indicated, and $A_0$ is the apparent real activation energy at the equilibrium potential; the horizontal line denotes the energy level corresponding to gaseous $H_2$.

high, i.e. that the activation energy of the reverse reaction should vanish before the potential has decreased too much. Earlier tentative calculations[6] of the height of activation barriers justify the belief that the barrierless process should be observable on metals with a high hydrogen overvoltage. A comparison of activation energy data for normal discharge on mercury with plausible values for the heat of adsorption of hydrogen on this cathode leads to the same conclusion.

These were the basic considerations used in formulating an experimental study of the hydrogen overvoltage of mercury under conditions likely to lead to barrierless discharge. However, before proceeding to a discussion of the experimental results, it may not be out of place to consider the characteristic features of the kinetics of this new type of electrode reaction.

The rate of discharge of hydrogen ions at constant potential and constant double-layer structure is proportional to their concentration (or activity, see below). This statement is, of course, applicable to any discharge process, ordinary as well as barrierless. However, if we compare the processes at constant overvoltage rather than at constant potential an entirely different set of relations applies. An increase in the concentration of species undergoing discharge, e.g. $H_3O^+$ ions, lowers the equilibrium potential, and therefore the rate at constant overvoltage increases as $C_{H_3O^+}^{1-\alpha}$ instead of as $C_{H_3O^+}$. For normal discharge $\alpha = 1/2$, and the current density is proportional to $C_{H_3O^+}^{1/2}$. For barrierless discharge, however, $\alpha = 1$, and the rate of reaction at constant overvoltage becomes independent of concentration: the accelerating effect on the reaction of the greater number of species undergoing discharge is exactly compensated by the retardation due to the lowering of the equilibrium potential.

A similar situation exists as regards the effect of the $\psi_1$-potential. A negative shift of the $\psi_1$-potential accelerates the discharge, on the one hand, due to the increased surface concentration of $H_3O^+$ ions, but, on the other hand, it retards the discharge by decreasing the potential jump across the dense part of the double layer. In normal discharge the former effect predominates, because the $\psi_1$-potential appears with the coefficient $\alpha = 1/2$ in the expression for the retarding effect. In barrierless discharge $\alpha = 1$, and these two effects exactly compensate each other.

Whereas the conclusion that overvoltage is independent of concentration of the discharging species applies equally

to the discharge of ions and to the oxidation–reduction of molecules, exact compensation of the $\psi_1$-effects can occur only in the reduction of a singly charged cation (or in the oxidation of a singly charged anion). In other cases the effects of the $\psi_1$-potential on the surface concentration and on the potential jump may not be mutually compensating.

We should stress that lack of dependence of the overvoltage on $C_{H_3O^+}$ and on the structure of the double layer is not at all inconsistent with the assumption of a slow discharge step. Thus, if we examine the rate of hydrogen evolution at constant potential we find that it is proportional to the concentration of $H_3O^+$ ions. But if it were possible to compare overvoltages in different solutions at constant surface concentration of hydrogen ions, the effect of the $\psi_1$-potential would be very clearly revealed.

The features of barrierless discharge discussed above can be described by the following equation, which we had previously derived[2] on the basis of the theory of absolute reaction rates:

$$i = \varepsilon \frac{kT}{h} \frac{\varkappa}{\gamma^{\neq}} 10^{18} a_{H_2O} P_{H_2}^{1/2} (1-\theta) \exp\left\{-\frac{1}{RT}\left[\Delta H_{a_H} + \right.\right.$$
$$\left.\left. + \Delta H_{a_{H_2O}} + T\left(\frac{1}{2} S^0_{H_2} - \Delta S^0_{a_{H_2O}}\right) - \eta F\right]\right\} \quad (3)$$

Here $\epsilon$ is the electronic charge, $\varkappa$ is the transmission coefficient, $\gamma^{\neq}$ is the activity coefficient of the activated complex, $a_{H_2O}$ is the activity of water, $\theta$ is the coverage of the surface by adsorbed hydrogen (for mercury $\theta \ll 1$), the subscript $a$ after $\Delta H$ and $\Delta S$ indicates that these quantities refer to the adsorption process, and the superscript 0 denotes standard values. The remaining symbols have their usual meaning.

We shall now introduce some refinements into this equation.

It follows from the above discussion and from Eqn. (3) that the overvoltage under conditions of barrierless discharge is practically independent of the composition of the solution: this, as well as $\alpha = 1$ (i.e. $b = 59$ mV), is the most characteristic criterion of slow barrierless discharge. For normal discharge, we know that the overvoltage can be very sensitive to the composition of the solution.

The lower the polarisation curve for normal discharge, the higher is the current density and the overvoltage at which it intersects the branch corresponding to barrierless discharge, i.e. the more easily can the phenomenon be demonstrated experimentally. We have therefore examined the hydrogen overvoltage of mercury in concentrated solutions of salts having a strongly adsorbable anion (iodide and bromide), because the overvoltage for normal discharge is lowest in solutions of this type.

The experimental procedure has already been described in detail[3]. Since it was essential that the results at low current densities be reliable and not distorted by effects such as depolarisation by oxygen, special care had to be taken in the purification of materials and solutions. To improve the efficiency of the electrolytic purification of the solution, we used a relatively thin layer of liquid which was vigorously stirred. This procedure enabled us to obtain satisfactorily reproducible polarisation curves free from depolarisation drift down to current densities of $10^{-7}$, $10^{-7.5}$, and $10^{-8}$ A cm$^{-2}$ for iodide, bromide, and chloride solutions respectively.

Some typical polarisation curves are shown in Fig. 4. Their shape is entirely in keeping with the suggested

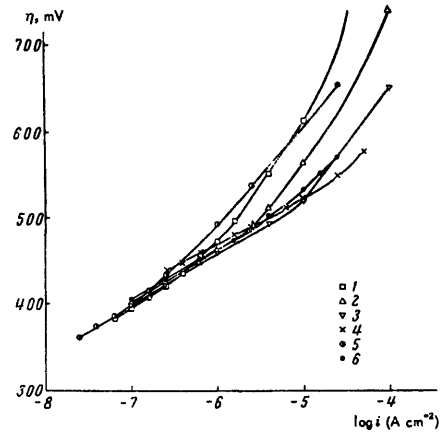

Fig. 4. Polarisation curves for solutions of the following composition (M):
1) 3.2 KI, 0.15 HCl; 2) 3.2 KI, 0.45 HCl; 3) 6 KI, 0.55 HCl; 4) 3 KI, 0.9 HCl, $1.3 \times 10^{-3}$ $N(Bu)_4Br$; 5) 6.6 NaBr, 0.85 HCl; 6) 11.8 LiBr, 0.1 HCl.

theory of the transition from barrierless to normal discharge§. The sharp inflection of the curves and the transition to a lower value of $b$ have been shown[3] to be not due to any conceivable experimental error, and can be taken as a firmly established fact.

The situation described above has been observed in 23 solutions of KI of different composition, covering a range of KI concentration from 0.8 to 6.0 M and a range of HCl concentration from 0.1 to 1.2 M, three of which contained tetrabutylammonium salts in concentration $10^{-4}$–$1.3 \times 10^{-3}$ M. Three solutions contained 6.5–11.8 M LiBr and 0.1–0.9 M HCl; two solutions contained 6.6 and 7 M NaBr and 0.85 M HCl. In every case the $b$ coefficient for the lower branch of the curve was close to 60 mV: the lowest value observed was 52 mV, the highest 63 mV, and in 21 out of 28 experiments $b$ varied between 55 and 60 mV. The average value for all the experiments was $b = 58.5$ mV, which effectively coincides with the theoretical value of 59.1 mV.

In the upper part of the curves (the region of normal discharge) we observe a strong dependence of the overvoltage upon solution composition, including acid concentration, concentration of the adsorbable anion, and concentration of added tetrabutylammonium salt¶. For the range of solution compositions examined in our work, the difference in overvoltage over this region can be 200 mV or higher. On the other hand, in the region where $b = 60$ mV all the curves lie within a band of about 20 mV, and 18 out of the 28 curves lie within 10 mV. There is no apparent relationship between the overvoltage and the composition of the solution. The scatter of the curves obtained with different solutions is of the same order of magnitude as the scatter of the curves obtained in different experiments for a solution of a given composition. We can conclude,

§ The high slope of the top part of some of the curves in iodide solutions is due to the well-known, large shift of the $\psi_1$-potential in these solutions on approaching the point of zero charge.

¶ This has been shown[7] to intensify the adsorption of $I^-$ very considerably when the surface is positively charged.

therefore, that in the region where $b \simeq 60$ mV the overvoltage is effectively independent of the composition of the solution.

The value $b$ = 58.5 mV and the lack of dependence of the overvoltage on solution composition are in complete agreement with the predictions of the theory, and enable us to state that slow barrierless discharge of $H_3O^+$ ions takes place on mercury at low current densities.

Various authors have observed slopes of the order of 60 mV in their semilogarithmic plots for different cathodes. However, their interpretations (which are not strictly substantiated even for their particular systems) are clearly not applicable to the mercury cathode.

Thus, Thomas[8] ascribes this slope to a logarithmic hydrogen adsorption isotherm, which is clearly not the case for mercury. Equally improbable (for the case of mercury) is the assumption of slow surface diffusion of the adsorbed hydrogen or slow detachment of the hydrogen from stable adsorption sites[9]. A different explanation, put forward by Bockris and coworkers[9], associates the appearance of a low value of $b$ with a change in $\psi_1$-potential near the point of zero charge. This argument is unconvincing on general grounds[10], and in our particular system it is refuted also by the fact that the inflection in the curve occurs well away from the point of zero charge (up to 0.4 V in concentrated HCl, see Ref. 4), and in a region where the shape of the polarisation curve for normal discharge has already become stabilised (see Fig. 4).

We had previously shown[11] that a slope of 59 mV should be observed if the slow step is non-activated electrochemical desorption, and discharge and ionisation are effectively at equilibrium. However, this explanation does not apply to the present problem, since it predicts a strong dependence of the overvoltage on solution composition.

Thus, of all the mechanisms discussed in the literature which predict $b$ = 59 mV, the barrierless discharge mechanism alone accounts for the whole of the experimental data.

The value $\alpha$ = 1 implies that over the same region of potential $\beta$ = 0, i.e. the ionisation proceeds as a non-activated process. Therefore, although no direct demonstration has yet been given of non-activated electrochemical processes, the present results can be taken as an indirect proof of the existence of such processes. It follows that the general kinetic features of any arbitrary electrode reaction can be expressed, in all probability, by a curve of the type given in Fig. 2. Whether or not any particular portion of the curve is experimentally accessible, however, depends on the quantitative aspects of each individual case.

An important feature of the barrierless discharge of hydrogen ions, the fact that its rate is independent of the concentration of $H_3O^+$ and of the $\psi_1$-potential, enables us to use this phenomenon to solve certain general problems not otherwise readily handled.

There has been some discussion[12] of the screening effect of tetraalkylammonium cations on the discharge of other ions. In normal discharge, the strong influence of these cations on the $\psi_1$-potential (and therefore on the overvoltage) can mask their screening effect if, of course, this effect is not very large. In barrierless discharge $\psi_1$-effects are absent, but any screening effects should make themselves felt as in normal discharge. According to our results, addition of tetrabutylammonium salts has practically no effect on the overvoltage. There is, in fact, a very small increase in potential, particularly at the lowest current densities, but it is of the order of 10–15 mV and therefore borders on experimental error. This question needs further study, but it is clear in any case that the screening effect in the discharge of hydrogen ions is relatively small.

A more interesting problem is that of the kinetic activity factor. Frumkin and Iofa[13] found that the overvoltage attending hydrogen evolution from concentrated acid solutions of chlorides at constant concentration of acid and $Cl^-$ ions (i.e., according to those workers[13], under conditions of practically constant $\psi_1$-potential) remains unchanged when the $Li^+$ cations are replaced by $K^+$, in spite of the large difference in the activity coefficient of $H_3O^+$ ($\gamma_{H_3O^+}$) in these solutions. They concluded that, as $\gamma_{H_3O^+}$ changes, the activity coefficient of the activated complex ($\gamma^{\neq}$) also changes so as to produce compensation. The ratio $\gamma^{\beta}_{H_3O^+}/\gamma^{\neq}$, which appears in the equation for normal slow discharge, was thus found to be equal to unity.

However, strictly speaking, the kinetic activity factor is not confined to the ratio $\gamma^{\beta}_{H_3O^+}/\gamma^{\neq}$. The equation for discharge, both normal and barrierless, includes also the activity of water raised to the power $\alpha$†, so that the full expression for the kinetic activity factor should be $\gamma^{\beta}_{H_3O^+}\gamma^{\alpha}_{H_2O}/\gamma^{\neq}$. Usually $\gamma_{H_2O}$ is close to unity, and this correction has no significant effect on the precision of the kinetic activity factor. It is very important in principle, however, because the results of Frumkin and Iofa have been generalised by Temkin[14] to include temperature variation (see below).

A rigid experimental evaluation of the effects associated with the activity of water is practically out of the question for normal discharge. Thus, appreciable departures of $\gamma_{H_2O}$ from unity occur only in very concentrated solutions, in which the error in estimating the $\psi_1$-effect due to specific adsorption is obviously much greater than any likely potential shift arising from water activity effects. In barrierless discharge, on the other hand, where no $\psi_1$-effect occurs, the conditions for demonstrating the effect of the activity of water are quite favourable.

To this end, we have studied the overvoltage in very concentrated, acidified solutions of LiBr in which the activity of water was very low (0.1 or less) although the mole fraction was higher than 0.6. If the overvoltage had been directly determined by the activity of water, we should have expected the overvoltage under these conditions to be 50–60 mV higher than in the 3–4 $N$ solutions of KI. In fact, as Fig. 4 shows, the two sets of curves are indistinguishable within experimental error. If, on the other hand, we expect to find only an effect determined by the mole fraction of water, the resulting increase in overvoltage is only 6–8 mV, i.e. a quantity of the order of the experimental error and therefore difficult to observe. Thus, we may conclude that the activity coefficient of water has no effect on hydrogen overvoltage under conditions of barrierless discharge. Hence, following Frumkin and Iofa, we state that $\gamma_{H_2O}/\gamma^{\neq} = 1$. Extending this result, and that of Frumkin and Iofa, to any arbitrary hydrogen ion discharge process, we can write the following approximate equation:

$$\gamma^{\neq} = \gamma^{\beta}_{H_3O^+}\gamma^{\alpha}_{H_2O} \quad \text{or} \quad RT \ln \gamma^{\neq} = \beta RT \ln \gamma_{H_3O^+} + \alpha RT \ln \gamma_{H_2O}. \qquad (4)$$

† This factor allows for the effect of the activity of water on the equilibrium potential.

For barrierless discharge it is easy to verify that $\gamma^{\neq} \simeq \gamma_{H_2O}$. Thus, the distinguishing feature of barrierless discharge is that the activated and the final states are identical: the highest point of the potential energy profile occurs just at the final state. The final state for the discharge of oxonium ions consists of an adsorbed hydrogen atom and a water molecule in the double layer. The activity coefficient of the adsorbed hydrogen is unity (small $\theta$), and therefore the activity coefficient of adsorbed water ($\gamma_{H_2O ads} \simeq \gamma_{H_2O}$) must be adopted as the activity coefficient of the transition state. Thus, the identity of the final and activated state have led us to the same conclusion as the experimental data on overvoltage in very concentration solutions.

Temkin[14], using the analogy between the transfer of a species from a concentrated to a dilute solution and the transfer of a species from one solution to another, and treating water at two not very different temperatures as two distinct solvents, found the entropy of the activated complex. According to Frumkin and Iofa[13], $RT\ln\gamma^{\neq} \simeq \beta RT\ln\gamma_{H_3O^+}$, i.e. $\Delta G^{\neq} \simeq \beta\Delta G^0_{H_3O^+}$, where $\Delta G$ is the change in standard Gibbs free energy attending the transfer of the species from the ideal to the real solution. Assuming that this relationship applies also to transfer from one temperature to another, dividing by $\Delta T$, and letting $\Delta T \to 0$, we obtain

$$S^{\neq} \simeq \beta S^0_{H_3O^+}. \quad (5)$$

An analogous argument for barrierless discharge, based on the equality $\gamma^{\neq} \simeq \gamma_{H_2O}$, leads to

$$S^{\neq} \simeq S^0_{H_2O}. \quad (6)$$

An expression of the type of (6) can also be obtained by an alternative approach, without resorting to the above approximation for the activity coefficients or to the analogy between change of temperature and change of solvent. As we have already pointed out, the activated complex for barrierless discharge coincides with the final state, i.e. with an adsorbed H atom and $H_2O$ molecule. Hence

$$S^{\neq} = S^0_{H_{ads}} + S^0_{H_2O_{ads}}. \quad (7)$$

$S^0_{H_{ads}}$ includes only the vibrational contribution. Since the vibrational frequencies of practically all chemical H bonds are fairly high‡, the corresponding partition function is close to unity and $S^0_{H_{ads}}$ is almost zero. Therefore

$$S^{\neq} = S^0_{H_2O_{ads}}. \quad (7a)$$

Since $\Delta S^0_{\alpha_{H_2O}}$ is not large§,

$$S^{\neq} \simeq S^0_{H_2O}. \quad (6)$$

‡ We shall show below that the energy of the adsorption bond is of the order of 30 kcal, which corresponds to a vibrational frequency of $\sim 1100\ cm^{-1}$, i.e. $S^0_{H_{ads}} \simeq 0.06$ e.u.

§ $\Delta G^0_{\alpha_{H_2O}}$ can be calculated as $10^{-15}N(\sigma_{Hg/H_2O} - \sigma_{Hg})$, where $N$ is Avogadro's number, $10^{-15}$ is the area in $cm^2$ occupied by a water molecule in the surface layer, $\sigma_{Hg/H_2O}$ is the mercury–water interfacial tension, and $\sigma_{Hg}$ is the surface tension of mercury. On differentiating this expression with respect to temperature, we find $\Delta S^0_{\alpha_{H_2O}}$. Using data on the temperature dependence of the surface tension of mercury[15] and of the interfacial tension at the electrocapillary maximum[16], we obtained $\Delta S^0_{\alpha_{H_2O}} = -1.15$ e.u. One could justifiably question how accurately this value, which applies to the adsorption of water at the potential of the point of zero charge, describes the state of the water molecule formed on discharge of an $H_3O^+$ ion. However, the order of magnitude is undoubtedly correct, and $\Delta S^0_{\alpha_{H_2O}}$ is much smaller than $S^0_{H_2O} = 16.72$ e.u.[17]

We have pointed out that the relationships between the activity coefficients found experimentally for normal and for barrierless discharge can be generalised in the form of Eqn. (4). Applying the same treatment to this generalised form, we find

$$S^{\neq} \simeq \beta S^0_{H_3O^+} + \alpha S^0_{H_2O}. \quad (8)$$

Eqn. (8) differs from Temkin's Eqn. (5) by a term containing the entropy of water. As was stated above, the starting expression for $\gamma^{\neq}$ used by Temkin makes no allowance for the activity coefficient of water, which is practically equal to unity in most cases. Allowing for this factor introduces an additional term into the expression for the entropy of the activated complex. In fact, Eqn. (8) states that the entropy of the activated complex has a value intermediate between the entropies of the initial ($H_3O^+ + e_{met}$) and of the final ($H_2O + H_{ads}$) states. (It is assumed that $Se_{met} \simeq 0$ and $S_{H_{ads}} \simeq 0$.) This conclusion appears reasonable, since the activated complex corresponds to a configuration intermediate between the initial and the final state. It is well known that the entropy of an activated complex is not in general equal to the mean of the entropies of the initial and the final states. However, in the present case [as pointed out by Temkin[14] in connection with Eqn. (5)] the entropy terms associated with the vibrational partition functions for the activated complex and for species in the initial and in the final state are quite small, and the entropy of the activated complex is almost entirely determined by its interaction with the solvent, as expressed by Eqn. (8).

If the entropy of the activated complex is taken to be the mean of the corresponding values for the initial and the final state, it is more correct to write Eqn. (8) in the form

$$S^{\neq} = \beta S^0_{H_2O^+_{ads}} + \alpha S^0_{H_2O_{ads}}. \quad (8a)$$

For $\alpha = 1$ and $\beta = 0$, this expression reverts to (7a), i.e. the expression obtained directly for the entropy of the activated complex under conditions of barrierless discharge.

For non-activated discharge, the transition state coincides with the initial state, whence it follows that

$$S^{\neq} = S^0_{H_2O^+_{ads}}. \quad (9)$$

But Eqn. (9) can also be obtained directly from (8a) by putting $\alpha = 0$ and $\beta = 1$.

The fact that Eqn. (8a) gives the right results, verified by an independent method, in the limiting cases, leads us to believe that the generalisation of experimental results used in its derivation is also reasonable, and that Eqn. (8a) can also be used in the case of $\alpha = \beta = 1/2$, i.e. for normal discharge.

In the derivation of the kinetic Eqn. (3) given above we took account of the identity of the activated and the final state[2], in particular as regards the value of the entropy of the activated complex [according to (7a)], but we had not brought out the significance of the kinetic activity factor. After introduction of the necessary refinements, the equation takes the following form (the ratio $\gamma_{H_2O}/\gamma_{H_2O\,ads}$ is assumed to be unity):

$$i = e\frac{kT}{h} \varkappa 10^{15} x_{H_2O} p_{H_2}^{1/2} (1-\theta) \exp\left\{-\frac{1}{RT}\left[\Delta H_{a_{H_2O}} + \Delta H_{a_H} + T\left(\frac{1}{2}S^0_{H_2} - \Delta S^0_{aH_2O}\right) - \eta F\right]\right\}. \quad (10)$$

The real activation energy $A$ is determined from the slope of the plot of $\ln i$ against $1/T$ at constant overvoltage [5]¶.

The corresponding expression for $A$ is obtained by differentiating Eqn. (10):

$$A = -R\left(\frac{\partial \ln i}{\partial 1/T}\right)_{\eta} = \Delta H_{a_{H_2O}} + \Delta H_{a_H} - \eta F + RT. \qquad (11)$$

From (10) and (11) we find the real pre-exponential factor $K$:

$$K = \varepsilon \frac{kT}{h} e\varkappa\, 10^{15} x_{H_2O} p_{H_2}^{1/2} (1-\theta) \exp\left(-\frac{{}^1/_2 S^0_{H_2} - \Delta S^0_{a_{H_2O}}}{R}\right). \qquad (12)$$

Fig. 5, in which a number of typical plots of $\log i$ against $1/T$ are shown for different solutions, satisfactorily confirms that the linear relationship is obeyed. Values of $K$ and $A$ were obtained from the experimental linear plots. These values were recalculated by means of Eqn. (1) for the equilibrium potential, i.e. for $\eta = 0$. In all, we obtained 16 independent sets of data: one for a solution of LiBr, two for NaBr, and the rest for KI (two of them with addition of tetrabutylammonium salts). The mean of all the experimental values is $\log K = 3.0\ (\pm 0.4)$ and $A_0 = 22.9\ (\pm 0.5)$ kcal × × mole$^{-1}$. (The figures in brackets denote the mean deviations from the average.)

Eqn. (12) allows us to calculate the pre-exponential term if we make the usual assumption of a transmission coefficient $\varkappa = 1$ (adiabatic process). All the necessary constants are known, and $\Delta S_{H_2O}$ has been evaluated above. (Even if the error in this estimate is of the same order of magnitude as the value itself, the error introduced into the calculation of $K$ is smaller than the experimental error.) The result of this calculation is $\log K = 5.7$. Thus we must record a discrepancy between theory and experiment in excess of the experimental error.

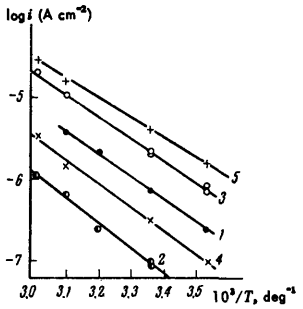

Fig. 5. Temperature variation of the current at constant overvoltage for solutions of different composition (M): 1) 11.8 LiBr, 0.1 HCl, $\eta$ = 460 mV; 2) 7 NaBr, 0.85 HCl, $\eta$ = 400 mV; 3) 4.2 KI, 0.45 HCl, $\eta$ = 470 mV; 4) 3 KI, 0.9 HCl, $1.3 \times 10^{-3}$ N$(Bu)_4$Br, $\eta$ = 500 mV; 5) same solution, $\eta$ = 440 mV.

For normal discharge, Temkin [14] found $\log K = 2.6-3.3$ (for two different solutions) from the data of Iofa and Mikulin [18]; using the data of Post and Hiskey [19], he obtained $\log K = 4$. Thus, the pre-exponential factor for normal discharge is not very different from the value obtained by us for barrierless discharge (the difference being of the order of magnitude of the experimental error).

Temkin's calculation [14] gave $\log K = 5$, the agreement between this and the experimental value being thought fully satisfactory. The small discrepancy was ascribed, with some reservations, to the effect of tunnelling by the proton. If, however, we use Eqns. (8) or (8a) to calculate the pre-exponential factor instead of the expression used by Temkin [Eqn. (5)], a procedure which we now believe to be more justifiable, the pre-exponential term becomes much larger, and $\log K$ takes the value 6.7–6.8. The value of $K$ obtained by this calculation is an order of magnitude larger than the theoretical value for barrierless discharge.

Thus, the discrepancy between theory and experiment is very significant both for normal and for barrierless discharge. It cannot be ascribed to the tunnel effect, since under conditions of barrierless discharge there is no potential barrier through which a proton could penetrate. The tunnel effect may possibly occur to some extent in normal discharge — the disagreement between theory and experiment is perhaps somewhat more serious in this case — but it is quite impossible to draw any definite conclusions from the data which have been discussed.

It should be noted that at least in barrierless discharge the discrepancy between theory and experiment is not associated with any assumptions made in the evaluation of the properties of the activated complex: in this case exact calculation was possible without any need for additional hypotheses. The cause of the discrepancy must be sought, therefore, in the approximations which underlie the theory of absolute reaction rates.

We have reported above our value ($A_0 = 22.9$ kcal × × mole$^{-1}$) for the activation energy for barrierless discharge at the equilibrium potential. As shown by Eqn. (11), and by the potential diagram of Fig. 3, this value enables us to calculate the adsorption energy of hydrogen, a quantity which has not so far been experimentally accessible because of the very low adsorbability of hydrogen on mercury.

Eqn. (11) includes the quantity $\Delta H_{a_{H_2O}}$. This can be found from the data on $\sigma_{Hg/H_2O}$ and $\sigma_{Hg}$ and their temperature variation, used above to evaluate $\Delta S^0_{a_{H_2O}}$. The result is $\Delta H_{a_{H_2O}} = -1.0$ kcal mole$^{-1}$, and the error in this value has little effect on any subsequent conclusions.

Using the experimental value of $A_0$ and the above estimate of $\Delta H_{a_{H_2O}}$, we find $\Delta H_{a_H} = 23.3$ kcal mole$^{-1}$. The error is hardly more than 1.5 kcal (assuming that the error in $\Delta H_{a_{H_2O}}$ is of the order of magnitude of the value itself). From a knowledge of the heat of adsorption of hydrogen and of its heat of dissociation [17], we can calculate the energy of the Hg–H adsorption bond. This turns out to be 29 kcal, a value close to a previous estimate based on a number of analogies and tentative calculations [2, 6, 20].

A case of great interest is that in which neutral molecules rather than $H_3O^+$ ions undergo barrierless discharge. We noted the phenomenon [4] in the evolution of hydrogen on

¶ Since the comparison of $i$ at different temperatures is made at constant concentration of $H_3O^+$ in the bulk (but not at the surface), the activation energy determined in this way is termed apparent, and does not include a term for the adsorption energy of $H_3O^+$ (see Fig. 3).

mercury from concentrated solutions of HCl and strongly acidified, concentrated solutions of KI.[4] Under these conditions the discharge of neutral molecules of the acid is predominant. The composition of the solution now has a significant effect: as was said at the beginning of this article, the effects of the $\psi_1$-potential on the potential drop across the fixed part of the double layer and on the surface concentration of reducible species are mutually compensating only in the case of singly charged cations. With neutral molecules the second factor is not operative. It is evident from Fig. 6 that the addition of tetrabutylammonium ions, which assist the action of $I^-$, raises the overvoltage quite significantly in the barrierless discharge region, as should be the case for the discharge of neutral molecules. In weakly acid solutions, however, where $H_3O^+$ ions are discharged, tetrabutylammonium ions have practically no effect on the overvoltage (Fig. 4). This example shows clearly that a change in the structure of the double layer affects the barrierless discharge process as much as any other discharge process, and that it is only because of the compensation of two opposing effects that the phenomenon is not directly observable in the barrierless discharge of hydrogen ions.

In addition to the evolution of hydrogen on mercury, considered here, there are other electrode reactions for which a barrierless process is likely.

Various authors[9,21-27] have observed a Tafel $b$ constant close to 60 mV, changing to a slope of over 100 mV at higher current densities, in the evolution of hydrogen from acid solutions at a silver cathode. The effect of solution composition on overvoltage was not studied in sufficient detail by those workers. Bockris and Conway[23] found that the overvoltage in pure 0.01 $N$ HCl and in a KCl (or $BaCl_2$) electrolyte is quite different over the region where $b \simeq 120$ mV, but is practically indistinguishable in the region of $b \simeq 60$ mV, as required by the barrierless discharge mechanism. Admittedly, the slope of $\sim 60$ mV was not detected in another series of experiments reported in the same paper. Disagreement at the top end of the curves, and exact agreement at the bottom end, has been reported also[9] for 0.1 $N$ and 0.4 $N$ HCl.

This reaction is being investigated by V. I. Bystrov in our laboratory. From preliminary results, it appears that change of pH has a powerful effect on hydrogen overvoltage in the region where $b \simeq 120$ mV, but at lower potentials ($b \simeq 60$ mV) the effect is very much weaker. On the whole, the situation seems to indicate slow barrierless discharge changing to normal discharge at higher potentials.

Even less is known about hydrogen evolution at cathodes of Au,[28] W,[9] and Mo,[28] and under certain conditions Pt [9] and Rh,[29] for which a slope of $b \simeq 60$ mV has also been reported. It is not possible to reach a firm conclusion, but only to point out that, with strongly hydrogen-adsorbing metals such as W and Mo, barrierless electrochemical desorption is most likely[2]. For the platinum metals we cannot exclude the possibility of an adsorption-electrochemical mechanism, in which the reaction rate is determined by the rate of electrochemical desorption of hydrogen atoms adsorbed on the cathode from the gas phase[11,30]. This electrochemical desorption could be barrierless[2].

Hydrogen evolution does not appear to be the only type of reaction in which the barrierless process is realised. Thus, the present writer and Rotenberg[31] have observed a perfectly sharp break in the polarisation curves for the anodic evolution of chlorine on graphite (see Fig. 7), the slope at the lower end of the curve corresponding to 60 mV. (The experimental slope is higher by a factor of two because of the peculiar current distribution in the porous electrode; the relation between the apparent and the true slope in porous electrodes is discussed, for example, in Ref. 32.) It is important to note that, in keeping with the theory, the addition of $SO_4^{2-}$ anions and $Fe^{3+}$ cations (both of which are adsorbed on graphite) has practically no effect on the lower part of the polarisation curves, whereas their effect in the region of $b \simeq 110$ mV, where we suppose that normal discharge is proceeding, is quite appreciable. Polarisation curves of similar shape have also been observed under somewhat different conditions[33,34].

The phenomena occurring during anodic evolution of oxygen are more obscure. Several authors[35-38] have

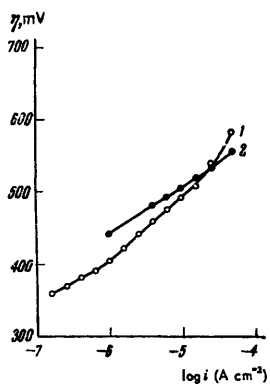

Fig. 6. Effect of tetrabutylammonium ions on the overvoltage in strongly acid KI solutions:
1) 2.2 M KI, 4 M HCl; 2) same solution, + $1 \times 10^{-3}$ M $N(Bu)_4Br$.

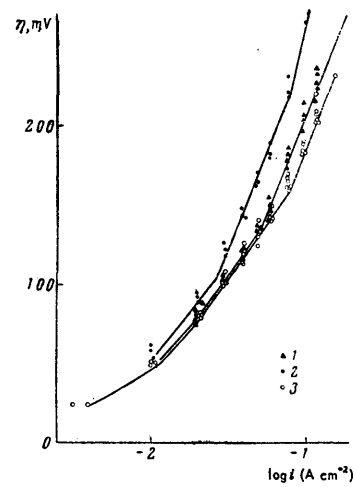

Fig. 7. Polarisation curves for the evolution of chlorine on graphite:
1) 4.4 M $Cl^-$, 1.5 M $H^+$; 2) solution 1 with addition of 0.2 M $Na_2SO_4$; 3) solution 1 with addition of 0.1 M $FeCl_3$.

reported slopes of the order of 60–70 mV on Au, Cu, and Co anodes, but an unambiguous discussion of these results is not possible as yet. Bardina[39] has obtained some interesting results in our laboratory on the anodic oxidation of high-temperature pyrolytic carbon below the equilibrium oxygen potential. We believe that these results can be most satisfactorily explained in terms of barrierless electrochemical desorption of $CO_2$ accompanying the discharge of $OH^-$ ions.

A slope of ~ 60 mV has been frequently observed in the anodic evolution of nitrogen from azide solutions on anodes of different materials[40-42]. The variation of potential with azide concentration[40,41] corresponds exactly with the requirements of barrierless discharge (or electrochemical desorption). However, another explanation is possible, based on the shape of the adsorption isotherm of nitrogen[42]. A choice between these possibilities must await further experimental work.

In conclusion, we can state that the existence of barrierless discharge in the evolution of hydrogen on mercury is a firmly established fact. A barrierless process offers the most plausible explanation of the features of hydrogen evolution on silver and chlorine evolution on graphite: we may hope that current investigations will finally resolve this problem. Furthermore, there are numerous data which justify the belief that many other electrode reactions can occur by the barrierless mechanism.

# THEORY OF THE MACROSCOPIC KINETICS OF HETEROGENEOUS AND HOMOGENEOUS-HETEROGENEOUS SYSTEMS

V. G. Levich

CONTENTS

1. Present state of development of macrokinetics 793

2. Macrokinetics at an immobile phase boundary, laminar flow 794

3. Macrokinetics at a mobile phase boundary (liquid–liquid or liquid–gas) 798

4. Turbulent flow 799

5. Homogeneous–heterogeneous systems 800

6. Statistical systems 800

## 1. PRESENT STATE OF DEVELOPMENT OF MACROKINETICS

The term macroscopic kinetics usually denotes the kinetics of chemical changes in real systems in which the reaction rate is affected by mass-transfer and heat-transfer processes. Transfer processes take the form of molecular diffusion and thermal conduction, on the one hand, and of convective transfer phenomena, on the other hand. In the latter, substance (mass or energy) is transferred by the macroscopic motion of the medium.

Mass-transfer processes are especially important in heterogeneous chemical changes. It is often found that in heterogeneous changes the overall rate of the reaction is determined by the rate of access of the reactants to the reaction surface or by the rate of removal of the reaction products from the surface. In this case we say that the kinetics of the heterogeneous reaction are diffusion-controlled. Diffusional kinetics are most often rate-determining in fast heterogeneous reactions.

In processes attended by large absorption or evolution of heat the overall kinetics are determined by heat transfer. To simplify the terminology, we shall combine mass--transfer and heat-transfer processes under the term "transport phenomena", and we shall use the term macrokinetics to describe the kinetics of a reaction involving complicating transport phenomena.

To the chemist the supply or removal of reagents or heat to or from reaction surfaces, vessel walls, etc., is of little interest, and is merely an obstacle to an understanding of the true reaction mechanism. To the technologist these processes are the main barrier preventing the achievement of the optimum reaction conditions. This is why the mechanism of mass- and heat-transfer processes has long been ignored by chemists and technologists alike, who have confined their attention to ways of eliminating diffusional and thermal limitations. It soon became apparent that adequate convection of the liquid or gaseous medium was essential for this purpose. Hence, the problems of macrokinetics became tightly bound up with problems of hydrodynamics.

We can identify three stages in the development of the macroscopic kinetics of chemical reactions. The first goes back to the turn of the century, when the basic qualitative ideas underlying the transport of reacting species and of heat in reaction vessels and in mass-exchange apparatus were formulated. Nernst's hypothesis of the diffusion layer, Langmuir's film theory, etc., relate to this period.

In the 1930's to 1950's many workers (mostly chemical technologists and heat engineers) were forced to study transport phenomena in greater detail, because of the developments in the design of reactors and mass-exchange apparatus. Transport equations applicable to moving media were formulated. Since these could not be solved exactly, the methods of group similarity theory were applied with success to the description of mass and heat transport processes.

The development of the basic (distinguishing) similarity criteria and the numerical treatment of experimental results constitute the second stage of the development of macroscopic kinetics. This period is characterised by a large number of experimental studies. In some cases, a practical description of the transport phenomena in macrokinetics was achieved by establishing the numerical relationships.

However, it became clear in recent years that this partial description was inadequate and not always satisfactory. Furthermore, in many cases it was quite impossible to base a model on the equality of distinguishing criteria. This is particularly true of models of chemical reactors, in which the various criteria are often mutually incompatible.

With heterogeneous reactions, whose rates can vary over fairly wide limits, it is easily possible to cover the whole range of reaction rates (from the activation-controlled to the transport-controlled region) under constant conditions of stirring.

This case is most commonly met in electrochemistry. It is easy to vary the rate of an electronic reaction over quite wide limits by controlling the potential difference applied to an electrochemical cell.

It is usually found that the current–voltage characteristic has the form of a rising curve with a plateau, indicating that the rate of the process is independent of the applied e.m.f. Since the rate of the electrode reaction is essentially a function of the e.m.f., it follows that in the plateau region the process is controlled by mass transfer: the supply of ions to the electrode surface. This phenomenon has been called concentration polarisation.

A. N. Frumkin laid the foundations of the quantitative theory of concentration polarisation about 20 years ago[1,2]. A few years earlier, the quantitative theory of combustion processes in gases had begun to be developed intensively[3,4]. Lastly, the quantitative study of heat-transfer processes belongs to the same period[5]. The achievement of fast reactions and the enhancement of mass-transfer and heat--transfer processes in chemical engineering urgently need a formulation of the quantitative laws of macrokinetics, applicable to the complicated conditions which exist in chemical reactors and in mass-exchange apparatus. For this reason, disconnected investigations in these fields have begun to merge into a general theory of macrokinetics during the past ten years.

The third stage in the development of macroscopic kinetics is intimately concerned with the quantitative description of transport processes in moving media under conditions approaching those obtaining under realistic working conditions in chemical plant.

The mathematical calculation (or quantitative description) of the macroscopic kinetics under complicated conditions was made possible by two circumstances:

1. The study of the hydrodynamic, physicochemical, and kinetic processes which together characterise chemical change in real systems.

Important theoretical and experimental data have been obtained in recent years on the mechanism of convective mass and heat transfer. These apply to laminar and to turbulent flow, in liquids and in gases, at phase boundaries, under various geometries, and under stationary and non-stationary conditions.

2. The general application to the solution of complicated problems of modern computational methods, relying on the use of high-speed computers.

Studies of macroscopic kinetics can be classified into three basic stages: (a) the study of "fundamental" processes in transport and macrokinetic phenomena; (b) the study of transport processes in statistical systems, including a large number of random fundamental transport steps; (c) the study of transport processes in chemical plant.

Each of these stages has its own special features, but they are all combined into a single complex. We can explain this by a simple example. Mass transfer to the surface of a single bubble, freely rising in a liquid, is a fundamental process according to our terminology. A column of bubbles executing a collective motion is an example of a statistical system with mass transport. In an absorption apparatus it is necessary to consider the motion of a column of bubbles, complicated by a large number of specific factors arising from the design of the column, e.g. non-uniform distribution of the bubbles over the cross-section.

Equations for matter and heat transport can be formulated on the most general assumptions concerning the properties of the medium.

When dealing with bulk or surface (catalytic) reactions involving the absorption or evolution of heat, we are faced with a system of interdependent equations for mass and heat transfer. The coupling between the equations of motion of the medium and the transfer equations arises from changes in viscosity and density of the medium with temperature or from volume changes in gas-phase reactions. The system of equations resulting from all these factors defies both analytical and numerical solution.

Nevertheless, in chemical kinetics and in chemical engineering the velocity, concentration, and temperature distribution in the reaction volume must be known. It is very important, therefore, to establish at least qualitatively the analytical dependence of these distributions on the basic external parameters of the system (prescribed flow rates, initial composition, etc.).

Indeed, the assignment of the velocity, concentration, and temperature distribution is essential both in order to establish the true kinetics of homogeneous and heterogeneous reactions and in order to establish the mode of operation of large-scale reactors and mass exchange apparatus. Therefore, the subdivision of real processes into similar phases or stages, susceptible to analytical or numerical study, is a very important aspect of this stage in the development of macrokinetics.

In the following Sections we shall discuss the realisation of this programme by considering various examples.

## 2. MACROKINETICS AT AN IMMOBILE PHASE BOUNDARY, LAMINAR FLOW

We shall begin the discussion with the fundamental process of transport to the surface of a solid body. The hydrodynamic behaviour of liquids and gases near a solid surface is known in fair detail both for laminar and for turbulent flow.

Consider the case of laminar motion. Analysis of the equations of momentum transfer (hydrodynamic equations), energy transfer (heat-transfer equations),and mass transfer indicates that all these transport processes show some definite similarities.

We know[6-8] that at high Reynolds numbers the total flow can be divided into a main region and a hydrodynamic (or Prandtl) boundary layer. In the main region the velocity of the liquid (or gas) has the constant value $U_0$ over the entire cross-section of the flow. The whole of the velocity change from $U_0$ to zero (at the solid surface) takes place in a thin boundary layer whose thickness is given by the formula

$$\delta_0 \sim \sqrt{\frac{\overline{vx}}{U_0}}, \qquad (1)$$

where $x$ is the distance along the surface of a streamlined body. The shear stress under these conditions is of the order of magnitude

$$\tau \sim \mu \frac{U_0}{\delta_0}. \qquad (2)$$

In formulae (1) and (2) $\mu$ is the normal and $\nu = \mu/\rho$ is the kinematic viscosity.

A quantitative expression for the velocity distribution under steady-state flow can always be calculated for not too complicated geometries of the streamline surface.

In isothermal processes such as those associated with mass exchange the convective diffusion equation can always be solved if the velocity distribution is known.

For a planar or axially symmetrical interface, the convective diffusion equation can be written in the form[7]

$$\left(\frac{\partial c}{\partial x}\right)_{\psi} = D \frac{\partial}{\partial \psi}\left[v_x(x, \psi)\frac{\partial c}{\partial \psi}\right], \qquad (3)$$

where $\psi$ is the hydrodynamic stream function, simply related to the velocity components, and $v_x$ is the velocity component along the surface:

$$v_x = -\frac{\partial \psi}{\partial x}.$$

An entirely similar expression (with the diffusion constant replaced by the thermal diffusivity) applies to the temperature distribution if heat evolution resulting from viscous dissipation in the medium can be ignored. The usual boundary conditions are the given concentration $c_0$ or temperature $T_0$ at a point remote from the surface, the balance between the numbers of particles transported to the surface and of reacting particles, and also the temperature at or the heat flow to the reaction surface. From a mathematical point of view, Eqn. (3) is formally identical with the equation for non-stationary heat conduction in an immobile medium and with a thermal diffusivity depending on time and position:

$$\chi_{eff} = Dv_x. \qquad (4)$$

Eqn. (3) can be solved numerically in all cases for which the function $v_x(x, \psi)$ is known analytically or numerically.

Analytical solution of Eqn. (3) is possible for the case of a liquid phase. This is because of the very large value of the Prandtl number $Pr_D = \nu/D$, where $\nu$ is the kinetic viscosity of the medium. In liquids, where $D$ is small

compared with $\nu$, the Peclet number $Pe = RePr_D = U_0L/D$ (where $U_0$ is a characteristic flow velocity and $L$ is a characteristic length) is large even at a relatively small Reynolds number Re (down to $Re \simeq 10^{-1}$). Therefore, a diffusion boundary layer (within which the main concentration changes occur) is formed near the surface of the streamlined body (Fig. 1). Outside the diffusion layer, in the main region, convective transport ensures that the concentration of material is constant, $c \simeq c_0$. In the diffusion layer the concentration changes from $c_0$ to the value $c_S$ at the reaction surface. The thickness $\delta_{diff}$ of this layer is smaller than that of the characteristic region of velocity change. This allows the stream function in Eqn. (3) to be used directly in the neighbourhood of the surface. Thus, the ratio of the thicknesses of the diffusion and of the hydrodynamic boundary layers can be evaluated in the most general case:

$$\delta_{diff} \sim \delta_0 (Pr_D)^{-1/3}, \quad (5)$$

and there is a geometrical similarity between $\delta_{diff}$ and $\delta_0$, as shown in Fig. 1. The thickness of the diffusion layer decreases with increasing flow velocity. The order of magnitude of $\delta_{diff}$ in liquids is $\sim 10\%$ of $\delta_0$, and for normal velocities it lies between $10^{-2}$ and $10^{-4}$ cm. The whole of the diffusional resistance is confined within this narrow layer. In gases $\delta_{diff}$ is of the same order of magnitude as $\delta_0$.

In laminar flow the thickness of the diffusion layer is inversely proportional to the viscous shear stress $\tau$:

$$\delta_{diff} \sim \frac{|\operatorname{grad} \vec{v}|}{U_0} \sim \frac{\tau}{\mu U_0}. \quad (6)$$

If the surface has a small curvature the thickness of the diffusion boundary layer varies with the distance from the leading edge of the body according to the formula

$$\delta_{diff} \sim \sqrt{\frac{x}{U_0}} D^{1/3} \nu^{1/6}. \quad (7)$$

Thus the thickness $\delta_{diff}$ of the diffusional layer varies from point to point along the surface of the body. If the concentration at the surface is given (e.g. if the diffusing particles are used up by a fast reaction, or in the case of dissolution), the boundary condition at the reaction surface can be written in the form

$$c = c_S \text{ at the surface}, \quad (8)$$

where $c_S$ is the constant concentration at the reaction surface itself (equal to zero in the special case of a fast reaction).

The equation for convective diffusion in liquids with boundary condition (8) at the reaction surface and the condition $c \to c_0$ in the main stream has been integrated for many solid reaction surfaces.

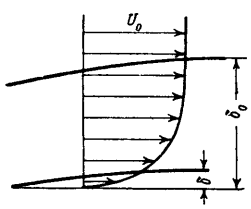

Fig. 1

Systems for which an analytical solution of the convective diffusion equation has been obtained are listed in the Table. Knowing the concentration distribution, we can find the diffusion flux accurately from the formula

$$j = D\left(\frac{\partial c}{\partial n}\right)_S, \quad (9)$$

where $\partial c/\partial n$ is the derivative along the normal to the surface $S$.

It has been shown that the diffusion flux is given, to the nearest order of magnitude, by the formula

$$j \simeq D\frac{\Delta c}{\delta_{diff}} = D\frac{c_0 - c_S}{\delta_{diff}}, \quad (10)$$

where $\Delta c$ is the total (fixed) concentration difference.

The significance of this result is as follows. In liquids the thickness $\delta_{diff}$ of the layer is so small that the concentration change from $c_0$ to $c_S$ can be satisfactorily approximated by a linear law. Formula (7) and the Table show that the diffusion flux varies along the reaction surface, increasing with velocity (for laminar flow) in proportion to $U_0^n$ (where $n \leqslant 1/2$), in proportion to the diffusion coefficient $D^m$ (where $m \leqslant 3/4$), and depending on the nature of the liquid. The dependence of $j$ on the diffusion coefficient $D$ is readily understood: molecular diffusion is a very slow process, and matter transport occurs mainly by convection. Under these conditions the slow stage of the transport process is the passage of matter through the thin layer of liquid adjacent to the solid surface, where its flux is determined by the viscosity.

The solution of the problem of convective diffusion in gases is somewhat more complicated than in liquids. In gases the diffusion coefficient is of the same order of magnitude as the kinematic viscosity, and therefore the thicknesses of the hydrodynamic and diffusion layers are of comparable magnitude. Consequently, we cannot use the approximate expression for the velocity close to the solid surface to solve the convective diffusion equation. The concentration distribution is best calculated numerically. However, the calculations have shown that in practice the concentration distribution can be again satisfactorily approximated by a linear law (over the thickness of the boundary diffusion layer).

The thickness of the diffusion layer in gases is given by the same expression as in the case of liquids, but with a different numerical coefficient (slightly dependent, strictly speaking, on the Prandtl number). The second difference between convective diffusion in gases and in liquids is that in the former the total pressure of the gaseous mixture can vary if the surface reaction is so fast that appreciable quantities of gas are generated (or consumed). The diffusion component of the gas mixture is also affected, since

TABLE.

| Regime | Type of surface | Refs. | Regime | Type of surface | Refs. |
|---|---|---|---|---|---|
| Laminar | rotating disc | 1,7 | Turbulent | semi-infinite plate | 7 |
| » | solid sphere | 7,9 | » | disc | 7 |
| » | semi-infinite plate | 7, 10–13 | » | inner surface of a tube | 7 |
| » | semi-infinite, non-uniform plate | 7,14 | » | rough surface | 7 |
| » | throttle | 6,7,15 | Natural convection | smooth vertical plate | 7 |
| » | inner surface of a tube | 1,7,16 | Turbulent | particle carried by a turbulent stream | 7 |

the total pressure of the gas should remain constant. These features can readily be allowed for in two-component gas mixtures, but they seriously complicate the calculations in multicomponent systems. However, they do not bring any qualitative changes into the general picture.

We shall now consider the case of a chemical reaction proceeding at the surface. Its rate depends on surface concentration, usually according to a power law:

$$Q = f(c_1) = kc_S^n. \tag{11}$$

In these circumstances boundary condition (8) no longer applies.

The boundary condition now imposed on the surface concentration is of the form

$$D\left(\frac{\partial c}{\partial n}\right)_S = f(c_S). \tag{12}$$

The convective diffusion problem is not amenable to analytical solution with boundary condition (12) if $f(c_S)$ is a non-linear function of its argument and the reaction surface has a complicated shape.

A solution of this boundary problem was found[7,14] only for the simplest case of $f = \kappa c_S$ at the surface of a semi-infinite sheet. The effective thickness of the diffusional stream turns out to be a complicated function of the distance $x$, and also of the rate constant of the reaction $k$, of the diffusion coefficient $D$, and of the flow velocity $U_0$. The variation of the effective thickness of the boundary diffusion layer with the rate constant ($k$) of the reaction is a clear indication of the arbitrariness of this concept.

The quantity most commonly measured is the total flux $J = \int j\,dS$, where the integration is carried out over the whole of the reaction surface. It is evident that, having measured $J$, we can find the coefficients $k$ and $n$ in the kinetic law (11) only by solving the corresponding integral equation. The integral equations can be formulated, and their solutions presented in series form, for the surface of a plate and for the interior of a tube[17,18].

If the shape of the reaction surface exposed to the flow is more complicated, great difficulty is encountered not only in solving but even in obtaining the integral equation. Therefore, the kinetic law of the reaction must be determined either by carrying out the reaction under activation control or by making the measurements on "uniformly accessible" surfaces, for which the current density or the thickness of the diffusion layer have a constant value all over the surface.

The first requirement is somewhat indeterminate. The value of the diffusion flux near the edge of the plate or at the mouth of the tube formally tends towards infinity. This means that in these regions the reaction is always activation-controlled. The relative contribution of activation control to the total diffusion flux over the entire surface depends on the size of the plate and on the kinetic law.

Conversely, the diffusion flux at the surface of a body of non-streamlined shape is always finite, and does not exceed the value $j \simeq \frac{D\Delta c}{\sqrt{\nu R/U_0}}$ if we take the leading part of a sphere as an example. (The trailing part is discussed below.) In any kind of stagnant region, such as depressions in the body, the diffusion flux is low, and the reaction can obey the laws of diffusion-controlled kinetics, whereas on the streamlined parts of the body activation control is possible. Hence, in order to find the true kinetic law of the surface reaction, it is advisable to carry out the measurements under conditions to which macrokinetic theory is applicable[19,20]. The work of Frumkin's school[21-23] on solid electrodes as well as on the dropping mercury electrode[24] offers a striking example of the successful use of developments in macrokinetic theory for the determination of the true kinetics of a surface reaction.

As was stated above, it is particularly desirable to carry out the kinetic measurements on a surface such that all points are equally accessible to diffusion.

For laminar flow of a liquid or a gas, only two surfaces of this type are available: (1) the surface of a rotating disc; (2) the inner surface of a pipe or crack, beyond the inlet section where diffusion occurs (whose length $L$ is approximately equal to 50 RePr).

The rotating disc was first used to study the kinetics of electrochemical reactions by Frumkin's school[25], and is now very widely applied in electrochemistry[26,27] and in studies of the kinetics of the dissolution of solids[28,29]. The investigations in which the rotating disc has been used are numbered in hundreds.

The thickness of the diffusion layer (as well as the flux density) is constant over the surface of the disc, and is given by

$$\delta_{\text{diff}} \simeq 1.61 \left(\frac{D}{\nu}\right)^{1/3} \sqrt{\frac{\nu}{\omega}}, \tag{13}$$

where $\omega$ is the angular velocity of rotation.

To determine the kinetic law, we only need to solve the transcendental algebraic equation[8]

$$kc_S^n + \frac{D}{\delta_{\text{diff}}}(c_S - c_0) = 0. \tag{14}$$

The function $j(\omega)$ for reactions with $n = 1$ and $n \ll 1$ is presented graphically in Fig. 2. These curves enable us to assess the degree of selectivity of surface reactions, falling in the region of mixed kinetics on going over from $n = 1$ (curve *1*) to $n \ll 1$ (curve *2*).

However, this unique, uniformly accessible surface has not as yet been used to any appreciable extent in the study of catalytic reactions. We know of only two investigations in which a rotating disc was used for catalytic measurements[30,31]. Yet, nothing short of a complete plot of $j$ against $\omega$ can provide a sufficiently accurate means of evaluating the constants $k$ and $n$ in the kinetic law (11). We believe that measurements of this type would be highly desirable.

Non-stationary processes can play an essential role in the study of the faster heterogeneous reactions. These processes have already found an extremely wide field of application in electrochemistry, where they can be very easily realised in practice by measurements of potential or current as a function of time[32]. In catalytic reactions meaningful measurements can be made on the surface of a disc by using pulsewise input of reactants or a variable surface temperature.

Kinetic studies on uniformly accessible surfaces are especially important when several competing or consecutive reactions take place. The theory of this type of process has also been worked out to a useful degree. In particular, the method of a disc with ring has been successfully applied by Frumkin and coworkers to reactions involving unstable intermediate products[22,23].

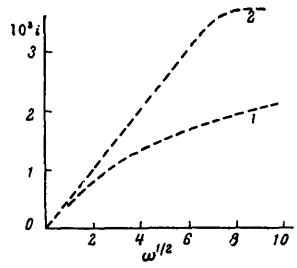

Fig.2.

The inner surface of a pipe cannot be used in liquid--phase processes, because the inlet section is very long in this case. It has been widely used, however, for reactions at the gas–liquid interface (see below).

In this context it is important to point out the relationship between the hydrodynamic theory of the boundary diffusion layer, discussed above, and the so-called "film theory", which has found very wide acceptance[33]. The underlying basis of this theory is the assumption that matter transport due to external convection is completely absent in a layer of thickness $d$, which is uniform over the reaction surface.

In liquids this is equivalent to assuming total absence of convective transport. Thus, the film theory in liquids coincides with Nernst's theory of the immobile diffusion layer.

In gases a somewhat different situation exists. In addition to convective transport, associated with the motion of the outer stream, we have a motion of the gas from (or towards) the reaction surface, due to the evolution (or absorption) of gas in the course of the reaction. The flow of gas arising from the removal or supply of particles from or to the surface is ignored in the film theory.

The main shortcoming of the film theory is the use of the arbitrary quantity $d$, which must be found by comparing the theory with measured mass fluxes. Yet, as the exact formula (7) shows, this thickness is in fact a function of the diffusion coefficient of the material (and therefore must be determined experimentally for each material), and also of the nature (viscosity) of the medium. Also, generally speaking, the thickness of the diffusion layer is variable from point to point along the reaction surface.

The attractions of the film theory are its relative simplicity and its ability to deal with complicated reaction kinetics. But these do not outweigh, in the writer's opinion, the drawbacks of this theory.

So far only mass transport phenomena have been considered. Heat transfer phenomena are no less important to the theory of macrokinetics. This is particularly true of gas reactions, which are frequently characterised by large heat changes.

The equations describing the transfer of energy (heat) in moving media are formally very similar to the corresponding equations for mass transfer. This circumstance, as already pointed out, justifies the use of the term transport phenomena.

Heat transfer phenomena have been studied in great detail in the physics of heat. However, as will be stressed below, heat-transfer problems in chemically reacting media have a number of specific features. In mobile media (liquids and gases) a thermal boundary layer, across which the main temperature drop occurs, is formed at the surface of a solid body maintained at a given temperature. This boundary layer is the analogue of the hydrodynamic and the diffusion layer.

The thermal Prandtl number $Pr_T = \nu/\chi$, where $\chi$ is the thermal diffusivity of the gas ($\chi = \varkappa/\rho c_p$, $\varkappa$ being the thermal conductivity), is of the order of 0.5–10 for gases and for most liquids alike. (The only exceptions appear to be some organic liquids and liquid metals[7].) The thicknesses of the boundary diffusion layer in a gas and of the thermal boundary layer in liquids are of the same order as the thickness of the hydrodynamic boundary layer. Therefore the equation for the temperature distribution must be solved by numerical methods.

Approximate methods of solution, such as Pohlhausen's method, have also found wide acceptance. In this method the distributions of velocity, concentration, or temperature in the boundary layer are described approximately by polynomials in powers of the distance from the surface[34]. There are also many other approximate methods, such as the method of integral moments[33]. The main disadvantage of these methods is that the error thereby introduced cannot be estimated quantitatively.

As regards the variation of concentration and temperature distribution in mobile media with the Prandtl number, the limitations of the analogy between mass transfer and heat (and also momentum) transfer must be borne in mind, particularly in the case of liquids. In gases the viscosity, thermal conductivity, and diffusion coefficients are relatively constant, so that the conditions under which the processes resemble each other are satisfied to a good approximation.

Non-isothermal reactions are very relevant to the study of the macrokinetics of heterogeneous chemical reactions. Non-isothermal processes are complicated by the interdependence of mass and heat transfer. In heterogeneous reactions this dependence is expressed not by the equations themselves, but by the boundary conditions, which take the following form at the reaction surface:

$$D\left(\frac{\partial c}{\partial n}\right)_S = kc_S^n e^{-\frac{E}{RT_S}} \quad \text{at the surface,}$$
$$\chi\left(\frac{\partial T}{\partial n}\right)_S = hkc_S^n e^{-\frac{E}{RT_S}} \quad \text{at the surface,} \qquad (15)$$

where $T_S$ is the surface temperature, $h$ is the heat of the heterogeneous reaction, and $E$ is the activation energy.

The experimental and the theoretical study of such reactions is also most conveniently carried out on a uniformly accessible surface, such as the surface of a rotating disc. In this case the surface temperature $T_S$ is constant along the surface, and simultaneous solution of the diffusion and thermal diffusivity equations involves the solution of a system of two transcendental algebraic equations.

By comparing the measured mass flux and surface temperature with experimental data, it is possible to determine the activation energy and the rate constant for a heterogeneous reaction.

Among other cases of diffusion-controlled kinetics at the boundary between a solid and a gas (or a liquid), diffusion to a porous catalyst particle deserves special mention.

Diffusion and heat transfer to a spherical particle from the external stream can be calculated. Departures from the spherical form merely introduce, in general, a different numerical coefficient.

In the case of isothermal reactions the problem of mass exchange in a pore can be solved for the general case. The main types of non-isothermal reaction, i.e. reactions of the first and of fractional orders, have been investigated in very recent years.

In this context, the so-called gradientless method of establishing the kinetics of catalytic reactions, which is now very widely applied, should be mentioned. In this method the main criterion of the presence of activation control is lack of dependence on the stirring rate. The method calls for three critical remarks.

1. Independence of the velocity of the external stream is a qualitative, but not a quantitative criterion of the transition to activation control.

2. The measured reaction rate is the combined result of the true chemical kinetics and of diffusional and thermal processes within the catalyst grains. The relation between these effects can be very complex, particularly in non-isothermal reactions. This can be demonstrated by calculations of non-isothermal reactions of zero, fractional[35], and first orders within the catalyst grain[36]. The presence of pores on whose surface the catalytic reaction proceeds is taken into account by introducing effective diffusion and thermal diffusivity coefficients for the particle. The effective activation energy $E_{eff}$ is related to $h$, $D$, and $\chi$ and can be very appreciably different from the true activation energy $E$: it can be either smaller or greater than $E$. Therefore, the constants in the kinetic equations obtained by this method have a somewhat indeterminate meaning.

3. The method of measurement requires that the reaction products be removed from the reactor. No allowance is made for the possibility of build up, or for the effect of other non-catalytic reactions during removal of the products.

For these reasons, the writer believes measurements on a uniformly accessible surface to be essential.

## 3. MACROKINETICS AT A MOBILE PHASE BOUNDARY (LIQUID–LIQUID OR LIQUID–GAS)

The interface between mobile phases will now be considered. There are several cases of "fundamental" processes in mobile media: near the surface of drops, of bubbles, jets, and liquid films on solid surfaces. It must be stressed that the hydrodynamics of systems with mobile interfaces have been examined very much less fully than the hydrodynamics of flow in the neighbourhood of a solid surface.

With a mobile interface mass transport occurs by two independent transport processes in each of the phases. In particular, mass transfer at the liquid–gas interface involves processes occurring in phases of vastly different hydrodynamic behaviour.

Very often the mass-transfer process is complicated by chemical reactions between the diffusing species. Mass transport towards the simplest surface from the hydrodynamic point of view, a single bubble or drop moving in a quiescent medium, has been most fully investigated. The diffusion flux towards a growing, immobile drop was calculated several years ago[37,38]. The use of the formula for the diffusion flux towards a growing mercury drop provided the quantitative foundation of the polarographic method.

Frumkin and his coworkers[24] have developed the quantitative theory of the macrokinetics of reactions from the theory of the growing drop, and this has led to important results on the kinetics of hydrogen ion discharge. More recently, the theory of convective diffusion from the external phase to the surface of a moving drop or bubble has been worked out, and in very recent years the author has arrived at the general macrokinetic theory for the surface of small drops and bubbles[39], with allowance for transport in both the external and the internal phase. He has also arrived at the theory for the diffusion flux towards the surface of large drops[40], which are subject to periodic oscillations during their motion.

The diffusion flux in this case is expressed by relatively cumbersome formulae. Their main feature is that the flux is proportional to the square root of the velocity, and is also a function of the exchange (partition) coefficient of the diffusing species between the phases, and of parameters of both phases.

The diffusion flux in the system consisting of "gas bubbles in a liquid" can be obtained from these formulae for the limiting case in which the density of the inner phase is much smaller than the density of the outer phase. With large bubbles, which are deformed during motion, the diffusion and thermal fluxes can be calculated to the nearest order of magnitude. It is useful to note that surface-active substances, which influence the hydrodynamic behaviour of drops and bubbles very considerably, must also affect the diffusion flux. Theoretical formulae for the diffusion and thermal fluxes towards the surface of a drop or bubble are in satisfactory agreement with experiment in the particular case of negligible mass transfer in the inner phase. However, the more general expressions for the flow, allowing for diffusion in the inner phase, have not yet been compared with experimental data, and neither have the formulae for large vibrating drops. The macrokinetics of the process in which species diffusing from the drop undergo chemical reaction in solution have been recently worked out[41]. Because of its practical importance, this process has been examined in a number of papers concerned with the so-called penetration theory.

According to this theory[42], the time needed for the diffusing substance to penetrate into the external phase is much smaller than the time during which its concentration profile is significantly modified by the non-uniform distribution of velocities in the stream. In other words, the theory assumes that the velocity at all points of the external phase which the diffusing particle can reach is equal to the velocity of the interface.

In fact, such is not the case at high Peclet numbers. Even a relatively small point-to-point variation in the velocity distribution in the external phase has a powerful influence on the transport conditions, since at high Peclet numbers convective transfer predominates over transport by molecular diffusion. Calculations show that the formulae of the penetration theory can be applied only over times so short that formation of the diffusion boundary layer has not gone to completion. This time is much smaller than the times involved in the transfer process under the realistic conditions of drops moving in extraction apparatus. Formulae suitable for long times have been obtained: these

give the diffusion flux both in the absence and in the presence of chemical reaction in the external phase.

The second case of flow with a mobile interface concerns thin liquid films flowing on a solid surface. The flow of very thin films is laminar, and the calculation of convective flux presents no difficulty. At somewhat greater thicknesses the flow becomes wavelike, and calculation shows that the diffusion or thermal flux increases by about 25% as compared with a smooth surface. However, we have no theory for convective diffusion in a film covered with ripples of relatively large amplitude. The successful experimental studies of convective diffusion in liquid films exposed to fast countercurrents of gas[43] are a further stimulus to the development of a theory. We also lack a theory for convective transfer in liquid or gaseous jets issuing into a quiescent medium from an orifice or a packed column. This list of important problems relating to "fundamental" transport processes at a mobile interface is far from complete.

However, the main achievement is that theoretical and experimental studies in recent years have provided a general picture of transport processes at a mobile boundary, and have explained their basic features.

## 4. TURBULENT FLOW

The flow of liquids and gases in practically all chemical reactors and mass-exchange apparatus is turbulent. Hence, the theory of mass transfer and heat transfer in the turbulent regime of flow of liquids and gases is at least as interesting as the theory of transport in the laminar regime. Modern theories of turbulence enable us to arrive to certain quantitative conclusions regarding the transport of mass and heat in a turbulent stream.

The most fully developed theory is that of local isotropic turbulence; the theory of a turbulent stream in the vicinity of a solid surface has been developed to a lesser extent.

The theory of turbulence near a mobile interface is in its initial stages of development. In the region of free turbulence, far from the interface, all the turbulence eddies transfer passive materials (solute, gaseous impurity, or heat). Agitation of the liquid, moving in a region of dimensions $L$, is caused by all eddies with velocities up to $\Delta U_0$ and characteristic length $L$. The effective turbulent diffusion coefficient $L_{\text{eff}} \simeq \chi_{\text{eff}} \simeq \Delta U_0 L$ is so large that the turbulence ensures concentration and temperature constancy over the whole of the volume except for a very thin turbulence boundary layer close to the interface.

Here the scale of the turbulence eddies $l$ decreases according to the law $l \propto y$, and at quite small distances according to the law $l \propto y^2$, where $y$ is the distance to the solid surface. At a distance $\delta_0$ from the solid surface, called the viscous sublayer, the turbulence eddies become so weak that momentum transfer in the liquid occurs by the molecular viscosity mechanism, and turbulence subsides. Nevertheless, the damped turbulence eddies are still able to transport mass and heat. At Prandtl numbers in excess of unity the molecular transfer mechanism begins to predominate over the convective mechanism in a liquid layer of thickness $\delta' \simeq \delta_0/\text{Pr}^{1/4}$, amounting to $10^{-4}$–$10^{-5}$ cm. This extremely thin layer is the diffusion boundary layer, within which is concentrated the major diffusional resistance. The concentration (or temperature) distribution in this layer is effectively linear. Under these conditions the flux is given by the expression[7]

$$j_{\text{turb}} \sim \sqrt{k_f} U_0 \text{Pr}^{-1/4} \Delta\varphi. \tag{16}$$

At low Prandtl numbers the molecular transport mechanism takes over from the convective mechanism in a layer of thickness

$$\delta'' \sim \frac{\delta_0}{\text{Pr}} \gg \delta_0, \tag{17}$$

and therefore[7]

$$j_{\text{turb}} \sim \frac{\sqrt{k_f} U_0 \Delta\varphi}{\ln \frac{L U_0 \sqrt{k_f}}{\nu} + \ln\text{Pr} - A}. \tag{18}$$

Here $\Delta\varphi$ is the concentration or temperature difference between the bulk and the layer of liquid close to the reacting or cooled surface, $k_f$ is the resistance coefficient, a slowly varying function of distance, and $U_0$ is the velocity.

For Prandtl numbers of the order of unity, we can write down interpolation formulae which combine both limiting laws, (16) and (18). These expressions agree satisfactorily with experiment[7,44].

It must be stressed that in a turbulent stream the exposed surface is not uniformly accessible owing to the dependence of $k_f$ on the coordinates, mentioned above. This is true, in particular, for the surface of a disc. The only geometries in which the surface is uniformly accessible are the inner surface of a tube (in the region beyond the inlet section), and the surface of a cylinder rotating about its axis and remote from the walls of the vessel. The resistance coefficient is constant over the entire length of the tube and the entire height of the cylinder. Therefore, what was said above regarding the surface of a disc under laminar flow applies to turbulent flow towards the surface of a tube and of a rotating cylinder.

A theoretical expression for the flow at high Prandtl numbers was derived by the writer for a smooth and a rough tube[7], and more recently for a cylinder.

Turbulent motion at a mobile interface has been investigated in far lesser detail. For the turbulent motion of a gas stream over a liquid surface, we can expect turbulence of an entirely different character to be set up in the gas and in the liquid.

Since the density of the liquid is much greater than that of the gas, turbulence near the liquid interface will be damped in much the same way as near a rough solid surface. This statement is correct if the mean gas velocity is greater than the maximum rate of propagation of the waves (given by $\sqrt[4]{4\sigma g/\rho}$, where $\sigma$ is the surface tension — 24 cm $s^{-1}$ for water). However, we still lack experimental data on the distribution of velocities in the gas close to a liquid surface, and particularly measurements of the mean amplitude as a function of stream velocity. There have been few systematic measurements of resistance coefficients for a gas stream at different depths of liquid layer, surface tensions, etc. These measurements would be very valuable.

Turbulence near a free liquid surface has been studied in fair detail in the context of wind-generated waves in deep liquids. A similar approach is permissible under the conditions encountered in chemical hydrodynamics. By

using the ordinary theory of turbulent transfer in conjunction with the hypothesis as to the scale of the eddies near the free surface

$$l \sim \bar{a} \tag{19}$$

where $\bar{a}$ is the average amplitude of the surface waves, we can obtain an expression for the density of the diffusional flow near the surface:

$$j \sim v_0 \Delta c. \tag{20}$$

Here $v_0$ is the characteristic velocity of the turbulence eddies in the stream, related to the mean flow velocity by the familiar expression

$$v_0 \sim \bar{U} \sqrt{k_f}.$$

The total diffusional flow is of the order of magnitude

$$J = jS$$

where $S = S_0(1 + \bar{a}^2)$ is the true area, and $S_0$ is the nominal area of the liquid surface. Neither the turbulence in the gas phase nor the turbulence in the liquid phase have in fact been studied close to a free boundary by the powerful experimental tools of modern hydrodynamics.

On the subject of the difficulties presented by mass transfer problems near a mobile surface, it may be pertinent to point out that many authors[45,46] have been forced by the complications and lack of understanding of these problems to put forward views not in keeping with modern developments in hydrodynamics. The surface renewal theory is typical of this approach.

In the surface renewal theory the concept of turbulent eddies used in the turbulence theory is replaced by unsubstantiated ideas involving the time of renewal of surface elements with an entirely arbitrary distribution function for these times. These quasi-hydrodynamic theories are almost valueless.

## 5. HOMOGENEOUS–HETEROGENEOUS SYSTEMS

In the study of radical reactions occurring in cracking, pyrolysis, and other reactions in fast moving liquids and gases the most important problem is that of the relations between reactions in the bulk and at the surface. The macrokinetics of such systems have been discussed for the idealised case of an immobile medium[47] or of a medium undergoing laminar flow in a tube[19,48].

The last few years have witnessed the development of a general hydrodynamic theory of the macrokinetics of systems comprising both homogeneous and heterogeneous reactions at very high flow rates (more precisely, streaming at high Reynolds numbers), as is almost invariably the case in practice[49].

Consider a tube in which a turbulent stream of a chemically active medium (liquid or gas) is moving, and assume that chemical reactions accompanied by absorption or evolution of heat are taking place in the bulk. The kinetics of homogeneous reactions are usually described by an expression of the type

$$Q_i = k_i c_i^{n_i} c_j^{n_j} \ldots e^{-E_i/RT}$$

where $Q_i$ is the rate of reaction of the $i$th component in the bulk phase, $c_i$ and $c_j$ are the bulk concentrations of the components, and $E_i$ is the activation energy.

In the presence of homogeneous reactions the convective transport equation becomes non-linear, and accurate analytical solutions cannot be obtained. At the surface of the tube heterogeneous reactions take place, and under steady-state conditions the number of species arriving at the surface from the bulk equals the rate of heterogeneous reactions. Since the kinetics of heterogeneous reactions are also expressed by non-linear laws, the boundary conditions at the surface of the tube are non-linear. At first sight it would appear that a system of non-linear partial differential equations with non-linear boundary conditions is too complex to permit analytical or numerical solution. However, in practice it is possible to apply the ideas of the boundary diffusion layer to this system.

The total flow can be subdivided into the main region and a thin diffusion (or thermal) layer adjacent to the surface. In the main region the turbulent mixing ensures that the distribution of velocities, concentrations, and temperature is close to the average over the cross-section. A significant change in concentration along the tube axis, resulting from chemical reactions, occurs on a scale comparable to the length $L$ of the reactor. If the change occurred over a shorter length one would simply shorten the reactor.

Surface reactions cause an appreciable change in concentration, from $c_S$ at the surface to $c_0$ in the bulk, over the very thin boundary layer $\delta'$.

It is clear, however, that in this thin layer we may ignore longitudinal changes in concentration of the main component at the outer limit of the boundary layer, and therefore we can also ignore the bulk reaction. The concentration change arising from the bulk reaction is significant at distances of the order of $L$, but not of the order of $\delta'$.

By coupling the solutions for the main region and for the boundary layer, we can arrive at the distribution of concentration, temperature, and reaction rate along the reactor.

In two real systems — the pyrolysis of ethane to ethylene and the radical–chain oxidation of hydrocarbons — the overall macrokinetics have been calculated. The rate of the characteristic deposition of side-products has been obtained for the former reaction, and the effect of the surface-to-volume ratio of the reactor has been obtained for the latter reaction.

## 6. STATISTICAL SYSTEMS

In the previous sections we have dealt with some simple "fundamental" mass- and heat-transfer processes. Their main characteristic is a simple and well defined set of geometrical conditions. Furthermore, the flow regimes were assumed to be fixed and uniform over the whole of the system, and random time-changes of regime or spatial variations in the properties of the system were not considered. In practice, one attempts to stir as intensively as possible in order to obtain high rates of transfer. In real situations the process usually occurs in a statistical system, composed of a set of "elementary" objects, rather than on a single object such as a solid reaction surface, a drop, etc. Therefore, in order to construct a physicochemical model of a real process we must, on the one hand, analyse the complex process into its individual stages (or fundamental steps), and, on the other hand, we

must make a particularly careful study of the simple stages, uncomplicated by incidental and random phenomena. We shall illustrate these statements by two examples.

Absorption is a very complicated phenomenon. Yet, it can be separated into a number of stages whose relative contributions to the overall process depend on the particular conditions. We can distinguish the following stages: (1) the gas jet emerges from the nozzle and breaks up; (2) the resulting bubbles are further broken down, or coalesce; (3) motion of individual bubbles; (4) motion of the system of bubbles; (5) mass transfer to a single bubble, taking account of external and internal diffusional resistance; (6) exhaustion of the solution with time; (7) non-uniform radial distribution of gas and liquid; (8) foaming; (9) mass transfer in the bubble walls of the foam.

Some of these stages are adequately characterised at the present time, others are insufficiently understood.

However, some of the stages play an insignificant part under actual process conditions. Thus, the overall process becomes very much simpler if the liquid layer is deep enough, if the proportion of gas is not too large, and if conditions are constant over the cross-section.

The bubbles of different sizes formed by the breaking up of gas jets are further comminuted (if they are coarse) and coalesce (if they are fine) relatively quickly. The main body of bubbles achieves an almost uniform size, and rises at a uniform rate. Their mutual effect can be estimated, and the speed at which they rise can be found[50].

The mass transport for bubbles of a given size and velocity is known; thus, all the above stages can be evaluated, and the operation of a gas bubbler under these conditions can also be evaluated. Obviously, however, the calculation has no meaning for bubblers of different design, which fail to satisfy the above assumptions.

A detailed experimental and theoretical study of all the stages listed above would give an indication of their relative importance in various types of apparatus.

For our second example, we shall consider a tubular reactor containing a granular, immobile layer of catalyst. In this case the fundamental stages are as follows.

1. The kinetics of the process. It is essential to know the overall mechanism, and sometimes also the true, detailed kinetic mechanism of the process, including true kinetic data such as the rate constant, the activation energy, the order of the reaction with respect to concentration, the heat of the reaction.

2. Diffusion and heat-transfer processes within the catalyst particles (as a function of catalyst structure, thermal conductivity, etc.). The effect of these processes on the kinetics.

3. Motion of a liquid or gas through the granular medium, convective diffusion and heat transfer in a porous medium, heat transfer in the catalyst skeleton. The influence of these processes on the kinetics has already been discussed. Convective transfer in a granular medium has not been adequately investigated. The longitudinal diffusion coefficient in a granular medium with stagnant regions has been recently calculated[51] on the basis of quite general assumptions as to the actual properties of the medium.

The radial convective diffusion and thermal conductivity coefficients must be very much smaller than the longitudinal coefficients; their dependence on velocity has been calculated from an unsatisfactory model[52]. Experimental results for $D_{\parallel}$ in porous media are in satisfactory agreement with theory, but $D_{\perp}$ is often found (experimentally) to be slightly dependent on velocity. Other results suggest that $D_{\perp}$ is proportional to $U_0$. The vast majority of the experiments refer to a porous, but not coarse-grained, structure. The large scatter of the values of $D_{\parallel}$ and $D_{\perp}$ obtained from experimental data indicates a dependence on the actual structure, packing density, etc. It must not be forgotten that the overall thermal conductivity of a granular medium includes the convective thermal conductivity and the thermal conductivity of the skeleton. Under these conditions the concentration and temperature distributions will show significant differences. The calculations which have been made up to now make no allowance for the difference between $D_{\parallel}$ and $D_{\perp}$ or for their dependence on velocity. The resulting error is not easy to assess.

4. Transition from a granular structure to a continuous medium. Many workers treat the granular medium filling the reactor as a continuous, porous medium.

In practice, very wide variations in the ratio of grain diameter to tube diameter are encountered. There is a need for more detailed studies as to the nature of the approximations made on going from a granular to a continuous medium: this is particularly important when a laboratory-scale process is transferred to industrial plant. Various models of a granular medium in a reactor with an immobile layer have been put forward: the cellular model[53], the cellular model with stagnant regions[54], the quasi-homogeneous model[55], etc. This in itself is a clear indication of the lack of a universal model applicable to real systems.

5. Simplification of the basic equations for mass and heat transfer in a porous medium within the framework of the quasi-homogeneous model.

6. Calculation of the average temperature distribution along the reactor.

7. Calculation of the stability of the operating conditions of the reactor.

8. Allowance for non-uniform gas flow over the cross-section of the reactor.

As in the previous example, we see that some of these stages have been investigated to a sufficient extent, whilst others are inadequately understood.

In conclusion it should be stressed that the complications of hydrodynamics and of mass- and heat-transfer processes in chemical reactors and mass-exchange apparatus are such that mathematical and experimental studies must be brought to bear on them jointly. The common aim of these studies should be to produce sound physicochemical approximations (models) which would serve as a basis for calculations on processes and apparatus. Calculations on reactors which allow for major factors but ignore second-order factors (usually called mathematical modelling) should always be compared with experiment in order to confirm that the approximations made are compatible with real processes in chemical plant.

# THE ELECTROCHEMICAL EFFECT OF HIGH COVERAGE

G.A.Tedoradze and A.B.Ershler

The inhibition of electrochemical reactions by adsorbed extraneous substances or reaction products is well recognised[1-8]. The basic causes underlying this phenomenon include blocking of the surface by an adsorption film, and the generation of an energy barrier opposing the reduction, through the adsorption of ions or polar molecules. In recent years, the inhibition of an electrochemical reaction by adsorbed reactant has been demonstrated by refined experimental techniques. This effect has been termed[9,10] the high-coverage effect.

Frumkin et al.[9] and Tedoradze and Dzhaparidze[10,11] were the first to compare the degree of coverage of the electrode surface by reactants, determined experimentally, with the rate of the electrochemical process, measured at the same potentials. They reported a decrease in current density with increase in coverage for the catalytic evolution of hydrogen from diphenylamine solutions. A qualitative explanation of the inhibition of the reduction of diphenylammonium ions at coverages of the electrode approaching unity has been given[9].

This article will describe the outward experimental symptoms of the high-coverage effect, and some possible causes. The reduction of organic substances at a mercury electrode, being the simplest case, will be treated in detail.

As long as the coverage of the surface by molecules of a reducible substance is not large, and interactions between these molecules (as well as the effect of adsorbed molecules of the product) can be ignored, the rate $i$ of an

electrochemical reaction is proportional to the surface concentration of the reducible substance ($\Gamma$), and is given to a first approximation by the expression

$$i = nF\Gamma k \exp\left[-\frac{\alpha nF}{RT}(\varphi - \psi_1)\right], \quad (1)$$

where $\varphi$ is the potential of the electrode, $\psi_1$ is the potential at the point in the electrical double layer occupied by the reacting site of the reducible substance, and $k$ is the value of the rate constant at $\varphi - \psi_1 = 0$. However, as Frumkin pointed out[12,13] in 1962, when the surface is largely covered with the reactant entirely different expressions should apply: formula (1), which assumes proportionality between the concentration of the activated complex and that of the reducible substance in its initial adsorbed state, is correct only for low and intermediate coverages of a uniform surface. At high coverages we can expect steric hindrance to oppose transition to the activated complex state, and the variation of the rate of the process with surface concentration may no longer be monotonic. Thus, the orientation of the adsorbate molecules on the surface may vary when the degree of coverage increases[14,15]. If this results in the reactive site of the molecule taking up a position remote from the electrode, we can assume that the formation of the activated complex will involve rotation of the adsorbed molecule on the electrode surface. At high coverages this reorientation can be impeded by neighbouring adsorbate molecules, and the probability of transition of a reacting molecule to the activated state is thereby decreased. However, this explanation of the high-coverage effect is not applicable to some substances. For example, the system of conjugated $\pi$-bonds allows motion of an electron along a molecule of dipyridylethylene, and it is impossible to choose an orientation of the reducible molecule on the electrode surface for which the steric hindrance effect is operative.

Transition to the activated complex state will also be hindered at high coverages if the activated complex occupies a greater area on the electrode surface than the molecule in its original adsorbed state[12,13]. The high-coverage effect observed[16-18] in the reduction of dipyridylethylene on mercury at pH values not far from neutrality appears to be a case in point.

It should be noted that a similar phenomenon has been reported[19-28] in the study of the reactions of organic substances in solution at high pressures: in some cases, formation of the activated complex involves an increase in the volume of the molecule (this is called the negative activation volume), and under these conditions increase in pressure inhibits the reaction. Cases are also known in which the activated complex is formed with a decrease in molecular volume (positive activation volume): the rate constant now increases with increase of pressure. One of the commonest causes of a change in volume by the molecule is identified, in the literature dealing with high-pressure chemistry, with unequal solvation of the initial state and the transition state. A difference in solvation can always be expected if the charge of the activated complex is different from that of the original molecule. In the examples which we shall consider, the volume of the activated complex may be greater than the volume of the adsorbed molecule in the initial state for yet other reasons, such as bond labilisation preceding bond rupture; replacement of a double bond by a single bond also causes an increase in volume, because double bonds are shorter than single bonds.

Phenomena reminiscent of the high-coverage effect can occur when two adsorbed species are involved[29] in the formation of the activated complex. If the difference in the adsorption energy of the two species is large, the surface concentration of the second component will be small at high coverages, and this will decrease the surface concentration of the activated complex and therefore also the rate of the electrochemical process.

The study of the variation of current density with surface concentration of (or coverage of the electrode by) the reducible substance is a direct and reliable method of observing high-coverage effects. To use this method, however, some serious experimental difficulties have to be overcome, because at least two surface-active substances are present on the electrode surface during the passage of Faradaic current, and their relative amounts depend on the duration of electrolysis. The method of differential capacity measurements, which is fairly accurate, gives only the total coverage of the electrode surface in this case. The electrocapillary curve method suffers from the same disadvantage, whereas the charging curve method, by which the surface concentration of reactant can be evaluated, is not accurate enough.

To measure the coverage of the surface by the reactant under conditions of Faradaic current flow through the cell, the differential electrode capacity method can be used if the product of the electrochemical reaction is not adsorbed on the electrode. The catalytic evolution of hydrogen on mercury is a reaction of this type. On the plot of the rate of reduction of the diphenylammonium ion against coverage, the high-coverage effect is shown by a current density maximum[9,11] at a $\Theta$ value close to 0.85. It should be noted that, if the current density–coverage curve goes through a maximum, the current density must also go through a maximum as a function of bulk concentration of the reducible substance. Bagotskii and Vasil'ev[30] have observed this type of variation. However, their maximum could be associated with inhibition of the electrode reaction by preferential adsorption of the reaction product on the electrode surface.

The influence of the reaction product on the rate of the electrode reaction will be minimal if the electrolysis is restricted to very short times and low current densities, so that the amount of product formed is insufficient to cause appreciable blocking of the surface. By constructing a family of plots of current density against surface coverage (or against bulk concentration of the reducible substance) at constant time, the inhibition caused by the reaction product can be separated from the high-coverage effect. These plots are most conveniently made on the basis of experimental $I-t$ curves.

Furthermore, the form of the $I-t$ curves can itself reveal the presence of a high-coverage effect. Thus, if the bulk concentration of the organic material is not very large (in practice, less than $10^{-3}$ M), the degree of coverage of the surface by the reactant reaches a value of the order of unity in a measurable time interval, determined by the diffusion of the organic molecules to the electrode surface [provided of course that the product $Bc$ in the adsorption isotherm equation $Bc = f(\Theta)$, where $B$ is a function of potential only, $c$ is the bulk concentration, and $\Theta$ is the coverage, is large enough to induce such a high coverage]. Therefore, we can expect to find that the reduction will proceed without high-coverage effects at short times, when the coverage is still low. As the lifetime of the drop increases, the surface coverage by the reactant will also

increase, and after a definite time the coverage may be sufficient to display the high-coverage effect. When this happens, the current must begin to fall off (because of the sharp decrease in the rate constant), and a maximum appears on the $I-t$ curve.

However, a maximum on the $I-t$ curve could have quite a different explanation: for example, adsorption of the reaction product, which blocks part of the surface. As shown by Koutecký and by Koryta[31,32], the $I-t$ curves begin to fall off due to this blocking effect at surface coverages of the order of 0.8–1 if the rate constant is large enough. If the fall of the $I-t$ curve due to adsorption of the reaction product is assumed to set in at that exact coverage of the electrode surface, the quantity of electricity $q_{max}$ which passes through the electrode up to the moment when the curve begins to fall off must be constant. The value of $q_{max}$ should be approximately equal to $nF\Gamma_\infty$, or larger than this quantity, since formation of the reaction product is invariably accompanied by desorption of the product into the solution: this is because the concentration of the product in the region adjacent to the electrode is close to zero.

If we increase the bulk concentration of the organic compound, the current at constant potential and constant time increases. Therefore the time corresponding to the maximum on the $I-t$ curve ($\tau_{max}$) will decrease, but $q_{max}$ will be practically unaffected by the bulk concentration of the reactant. The changes in potential of the electrode at constant bulk concentration lead to the same result. In this case an increase in potential causes an increase in current, but the value of $q_{max}$ remains independent of potential. However, the latter (and experimentally simpler) method is applicable only over a narrow range of potentials close to the potential of maximum adsorption of the reaction product. As we approach the potential of the desorption peak, $q_{max}$ and $\tau_{max}$ begin to increase rapidly because of the faster desorption of the products from the electrode. Thus, in order to eliminate the effect of the reaction product on the rate of the electrode process, it is enough to arrange for the measurements to be completed in times much shorter than $\tau_{max}$. The approximate constancy of $q_{max}$ with change of potential, for the fall in the curve induced by reaction products, was demonstrated by Levinson in her investigation of the reduction of $\alpha\alpha\alpha\omega$-tetrachloroalkanes (Fig. 1).

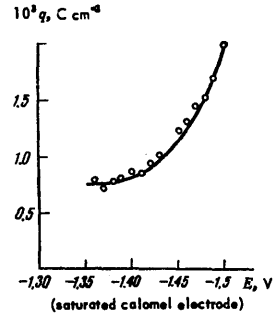

Fig. 1. Potential variation of the quantity of electricity passing through the electrode up to the onset of the fall of current in the reduction of $\alpha\alpha\alpha\omega$-tetrachlorononane; solution composition: 0.0031 M $CCl_3(CH_2)_7CH_2Cl$ + 70% $CH_3OH$ + + 0.25 M $Cs_2CO_3$; from data of I. M. Levison.

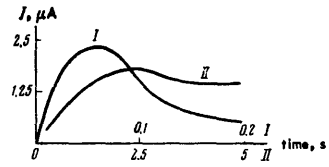

Fig. 2. Variation of the current with time in the reduction of dipyridylethylene; potential -0.83 V (s.c.e.); pH 5; concentration of reactant $2 \times 10^{-3}$ M; from Ref. 18.

In the high-coverage effect, on the other hand, if concentration polarisation is small, the instant when the current begins to fall off (at constant bulk concentration and near the potential of the adsorption maximum of the reactant) is independent of the current, since it is determined by entirely different factors. Provided $Bc$ is large enough, $\tau_{max}$ is independent of potential, and the value of $q_{max}$ increases as the electrode potential increases, but if the currents are much smaller than the limiting diffusion current $q_{max}$ can be significantly lower than $nF\Gamma_\infty$. Current falls of this type are found in the reduction of dipyridylethylene on mercury in aqueous solutions[17,18]. Curve *1* of Fig. 2 shows that $4 \times 10^{-5}$ C cm$^{-2}$ (including the charging current) have passed through the electrode up to the onset of current fall. Therefore, the whole of the reaction product can block no more than one-half of the electrode surface (assuming that the product takes up 46 Å$^2$ of the surface, i.e. the same area as the reducible compound[18]). We conclude that the current fall on the $I-t$ curve arises from the high-coverage effect.

In the case of the high-coverage effect, the value of $q_{max}$ should decrease with increase in the concentration of reactant. If the rate of adsorption of the organic compound is determined by the rate of diffusion to the dropping mercury electrode[33,34], the following equation will apply

$$0.74c\frac{\sqrt{D\tau_{max}}}{\Gamma_\infty}\left(1+3.4\frac{\sqrt{D\tau^{1/6}_{max}}}{\sqrt[3]{m}}\right)\geqslant 1,$$

where $D$ is the diffusion coefficient, and $m$ is the mercury flow rate, derived from the well-known Koutecký equation[35].

The polarograms and polarisation curves of systems showing the high-coverage effect have a characteristic asymmetric shape, with an abrupt transition to the limiting diffusion current (Fig. 3). Thus, in the reduction of

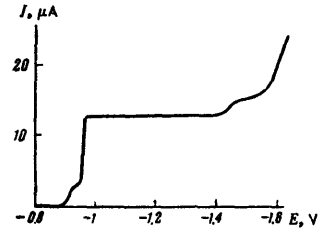

Fig. 3. Polarogram for the reduction of dipyridylethylene in aqueous solution of pH 6.7; concentration of reactant $2 \times 10^{-3}$ M; from Ref. 18.

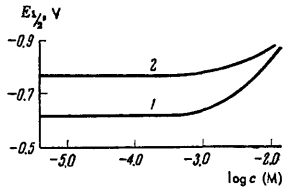

Fig. 4. Variation of the half-wave potential for the reduction of di(methoxycarbonylmethyl)mercury [$Hg(CH_2COOCH_3)_2$] with the logarithm of bulk concentration in 50% methanol.

dipyridylethylene, the current increases by a factor of 4 over a range of 7 mV. If the surface concentration is decreased by making the solution more dilute with respect to the reducible substance or by adding an organic solvent, the wave reverts to the normal, symmetrical shape, and the half-wave potential shifts in the positive direction. In the reduction of di(methoxycarbonylmethyl)mercury, Butin et al.[37] observed a rather large (about 200 mV) positive displacement of the half-wave potential upon lowering the bulk concentration of the reducible compound from 0.02 to 0.001 M. At still lower bulk concentrations the half-wave potential becomes insensitive to concentration (Fig. 4).

However, we must stress that neither an asymmetric polarogram nor an increase in rate with dilution of the solution can be taken as sufficient criteria for the recognition of the high-coverage effect. According to Feoktistov, if the coverage of the electrode surface by the reactant is high at the half-wave potential, this potential for the reduction reaction suffers a negative shift even in the absence of the high-coverage effect. The maximum value of this shift is given by the formula

$$\Delta\varphi_{1/2} = \frac{RT}{\alpha nF} \ln c,$$

where $c$ is the bulk concentration of the organic substance. The reaction products can also give rise to similar effects.

Thus, Laviron† [16] suggested, from the shape of the polarogram and of the $I-t$ curves, that auto-inhibition of the electrode process by the reducible substance occurs in the reduction of dipyridylethylene, but he did not discuss the physical significance of this term. A more detailed examination of this process[17,18] showed that if the time of electrolysis on each drop exceeds 1 sec, as was the case in the work of Laviron[16], inhibition of the reduction of dipyridylethylene by the reaction product takes place (Fig. 3). Adsorption of the reaction products is responsible for the preliminary wave in the reduction of dipyridylethylene[18]. The genuine high-coverage effect is observed on the polarisation curves measured[17,18] with shorter electrolysis times (Fig. 11, see below).

The high-coverage effect is most clearly revealed by galvanostatic measurements. If the bulk concentration of reducible material is not large, but the density of polarising current is appreciable, we can ignore the diffusion of reactant from the bulk during the measurement, and the shape of the potential–time curve (ignoring the double-layer charging current) is described by Eqn. (1). For galvanostatic measurements, this equation is conveniently written in the form

$$\varphi = \psi_1 - \frac{RT}{\alpha nF} \ln i + \frac{RT}{\alpha nF} \ln nF k\Gamma = \varphi_0 + \frac{2{,}3\,RT}{\alpha nF} \log k \frac{\tau - t}{\tau_1}, \qquad (2)$$

where $t$ is the electrolysis time, $\tau$ is the transition time, $\tau_1$ is the value of the transition time when $\Gamma = \Gamma_\infty$, $i$ is the polarising current density, and $\varphi_0$ is a constant depending on $i$. If the reduction is preceded by chemical reaction, e.g. protonation of the reducible substance in the adsorbed state, the variation of potential with time becomes more complicated[17], but in any case the potential of the electrode (in the absence of the high-coverage effect) drifts monotonically towards more negative values as the surface concentration decreases during the course of electrolysis. As was stated at the beginning of this article, the high-coverage effect can be so large that the product $k\Gamma$ increases as $\Gamma$ decreases at high coverages. In the galvanostatic regime this causes a drop of potential with time at short times, thus explaining the appearance of a maximum on the potential–time curve. Curves of this type were first reported and discussed by Zolotovitskii and the present writers[17].

The phenomenon was described mathematically[17] by assuming, as a first approximation, that over a given range of surface concentrations the rate of electron transfer decreases linearly with increasing coverage. This type of variation of current density with coverage corresponds to the following empirical formula for the electron transfer rate constant[9,11]:

$$nF\Gamma_\infty k = \frac{k'}{\theta} - k''. \qquad (3)$$

Here $k'$ and $k''$ are constants. Fig. 5 shows theoretical curves of electrode potential against electrolysis time calculated on the assumption that over a range of coverages the rate constant varies as required by Eqn. (3), but at low enough coverages this quantity becomes truly constant.

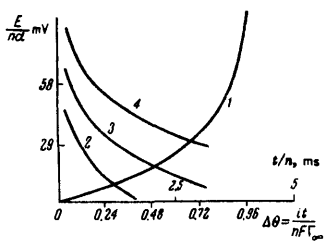

Fig. 5. Variation of electrode potential (relative to $\varphi = -\frac{0{,}058}{\alpha n} \log i$) with normalised time $\Delta\theta = \frac{it}{nF\Gamma_\infty}$ at $i = 3 \times 10^{-4}$ A cm$^{-2}$, $\alpha n = 1$, $\Gamma_\infty = 5 \times 10^{-10}$ mole cm$^{-2}$:
1) no high-coverage effect, $nF\Gamma_\infty k = 10^{-5}$ A cm$^{-2}$; [2)–4) under the conditions of the high-coverage effect the rate constant varies with coverage according to formula (3)] 2) $k' = 2.24 \times 10^{-5}$, $k'' = 2.17 \times 10^{-5}$; 3) $k' = 1 \times 10^{-5}$, $k'' = 0.97 \times 10^{-5}$; 4) $k' = 4.45 \times 10^{-6}$, $k'' = 4.31 \times 10^{-6}$ A cm$^{-2}$; from Ref. 17.

† Presumably this work is described by Tedoradze in Ref. 16, since Laviron is not mentioned in Ref. 16 (Ed. of Translation).

The disappearance of the high-coverage effect coincides with the transition from curves *2–4* to curve *1*. Irrespective of how accurately the high-coverage effect is described by the empirical formula (3), a minimum on the potential–time curve is a sufficient criterion for the existence of this effect.

In order to demonstrate the high-coverage effect with the aid of charging curves, the measurements must be made under conditions such that diffusion of the reactant to the electrode can be ignored. Otherwise, a potential minimum could arise from a trivial cause: the tangential motion of the mercury surface. We have observed this phenomenon in practically every system examined.

Charging curves with a potential minimum due to the high-coverage effect have been observed in the reduction at a mercury electrode of dipyridylethylene[17,18] (Fig. 6), ethyl bromoacetate and bromobutyrate, and di(methoxycarbonylmethyl)mercury[38].

We have found in the literature a number of charging curves showing a potential minimum, but nowhere was the cause of the phenomenon discussed[39-41].

A paper by Lorenz and Schmalz[39] describes the charging curves of eosin. Fig. 7 shows that the charging curve obtained for prepolarisation at a potential corresponding to a coverage close to the limiting value has a clear minimum, which disappears (as in the reduction of dipyridylethylene discussed above) if the electrode is previously held at a potential for which the coverage is less than unity. The transition times are so small in this case that the potential minimum cannot possibly be associated with the polarographic maximum.

Similar effects have been observed in the reduction at a mercury electrode of developers for colour photography[40] and in the reduction of hydroxylamine at a platinum electrode[41] previously activated at a potential of +0.1 V (normal calomel electrode). It should be noted that the adsorption of hydroxylamine on anodically oxidised platinum is insignificant. The potential minimum on the charging curve also disappears if the electrode is passive.

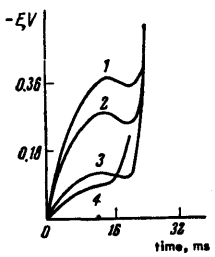

Fig. 6. Charging curves for dipyridylethylene after holding the electrode at various potentials (the zero of each curve is taken as the previous holding potential). Holding potentials: 1) -0.6; 2) -0.7; 3) -0.9; 4) -0.92 V (s.c.e.); polarising current density 10 mA cm$^{-2}$; from Ref. 18. Prior polarisation at the potential of incipient desorption of dipyridylethylene shortens the transition time and removes the fall of potential on the charging curve.

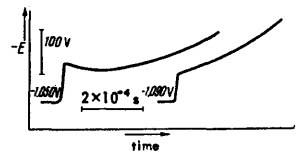

Fig. 7. Cathodic charging curve for eosin at a current density of 40 mA cm$^{-2}$; the numerals denote the prior polarisation potential; potential of incipient desorption of eosin -1.05 V; from Ref. 39.

We shall now briefly describe the electrochemical behaviour of various systems in which the high-coverage effect has been observed.

Diphenylamine[9-11]. When mercury is cathodically polarised in acid solutions of diphenylamine, the diphenylammonium cations formed by protonation of diphenylamine (B) are reduced:

$$B + H^+ \rightarrow BH^+; \quad BH^+ + e \rightarrow BH.$$

The unstable BH radicals decompose with formation of diphenylamine and molecular hydrogen:

$$2\,BH \rightarrow 2B + H_2.$$

Thus, the only product of the electrolysis of diphenylamine solutions is molecular hydrogen, which has no effect on the differential capacity of the mercury electrode[42]. The coverage of the electrode surface by diphenylamine was therefore measured from the change in differential capacity of the mercury electrode in the presence of a surface-active material. Polarisation curves for the discharge of diphenylammonium ions at various concentrations of diphenylamine are shown in Fig. 8, whence it can be seen that the overvoltage for hydrogen evolution at low current densities at first decreases and then increases with increase of catalyst concentration. The variation of current density with electrode coverage is different in 0.2 *N* and 1 *N* HCl solutions of diphenylamine. In 0.2 *N* HCl and at coverages below 0.9 (curve *b* of Fig. 9) the current density varies approximately linearly with the coverage of the electrode surface by the catalyst. At still higher coverages the rate of the reduction process falls off.

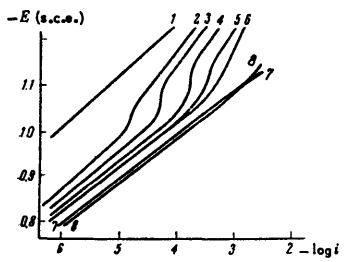

Fig. 8. Polarisation curves for the solutions 1 M HCl + $x$ M $(C_6H_5)_2NH$: 1) $x = 0$; 2) $x = 4.85 \times 10^{-5}$; 3) $x = 9.6 \times 10^{-5}$; 4) $x = 1.33 \times 10^{-4}$; 5) $x = 2.66 \times 10^{-4}$; 6) $x = 3.6 \times 10^{-4}$; 7) $x = 1.48 \times 10^{-3}$; 8) $x = 1.9 \times 10^{-3}$; from Ref. 9.

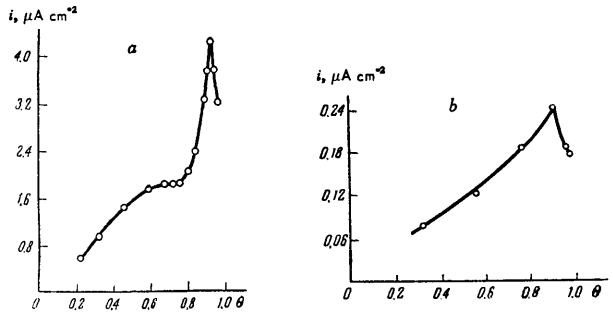

Fig. 9. Variation of the rate of electrochemical reaction with coverage of the mercury surface by an equilibrium mixture of diphenylamine and diphenylammonium ions at a potential of -0.8 V (s.c.e.); curve *a* was obtained in 1 M HCl, curve *b* in 0.2 M HCl; from Ref. 11.

In 1 *N* HCl the approximately linear variation of current density for reduction of the diphenylammonium ion with coverage of the electrode surface by catalyst holds only up to $\Theta < 0.5$. At higher coverages the current density is at first independent of coverage and then shows a steep rise. For $\Theta$ values close to 0.9 the current density (as in the case of 0.2 *N* HCl) suffers an appreciable drop with increase of surface coverage of the electrode by diphenylamine. The complicated shape of this plot has been qualitatively explained by invoking blocking of the electrode surface by electrochemically inactive diphenylamine molecules. However, it is impossible to explain the fall in current at high coverages, whether in 0.2 *N* or in 1 *N* HCl, in terms of blocking. The reasons are as follows.

Measurements of the differential capacity of the electrical double layer give only the degree of coverage of the electrode by the equilibrium mixture of diphenylamine and diphenylammonium. In 0.2 *N* HCl the adsorption layer consists almost entirely of molecules of diphenylamine. In 1 *N* HCl the proportion of diphenylammonium in the adsorption layer becomes much greater. Therefore, inhibition of the process through surface blocking by diphenylamine molecules should be less pronounced in the latter case, or else it should set in at higher coverages, but neither of these effects is found in practice (see Fig. 9).

Dipyridylethylene in water–alcohol mixtures is reduced reversibly, according to Volke and Holubek's polarographic data[43], by addition of two electrons and two protons:

$$\text{Py—CH=CH—Py} + 2e + 2H^+ \longrightarrow \text{Py—CH}_2\text{—CH}_2\text{—Py},$$

where Py is a pyridine ring.

Measurements of Faradaic impedance[18] show that in aqueous solution at pH ≤ 2 the reduction is likewise reversible. Essentially, at pH ≤ 2 dipyridylethylene exists in solution and is reduced in a weakly adsorbed protonated form, whereas at pH > 9 it exists in solution and on the surface exclusively as readily adsorbed, unprotonated molecules, and protonation is not one of the potential-determining stages. Between pH 4 and pH 9 both the protonated and the unprotonated forms exist in solution, but the mercury surface is covered only with unprotonated molecules, owing to the large difference in adsorbability between the two forms. However, despite the fact that under these conditions the dipyridylethylene is adsorbed mostly in the unprotonated form, it is the protonated species which undergo reduction (the half-wave potential is a function of pH). This is the region of pH in which the high-coverage effect can be observed on the polarograms, on the current–time curves, and on the charging curves (Figs. 3 and 6) if the surface concentration of reducible material exceeds $3 \times 10^{-10}$ mole cm$^{-2}$. On decreasing the surface concentration by diluting the solution or by adding ethanol (up to 50 wt.%), the high-coverage effect was removed (Fig. 10).

It should be noted that a similar phenomenon is observed also in the reduction of diphenylammonium ions in 0.2 *N* HCl: a negative shift of the potential causes partial desorption of diphenylamine molecules and makes the relation between $\log i$ and the potential deviate from linearity in the sense of accelerating the process[44].

Ethyl bromoacetate and α-bromobutyrate are reduced irreversibly without prior protonation by addition of two electrons and one proton and splitting off a molecule of bromine. The high-coverage effect was detected in both compounds by the charging-curve method at $\Gamma > 2 \times 10^{-10}$ mole × × cm$^{-2}$; for the second compound the effect disappears at $\Gamma < 1 \times 10^{-10}$ mole cm$^{-2}$. However, studies of the variation of current (at constant potential and electrolysis time) with bulk concentration have made it clear, in both cases, that, when the charging curve indicates a surface concentration of reactant close to the limiting value, and the high-coverage effect operates, the current density remains proportional to the bulk concentration of reactant. Further increase in bulk concentration causes some deviation from linearity in the relation between current density and bulk concentration, but no maximum has been observed on this curve. We have concluded[38] that under conditions of constant-potential electrolysis (before plotting the charging curve) there is an accumulation of an intermediate (or side-product) of the reduction of bromoalkanoic acids at the electrode, this product being highly surface-active. Therefore the shape of the charging curve is determined by the adsorption of this intermediate. Since these products could be the corresponding organomercury compounds, we examined the charging curve of di(methoxycarbonylmethyl)mercury and methoxycarbonylmethylmercury bromide under conditions similar to those used for the esters of the bromoalkanoic acids. Clearly defined minima, indicative of the high-coverage effect, were observed on the charging curves of the symmetrical organomercury compound at $\Gamma = 2.5 \times 10^{-10}$ mole cm$^{-2}$.

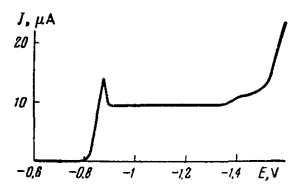

Fig. 10. Polarogram for the reduction of dipyridylethylene in 50 wt.% ethanol; pH 6.7; concentration of dipyridylethylene $2 \times 10^{-3}$ M; from Ref. 18.

Zhdanov and Pozdeeva[45] found a high-coverage effect in the reduction of the 1,2-diphenyl-3-hydroxycyclopropenyl cation, which undergoes one-electron reduction in the first wave. The radicals formed by the electrode reaction disappear from the solution by two competing reactions: dimerisation, or decomposition to diphenylcyclopropenone and hydrogen. The half-wave potential of this wave moves towards more negative potentials upon increasing the concentration of diphenylcyclopropenone in solution. The shift can amount to 400 mV in 5 : 30 ethanol for concentrations between $10^{-5}$ and $10^{-4}$ M. Solutions which are dilute in ethanol show a sudden increase in current before the limiting current is reached. On the current–time curves corresponding to the first wave we find a falling off of the current before a quantity of electricity sufficient to give rise to surface blocking has passed through the electrode: therefore, the fall of current can only be ascribed to the high-coverage effect[45].

Phenomena interpreted as high-coverage effects have been observed also in the study of anodic reactions on platinum by Bagotskii and Vasil'ev[30], Hira Lal et al.[46], Podlovchenko and Iofa[47], Petrii et al.[48], Podlovchenko et al.[49], and Khazova et al.[50] (see Fig. 11). Some other results[29,51] also justify the conclusion that the high-coverage effect was operative.

Lastly, it may not be out of place to mention the results of a study[52] of the electrochemical behaviour of cobalt complexes on platinum. Anson found[52] that the oxidation process is accelerated when chloride, bromide, and iodide ions, and also pentanol (which is readily adsorbed on platinum[53]), are added to an aqueous solution of a divalent cobalt complex ($CoY^{2-}$, where Y is ethylenediamine tetraacetic acid). Special experiments having shown that chemical reaction between the reactant and the additives could not account for this effect, the author[53] suggested that the cause lay in adsorption of the additive, and consequent desorption of the reactant from the electrode.

In fact, if we plot the product $i\tau$ against $1/i$ from Anson's experimental results[52] (Fig. 12), we find that, when iodide ions are present in a solution of $CoY^-$, the graph goes through the origin, which shows that the cobalt complex is not adsorbed. If iodide ions are not added to the solution of $CoY^-$, the graph yields an intercept on the ordinate axis corresponding to the quantity of electricity needed to remove the adsorbed chelate. However, the surface concentration of the complex cannot be calculated in this way because the true surface area of the electrode is not quoted in the original paper[52]. The plots of $i\tau$ against $1/i$ for

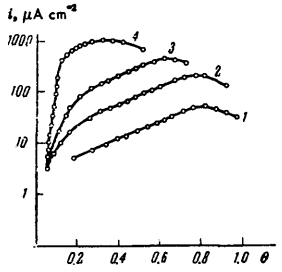

Fig. 11. Variation of the rate of oxidation of methanol on platinum with degree of coverage; from Ref. 50.

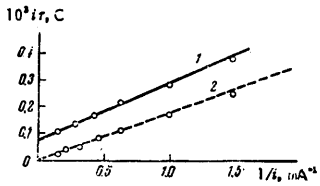

Fig. 12. Variation of the product $i\tau$ (where $\tau$ is the transition time) with $1/i$ for the reduction of cobalt(III) ethylenediaminetetraacetate on platinum:
1) in the absence of iodide ions; 2) in the presence of $10^{-4}$ M KI; concentration of complex $13.3 \times 10^{-3}$ M; phosphate buffer (pH 7); from Ref. 52.

the oxidation of $CoY^{2-}$ in the presence and in the absence of surface-active additives are similar to those for $CoY^-$.

Although this paper does not give the short-time charging curves for cobalt chelates, it would appear that high-coverage effects are present, and are neutralised by surface-active additives.

We may conclude that the study of the high-coverage effect is still in its early stages. In some cases, a choice between the various possible causes of the effect can be made on the basis of the structure of the reacting molecule. The most important requirements now are additional experimental information on the high-coverage effect and new criteria on which to base an unambiguous choice between possible alternative mechanisms. Studies of the influence of temperature and of the nature of the metal are a promising long-term approach.

CONTENTS

I. Introduction 811

II. General characteristics of anionhalogenates 812

III. Isopolyhalogenates 815

IV. Heteropolyhalogenates with a linear anion 817

V. Heteropolyhalogenates with a square planar anion 820

VI. Use of anionhalogenates 822

## I. INTRODUCTION

Anionhalogenates is the name given to complexes of the type $M[X'_nX''_mX'''_k]$, where $M^+$ is the cation of an alkali metal, ammonium, or thallium(I) or the singly-charged cation of an organic base, and $X_j^i$ represents various halogens constituting a complex singly-charged anion†. Usually $n + m + k = 3$, 5, 7, or 9. Anionhalogenates containing four different halogens are unknown.

† In some instances doubly- and triply-charged metal ions can be the cations.

These complexes are often called polyhalide compounds (polyhalogenides), which is not completely accurate, as the latter could also include some polynuclear compounds, for example $K_2[Mo_3Cl_4Br_4].2H_2O$, $Ta_6Br_{14}.7H_2O$, etc. Cationhalogenates (not considered in the present review) are also known; they include a small number of complexes with the general formula $[X'_nX''_m]MX'''_k$, where M = Sb, Bi, Nb, Ta, Ti, and a few other elements, $X'''_k$ is fluorine or chlorine, and $X'_n$ and $X''_m$ are different halogens.

The terminology we have suggested is not completely new. Zintl and Kaiser[1] recommended that compounds of the alkali metals with the elements occupying the four nearest places before each of the noble gases in the Long Periods should be called "polyanion salts". Fialkov[2] also classified polyhalides into cationic and anionic complexes, emphasising that the latter "have much in common with the halogeno-salts which are formed by other non-metallic and multivalent elements", but Grinberg[3] considers it more correct to term, for example, compounds of the type $M[ICl_4]$ tetrachloroiodates.

It is characteristic of anionhalogenates that their complex anion is entirely constructed from halogens with iodine or bromine most often as the central atom. In ions containing different halogens, the more electronegative (the lightest) halogens always are coordinated around the less electronegative (heavier) halogen, which is located at the centre of the complex anion.

It is thought[2] that the formation by any substance of complexes of anionic or cationic type depends considerably on the ability of this substance to show either donor or acceptor properties with respect to the halogens. Thus in reacting with antimony pentafluoride, bromine trifluoride is a donor of fluorine and therefore gives a cationic complex $[BrF_2]^+$ in the compound $[BrF_2][SbF_6]$; however, in reacting with potassium fluoride bromide trifluoride behaves as an acceptor of fluorine, by forming the anionic complex $[BrF_4]^-$ in potassium tetrafluorobromate $K[BrF_4]$.

As Wells and Wheeler[4,5] have already proposed, anionhalogenates are classified according to the number of atoms

of halogens in the molecule of the compound, into trihalogenides, pentahalogenides, etc. Such a formal classification is scarcely justified, since it does not reflect the physicochemical and structural features of the anionhalogenates. We consider it more correct, in conformity with Werner's views[6], to divide the anionhalogenates into two large groups: the isopolyhalogenates (in Werner's terminology, "pure polyhalogenides") and heteropolyhalogenates (in Werner's terminology, "mixed polyhalogenides"). In the last group, taking into account stereochemical data, it is desirable to distinguish between heteropolyhalogenates with a linear anion and heteropolyhalogenates with a square planar anion.

Anionhalogenates are not just of purely scientific interest; they are beginning to find ever-increasing use, both in the technology of the separation of alkali metals with very similar properties, and also in the preparation of extremely pure rubidium and caesium salts[7-14].

## II. GENERAL CHARACTERISTICS OF ANIONHALOGENATES

The anionhalogenates are a class of complexes whose stability in the solid state and in solution is greatly determined by the polarisation interaction of the ions and molecules, and consequently by the dimensions and charge of both the outer-sphere cation and the central atom. It is known, for example, that small cations (lithium and sodium), which are surrounded by an electric field of rather considerable potential, coordinate the most electronegative ligands of the complex anion, thus destroying the latter. Therefore all the attempts to isolate from solution anhydrous anionhalogenates of lithium and sodium were unsuccessful and yielded only the simple halides of these metals. For the same reason, anionhalogenates with doubly-charged‡ (and especially triply-charged) cations are almost unknown. Multicharged ions can here only enter into the composition of anionhalogenate molecules when they are capable of forming large complex cations, for example, $[Be(H_2O)_6]^{2+}$, $[Co(NH_3)_6]^{3+}$, etc., which exhibit low polarising power and therefore have little effect on the coordination of the ligands in the complex anion. Thus Ephraim and Mosimann[17] prepared $[Co(NH_3)_6][I(I)_2]_3$ and salts of tetrachloroiodic acid with beryllium(II), zinc(II), manganese(II), cobalt(II), nickel(II) and the alkaline earth metals with the general formula $[M(H_2O)_6][ICl_4]_2$.[18,19] For this reason when lithium and sodium form anionhalogenates it is always with molecules of solvent, which stabilise the complex owing to the decrease in the energy of interaction of the cation with one of the ligands.

The thermal stability (see Table 1) of the anionhalogenates of a single alkali metal is determined by the nature of the complex anions. The alkali metal diiodoiodates and dibromoiodates have the greatest thermal stability. The thermal stability of the anionhalogenates is also determined by the size of the outer-sphere cation (see Table 1): it increases with the radius of the cation and therefore the caesium salts are the most stable of the alkali metal anionhalogenates. From the standpoint of the electrostatic theory the thermal stability of the anionhalogenates is the greater, the weaker the electric field of the cation, that is, the less its ability towards counterpolarisation, which weakens the chemical bond between the halogen atoms[3].

‡ With the exception[15,16] of $Ba[IF_4]_2$ and $Ba[BrF_4]_2$.

TABLE 1. Dissociation pressures of anionhalogenates, mmHg.

| Compound | Temperature, °C | | | | | Reference |
|---|---|---|---|---|---|---|
| | 25 | 50 | 100 | 150 | 200 | |
| $K[I(I_2)]$ | — | — | 115 | 450 | — | 20 |
| $(NH_4)[I(I_2)]$ | $1.6\cdot10^{-3}$ | — | — | 760(146°) | — | 21,22 |

| $Rb[IBr_2]$ | — | — | 33 | 248 | 760(186°) | 20 |
| $Cs[IBr_2]$ | — | — | — | 39 | 203 | 20 |
| $[K(H_2O)][ICl_2]$ | 12 | 48 | 276 | 704(136°) | — | 20,27 |
| $Rb[ICl_2]$ | — | — | 96.5 | 507 | — | 20 |
| $Cs[ICl_2]$ | — | — | 24(112°) | 114 | 563<br>760(209°) | 20 |
| $K[I(BrCl)]$ | 13.5 | 48 | 166(79°) | — | — | 27 |
| $Cs[I(IBr_2)]$ | $4.8\cdot10^{-3}$ (6°) | — | — | 290(172°) | 655 | 20,30 |
| $(NH_4)[Br(Br_3)]$ | 7 | 32 | — | — | — | 20,31 |
| $Rb[Br(Br_3)]$ | 7(35°) | 18 | 565 | — | — | 20,32 |
| $Cs[Br(Br_3)]$ | — | — | 132 | 760(148°) | — | 20 |
| $(NH_4)[BrCl_2]$ | 105 | 484 | — | — | — | 20 |
| $Rb[BrCl_2]$ | 27 | 60 | 760(93°) | — | — | 20 |
| $Cs[BrCl_2]$ | — | — | 132 | 760(138°) | — | 20 |
| $Rb[Br(BrCl)]$ | 39 | 80 | 760(81°) | — | — | 20 |
| $Cs[Br(BrCl)]$ | — | 15(54°) | 270 | 760(124°) | — | 20 |

This partly explains why complicated complex anions such as $[I(I_2)_4]^-$, $[Br(Br_2)_2]^-$, $[I(I_3Cl)]^-$, $[I(I_5Br)]^-$, etc. are unstable in aqueous solutions of caesium halides but comparatively readily form stable, well-crystallising compounds with large singly-charged organic cations, for example, tetramethylammonium and trimethylphenylammonium. Symmetrically constructed anionhalogenate complex ions with iodine as the central atom are always the most stable (see Table 1). We must note in passing that Ephraim's results[20] on the thermal stability of many anionhalogenates are rather too high owing to the imperfections of the method used. All the alkali metal anionhalogenates decompose on heating close to the melting point but when heated in a sealed capillary they melt at quite definite temperatures.

In aqueous solutions the anionhalogenates undergo complex transformations[33-35]. At first the compound dissociates:

$$Rb[IBr_2] \rightleftharpoons Rb^+ + [IBr_2]^-.$$

Then the complex anion decomposes into its original components:

$$[IBr_2]^- \rightleftharpoons IBr + Br^-.$$

After this, the interhalogen compound formed undergoes hydrolysis:

$$IBr + H_2O \rightleftharpoons IOH + H^+ + Br^-;$$
$$5IOH \rightleftharpoons 2I_2 + IO_3^- + H^+ + 2H_2O.$$

From the increase in the degree of hydrolysis at 25° in 0.05 M aqueous solutions, the complex anions can be arranged in the following series:

$$[ICl_4]^- < [IBr_2]^- < [I(BrCl)]^- < [ICl_2]^-.$$

Moderately concentrated aqueous solutions of anionhalogenates which contain iodine show a strong acid reaction, although it is impossible to detect the liberation of elemental iodine even by spectrophotometry. Evidently here the hydrolysis of the interhalogen compound stops at

the stage of formation of hypoiodous acid, which is stabilised under certain conditions by the addition of a neutral molecule of an interhalogen compound, for example, IOH.IBr.

The hydrolysis is accelerated when the pH is increased and in alkaline solutions it goes to completion, with formation of the corresponding halide, iodate, and iodine (or iodide)[2]. The hydrolysis is suppressed by the introduction into the solution of acids, halogens, iodates, or halides of the alkali metals.

A point worth remembering is that in aqueous solutions some anionhalogenates also undergo partial disproportionation:

$$2Cs[I(BrCl)] \rightleftharpoons Cs[IBr_2] + Cs[ICl_2].$$

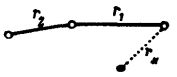
The solvolytic reactions of anionhalogenates have been little studied and the above facts really exhaust all our present knowledge in this field.

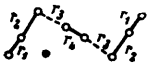
The theory of the absorption spectra of the anionhalogenates which is now being developed allows for the use of the $p$-orbitals of iodine and bromine central atoms in forming bonds[28,36-38]. The position of the absorption bands of the anionhalogenates is almost independent of the outer-sphere cation and solvent and depends mainly on the corresponding energy transitions characteristic of the type of chemical bond involved. Spectrophotometric investigations[39-48] of various solutions of diiodoiodates indicate that the chromophoric group $I^+-I^-$ corresponds to two absorption bands, at 290 and 360 m$\mu$. The chromophoric group $Br^+-Br^-$ in dibromobromates characterises the absorption bands at 265 and 395 m$\mu$,[40,42,49] and the $I^+-Br^-$ chromophoric group in dibromoiodates corresponds to absorption bands[40,42] at 256 and 380 m$\mu$. Analogously, the $I^+-Cl^-$ bonds in dichloroiodates have absorption bands at 227 and 340 m$\mu$,[40,42,50-52] and the $Br^+-Cl^-$ bonds in dichlorobromates absorption bands at 254 and 385 m$\mu$.[42] In its energy transitions the $Br^+-Cl^-$ bond appears to be close to the $I^+-Br^-$ bond. The successive replacement of the ligands (iodine atoms) in diiodoiodates by bromine and chlorine leads to a displacement of the absorption band at 290 m$\mu$ to shorter wavelengths.

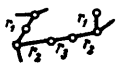
The absorption spectra of anionhalogenates with two different ligands usually show absorption bands corresponding to a few chromophoric groups. For example, water-alcohol solutions of bromochloroiodates have absorption bands at 220, 255, and 455 m$\mu$;[53] in other solvents, the absorption band characteristic of the $I^+-Cl^-$ chromophoric group can be displaced to 237 m$\mu$,[40] and sometimes there is superposition of the absorption bands of the $I^+-Cl^-$ and $I^+-Br^-$ chromophoric groups and the formation of an inflection at 230-250 m$\mu$.[42] In trifluoroacetic acid the absorption band of tetramethylammonium bromochloroiodate, for example, is at 486 m$\mu$.[54] The absorption spectra of the iodochloroiodates show all the frequencies characteristic of both the $I^+-I^-$ and the $I^+-Cl^-$ bonds[40,42,51]. A somewhat different absorption spectrum is observed for bromochlorobromates and iodobromoiodates, where perturbations in the $Br^+-Br^-$ and $I^+-I^-$ chromophoric groups dominate and therefore in the spectra of these compounds there are only absorption bands at 265 and 400 m$\mu$ [42,55] and 280 and 360 m$\mu$ respectively[40,42].

The dependence of the molar extinction coefficient on the nature of the solvent shows that the latter play an important part in the corresponding energy transitions of the excited complex anion. Thus, in alkali metal diiodoiodates and dibromoiodates, as the dielectric constant of the solvent is reduced the molar extinction coefficient for the absorption bands at 290 and 256 m$\mu$ increases linearly. Almost the same thing is observed for the absorption bands at 360 and 380 m$\mu$. Such a linear dependence is not observed for dichloroiodates and bromochloroiodates; here there is another relation: the molar extinction coefficient of the complexes increases (although also not proportionately) with the dipole moment of the solvent.

A study of the infrared and Raman spectra[56,57] allowed the force constants of the bonds of the ions $[Br(Br_2)]^-$, $[ICl_2]^-$, $[ICl_4]^-$, and $[BrCl_2]^-$ to be calculated. It was found that the force constants for the interaction between bonds at an angle of 180° in these ions, equal to $0.26 \times 10^{-5}$-$0.36 \times 10^{-5}$ dyn cm$^{-1}$, can be arranged in a sequence which corresponds qualitatively with the thermal stability sequence: the less stable anionhalogenates correspond with the smaller force constants.



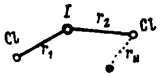


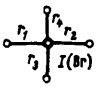


The nature of the chemical bonds in anionhalogenates is discussed mainly in terms of localised covalent bonds (the localised electron pairs method) and molecular orbitals (delocalisation of the $p$-electrons of the halogen atoms)[4,58,59]. Electrostatic theory, which is more graphic, is also sometimes used[3,60-65]. For example, the formation of a bond between the $I^-$ ion and an iodine molecule can be explained by the polarisation of the latter by the $I^-$ ion, the creation of a dipole, and subsequent ion-dipole interaction. This leads to an increase in the interatomic distance in the iodine molecule, from 2.67 Å to 2.82-2.90 Å (see Table 2). The decrease in the electrostatic interaction between the cation and an $[I(I_2)]^-$ anion, associated with the increase in the dimensions of the cation (replacement of ionic bonds by covalent), leads to a decrease in $r_1$ and an increase in $r_2$. In tetraphenylarsonium diiodoiodate, for example, the complex anion is already becoming strictly symmetrical ($r_1 = r_2 = 2.90$ Å) with the greatest value of $r_k$ (see Table 2). The electrostatic interaction of small cations with the $I^-$ ion is so strong that a complex anion is not formed. For that very reason, as we have already mentioned, potassium diiodoiodate exists only as a crystalline hydrate in which the water forms part of an aquocation[66].

From the standpoint of the molecular orbital method[36,37,66,73,77,82-84], the bonding in anionhalogenates is explained by the large value of the overlap integral of the $p$-orbitals, which are extended in the direction of the bonds. The molecular orbitals here are represented by linear combinations of the most distant $p$-orbitals of the halogen atoms. The delocalisation energy calculated for different configurations of the number of halogen atoms involved, was least for the structures of the anionhalogenates which were actually observed. The large value of the integral of the interaction perpendicular to the position of the various $p$-orbitals of one halogen atom in relation to the $p$-orbital of another atom naturally explains the fact that all the valence angles in the anionhalogenates are close to 90°, or to 180° (see Tables 2 and 3).

Some remarks must be made about several anionhalogenate structures. The complex $Cs_2I_8$§ or $2CsI_3.I_2$ [76] consists of two asymmetric $[I(I_2)]^-$ ions which are weakly interacting with one molecule of iodine[4,70,76]. The complex anion $[I(I_2)_2]^-$ or $[I_5]^-$ has a planar, V-shaped form (Table 2)





§ The diamagnetism of $CsI_4$ [85] necessitated doubling the formula, since otherwise this compound would contain an odd number of electrons and be paramagnetic.

TABLE 2. Interatomic distances in isopolyhalogenates.

| Compound | Form of structural species | Interatomic distances $r_1$ | $r_2$ | $r_3$ | $r_k$ | Angle between bonds, deg | Reference |
|---|---|---|---|---|---|---|---|
| $NH_4[I(I_2)]$ |  | 3.10 | 2.82 | — | 3.6 | 177 | 66,69 |

Symbols: see Table 2.

in which the interaction between the iodine central atom and the iodine molecules is much stronger[77] than in the $[I_3]^{2-}$ ion. In the crystal lattice of the complex compound $M[I(I_2)_3]$ each $[I(I_2)]^-$ ion is surrounded by four iodine molecules and each iodine molecule by two $[I(I_2)]^-$ ions (unit cell)[4,79].

In ammonium bromochloroiodate the cation is coordinated with four chlorine atoms and four bromine atoms, which are arranged alternately at the corners of a greatly distorted cube (see Table 3). Hence the structure of this complex is reminiscent of the structure of caesium chloride[90]. Calculation of the structure of the $[I(BrCl)]^-$ ion by the molecular orbital method showed that a linear configuration of this complex anion with a centrally situated iodine atom is the most favourable energetically[97].

The $[ICl_4]^-$ ion has a slightly pyramidal configuration with an iodine atom at the apex of the pyramid (see Table 3). The chlorine atoms lie in a plane 0.02–0.05 Å from the iodine atom and occupying the corners of a somewhat distorted square[82,92,93]. The potassium ions are situated between the planes of such squares and are coordinated with six chlorine atoms at a mean distance of 3.32 Å. Apparently the size of the potassium cation is limiting for the formation of a sufficiently stable crystal lattice of potassium tetrachloroiodate. Hence in all the anionhalogenates which have been considered the angles between the bonds are approximately 90° and 180° and the interatomic distances are always greater than the sum of the covalent radii; this is expressed especially sharply in the isopolyiodates (see Tables 2 and 3).

The results of X-ray structural analysis and studies of isotopic exchange reactions of the halogens[98], which show the equality of all the bonds in the complex anion, provide a basis for assuming that in the latter the central atom is

a positively charged bromine atom or an iodine atom with a valency electron orbital displaced towards the ligands [2,37,38,99]. This is also suggested by the formal charges of the halogens which are constituents of the complex anion. Thus the charges of the iodine, bromine, and chlorine atoms in the $[I(BrCl)]^-$ ion are respectively [97] +0.07, -0.045, and -0.62. The formal charge in the $[I(I_2)]^-$ ion for the two extreme iodine atoms is -0.5 whereas for the central atom it is almost zero. In the $[ICl_2]^-$ ion the formal charge of each chlorine atom [4,37] is -0.55, and that of the iodine is +0.11. In the $[ICl_4]^-$ ion the chlorine atom has a formal charge of -0.52 and the iodine atom +1.07.

In several chemical properties there is great similarity between the halogens and cyanogen $(CN)_2$ and thiocyanogen $(NCS)_2$, which may be able to form both independent complexes with the alkali metals analogous to the anionhalogenates, for example $Rb(NCS)_3$, and also mixed complexes in which the halogens participate.

## III. ISOPOLYHALOGENATES

### Difluorofluorates

The alkali metal difluorofluorates, which contain the anion $[F(F_2)]^-$, have not been prepared. Repeated attempts to make them [100-107] by the action of fluorine free of hydrogen fluoride on the alkali metal chlorides, bromides, and iodides at 15–250° usually led either to the production of compounds with a variable fluorine concentration, for example, $RbF_{1.96-1.98}$, or to the isolation of compounds of the type $M[ClF_4]$ and $M[IF_6]$.

### Dichlorochlorates

The alkali metal dichlorochlorates have also not yet been obtained. Various attempts to isolate them from aqueous solutions were unsuccessful [32,108-115] evidently on account of the low degree of conversion (0.74%) of $Cl^-$ ions into $[Cl(Cl_2)]^-$ ions in aqueous hydrochloric acid solutions by the reaction:

$$Cl_2(gas) + Cl^- \rightleftharpoons [Cl(Cl_2)]^-.$$

Zimmerman and Strong [113] found the instability constant of the $[Cl(Cl_2)]^-$ ion to be 5.23. The formation of the complex anion is possible also during the dissociation of iodine trichloride by the equation $ICl_3 \rightleftharpoons I^+ + [Cl(Cl_2)]^-$. On dilution of the solution the $[Cl(Cl_2)]^-$ ion decomposes with evolution of chlorine [115].

Solid dichlorochlorates have been obtained only with large cations, such as tetramethylammonium, tetraethylammonium, etc. [116]

### Dibromobromates

These are a more stable class of compounds than the dichlorochlorates. Thus, Ray [117] isolated hydrogen dibromobromate $H[Br(Br_2)]$ from a concentrated solution of bromine in 1.5 *N* hydrobromic acid below 0°, as yellow, extremely unstable crystals. As long ago as 1903, Rikhter-Rzhevskaya [118] suggested the formation of a compound in the $HBr-Br_2-H_2O$ system. The heat of formation of the complex acid at 25° is 1.29–2.03 kcal $mole^{-1}$. [49,117,119-121]. Therefore the absence [122] of compounds of the type $HBr_n$ in the $HBr-Br_2$ system below -50° is improbable.

Many investigators [109,123-133] have studied the equilibrium:

$$Br^-.aq + Br_2(liquid) \rightleftharpoons [Br(Br_2)]^-.aq.$$

It was found that the equilibrium constant determined either by the distribution of bromine between carbon tetrachloride and aqueous solutions (0.1–0.5 moles per 1000 g $H_2O$) [109,123,124,130,131] or from the solubility of bromine in aqueous 0.01–1.0 *N* solutions of sodium and potassium bromides [125-130,132,134,135] is 16–20.7 $mole^{-1}$ litre at 25–33°; the most accurate results [125] give 16.0 $mole^{-1}$ litre at 25°.

Ammonium, rubidium, and caesium dibromobromates have been isolated as solids but the existence of potassium and sodium dibromobromates has been established only in aqueous solutions. The instability constants obtained by various investigators [49,120,127,134,136,137] for aqueous solutions of sodium and potassium dibromobromates at 0–25° range from $4.4 \times 10^{-2}$ to $6.2 \times 10^{-2}$.

In studying the $KBr-Br_2-H_2O$ system at 0°, 25°, and 85°, Harris [138] and Zernike and coworkers [139] found only the crystalline hydrate $KBr_6.1.5H_2O$¶, which separates from solutions rich in bromine as long, red needles, m.p. 25.85°. An analogous sodium compound was not obtained. These reliable investigations [138,139] raise doubt about the earlier reports [20,114,130,131,140-142] of the possibility of obtaining at 0–85° potassium dibromobromate and tetrabromobromate as individual chemical compounds. The existence of a series of potassium polybromobromates in aqueous solution is postulated, particularly the tetrabromobromate [135], with an instability constant of $2.46 \times 10^{-2}$. Evidently, during the separation of the polybromobromates from aqueous solutions destruction of the aquocation occurs, with simultaneous breakdown of the molecule; this is shown indirectly by the fact that dry potassium bromide does not react with bromine [143].

Ammonium, rubidium, and caesium dibromobromates are usually obtained by the addition of bromine, in slight excess (2–3%) of the stoichiometric quantity, to hot, concentrated, aqueous solutions of the bromides. On cooling the solution to 0°, very hygroscopic, orange-red crystals separate [5,21,108,143-145]. These complexes can also be obtained by a dry method – either by heating stoichiometric proportions of the alkali metal bromide and bromine until a melt is formed [31,32,143,145], or by the action of bromine vapour on the bromides [143].

Caesium dibromobromate was the only compound observed in a study [147] of the $CsBr-Br_2-H_2O$ system at 0° and 25°. The compounds taken earlier [31,146] to be $Cs[Br_4]$ and $Cs[Br(Br_2)_2]$ do not exist and the solid phase which was then isolated must be considered to be a mixture of bromine-10-water and caesium dibromobromate; Rae [145] and Cremer and Duncan [148] have also noted that it is impossible to obtain $Cs[Br_4]$.

Ether and absolute ethanol decompose ammonium, rubidium, and caesium dibromobromates [33,149] with precipitation of the corresponding bromide. Complex anions containing more than three bromine atoms can exist in solution, from which they can be isolated as compounds with large organic cations. For example, tetramethylammonium octabromobromate is known [150]; it melts congruently at 56.7°.

¶ Because of the diamagnetism of $KBr_6.1.5H_2O$, the formula $2KBr.5Br_2.3H_2O$ was proposed for it.

Diiodoiodates

These are the most studied of all the alkali metal anion-halogenates. Hydrogen diiodoiodate was first obtained as a solid film[46] and then as red crystals on cooling a concentrated solution of iodine in 1.5 *N* aqueous hydriodic acid to -4°.[117] The compound $H[I(I_2)].4C_6H_5CN$ is also known[151].

The equilibrium $I^- + I_2(solid) \rightleftharpoons [I(I_2)]^-$ has been studied frequently[39,152-162] in aqueous and non-aqueous solutions. The instability constant of the $[I(I_2)]^-$ ion, determined at 25° from the distribution of iodine between the aqueous phase and organic solvents (carbon disulphide, carbon tetrachloride, nitrobenzene, etc.) was found to be $1.3\times10^{-3}$–$1.43\times10^{-3}$ for 0.03–1.0 *N* KI solution[59,124,152,153,157,158,163-165]. The heat of the reaction $I_2(solid) + I^-.aq \rightleftharpoons [I(I_2)]^-.aq$ at 25° is 0.893 kcal mole$^{-1}$.[166-169] The heats of formation of the alkali metal and ammonium diiodoiodates in aqueous solutions at 10–20° increase with the atomic weight of the cation[153].

In addition to the diiodoiodate anion, the presence of the ions $[I_{14}]^{3-}$, $[I_4]^{2-}$, and $[I_6]^{2-}$ in aqueous solutions has also been established[155]; their instability constants at 20–25° are 4.5, $1.2\times10^{-2}$, and $1.6\times10^{-6}$ respectively. However, complexes with the first two anions could not be isolated from the solutions; the third anion is evidently a dimer of the $[I(I_2)]^-$ ion, as Job suggested[49,170].

Study of the electrical conductivity of solutions of the alkali metal iodides and iodine in nitrobenzene have indicated the possible existence of di-, tetra-, hexa-, and octa-iodoiodates[160,161,171].

Lithium diiodoiodate was obtained only as the double salt [sic] with benzonitrile, $Li[I(I_2)].4C_6H_5CN$, which forms[151] dark green acicular crystals unstable in moist air and melting at 92.5°. The analogous lithium diiodoiodate–*o*-toluonitrile compound is known[151]. According to Dawson[161,171] the formation of lithium tetra-, hexa-, and octa-iodoiodates is possible in nitrobenzene saturated with iodine.

Free sodium diiodoiodate has not been isolated. Only sodium iodide dihydrate, with iodine as impurity, crystallises from solutions containing sodium iodide and iodine at 25°.[172-175] On lowering the crystallisation temperature to 10–12°, a product separates which Grace[176] thought to be sodium diiodoiodate tetrahydrate. A study[177] of solubility in the sodium iodide–iodine–water system at 0° showed the absence of solid phases corresponding to sodium diodoiodate; the compounds obtained were the double salts $NaI.Na[I(I_2)].6H_2O$ and $Na[I(I_2)].Na[I(I_2)_2].4H_2O$. The later results of Briggs and coworkers[178], who studied the same system at 0° and -15° support the existence of rather complex solid phases, of low stability and greatly hydrated, of the type $Na_4I_{14}.(13-15)H_2O$, $Na_5I_{11}.(17-19)H_2O$, and $Na_2I_8.(10-11)H_2O$, m.p. 16.4°, 2°, and -7° respectively. The first of these phases approximates in composition to sodium diiodoiodate tetrahydrate.

With strongly polar organic solvents, such as nitriles and nitro-compounds of the aromatic series, sodium diiodoiodate forms rather stable addition products which crystallise well and contain two molecules of solvent[151].

Potassium diiodoiodate separates as extremely hygroscopic azure-black (or dark brown) crystals of cubic or prismatic form when a concentrated KI solution containing the stoichiometric amount of iodine is cooled to 0°.[179-183]

Careful study of the potassium iodide–iodine–water system at 0° and 25° by several investigators[155,184-189] has shown that potassium iodide and iodine can react in aqueous solution, forming only two incongruently melting complexes $K[I(I_2)].H_2O$ and $K[I(I_2)_3].H_2O$. Potassium diiodoiodate monohydrate has two modifications[189], m.p. 12.3° and 30°; potassium hexaiodoiodate monohydrate melts at 38°. It has been shown[190] that small quantities of a complex close in composition to potassium octaiodoiodate can form in 5.4 *N* aqueous KI saturated with iodine.

Potassium diiodoiodate was not observed[191,192] in the solid phases which separate in the potassium iodide–iodine–40–60% ethanol (or methanol) systems at 25°.

Potassium diiodoiodate readily forms various addition products with organic solvents. It was found[171,172,176,193,194] that $K[I(I_2)].C_6H_6$, $K[I(I_2)_2].2C_6H_6$, and $K[I(I_2)_4].3C_6H_6$ separate in the solid phase in the potassium iodide–iodine–benzene system at 6–25°.

The formation of stable solvated potassium polyiodoiodates in non-polar benzene is very interesting when it is considered that such solvation is characteristic only for organic solvents with a high dipole moment. Incongruently melting brown-green crystals of $K[I(I_2)].2C_6H_5CN$ separate from benzonitrile containing potassium iodide and iodine[151]. When nitrobenzene, nitromethane, and some other nitro-compounds are saturated with iodine and potassium iodide, a viscous, dark brown liquid is formed, with a constant ratio of these components, corresponding to potassium octaiodoiodate, which could not be isolated[161,195-198].

The ease of formation of potassium diiodoiodate in aqueous and non-aqueous solutions and the difficulty of obtaining it in the absence of a solvent† are linked with the solvation of the cation, which results in an increase in its volume and a decrease in its polarising action on the complex anion[199-201]. With large cations, stable isopolyiodates are formed in the absence of a solvent[173,198,202]. Thus in the $(CH_3)_4NI$–$I_2$ system the formation of tetramethylammonium octaiodoiodate, m.p. 106.4°, has been shown[173]; it crystallises from benzene as a finely crystalline green-brown powder, which is stable in the air and is not decomposed by water[200,203].

The formation of potassium diiodoiodate in the potassium iodide–iodine system between 75° and 160° and at iodine concentrations of 47–100 mole % has not been established[204-206].

Ammonium diiodoiodate crystallises[181] from aqueous solutions as dark blue crystals, density 3.749 g cm$^{-3}$, which slowly deliquesce in the air. Studies[208,209] of the ammonium iodide–iodine–water system at 0° and -15° showed the existence of incongruently melting diiodoiodates (anhydrous and trihydrate) and tetraiodoiodate monohydrate, with decomposition temperatures 175.7° and 9.8° respectively. The existence of the octaiodoiodate in nitrobenzene saturated with ammonium iodide and iodine has been demonstrated[171], whereas in benzene, toluene, and benzonitrile at 6–25° complexes other than the unsolvated ammonium diiodoiodate were not observed[151,210].

Rubidium diiodoiodate separates as red-brown rhombs, readily soluble in water, absolute alcohol, and ether[5,146,211-214]. Its solubility[23] in water is 77.5 wt. % at 25° and 84.1 wt. % at 40°.

† The existence of anhydrous and non-solvated potassium diiodoiodate is doubted[199,206,207].

Investigation[173,185,213] of the rubidium iodide–iodine–water system showed the existence of only one anhydrous rubidium diodoiodate, congruently soluble in water at temperatures between 7.8° and 132°.

Hexa- and octa-diodoiodates including four molecules of the solvent have been isolated at 6° from benzene containing rubidium iodide and iodine, but only rubidium diiodoiodate from toluene[24,172,173,176]. In the absence of water or an organic solvent reaction of iodine and RbI was not observed at 60–238°.[205,214]

Caesium diiodoiodate is deposited from aqueous solutions as rhombs or acicular blue-black crystals which become tabular after recrystallisation from absolute alcohol[108,185,211]. Caesium diiodoiodate is stable at room temperature[211]: decomposition with formation of free iodine starts at 115°. $Cs[I(I_2)]$ dissolves incongruently at 25°.[108]

Studies[215,216] of the caesium iodide–iodine–water system at 25° showed that only two[217,218] isopolyiodates can be isolated from aqueous solutions: the diiodoiodate and the polynuclear compound $Cs_2[I_8]$. The individuality of the latter was established not just by chemical and X-ray analyses[76,215] but also by measurement of the rate of loss of iodine from mixtures of caesium iodide and iodine over sodium hydroxide[219].

In studying[176,220] the caesium iodide–iodine–benzene (toluene) systems at 6° and 25°, $Cs[I(I_2)]$ and $Cs_2[I_8]$ were obtained, with heats of dissociation of -17.50 and -15.8° kcal mole$^{-1}$ respectively. Furthermore, a solvate of composition $Cs[I_{9-10}].(1.5–2.0)C_6H_6$, very unstable in air, was isolated from benzene[176,220]; its existence had been mentioned earlier[171,172].

Interesting results have been given[221] about the formation of the compounds $Cs[I(I_2)]$ and $Cs_2[I_8]$ in the caesium iodide–iodine system, which was studied between 60° and 303°.

Yamatera[222] recently suggested the existence of double diiodoiodates of rubidium and caesium: $2Cs[I(I_2)].Rb[I(I_2)]$, $3Cs[I(I_2)].2Rb[I(I_2)]$, and $Cs[I(I_2)].Rb[I(I_2)]$, but they could not be isolated.

Thallium diiodoiodate, isomorphous with $Rb[I(I_2)]$ and $Cs[I(I_2)]$, and tetraiodoiodate are known[30,223,224]. Thallium diiodoiodate separates as black-violet crystals during slow evaporation of a methanol solution of TlI and iodine in a molar ratio between 1 : 1.18 and 1 : 1.30. Its aqueous solutions exhibit the tautomeric equilibrium $Tl[I(I_2)] \rightleftharpoons TlI_3$, which is sharply displaced to the right, owing to the partial oxidation of thallium by iodine and the formation of the stable $[TlI_4]^-$ complex ions in the presence of a large excess of iodine and alkali metal halides: the stability of the alkali metal tetraiodothallates rises from caesium to lithium.

The thallium(I) tetraiodoiodate isolated by Mironov[223] forms light, glistening plates, the colour of iodine, which decompose to TlI and $I_2$ when heated to 60–100°.

## IV. HETEROPOLYHALOGENATES WITH A LINEAR ANION

The common main feature of these compounds is their stereochemical similarity, based on linearity of the complex anion, which consists of three halogen atoms. In the crystals these elongated complex anions are, in the presence of potassium, rubidium, or caesium cations, situated parallel to some plane but at right angles to one another. Therefore the crystals of the heteropolyhalogenates with a linear anion are characterised by high negative double refraction. From the standpoint of the localised electron pair theory[225], the mutual orientation of the chemical bonds in the three-halogen linear anion can be represented on the basis of $dsp^3$ hybridisation in the form of a trigonal bipyramid with two halogen-ligands at its vertices and with three lone pairs of electrons in the plane of the central section.

### Dichloroiodates

The dissolution of iodine monochloride in concentrated hydrochloric acid gave[35,45,143,226–231] a dark brown liquid with 80% $H[ICl_2]$. The instability constant of hydrogen dichloroiodate[230] in perchloric acid at 25° is $6 \times 10^{-3}$.

According to recent work[232] solutions of iodine monochloride in hydrochloric acid of various concentrations contain only the complex acid hydrogen hexachloroiodate(V).

Of the alkali metal dichloroiodates, the lithium compound has not yet been obtained and the possibility of obtaining sodium dichloroiodate is doubted[35,143,148,223].

Potassium dichloroiodate[5,37,38,183,234] crystallises as a monohydrate of low stability[234], and the anhydrous compound can be obtained by drying this over magnesium perchlorate[37]. Potassium dichloroiodate was also found to be formed in the KCl–ICl system in nitrobenzene[235,236] and in studying electrical conductivity in the KCl–ICl system[235,237,238]. A thermogravimetric study of this compound showed that it decomposes at 108–110°: the iodine monochloride formed boils off[2]. It has been suggested that a compound of the type KCl.2ICl exists[239].

Crystals of ammonium dichloroiodate are extremely hygroscopic, gradually lose iodine monochloride in air, and are readily soluble in water. There is 87% hydrolysis of ammonium dichloroiodate in its 0.05 *N* aqueous solution at 25°.[35]

Rubidium dichloroiodate crystallises[5,20,37,143,240] as bright yellow anisotropic hexagonal crystals, whose solubility[241] in water is 54.93 wt.% at 25°.

A study[241] of the rubidium chloride–iodine chloride–water system at 25° showed that the solubility isotherm consists of an RbCl crystallisation branch, of insignificant extent, and the much longer crystallisation branch of the congruently soluble anhydrous rubidium dichloroiodate which is formed in the system.

On heating, rubidium dichloroiodate has been found[241] to be stable up to 136°, above which it decomposes with formation of RbCl and liberation of ICl. The endothermic effect associated with the thermal decomposition of $Rb[ICl_2]$ is at 210°.

Caesium dichloroiodate, according to Wells and Penfield[108], is dimorphous. Crystals of the hexagonal modification separate as hexagons when $Cs[ICl_2]$ is recrystallised from aqueous solutions. The same structure is also observed with caesium dichloroiodate crystals, obtained on passing chlorine into 20% caesium chloride solution containing iodine which has been heated almost to boiling[183,240].

A study[37,88] of the crystal structure of caesium dichloroiodate obtained from aqueous solutions containing various amounts of caesium chloride did not confirm the polymorphism of this compound.

Thorough investigations[242] of the solubility of caesium and rubidium dichloroiodates in hydrochloric acid of various concentrations showed that the solubility curves have minima, at 12.5 M HCl, with concentrations of 2.59 and 10.83 g per 100 ml solution respectively at 0°. In studying the solubility of alkali metal chlorides in iodine monochloride it was found[243] that the golden yellow residues from the evaporation of the filtrate were the dichloroiodates of the corresponding metals. However, the stabilities given[243] for the compounds differ considerably from the results of other authors.

The formation of alkali metal dichloroastatates $M[AtCl_2]$ in solution has been established[244].

## Dibromoiodates

The alkali metal dibromoiodates correspond with the acid $H[IBr_2]$, aqueous solutions of which were obtained by Cremer and Duncan[35,143] on dissolving iodine bromide in concentrated hydrobromic acid, as a dark red viscous liquid containing 6% water. The instability constant of hydrogen dibromoiodate(I)[245,246] at 25° is $2.7 \times 10^{-3}$–$3.3 \times 10^{-3}$. Of all the alkali metal dibromoiodates, only the lithium salt has not been obtained, although the possibility of preparing sodium dibromoiodate is doubted[35,148,218].

Potassium dibromoiodate crystallises[5,20,27,29] as the monohydrate, which forms red rhombs, decomposing in air[143,148,183,218,247].

The formation of potassium dibromoiodate was established in physicochemical investigation of the various systems. $KI-Br_2-I_2$ (by electrical conductivity[248]), $KBr-IBr-C_6H_5NO_2$ (by cryoscopy and electrical conductivity[249]), and KBr–IBr.[250]

Thermographic investigation of potassium dibromoiodate showed[2] that partial decomposition of this complex starts at 120°, with a small endothermic effect; complete decomposition takes place at 160°, the iodine bromide formed boiling off.

Potassium dibromoiodate is readily soluble in water (1200 g dissolve in 100 ml water at 18°[27]), decomposes in alcohol and ether, with precipitation of potassium bromide and reacts both with ammonia[251] and with amines, to form addition products of the type $K[IBr_2].2NH_3$, and with ozone and chlorine[148] by the reactions:

$$K[IBr_2] + O_3 \rightarrow KIO_3 + Br_2;$$

and

$$K[IBr_2] + Cl_2 \rightarrow K[ICl_2] + Br_2.$$

These reactions confirm the results of other investigators (see Section II) concerning the coordinating ability of the postively charged iodine central atom.

Ammonium dibromoiodate was obtained as dark red prisms[20,148,218,247]. This compound, unlike the analogous potassium compound, is stable in absolute ethanol, ether, and carbon tetrachloride. Therefore these solvents are sometimes used[143,252] as media for its preparation.

Rubidium and caesium dibromoiodates have been isolated from solutions as red rhombs and prisms[5,21,148,151,218,253,254], which exhibit very low birefringence (the refractive index of $Rb[IBr_2]$ is[255] 1.418). There is a complete analogy between caesium, rubidium, ammonium, and potassium dibromoiodates as regards conditions of preparation and chemical properties[256].

A study of solubility[255] in the rubidium bromide–iodine bromide–water system at 25° showed that iodine and rubidium bromides react to form only one rubidium dibromoiodate, which is anhydrous and congruently soluble. Thermographic and thermogravimetric investigations[255] showed that decomposition, with liberation of iodine bromide, starts at 60° and ends at 238°. The endothermic effect due to this decomposition is at 233°.

The stability of the alkali metal dichloro- and dibromo--iodates in carbon tetrachloride does not correspond with their thermal stability: in carbon tetrachloride at 25° dichloroiodates are more stable[27]. The equilibrium concentration of iodine monochloride in carbon tetrachloride for potassium, ammonium, rubidium, and caesium dichloroiodates is: $2.9 \times 10^{-3}$, $5.7 \times 10^{-2}$, $3.5 \times 10^{-4}$, and $6.0 \times \times 10^{-5}$ M respectively; those of iodine monobromide under the same conditions for potassium, ammonium, rubidium, and caesium dibromoiodates are $4.7 \times 10^{-2}$, $8.4 \times 10^{-3}$, $1.0 \times 10^{-3}$, and $1.4 \times 10^{-4}$ respectively[27].

## Dichlorobromates

Ammonium, rubidium, and caesium dichlorobromates crystallise as bright yellow prisms. They can be made by passing chlorine into hot (50–60°) concentrated aqueous solutions of ammonium, rubidium, and caesium chlorides containing the equivalent amount of bromine[5,20,108,240]. Caesium dichlorobromate can also be made by a "dry method"[143]. Rubidium dichlorobromate decomposes, without melting, at 110°, with evolution of bromine chloride. Caesium dichlorobromate can be recrystallised from aqueous alcoholic solutions, but it breaks down completely in absolute ethanol and ether.

It is suggested[257] that in the dissolution of bromine monochloride in hydrochloric acid the complex acid $H[BrCl_2]$ is formed, with instability constant[117] 0.058 at -1.5°.

## Iodochloroiodates

These compounds of the alkali metals and ammonium are derivatives of the acid hydrogen iodochloroiodate, $H[I(ICl)]$, which has not been isolated in the free state. Its instability constant in 0.06–6.5 M HCl is[44,51,117,258,259] 0.6–0.81 at 25° and 0.543 at 3.8°. The instability constants of lithium, sodium, and potassium iodochloroiodates in 0.05–6.0 M aqueous solutions of the chlorides of these metals are[49,51,142,260-263] respectively 0.79, 0.44–0.77, and 0.43–0.67 at 25°.

It is worth mentioning that the values of the instability constants[258,264,265] determined by different authors differ considerably; it is clear that the constant depends not only on the concentration of hydrochloric acid or metal chloride but also on the nature of the extractant used to determine the distribution of iodine between the two phases. Some investigators[240] assume that under these conditions the ions $[I(I_2)_2]^-$ and $[ClI_4]^-$ are formed as well as $[I(ICl)]^-$.

The alkali metal and ammonium iodochloriodates exist only in solutions; attempts to obtain them in the free state have been unsuccessful[5,41,108,260,265-267]. Study of the equilibrium in the potassium chloride–bromine–water system at ordinary temperatures showed that only potassium chloride separates in the solid phase[264,265].

Obviously the polarising action of even a cation as large as caesium is completely sufficient to destroy the coordination of the chlorine and iodine atoms around the iodine central atom. Only tetraethylammonium iodochloroiodate has yet been isolated[116].

### Iodobromoiodates

The alkali metal iodobromoiodates can also be considered as derivatives of a complex acid, H[I(IBr)], which Ray[117] succeeded in obtaining at -4° as orange-red crystals (mixed with ice) from concentrated solutions of iodine in 1.5 *N* aqueous hydrobromic acid. At ordinary temperatures this acid is unstable[41,265]; its instability constant at 25° is[258,268] 0.083. It is thought[259,269] that the anion $[I(IBr)]^-$ may be the product of the dissociation of dibromoiodates, by the reaction:

$$2[IBr_2]^- \rightleftharpoons [I(IBr)]^- + [Br(Br_2)]^-.$$

Lithium, sodium, potassium, ammonium, and rubidium iodobromoiodates are unknown in the solid state and the existence of lithium iodobromoiodate even in solution has not been established. The instability constant of sodium iodobromoiodate in 0.9–8.3 *N* aqueous KI at 25° is[126,260,264] 0.069–0.081. In the sodium bromide–iodine–benzene system at 6° the formation of sodium iodobromoiodate was not established[24].

The instability constant[49] of potassium iodobromoiodate in 0.02–8.3 *N* aqueous potassium bromide at 25° is[124,260,262–264] 0.065–0.078.

The formation of complexes was not observed in the potassium (or rubidium) bromide–iodine–benzene systems[24] at 6° or in the potassium bromide–iodine–carbon tetrachloride system[27] at 25°.

Caesium iodobromoiodate is the only alkali metal compound of this type to have been isolated in the free state; it was obtained as reddish-brown rhombs undergoing marked hydrolysis in water and solvolysis in ether[10,108,270].

The study[24,30] of equilibria in the caesium bromide–iodine–benzene (toluene) system at 6° has shown the existence of only one unsolvated caesium iodobromoiodate with a dissociation pressure of 0.00486 mmHg at 6°. According to some results[265] the formation of a compound of the type $CsBr.12I_2$ is possible in a solution containing caesium bromide and iodine.

### Bromochlorobromates

It has been shown[55,117,134,271] that the complex acid H[Br(BrCl)] is formed in hydrochloric acid solutions containing bromine; its instability constant[258] is 0.708 at 30°.

Study of the equilibria at -1° in the sodium (potassium) chloride–bromine–water systems has shown that sodium and potassium bromochlorobromates may exist in aqueous solutions, with instability constants of 0.18–0.77 and 0.17–0.91 respectively at 25–30°.[124,134,263] Only the rubidium and caesium bromochlorobromates have been obtained in the free state[42,108].

### Bromochloroiodates

This group of anionhalogenates is the most interesting since the complex anion consists of three different halogens. An acid corresponding to these compounds is known, H[I(BrCl)], formed to the extent of 83% acid and 17% water during the dissolution of iodine monobromide in concentrated hydrochloric acid[143]. The instability constant[53,230] of the complex anion at 25° in 0.05–0.09 *N* HCl and in aqueous alcoholic media is 0.022.

Only the ammonium, rubidium, and caesium bromochloroiodates have been obtained from aqueous solutions as individual chemical compounds and described.

A spectrophotometric investigation[53] of the reaction of KCl with iodine monobromide in aqueous alcoholic solutions showed that within the range of component concentrations 0.005–0.5 M potassium bromochloroiodate is not formed, but the complexes 7KCl.3IBr, 3KCl.2IBr, and 2KCl.3IBr.

Ammonium, rubidium, and caesium bromochloroiodates have been isolated as long garnet-red or reddish-orange prisms[5,90,123,272], incongruently soluble in water. They are rather stable when stored in sealed vessels, but in air they gradually lose iodine monobromide and are converted into the chlorides. Rubidium bromochloroiodate decomposes at 231.5° into rubidium chloride and iodine monobromide[9,272]. In aqueous alcoholic solutions containing rubidium chloride and iodine monobromide at concentrations of 0.001–0.01 M, the formation of compounds of the type RbCl.2IBr is possible[53]. The conventional solubility of rubidium and caesium bromochloroiodates in water is 34.7 and 3.7% at 0°, and 56.8 and 6.3% at 20° respectively[272].

When rubidium and caesium bromochloroiodates are recrystallised from aqueous solutions, their molecular compositions change, approaching that of dibromoiodates[13,108]. This behaviour of bromochloroiodates is due to their partial disproportionation by the reaction:

$$2[I(BrCl)]^- \rightleftharpoons [IBr_2]^- + [ICl_2]^-$$

and the lower solubility of the dibromoiodates.

### Hexafluoroiodates

The hexafluoroiodates can be considered as derivatives of the hexaiodoiodates $M[I(I_2)_3]$, in which fluorine atoms replace iodine atoms. They evidently have a Γ-shaped anion, with a structure similar to that of the $[I(I_2)_3]^-$ ion (see Table 2).

Lithium hexafluoroiodate is unknown and sodium hexafluoroiodate could not be obtained by fluorination of sodium iodide[104,273]. Potassium hexafluoroiodate[14,16,273–266] separates as white crystals in a very low yield on cooling a saturated (97–98°) solution of potassium hydrogen fluoride, fluoride, or nitrate in iodine pentafluoride. Carbon tetrachloride does not affect potassium hexafluoroiodate, but dioxan brings about slight decomposition of it[16]. The compound is stable up to 150–200° above which it gives iodine pentafluoride and potassium fluoride.

The preparation of rubidium and caesium hexafluoroiodates is identical with that of the potassium salt, but here it is possible to isolate other complexes as well[273]: $2RbF.IF_5$ and $Cs[IF_4].IF_5$. The last of these decomposes at 60° into $IF_5$ and $Cs[IF_4]$. Rubidium hexafluoroiodate can also be obtained by fluorination of rubidium iodide at 100–300° in the absence of hydrogen fluoride[104].

### Other Heteropolyhalogenates

Bode and Klesper[104] obtained rubidium hexafluorobromate by fluorinating rubidium bromide with elemental fluorine

above 200°. They did not establish the existence of potassium and sodium hexafluorobromates. Hexafluorochlorates have not been obtained. In the fluorination of rubidium chloride a compound $Rb_3[ClF_6]$ was isolated[104], which later investigators[105] found to be a double salt $2RbF.Rb[ClF_4]$. Alkali metal hexaiodobromates have not been obtained in the free state. From solutions of tetramethylammonium tetraiodobromate in boiling alcohol saturated with iodine, dark green crystals of $[(CH_3)_4N][BrI_6]$, melting at 109°, could be isolated[116,120].

## V. HETEROPOLYHALOGENATES WITH A SQUARE PLANAR ANION

The principal common feature of the anionhalogenates described below is the structure of their five-halogen anion (see Section II). Mooney[92] considered that the bonds in this anion must be formed by the combination of the $sp^3d^2$ orbitals and belong to the octahedral type. Two positions in the octahedron around the atom of iodine (or bromine) are apparently occupied not by atoms but by two lone pairs of electrons of the iodine (or bromine) atom: one above the plane of, for example, the $[ICl_4]^-$ ion and the other below this plane[225]. Hence the structures of the anionhalogenates of this group are reminiscent of the structures of the octahedral complex anions $[TeBr_6]^{2-}$, $[SnCl_6]^{2-}$, $[PbCl_6]^{2-}$, etc. Actually, the I–Cl interatomic distance of 2.34 Å falls within the limits of the Te (or Sn, Pb, Se, Pt)–Cl interatomic distances, which vary between 2.32 and 2.54 Å.

### Tetrafluoroiodates

Potassium, rubidium, and caesium tetrafluoroiodates are obtained as white powders which decompose in moist air. The stability of these complexes depends greatly on the size of the cation[105,273]. It has been found that potassium tetrafluoroiodate can be isolated from its solution in $IF_5$ only at temperatures below 70°, and rubidium tetrafluoroiodate at 70°. Caesium tetrafluoroiodate forms a compound with $IF_5$ of the type $Cs[IF_4].IF_5$, separating below 60°. When $Cs[IF_4].IF_5$ is heated to 100° in a vacuum, it decomposes with the formation of caesium tetrafluoroiodate. Caesium tetrafluoroiodate separates immediately from its solution in iodine pentafluoride above 120°.

Potassium tetrafluoroiodate slowly decomposes even at room temperature, with loss of iodine; therefore the chemical analysis of this compound gives a low (2–3%) figure for iodine and a high one for fluorine. Rubidium and caesium tetrafluoroiodates are more stable.

### Tetrachloroiodates

The alkali metal and ammonium tetrachloroiodates are salts[19,31,143,146,278,279] of the acid hydrogen tetrachloroiodate(III), $H[ICl_4].4H_2O$. This compound, which Caglioti[280] first isolated in the free state, crystallises as orange-yellow hygroscopic plates, not very stable in air. There is 13% hydrolysis of $H[ICl_4].4H_2O$ in its 0.05 *N* aqueous solutions at 25°.[35] In 4–6 *N* hydrochloric acid, ~4.5% of the iodine trichloride present in the form of hydrogen tetrachloroiodate dissociates into iodine chloride and chlorine[281,282].

Hydrogen tetrachloroiodate(III) is the only anionhalogenate acid for which all the alkali metal salts are known.

Lithium tetrachloroiodate is isolated as the tetrahydrate, which forms yellow hygroscopic acicular crystals when chlorine is passed into a suspension of iodine in a concentrated aqueous solution of lithium chloride[146,247,283]. In air, lithium tetrachloroiodate rapidly deliquesces give a yellow liquid.

Sodium tetrachloroiodate[247,283] crystallises as the dihydrate, which is not very stable in air, and forms pale orange rhombs.

Potassium tetrachloroiodate was first obtained as the monohydrate by Filhol[278,279]. It forms golden-yellow crystals[27,143,146,283] which are monoclinic, with lattice parameters[93]: $a = 13.282$, $b = 14.351$, $c = 4.284$ Å, $\beta = 95.72°$, isomorphous with $K[AuCl_4]$.[25] To obtain the anhydrous product the monohydrate was held in a desiccator over phosphorus pentoxide at 4°, or was dried at 40–50° in a stream of chlorine to constant weight[37,38].

The heat of dissociation of the anhydrous potassium tetrachloroiodate in the range 67.5–85° is 29.5 kcal mole$^{-1}$. The dissociation proceeds in two stages[26,218,247]:

$$K[ICl_4] = K[ICl_2] + Cl_2,$$
$$K[ICl_2] = KCl + ICl,$$

but at 15° iodine trichloride can be isolated[25].

A redox equilibrium is characteristic for solutions of alkali metal tetrachloroiodates:

$$[ICl_4]^- \rightleftharpoons [ICl_2]^- + Cl_2,$$

by virtue of which their concentrated aqueous solutions attack all metals, including gold and platinum, and also react with iodides, with liberation of iodine[35,284]:

$$[ICl_4]^- + 3I^- \rightarrow 2I_2 + 4Cl^-.$$

Ammonium tetrachloroiodate, which crystallises with three molecules of water, has similar properties[25,143,247,278,279].

Spacu and Popea[285] found that the reaction of ammonium tetrachloroiodate trihydrate with ammine complexes leads to the formation of very stable dichloroiodates with a complex cation.

Rubidium and caesium tetrachloroiodates crystallise as anhydrous orange-yellow monoclinic crystals[26,38,143,146,148,247,286,287].

The solubility of rubidium tetrachloroiodate in water at 0° is 7.2%.[283] At room temperature rubidium tetrachloroiodate gradually decomposes with liberation of iodine trichloride. It is noteworthy that Mooney[92] think that rubidium and potassium tetrachloroiodates cannot be isomorphous. A study of the kinetics of the thermal decomposition of caesium tetrachloroiodate showed that the first stage of this process, at 28–116°, is the formation of caesium dichloroiodate, which decomposes at 116–118° into caesium chloride and iodine monochloride (the rate of the first reaction is considerably greater than that of the second). Caesium tetrachloroiodate dissolves slightly in water[146,218].

### Tetrabromoiodates

The alkali metal tetrabromoiodates have not yet been obtained in the free state, and are obviously not stable under ordinary conditions[218]. The complex anion $[IBr_4]^-$ exists in hydrobromic acid solutions and has an instability constant of $5.0 \times 10^{-2}$.

### Trichlorofluoroiodates

Booth and coworkers[274,288] obtained the alkali metal and ammonium trichlorofluoroiodates with the general formula $M[I(Cl_3F)]$ as orange-yellow needles. However, the methods of analysis used by these authors and the fact that they did not determine fluorine directly means that the existence of these compounds at room temperature in the free state has not been substantiated.

### Iodotrichloroiodates

Potassium iodotrichloroiodate was obtained as ruby-red crystals below 45° by Cornog and Bauer[239] in studying the KCl–ICl system. The formation of such a complex was confirmed by the same investigators by studying the solubility of potassium chloride in iodine monochloride. However, Fialkov expressed doubt about the possibility of forming the anion $[I(ICl_3)]^-$ in this system[2,238]. It is worth mentioning that solid tetramethylammonium iodotrichloroiodate was obtained over 100 years ago[289].

### Tetrafluorobromates

In studying the reaction of isotopic exchange of $^{18}F$ between HF and $BrF_3$, Rogers and Katz[290] observed rapid and complete exchange in the liquid phase at 27°. The exchange of fluorine can be explained by the presence in the system of the equilibrium

$$HF + BrF_3 = H^+ + [BrF_4]^-.$$

The formation of the complex anion $[BrF_4]^-$ is also possible as a result of the dissociation of bromine trifluoride[291]:

$$2BrF_3 \rightleftharpoons [BrF_2]^+ + [BrF_4]^-.$$

The solubility of the alkali metal fluorides in bromine trifluoride at 25° increases from lithium fluoride (0.125%) to caesium fluoride (18.8%).[292] The sodium, potassium, rubidium, and caesium fluorides, which are readily soluble in bromine trifluoride, form complexes with it, but the rubidium and caesium tetrafluorobromates were obtained in this way only as solutions in bromine trifluoride[15]. Lithium fluoride does not react with $BrF_3$ but the chloride reacts with release of elemental chloride and bromine:

$$6LiCl + 2BrF_3 = 6LiF + 3Cl_2 + Br_2.$$

Ammonium fluoride and chloride react with bromine trifluoride explosively. Of all the alkali metal tetrafluorobromates, only the potassium salt has been isolated in a sufficiently pure form; the others usually contain fluorides as impurities, and a sufficiently effective method to remove these has not yet been found. The stability of the tetrafluorobromates corresponds to the sequence[105]: $K[BrF_4] > Na[BrF_4] > Rb[BrF_4] > Cs[BrF_4]$.

Sodium tetrafluorobromate was obtained by reaction of sodium carbonate or fluoride with bromine trifluoride[293]. Heating sodium chloride, bromine, or iodide with bromine trifluoride to 120° and then cooling the solution with liquid air and sucking off the excess of bromine trifluoride leads to the formation of solid phases of variable composition[15] but the fluorination of sodium bromide gives only sodium fluoride in the residue[104,273].

Sodium tetrafluorobromate decomposes rapidly at 80° and does not react (unlike bromine trifluoride) with organic solvents.

Potassium tetrafluorobromate was obtained as a white crystalline powder by recrystallising from bromine trifluoride the product of the reaction of bromine trifluoride with potassium fluoride, chloride, nitrate, chlorate, iodate, or other potassium compounds[15,96,293-296].

When heated, potassium tetrafluorobromate attacks platinum, to give the fluoride and potassium hexafluoroplatinate, and it reacts with potassium bromide and iodide with the violent evolution of bromine and iodine.

Rubidium and caesium tetrafluorobromates are stable only in the presence of an excess of rubidium and caesium fluorides[15,200]. It is possible to obtain these complexes by fluorinating[104,105] rubidium or caesium bromides at 200–250°.

### Tetrafluorochlorates.

Study of the infrared spectra of mixtures of hydrogen fluoride and chlorine trifluoride showed that in the $HF–ClF_3$ system the complex $H[ClF_4]$ is formed at low concentrations of the components. The heat of the reaction $HF + ClF_3 = H[ClF_4]$ is 3.92 kcal mole$^{-1}$.[297] Potassium, rubidium, and caesium tetrafluorochlorates are made[104,105] by the fluorination of the chlorides of these metals at 160–210°. The tetrafluorochlorates are white substances with low melting points (100–200°), and react vigorously with water and alkali metal iodides.

Other tetraheterohalogenates have not been obtained. Only the tetramethylammonium tetraiodochlorate is known[116]; it separates as azure-green crystals from an alcoholic solution when tetramethylammonium chloride and iodine react. Tetramethylammonium tetraiodobromate $[(CH_3)_4N].[BrI_4]$ is also known; it was made by the reaction of tetramethylammonium bromide and iodine in boiling alcohol. On cooling the solution, dark green crystals separated[116], m.p. 124.5°. Caesium and rubidium tetraiodobromates can exist in aqueous solutions[258].

Of the other anionhalogenates which do not belong to any of the classes considered above, we must remember potassium heptafluorochlorate $K_2[ClF_7]$, which was obtained[298] by the action of concentrated hydrofluoric acid on potassium chlorate. However, recent work[16] rejects the possibility of making this compound.

## VI. USE OF ANIONHALOGENATES

The chemical properties peculiar to anionhalogenates (ease of thermal decomposition, comparatively low solubility, etc.) were appreciated by even the first investigators of this interesting class of compounds. Thus, first Wells[299] and then Archibald[300] proposed to use the fractional crystallisation of rubidium and caesium dichloroiodates for obtained the pure chlorides. To obtain $Cs[ICl_2]$ Wells dissolved the stoichiometric amounts of caesium nitrate and iodine in hydrochloric acid (1 : 1) at a temperature close to the boiling point of the solution. On cooling, crystals separated; they were recrystallised once or twice from hot acid (1 : 1), then heated to yield pure caesium chloride. Later, Archibald[7] developed the technological production of pure rubidium and caesium compounds free from Li, K, Na, Si, Fe, and Al, based on the use of fractional crystallisation of rubidium and caesium dichloroiodates and dibromobromates. Subsequently Archibald's method was perfected by Ishibashi and coworkers[8], who

found that fourfold recrystallisation of rubidium dichloroiodate gives a spectrographically pure preparation (as regards potassium) even when the initial solution is saturated with potassium. To use this method, rubidium sulphate or any other rubidium salt is dissolved in the minimal quantity of concentrated hydrochloric acid, the stoichiometric quantity of iodine monochloride is added and the mixture cooled to 0°. The precipitate of rubidium dichloroiodate is filtered off, washed with a little cold concentrated hydrochloric acid, dissolved in a little more of this acid containing iodine monochloride, and recrystallised, by adding each time a little iodine monochloride in hydrochloric acid[7,8]. Fractional crystallisation of caesium dichloroiodate was used to obtain pure caesium chloride. After seven recrystallisations a 99.9% product was obtained from 71% caesium chloride[7,8]; this product did not give the spectrographic lines of rubidium. The separation factor of rubidium and caesium[8] when fractional crystallisation is used was 29.1.

Some chemical and physical properties of diiodoiodates were used for the separation of some alkali metals in the presence of others[222]. The possibility of using diiodoiodates for the extractive separation of the alkali metals has also been mentioned[301]. Study[213] of the $RbI-I_2-H_2O$ system showed that the crystallisation of rubidium diiodoiodate is most favourable between 0° and 5° and at a concentration of the components in the solution determined by the section of the isotherm of the crystallisation of this complex, which is adjacent to the $RbI + Rb[I(I_2)]$ eutonic point. On this basis a method of freeing rubidium diiodoiodate from caesium impurity was developed[212,302,303]. After four successive precipitations of rubidium diiodoiodate with the separation of 40% of the rubidium iodide present in the solution, rubidium iodide with 0.02% caesium was obtained from the filtrate — the initial rubidium iodide contained 1.5% caesium. The crystallisation coefficient for this process (Khlopin constant) was 23.4 at 25°.[212,302]

The precipitation of rubidium bromochloroiodate from aqueous solutions was proposed for the preparation of especially pure rubidium chloride, free from potassium impurity[9,11,12,270,271]. It appeared that the coprecipitation of potassium with rubidium bromochloroiodate is very slight; after a single precipitation the concentration of potassium had fallen from 0.5–1.0% to 0.02% or less, and in the precipitation from acetic acid medium the purification factor reaches 300 (from 0.06 to 0.0002%); the factor for purification from lithium is here 15–55 and that for sodium 30–37.[9,272] The precipitate is enriched in caesium when this is present, owing to the lower solubility and greater stability of caesium bromochloroiodate, compared with the rubidium salt.

The precipitation of caesium iodobromoiodate from aqueous alcoholic solutions was recently suggested[10,270] for the preparation of especially pure caesium bromide containing ~0.002% lithium and sodium and 0.005% potassium, and 0.02% rubidium as impurities.

Alkali metal bromides can be separated (with isolation of caesium bromide) by making use of their differing abilities to form stable and readily soluble polybromates[14]. The ease of passing from some anionhalogenates to others without the introduction into technological processes of expensive reagents and the simplicity of thermal decomposition has enabled a complex technological scheme[13] to be worked out for the purification of commercial rubidium chloride with the simultaneous preparation of especially pure caesium salts.

The possibilities of the alkali metal anionhalogenates are, of course, not yet finally exhausted, since the appearance of new representatives of them in the course of the search for new methods of preparation and new interesting properties of the compounds already known cannot be ruled out.

## I. INTRODUCTION

Aroyleneimidazole dyes are usually regarded as forming a separate group of synthetic dyes. They are characterised by the structure

The ring A may be substituted with various groups or fused rings, and positions X and Y may contain hydrogen atoms, various substituents, or another benzimidazole group[1-3].

For obvious reasons this group is also taken to include imides of *ortho*- or *peri*-dicarboxylic and tetracarboxylic acids, as well as compounds, obtained by the interaction of these acids with aromatic *peri*-diamines, which, although they contain no imidazole ring, are very similar to the parent compounds in method of preparation and dyeing properties.

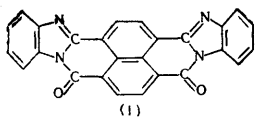
The early aroyleneimidazole dyes were vat dyes. Their brilliance and beauty of shade, great fastness, and comparatively simple manufacture gave the impression that such dyes would displace thioindigoid dyes from the market.

The most important representative of the group of aroyleneimidazole dyes is Indanthren Scarlet GG (Vat

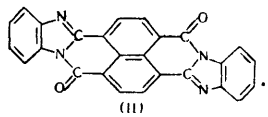
Scarlet 2J), which consists of a mixture of *cis*- and *trans*--naphthoylenebisimidazole — Indanthren Bordeaux RR (Vat Bordeaux) and Indanthren Brilliant Orange GR (Vat Brilliant Orange) — which are formed by the reaction of naphthalene-1,4,5,8-tetracarboxylic acid with *o*-phenylenediamine.

Development of the aroylenebenzimidazole dyes was halted for a long time, but during the past four or five years great interest has been renewed in dyes of this group, mainly based on naphthalene-1,8-dicarboxylic acid, which have found application as disperse dyes for the coloration of synthetic materials and fibres.

Besides the two main intermediates — naphthalene--1,4,5,8-tetracarboxylic and -1,8-dicarboxylic acids — other aromatic dicarboxylic acids have been used for the production of aroyleneimidazole dyes, e.g. naphthoylenebenzimidazole-*peri*-dicarboxylic acid, perylenetetracarboxylic acid, anthraquinone-2,3-dicarboxylic acid, pyrenic acid, etc.



## II. DYES BASED ON NAPHTHALENE-1,4,5,8-TETRACARBOXYLIC ACID



The practical use of *ortho*- and *peri*-diamines in the synthetic dye industry began during 1925–1930, when several patents appeared describing the interaction of *ortho*- and *peri*-diamines with naphthalene-1,4,5,8-tetracarboxylic acid. The insertion of a naphthalene ring system between two benzimidazole ring systems gave the necessary affinity of the dye for the fibre; the conjugated carbonyl groups facilitate the formation of leuco-compounds and their reoxidation.

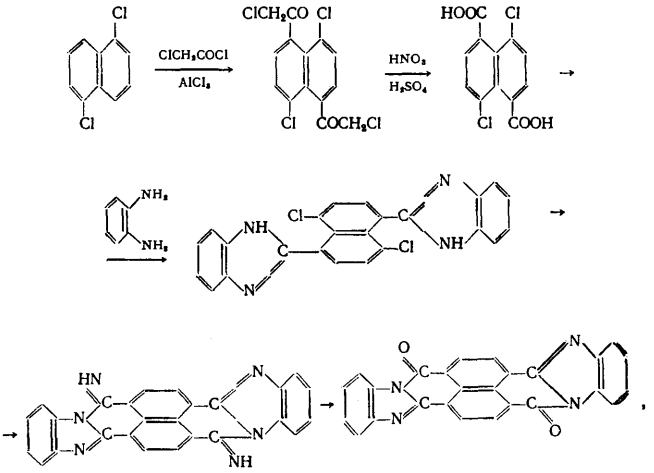
The excellent dyeing properties of the dyes and the straightforward manufacturing process made possible the rapid development of the initial discoveries in this field.

### 1. Industrial Production of Indanthren Scarlet GG (Vat Scarlet 2J)

Indanthren Scarlet GG was the first and is still the most important of these dyes. It is formed by heating *o*-phenylenediamine with naphthalene-1,4,5,8-tetracarboxylic acid in glacial acetic acid[4-9]. The dye is not a pure substance: the reaction involves the formation of equal proportions of the *cis* (I) and *trans* (II) isomers.

(I)

(II)



Both isomers can be isolated from the dye. Like all *trans* isomers of aroylenebenzimidazole dyes, (II) shows a hypsochromic shift in its absorption spectrum compared with the *cis* isomer.

The *trans* isomer appears on the market under the name Indanthren Brilliant Orange GR, and the *cis* isomer as Indanthren Bordeaux RR. Both are used as vat dyes for the dyeing of cotton. Whereas there is a great demand for the *trans* isomer because of its interesting shade, the Bordeaux finds limited use, and new applications are still being sought for it. The latter was placed on the market in a very finely divided form under the name Permanent Red TG Extra[10] as a colorant for lacquers, cellulose nitrate varnishes, and air-drying and stoving artificial--resin varnishes, and for the mass coloration of polymethacrylate, polystyrene, and polyethylene. It is distinguished by good fastness to solvents and to heat-treatment, and unusually high light fastness (grade 8 in cellulose nitrate varnish!). The orange dye is also suitable for similar application, and has been placed on the market as a pigment under the name PV Fast Orange GRL.[11]

The technical manufacture of Indanthren Scarlet GG itself is relatively straightforward. The process was originally conducted in boiling acetic acid[9]. The dye formed is accompanied by ~10% of naphthoylenebenzimidazole-*peri*-dicarboxylic acid, which must be removed by subsequent treatment. It is more convenient to conduct the reaction in water containing 1–2% of sulphuric acid at a moderate pressure. Kinetic study of the process shows that the optimum temperature for the reaction is 120–130°. Decomposition products are formed at higher temperatures[12,13].

The dye is obtained in almost quantitative yield, without the formation of naphthoylenebenzimidazole-*peri*-dicarboxylic acid, by working without a solvent at 140°, when both components are molten. The dye thus obtained contains rather more of the *trans* isomer, and hence has a more interesting shade than the dye synthesised as described above; its other dyeing properties are similar[14].

As already mentioned, the presence of both isomers in the final product is inconvenient for application. Methods were therefore sought for obtaining the pure *trans* isomer, or at least mixtures in which the content of the orange dye had been increased. A process was therefore worked out for preparing the pure orange dye by the scheme[15]

but this proposed synthesis cannot compete with the original method.

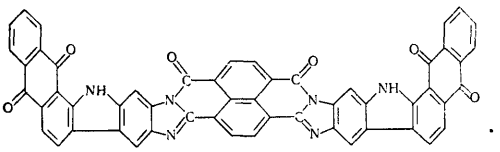
### 2. Effect of Solvent and Substituents on the Formation of Isomers of Indanthren Scarlet GG

The ratio of *cis* and *trans* isomers remains practically unchanged when a different solvent is used for the reaction, e.g. chlorobenzene, nitrobenzene, 2-ethoxyethanol,

glycerol, dimethylaniline. On the other hand, the relative proportions are changed fundamentally when halogen atoms are introduced into the positions 2,6 or 2,7 of the naphthalene-1,4,5,8-tetracarboxylic acid[16].

The above *trans* derivative is almost the sole product of the reaction of 2,6-dichloronaphthalene-1,4,5,8-tetracarboxylic acid with *o*-phenylenediamine, whereas the corresponding 2,7-dichloro-acid yields a monoaroylenebenzimidazole derivative. Measurement of the relative reaction velocities of 2,6- and 2,7-dichloronaphthalene-1,4,5,8--tetracarboxylic acids in comparison with the unsubstituted acid has established that at the same time the chlorine atoms slow down the reaction.

Analysis of the kinetic data and of the effect of steric, mesomeric, and inductive factors on the course of individual stages in the reaction indicates that the two consequences of the introduction of chlorine atoms into the molecule differ in origin. The general slowing down in the reaction is due to the fact that the chlorine atom impedes addition of the nitrogen atom of *o*-phenylenediamine by sterically blocking the neighbouring carbonyl carbon atom, while the effect on the relative proportions of *cis* and *trans* dye isomers is due to the fact that the chlorine atom, by mesomeric and inductive interaction, lowers the activity of the *ortho*-carbonyl group during final closing of the imidazole ring.



### 3. Oxidation of Naphthoylenebisbenzimidazole

According to the patent literature, oxidation of Indanthren Scarlet GG with sexivalent chromium in acid medium should yield Indanthren Brilliant Orange[17]. The product will be more or less yellowish or reddish depending on the quantity of oxidant employed; it is stated that oxidation of a mixture of the two isomers yields new dyes of quinoid character, whose shade moves towards the desired orange. However, oxidation of the pure *cis* isomer (Bordeaux) yields a dye similar in shade to the original dye[18]. The orange *trans* isomer also gives a dye similar in shade to the original dye. Oxidation of the individual isomers or of a mixture in 80% sulphuric acid, in which the dye dissolves completely (whereas in 60% sulphuric acid it is partly in suspension), yields dyes similar in shade to the original dyes.

Oscillographic polarography has proved that the structures of the *cis* and *trans* isomers remain unchanged on oxidation. These facts suggest that, during oxidation of a mixture of the isomers, neither undergoes chemical conversion to a dye of different shade; rather, the change in shade occurring during oxidation of the dye in suspension is due to the greater rate of reaction of the more soluble *cis* isomer compared with the less soluble *trans* isomer, with the formation of almost colourless products which are insoluble in alkalis.

### 4. Derivatives of Naphthoylenebenzimidazole

Chlorination of Indanthren Scarlet GG with chlorine in nitrobenzene[19] gives an orange vat dye, and chlorination with sulphuryl chloride gives a brown vat dye[20]. Bromination of Indanthren Bordeaux RR yields a dibromo-derivative, which on interaction with 1-aminoanthraquinone yields an anthrimide, cyclisation of which forms reddish--brown carbazole dyes[21].

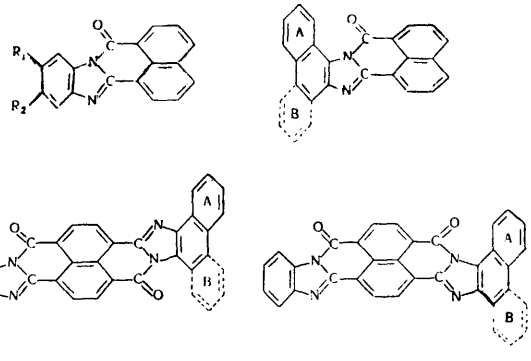
When Indanthren Scarlet GG (or the individual isomers) is nitrated, orange and red pigments are obtained[22], which however, when applied as vat dyes, give greys and blacks on cotton[19] owing to reduction of the nitro-groups during vatting.

By using the corresponding substituted *ortho*-diamines, we can obtain various substituted aroylbenzimidazole dyes of various shades. Of the large number of dyes obtained in this way, Indanthren Printing Brown B, synthesised by the interaction of 4-ethoxyphenylene-1,2-diamine and naphthalene-1,4,5,8-tetracarboxylic acid, and Indanthren Printing Brown 5R, obtained by reaction of 4-chlorophenylene-1,2-diamine with the same acid, have found industrial application[4,7].

Dyes prepared by the use of *ortho*-diamines of the naphthalene[19], phenanthrene[23], and fluorene[24] series have not found application because of solubility difficulties during vatting.

On the other hand, dyes for which 1,2- and 2,3-diaminoanthraquinones are used as the amine component appear to be very interesting. When such diamines react with naphthalene-1,4,5,8-tetracarboxylic acid in high-boiling solvents, vat dyes are formed which produce on cotton olive shades of high fastness properties[25].

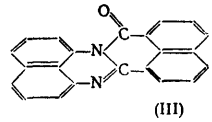
Some of the *ortho*-diamines which are not very readily available can be replaced in the reaction by the corresponding *ortho*-nitroamino-[26] or *ortho*-aminoazo-compounds[27]. The intermediates formed when they react with naphthalene-1,4,5,8-tetracarboxylic acid are further reduced in alkaline medium with sodium sulphide or dithionite, or else with iron in acid medium with simultaneous formation of the naphthoylenebenzimidazole skeleton.



## III. SEPARATION OF ISOMERIC AROYLENEBENZIMIDAZOLES

As already mentioned in the previous Section, reaction of *ortho*- or *peri*-dicarboxylic or tetracarboxylic acids with aromatic *ortho*- or *peri*-diamines involves the formation of mixtures of isomers of the corresponding aroylenebenzimidazoles. Various technical processes are available for the separation of these isomers, and can in principle be divided into four groups. (*a*) The mixture of isomers is dissolved at an elevated temperature in an alkali-metal alkoxide or amide; on cooling, the insoluble *trans* derivative separates, while the soluble *cis* derivative is obtained by acidifying the filtrates[28]. (*b*) A solution of the dye in concentrated sulphuric acid (or chlorosulphuric acid) is cautiously diluted with water; at first the less soluble sulphate of the *trans* isomer separates, and after its removal the *cis* isomer is obtained by further dilution[29]. (*c*) The technical dye is stirred into mixtures of organic sulphonic acids and organic solvents, and separation is effected by use of the differing solubilities of salts of the individual isomers[30]. (*d*) The mixture is stirred into chlorosulphuric acid in the presence of hydrochloric, hydrobromic, or sulphuric acid, and the insoluble *trans* form is filtered off[31].

All these processes are directed primarily towards obtaining the pure, coloristically more valuable *trans* isomer from the dye produced by the interaction of naphthalene-1,4,5,8-tetracarboxylic acid and *o*-phenylenediamine. The *cis* isomer contains almost all the impurities formed in this reaction, which comprise firstly those soluble in alkalis and organic solvents (mainly naphthoylenebenzimidazole-*peri*-dicarboxylic acid) and secondly impurities which are soluble solely in organic solvents.



The steadily increasing demand for Indanthren Bordeaux RR as a pigment is responsible for the more exacting purity requirements. The very pure *cis* and *trans* isomers are obtained by a somewhat modified process[32], in which the sparingly soluble adduct of the *trans* isomer with potassium ethoxide is separated in a medium containing excess alcohol, while the *cis* isomer is isolated from the filtrate by alkaline hydrolysis after salting-out in water[32].

Only two isomers are formed in the reaction of naphthalene-1,4,5,8-tetracarboxylic acid with *o*-phenylenediamine. The number of isomers increases when substituted *ortho*-diamines are used. It has not proved possible to separate these isomers by a technical process. Only partial separation, i.e. into *cis* and *trans* isomers, is achieved. Several aroyleneimidazole dyes can be separated into their isomers by chromatography[33]. Dyes (I)–(VI) have been separated chromatographically on aluminium oxide, and the fluorescence spectra of the resulting isomers determined.

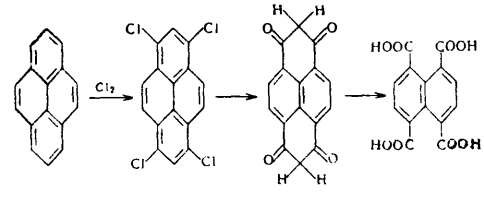
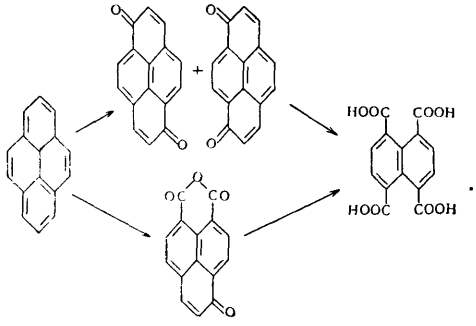
## IV. PRODUCTION OF NAPHTHALENE-1,4,5,8-TETRACARBOXYLIC ACID



The principal intermediate in the manufacture of aroyleneimidazole dyes, naphthalene-1,4,5,8-tetracarboxylic acid, is obtained mainly in two ways.

The first process[34-36] starts from acenaphthene and is conducted according to the scheme



The second process starts from pyrene, from which naphthalene-1,4,5,8-tetracarboxylic acid can be obtained by chlorination or oxidation.

When chlorination is used, the chlorination or bromination of pyrene is followed by oxidation of the tetrahalogenopyrene:

According to the literature[37-40] high yields are obtained by this method, but technologically it makes increased demands on the equipment. A simpler process is oxidation, which, furthermore, does not require complicated

apparatus. The course of the process can be clearly represented by the following scheme

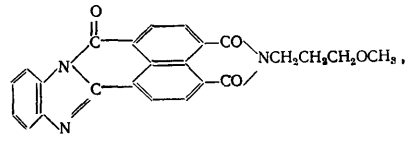
The oxidation of pyrene to a mixture of pyrene-3,8- and -3,10-quinones and pyrenic acid has been known since 1870.[41] The structure and properties of these substances have been investigated by several workers[42-51]. Pyrenequinones and pyrenic acid are obtained by oxidising pyrene with chromic mixture in aqueous suspension or with chromium trioxide in acetic-acid solution. Subsequently pyrenequinones were also obtained by the oxidation of pyrene with hydrogen peroxide in glacial acetic acid[52]. This last method is unsuitable for the manufacture of pyrenequinones, since it requires the use of a large excess of a comparatively expensive oxidant, and the oxidation product is insufficiently pure.

The oxidation of pyrene with chromium trioxide in acetic acid was mentioned in the very early literature, but a more detailed method has been given only in a patent[53] of the Rütgerswerke AG. In this method double the theoretical quantity of chromium trioxide is used, and the reaction mixture is boiled; a quantitative yield of almost 100% quinone is formed. However, the industrial application of this method is impeded by the high cost of acetic acid.

The oxidation of pyrene in suspension with chromic mixture has been examined in greatest detail by Bamberger and Philip[44-46] and in the patent mentioned above[53]. According to Bamberger, finely ground pyrene is oxidised by the theoretical quantity of dichromate in sulphuric acid diluted with five volumes of water. The paper gives neither the precise temperature conditions nor the yield and purity of the product, only that the latter contains pyrenic acid. Bamberger's results were checked by Vollmann[39], who does not give the procedure but describes in greater detail the reaction product, allegedly obtained in 90% yield; it contained hardly any unchanged pyrene and only a few per cent of pyrenic acid. The Rütgerswerke patent contains quite contradictory data on the substance obtained by Bamberger and Philip's method, and states that the reaction product consists of 36% of pyrenequinones, 14% of chromic salts, 50% of unchanged pyrene, and traces of pyrenic acid. The patent gives a recipe according to which 98–99% quinones can be obtained in almost quantitative yield. This recipe differs from Bamberger and Philip's procedure in the quantity of dichromate used (178% of theoretical) and a smaller quantity of sulphuric acid. Here, too, the temperature conditions of the reaction are given in insufficient detail.

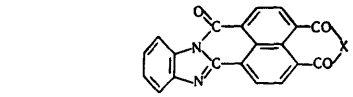
It follows from the contradictions in the literature quoted that insufficient study has been made of the conditions for the oxidation of pyrene to pyrenequinones, and that the oxidation process is very sensitive to variation in the conditions.

The oxidation of pyrene to pyrenequinones with hydrogen peroxide in acetic acid and with oxygen or air in the presence of a catalyst has been described. Owing to the unsatisfactory course of the oxidation, neither method is applicable to manufacture.



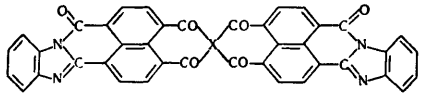
Naphthalene-1,4,5,8-tetracarboxylic acid can be obtained from the pyrenequinones (or pyrenic acid) by oxidation in either acid or alkaline medium. In acid medium excess of oxidant (dichromate in dilute sulphuric acid) is used. Pyrenic acid, which itself was obtained in low yield, is supposedly converted into naphthalenetetracarboxylic acid in quantitative yield. The yield of the latter acid from pyrenequinones is insignificant. This method of oxidation forms the subject of a 1932 patent of the IG. Farbenindustrie AG.[54], according to which pyrene is dissolved in concentrated sulphuric acid and, after dilution with water, oxidised with excess of dichromate. The intermediate oxidation products, pyrenequinones, are not isolated. The yield of naphthalenetetracarboxylic acid is not high.

Considerably better results are achieved by oxidising pyrenequinones in alkaline medium. Information on this method is given only in two patents dating from 1933. According to the first patent[55] pyrenequinones or pyrenic acid are oxidised in alkaline medium by heating with excess of permanganate solution; the excess of permanganate remaining should accelerate crystallisation of the naphthalenetetracarboxylic acid from solution after acidification, and is removed in the purification of the acid. According to published data, the yield of naphthalenetetracarboxylic acid by this method is 70–75% based on the pyrene taken for the reaction. The second patent[56] describes the use of an alkaline solution of sodium hypochlorite or of a mixture of bleaching powder and calcium hydroxide for the oxidation. The operating technique is very simple: a suspension of pyrenequinones is stirred up with an alkaline solution of sodium hypochlorite, and the mixture allowed to stand for a few hours at room temperature and then for a few hours at 50–80°. The quinones are converted into naphthalenetetracarboxylic acid, which is isolated. According to the patent the yield is 70–80% based on the pyrenequinones.

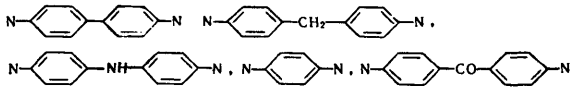


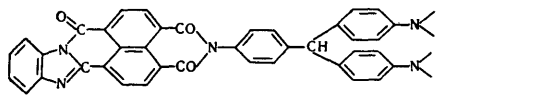
## V. DYES BASED ON NAPHTHOYLENEBENZIMIDAZOLE-*peri*-DICARBOXYLIC ACID

Besides the symmetrical dyes obtained by reaction of naphthalenetetracarboxylic acid with two moles of an *ortho*-diamine, unsymmetrical dyes can also be synthesised. When the acid reacts with *o*-phenylenediamine in aqueous medium in the presence of sodium acetate, equimolar cyclisation yields the so-called naphthoylenebenzimidazole-*peri*-dicarboxylic acid[57-59], which can react further with other variously substituted aromatic *ortho*- or *peri*-diamines or else with aliphatic or aromatic amines. In the former case, vat dyes of various shades are formed[62], and in the latter case disperse dyes[63].

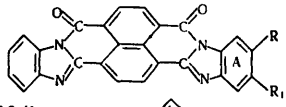


Among disperse dyes of this type, Samaron Brilliant Yellow HRL[60] having the structure[61]

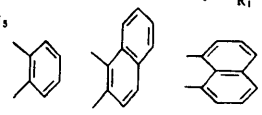




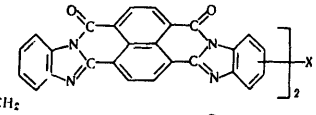
has appeared on the market. This group includes also dyes of types (I)–(V)

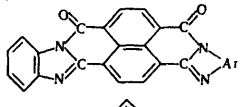


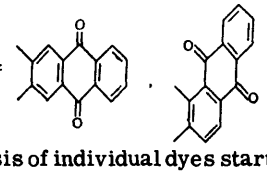
I: X = O, NH, $NCH_3$,  , $NCH_2CH_2OH$,  , $NCH_2CH_2CN$, $N(CH_2)_7CH_3$, $N(CH_3)_{17}CH_3$



II: X = 

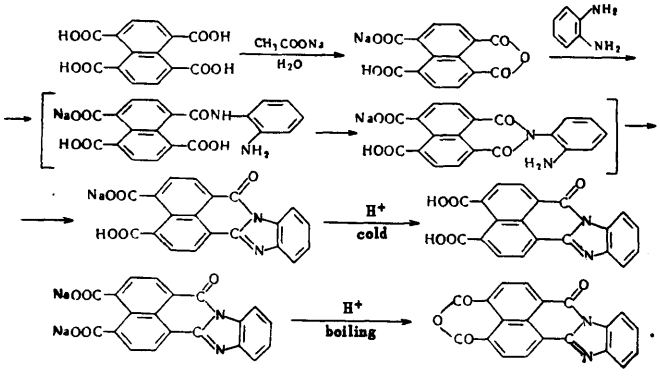






III: R, $R_1$ = $CH_3$, Cl, $OC_2H_5$

A = 



IV: X = 

V: Ar = 

The synthesis of individual dyes starts from naphthoylenebenzimidazole-*peri*-dicarboxylic acid (X), which is made to react with various aliphatic or aromatic amines. This acid is obtained, according to patent information[59], by the reaction of naphthalene-1,4,5,8-tetracarboxylic acid with one molecule of *o*-phenylenediamine in aqueous sodium acetate solution. The disagreement on the mechanism of this reaction encountered in the literature has been cleared up by Arient and Dvořák, who suggest the following scheme to explain the course of the reaction[64]

These workers have established the relation between the structure and the spectra of dyes of types (I)–(V).[64] The effect of substituents in dyes of this type on the bathochromic shift in the absorption band increases in the sequence

O, $NCH_3$, $N(CH_2)_{17}CH_3$, $NCH_2CH_2OH$,  ,  , $NH$, $NCH_2CH_2CN$.

These dyes can be employed as either vat or disperse dyes. With lengthening of the aliphatic chain, dyeing power is lost owing to the insolubility of the vat; dyeing power also decreases as the chain becomes longer when the compounds are used as disperse dyes.

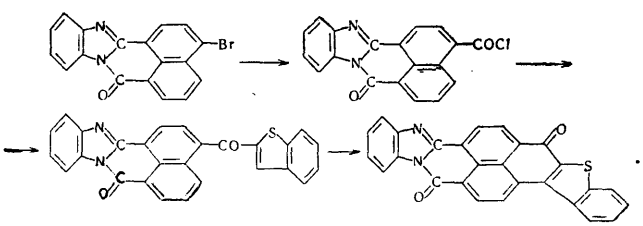
The doubling of the naphthoylenebenzimidazole-*peri*-dicarboxylic acid moiety in dyes of type (II) results in a bathochromic shift in colour compared with dyes of type (I). The element uniting the two moieties of the dye molecule has hardly any perceptible effect. The dyes can be applied as vat dyes with good fastness properties.

The absorption spectrum of dyes of type (III) is considerably affected by substituents — methyl, chlorine, and ethoxyl — in the molecules of symmetrical and unsymmetrical aroylenebenzimidazoles. In contrast to the previous types (I) and (II), these dyes exhibit a considerable bathochromic shift, and they yield reds, violets, and browns. The influence of substituents is strongly marked within this group; their bathochromic effect increases in the sequence H, $CH_3$, Cl, $2CH_3$, $OC_2H_5$. Dyes formed from naphthoyleneimidazole-*peri*-dicarboxylic acid with naphthylene-1,2- and -1,8-diamines exhibit a further shift in the absorption band towards longer wavelengths. Analogous results have been obtained for naphthalene-1,4,5,8-tetracarboxylic acid.

All dyes were separated into *cis* and *trans* isomers, which showed an analogous variation in colour to that observed with their mixtures. Most of the dyes, mainly derivatives of naphthoylenebenzimidazole-*peri*-dicarboxylic acid, are distinguished by their brilliance and excellent fastness, and can be used as vat dyes. Dyes derived from naphthalenetetracarboxylic acid are sparingly soluble (with the exception of naphthoylenebisbenzimidazole), so that they cannot be used as vat dyes. Dyes containing the naphthalene ring system have inadequate fastness.

The influence of naphthoylenebenzimidazole-*peri*-dicarboxylic acid on the relative proportions of *cis* and *trans* isomers formed in the synthesis of such dyes was checked, its reaction with *o*-phenylenediamine being taken as example. The ratio of these isomers obtained with such a consecutive synthesis was practically 1 : 1, equal to the ratio obtained by the direct interaction of naphthalene-1,4,5,8-tetracarboxylic acid with *o*-phenylenediamine. This indicates that naphthoylenebenzimidazole-*peri*-dicarboxylic acid exerts no influence on the formation of one isomer or the other.

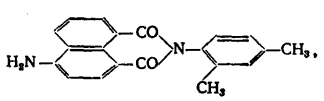
Dyes of type (IV), i.e. dyes having two naphthoylenebisbenzimidazole moieties, have been obtained by the reaction of naphthoylenebenzimidazole-*peri*-dicarboxylic acid with 3,3′,4,4′-tetraaminobenzophenone and with diphenylmethane-3,3′,4,4′-tetraamine. In the former case the dye contains one double conjugated system, but in the latter case it contains two conjugated systems isolated from one another by the methylene bridge. A dye resulting from the diphenylmethanetetra-amine has a red colour with a moderate hypsochromic shift in comparison with naphthoylenebisbenzimidazole; a dye from the tetraaminobenzophenone shows practically the same absorption.



Dyes of type (V), which result from the reaction of naphthoylenebenzimidazole-*peri*-dicarboxylic acid with 1,2- and 2,3-diaminoanthraquinone, exhibit a large bathochromic shift towards reddish browns and browns.

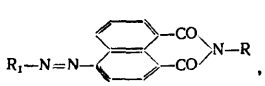
## VI. DYES BASED ON NAPHTHALIC (NAPHTHALENE--1,8-DICARBOXYLIC) ACID

Interest in this group of dyes has arisen during the past four or five years. They are suitable for use as disperse dyes for the coloration of polyester, polyamide, polyvinyl, and polyethylene fibres. They are distinguished by brilliance, thermal stability, and excellent fastness to light, organic solvents, gas fumes, and sublimation.

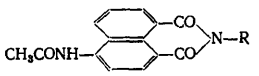


### 1. Preparation of Dyes

These dyes are obtained by the reaction of naphthalic acid with various substituted aromatic diamines (yellows and oranges with intense fluorescence) or *peri*-diamines (reds and violets) in an organic solvent. Derivatives of 1,2-*peri*-naphthoylenebenzimidazole are the most interesting. Many of its derivatives, with chlorine, bromine, alkyl, alkoxyl, hydroxyl, nitro, acylamino, etc. substituents, have been described in the patent literature[65-69]. Derivatives of this intermediate are also used, according to the patent literature, as intermediates for the synthesis of brown vat dyes[70].



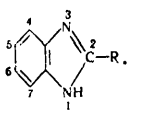
The process for obtaining naphthaloperinone dyes, which are formed by the reaction of naphthalic acid with naphthylene-1,8-diamine, is analogous to the preparation of naphthoylenebenzimidazole dyes[71-75]. A whole range of derivatives having various substituents has been patented[76-78]. Orange and red lakes for the mass coloration of polyamides and polyesters can be obtained by the sulphonation of some substituted naphthaloperinones, the resulting sulphonic acids being precipitated as their barium salts[79].



Naphthalimides are employed to a less extent as disperse dyes. They are obtained by the action of ammonia or primary amines on naphthalic anhydride. Among such dyes are Celliton Brilliant Yellow FF2

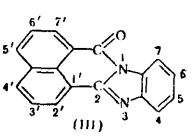
for cellulose acetate rayon, red and brown disperse dyes of the type[80]

and fluorescent brightening agents of the type[81,82]



where R = H, Alk, Ar and $R_1$ = Ar.

The introduction of substituents into the dye produces a change in their shade. Nitration occurs especially readily; the resulting mono- or di-nitro-derivatives can be used firstly as individual dyes and secondly as intermediates for the synthesis of new compounds.



### 2. Substituted 1,2-*peri*-Naphthoylenebenzimidazoles

The work of Efros on the nitration of simple 2-alkyl and 2-aryl derivatives of benzimidazole showed that the presence of the imidazole ring in the benzimidazole molecule disturbs the distribution of electrons in the benzene ring, in the sense that the 5–6 bond approaches a single bond in character, while the 4–5 and 6–7 bonds become more nearly double bonds. This explains the unusual course of several substitutions, for example the dinitration of 2-methylbenzimidazole, when 2-methyl-5,6-dinitrobenzimidazole is formed[84].

Arient and Marhan[85] subjected 1,2-*peri*-naphthoylenebenzimidazole (III) and its 3'-, 4-, 4'-, 5-, 6-, and 7-nitro-derivatives to nitration. Each isomer was nitrated under identical conditions, by the action of the nitrating mixture on a solution of the original compound in concentrated sulphuric acid at 20°. The products were isolated by salting-out the solution into water. The course of the nitration was investigated chromatographically. The mono- and di-nitro-compounds formed were identified by comparing their electronic spectra with those of known specimens.

The nitration of 1,2-*peri*-naphthoylenebenzimidazole yields a single compound, which was identified as the 6-nitro-derivative. In the nitration of 4'-nitro-1,2-naphthoylenebenzimidazole, too, a nitro-group enters position 6, with the formation of 4',6-dinitro-1,2-*peri*-naphthoylenebenzimidazole, and the nitration of 3'(and 6')-nitro-1,2--*peri*-naphthoylenebenzimidazole yields 6,3'(and 6')--dinitro-1,2-*peri*-naphthoylenebenzimidazole

(III)

The high reactivity of position 6 is due to the activating effect of the non-acylated nitrogen in position 3, reaction at the *ortho* position in the benzene ring (position 4) evidently being sterically hindered. The activating influence of the lone electron pair on the other, acylated nitrogen in position 1 is distributed between the acylating part of the molecule and the benzene ring (in lesser degree). This result is fully consistent with mathematical calculation of

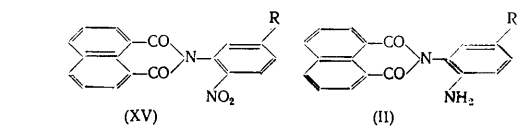
the electron distribution at individual carbon atoms in the naphthoylenebenzimidazole structure[86], according to which the reactivity of the carbon atoms diminishes in the sequence 6, 5, 6′, 3′.

Further nitration of derivatives of 1,2-*peri*-naphthoylenebenzimidazole in which the nitro-group is located in positions 4–7 in the benzene ring involves entry of the second nitro-group in position 6′. A nitro-group in position 5 or 7 prevents entry of the next nitro-group in position 6, which is the most active. A nitro-group in position 4 deactivates the benzene ring, and interferes with the activating influence of the lone electron pair of the non-acylated nitrogen.

In the synthesis of known derivatives of 1,2-*peri*-naphthoylenebenzimidazole, these workers have also investigated, apart from methods of preparation, the influence of substituents in *o*-phenylenediamine or in naphthalic acid on the course of the reaction[87].

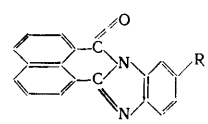
Reaction of naphthalic anhydride with 4-nitrophenylene-1,2-diamine may yield 5- and 6-nitro-1,2-*peri*-naphthoylenebenzimidazole (IX) and (IV). The effect of the nitro-group on the basic character of the two amino-groups in nitro-*o*-phenylenediamine has not yet been accurately established, but the influence of the nitro-group in nitroanilines on the variation in pH is well known. The course of the reaction can be approximately predicted on the basis of these results. The weakening of electron density on the amino-nitrogen *para* to the nitro-group induces great reactivity in the second amino-group, and consequently preferential formation of *N*-(2-amino-5-nitrophenyl) naphthalimide (II: R = $NO_2$), which is converted with ring-closure into 6-nitro-1,2-*peri*-naphthoylenebenzimidazole (IV). In fact, the reaction of naphthalic anhydride with 4-nitrophenylene-1,2-diamine has been used to synthesise the 6-nitro-derivative (IV) as the main product, whereas the 5-nitro-isomer (IX) was formed in far smaller quantity; the latter was identical with a substance obtained from 2,4-dinitroaniline and naphthaloyl dichloride (XVI). Their interaction gave *N*-(2,4-dinitrophenyl)naphthalimide (XIV: R = $NO_2$), which was partly reduced, the resulting *N*-(2-amino-4-nitrophenyl)naphthalimide (VIII: R = $NO_2$) then being converted into the pure 5-nitro-isomer (IX). The yield of 6-nitro-1,2-*peri*-naphthoylenebenzimidazole from 2,5-dinitroaniline and naphthaloyl dichloride is not very high. The *N*-(2,5-dinitrophenyl)naphthalimide (XV: R = $NO_2$) formed in this reaction is hydrolysed to a considerable extent on reduction. The reactivity of 2,4-dinitroaniline is so low that it reacts only with the dichloride (XVI). A similar conclusion was reached by Krasovitskii and Matskevich, who obtained negative results for the reaction of naphthalic anhydride with nitroanilines[83].

The 4- and 7-nitro-1,2-*peri*-naphthoylenebenzimidazoles were obtained in an analogous manner. Reaction of 3-nitrophenylene-1,2-diamine with naphthalic anhydride gives only one of the two possible isomers, to which Arient and Marhan ascribe the structure 4-nitro-1,2-*peri*-naphthoylenebenzimidazole (XIX). The isomeric 7-nitro-derivative (XVIII) is formed by reaction of the dichloride (XVI) with 2,6-dinitroaniline. Owing to considerable steric hindrance, reaction takes place with great difficulty and gives a low yield.



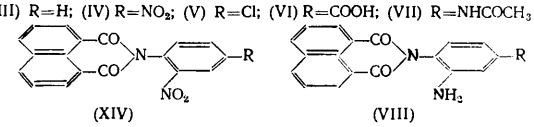
Naphthoylenebenzimidazole derivatives containing substituents in the naphthalene ring or in both the naphthalene and the benzene rings have been obtained by methods similar to that employed to obtain the benzene-substituted derivatives[85]. Reaction of 3-nitrophthalic acid with *o*-phenylenediamine and its mononitro-derivatives gave 3′(and 6′)-nitro- and 4,3′(and 6′)- and 6,3′(and 6′)-dinitro--1,2-*peri*-naphthoylenebenzimidazoles; 4-nitrophthalic acid similarly gave the 4′(and 5′)-nitro- and the 4,4′(and 5′)- and 6,4′(and 5′)-dinitro-derivatives.

An *ortho*-diamine containing a chlorine atom behaves in a more specific fashion than a nitro-derivative. Reaction of 4-chlorophenylene-1,2-diamine with naphthalic anhydride (I) begins at the amino-group *para* to the chlorine atom, the final product being 5-chloro-1,2-*peri*-naphthoylenebenzimidazole (X), which is identical with the compound prepared from 4-chloro-2-nitroaniline and naphthaloyl dichloride (XVI) by a method analogous to the synthesis of 5-nitro-1,2-*peri*-naphthoylenebenzimidazole. For comparison, 6-chloro-1,2-*peri*-naphthoylenebenzimidazole (V) was obtained also by Sandmeyer's reaction from the amine resulting from the reduction of the 6-nitro-derivative (IV).



Naphthalic anhydride (I) was then made to react with 4-methylphenylene-1,2-diamine and 3,4-diaminobenzoic acid. In both cases reaction occurred with that amino--group which had become the more reactive under the influence of the remaining substituent. As was to be expected, 4-methylphenylene-1,2-diamine yielded mainly 5-methyl-1,2-*peri*-naphthoylenebenzimidazole (XI), together with a smaller quantity of the 6-methyl isomer. The isomers could not be separated chromatographically, but the acids obtained by their oxidation were separated chromatographically and identified. 1,2-*peri*-Naphthoylenebenzimidazole-5-carboxylic acid was obtained by oxidising pure 5-methyl-1,2-*peri*-naphthoylenebenzimidazole, prepared by fusing 4-methyl-2-nitroaniline with the anhydride (I). With permanganate or dichromate in sulphuric acid hardly any oxidation occurs (only traces of the corresponding acids were obtained).

Almost quantitative oxidation was accomplished by the action of oxygen in glacial acetic acid in the presence of a cobalt compound as catalyst.



The final product of reaction of the anhydride (I) with 3,4-diaminobenzoic acid was 1,2-*peri*-naphthoylenebenzimidazole-6-carboxylic acid (VI).

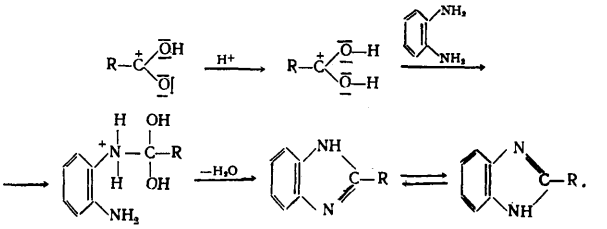
### 3. Interaction of Benzene-1,2,4,5-tetraamine with Dicarboxylic Acids

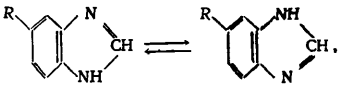
Many workers have investigated the reaction of aromatic *ortho*-diamines with carboxylic acids. Benzimidazoles were first obtained by this method by Phillips[88], by interaction of the components in boiling dilute hydrochloric acid. High yields were obtained with aliphatic acids, whereas aromatic acids reacted very feebly. Roeder and Day[89] explained the formation of benzimidazole compounds by a mechanism involving an intermediate monoacyl derivative



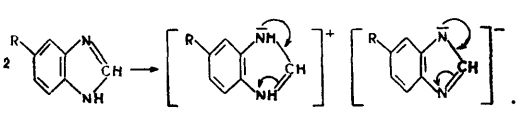
At the same time it was established that the postulated intermediate compound should be capable of enolisation, since the compound (II), unlike (I), is incapable of forming an imidazole ring.

(I) (II)

The synthesis of imidazole derivatives by Phillips' method has been widely investigated and developed by Soviet workers, who have established[90] that the concentration of hydrochloric acid used greatly affects the yield. The reaction was conducted by heating equimolecular quantities of the *ortho*-diamine with the carboxylic acid in dilute hydrochloric acid medium in sealed tubes at 150–180°. By this method 2-aryl derivatives were also obtained in high yields. With increase in the hydrochloric acid concentration the yield of the benzimidazoles first increased to a definite level, after which the yield fell again.



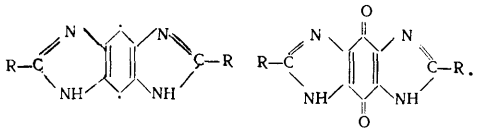
The optimum hydrochloric acid concentration differs for different carboxylic acids and also diamines. Hydrochloric acid forms salts with the amine, and this retards the reaction, since the amine reacts as the free base. The main factors determining the yield obtained are the concentration of the hydrochloric acid and the basic strength of the amine: it was concluded from the results[91,92] that hydrochloric acid of lower concentration must be used with amines which are stronger bases. However, the highest yield was achieved with *o*-phenylenediamine: other *ortho*-diamines, which were stronger or weaker bases, gave lower yields. The effect of the hydrochloric acid on the carboxylic acid is to diminish the ionisation of the latter, and the addition of a proton to the polarised oxygen atom of the carboxyl results in a positive charge on its carbon atom. From measurements of the dissociation constants of the acids, Porai-Koshits and Kharkharova drew the significant conclusion that reactivity decreases in the sequence — aralkane-, alkane-, and arene-carboxylic acid — and that the optimum concentration of hydrochloric acid should be higher the higher the degree of dissociation of the carboxylic acid. On the basis of these results a new mechanism was then proposed for the formation of benzimidazole derivatives



It has recently been established[93] that polyphosphoric acid could be used to obtain high yields of alkyl and aryl derivatives of benzimidazole.

Efros investigated substitution reactions in benzimidazole and its derivatives[94-97], and found that no clear substitution rules exist for the benzene ring in benzimidazole, although positions 5 and 6 are more active than the others. The nitration of benzimidazole, for example, yields only the 5,6-dinitro-derivative. His results demonstrated that, under the influence of the imidazole ring, the benzene ring loses its aromatic character, in the sense that the bond between the rings and the 4–5 and 6–7 carbon–carbon bonds approach double bonds in character.

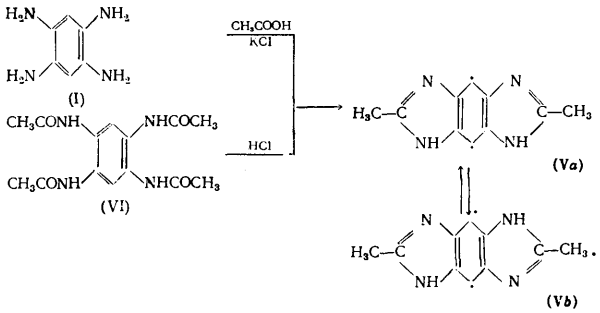
The unsuccessful earlier attempts to isolate the two hypothetical isomers



are explained by the ease of their tautomeric interconversion[98]. Study of the amphoteric character of benzimidazole proved significant for an understanding of some of its properties[99]. In acid medium it exists as a cation, whereas in alkaline medium its acid properties are developed, and the corresponding anion is formed. Among salts of benzimidazole, the greatest interest attaches to those which can be used for the gravimetric determination of certain metals. In neutral medium benzimidazole can exist in a state of equilibrium between the hypothetical cationic and anionic forms

Efros prepared[94] several derivatives of linear diimidazobenzene (III) by reducing 5,6-dinitrobenzimidazole, and

then treating the resulting *ortho*-diamine with a carboxylic acid. Whereas the first imidazole ring is formed readily under mild conditions, it was necessary to work under pressure to close the second ring. Both symmetrical and unsymmetrical derivatives can be obtained in this way. Earlier Kym and Ratner[100] had synthesised 2,6-dimethyldiimidazobenzene (V) by fusing 5,6-diaminobenzimidazole with anhydrous sodium acetate and acetic anhydride. This derivative was described also by Ruggli and Fischer[101], who synthesised it by the action of acetic anhydride on the substance obtained by reducing supposedly pure 4,6-diphenylazophenylene-1,3-diamine. The properties of substances described by different workers differ somewhat.

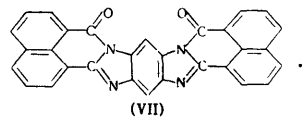


The above effect of the imidazole ring on the benzene ring in benzimidazole stabilises the double bond between the rings. This entails an increase in electronic charge at the free *meso* positions in the linear diimidazobenzene (III), which appears in their considerable radical unsaturation[102,103]. In their properties these compounds show a notable resemblance to anthracene, especially in their ease of oxidation to the quinones (IV).

(III) (IV)

Arient and Marhan have established[104] that the direction of the reaction depends on the medium in which it occurs. Prolonged boiling of the tetraamine with 90% acetic acid gives the linear 2,6-dimethyldiimidazobenzene (V). Heating the tetraamine (I) with acetic anhydride yields 1,2,4,5-tetraacetamidobenzene (VI) in addition to (V). In the presence of an equivalent quantity of anhydrous sodium acetate to neutralise the hydrogen chloride present in the tetrahydrochloride of the tetraamine, only (VI) is formed. Substitution in the imidazole ring obviously requires the presence of dissociated hydrochloric acid, which catalyses the reaction. In dilute acetic acid, where hydrochloric acid is liberated on hydrolysis of the benzene-1,2,4,5-tetraamine hydrochloride, only the diimidazo-derivative is formed.

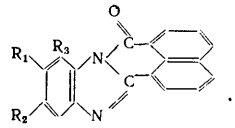
In anhydrous medium, formation of the latter, which occurs to a considerably smaller extent, is accompanied by acetylation of the amino-groups of the tetraamine. In the presence of a substance which will combine with hydrogen chloride, ring-closure is completely suppressed, the sole process being acetylation of all the amino-groups. The resulting 1,2,4,5-tetraacetamidobenzene (VI) is stable in aqueous medium, and is not hydrolysed on being heated; boiling in hydrochloric acid readily converts it into the diimidazo-derivative with the elimination of two acetyl groups:



The two workers obtained the highest yield of (V) by treating the tetraamine with acetic acid in dilute hydrochloric acid medium under pressure at 180°. Their results agree well with those obtained by Porai-Koshits and his coworkers[90,91] in the synthesis of 2-alkylbenzimidazoles. In this case, too, the yield of benzimidazole first increased with increase in the concentration of hydrochloric acid, reached a definite maximum, and fell again.

Reaction in water and 5–20% hydrochloric acid gives the diimidazobenzene (V) as the main product. In more concentrated hydrochloric acid the hydrolysis of the benzenetetraamine hydrochloride, which itself cannot react, is in considerable measure suppressed, and a large part of it remains unchanged at the end of the reaction. Use of excess of acetic acid slightly increases the yield. The fine white crystalline needles of the compound (V) obtained are completely homogeneous, and their properties do not indicate the existence of two isomers (V*a*) and (V*b*). By analogy with benzimidazole it can be assumed that these represent two tautomeric forms of the same substance. The compound (V) is also amphoteric in character, dissolving in dilute acids and forming salts (mostly insoluble in the cold) with several metals.

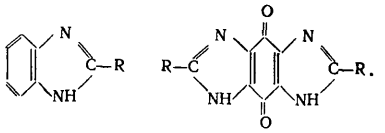
The tetraamine reacts with formic, phenylacetic, and cinnamic acids under the same conditions as with acetic acid. With formic acid, the linear diimidazobenzene (III: R = H), similar in properties to the dimethyl derivative (V), is formed. Similarly, phenylacetic acid yields the 2,6-dibenzyldiimidazobenzene (III: R = $C_6H_5CH_2$), and 5-amino-2-benzyl-6-hydroxybenzimidazole as by a product. When cinnamic acid is used, the 2,6-distyryldiimidazobenzene (III: R = $C_6H_5CH:CH$), which possesses an intense fluorescence, is formed.



Benzoic acid and benzoyl chloride do not react with benzenetetraamine; nor does the more reactive *p*-nitrobenzoic acid give the expected compound, but decomposes under the reaction conditions. The behaviour of these acids had been investigated earlier[105].

On the basis of a study of the simpler linear diimidazobenzenes, Arient and Marhan attempted to obtain the bisaroyleneimidazo-derivative (VII) by reaction of the tetraamine with naphthalic acid[106].

(VII)



Instead of the suggested compound (VII), however, the principal reaction product was 5,6-diacetamido-1,2-*peri*-naphthoylenebenzimidazole (VIII). Doubt is cast on data given in a French patent[107], describing the preparation of a diimidazo-derivative, since a monoimidazole is also formed when the reaction is carried out under severe conditions — in boiling tetrahydronaphthalene — as indicated in the patent.

(VIII) $R_1 = R_3 = CH_3CONH$; $R_2 = H$; (IX) $R_1 = CH_3CONH$; $R = R_3 = H$; (X) $R_1 = CH_3COO$; $R_2 = R_3 = H$; (XI) $R_1 = R_2 = CH_3CONH$; $R_3 = CH_3$.

The main product contains, besides unchanged naphthalic acid, also 5-acetamido-1,2-*peri*-naphthoylenebenzimid-azole (IX) and 5-acetoxy-1,2-*peri*-napthoylenebenzimid-azole(X).

The formation of only one ring can be explained by distortion of the electron cloud of the benzene ring in the tetraamine resulting from the action of the aroyleneimidazole ring. A series of detailed investigations was made[108-111] on the effect of the imidazole ring on the electron distribution of the benzene ring in benzimidazole derivatives (XII). The results show that the benzene ring loses its aromatic character, and the bond between the rings approaches closely to a double bond in character. The simplest compounds of the diimidazo-type resemble anthracene in their chemical properties, mainly in their ease of oxidation to quinones (XIII).

(XII)

(XIII)

In conformity with this work, it may be supposed that the loss of symmetry and hence of aromatic character in the benzene ring of compound (VIII), resulting from the effect of the aroyleneimidazole structure, is so great that the 4–5 and 6–7 carbon–carbon bonds approach double bonds in character, while the 5–6 bond becomes more nearly a single bond. Consequently the carbon atoms at positions 5 and 6 appear as the two ends of the conjugated system of benzimidazole, which are subject to the action of the heterocyclic nitrogen atoms. This breakdown in the uniform distribution of the electron cloud of the benzene ring has an unfavourable effect on the formation of the diimidazo-compound.

The benzenetetraamine can be replaced in the synthesis of 5,6-diacetamido-1,2-*peri*-naphthoylenebenzimidazole (VIII) by 4,6-dinitrophenylene-1,3-diamine. This reacts in an analogous manner with naphthalic acid in glacial acetic acid medium on simultaneous reduction of the nitro-groups with iron. Application of the same method to 3,5-diphenylazotoluene-2,6-diamine gave the dye (XI), whose properties were analogous to those of the benzene derivative.

## 4. Mechanism of Interaction of Phthalic Anhydride with *o*-Phenylenediamine

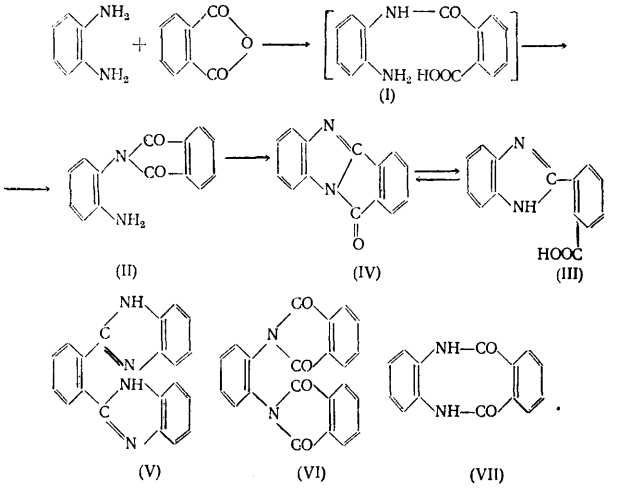
Products of the condensation of *o*-phenylenediamine with phthalic anhydride were described in the earlier papers, the results being well known[112,113]. Depending on the stoichiometric proportions of the components and the reaction conditions, *o*-phthalimidoaniline (II), *o*-benzimidazol-2′-ylbenzoic acid (III), 1,2-*o*-benzoylenebenzimidazole (IV), *o*-bisbenzimidazol-2′-ylbenzene (V), and *o*-diphthalimidobenzene (VI) were obtained. By the reaction of phthaloyl dichloride with *o*-phenylenediamine, Stetter prepared[114] a compound having an eight-membered ring (VII). Porai-Koshits and Antoshul'skaya[115] investigated the production of compounds (III)–(VI) by fusing the components in various proportions, and found that the diphthaloyl derivative (VI) is formed with the greatest difficulty, whereas compounds (III) and (V), which contain imidazole rings, are more readily formed. The compound (IV), unlike other aroyleneimidazole compounds, exhibits properties characteristic of lactam rings, and can be cleaved to give *o*-benzimidazol-2′-ylbenzoic acid and its derivatives.

In order to explain the interrelationship of the individual stages in the conversion, Arient and Marhan examined the reaction of *o*-phenylenediamine with phthalic anhydride under mild conditions[116]. They found that two amino-compounds are formed initially, one existing for a very short time and being present in very small amount. This is probably the addition product (I). When the boiling point is reached, only the amino-compound (II) is present in the mixture, and the imidazole derivative (III) is formed. The composition of the mixture remains almost unchanged on further heating, the reaction product containing the two compounds in roughly equal proportions.

The reaction in methanol is considerably affected by the presence of hydrochloric acid. As its concentration increases, the quantity of the imidazole derivative (III) first increases at the expense of the amino-compound (II), and at the same time *o*-bisbenzimidazol-2′-ylbenzene (V) is also formed; when 0.5 equivalent of hydrochloric acid is used per mole of *o*-phenylenediamine, (V) becomes the main reaction product.

Further increase in the concentration of hydrochloric acid leads again to the formation of the amino-compound (II) as the final reaction product. The highest yield is obtained in the presence of one equivalent of hydrogen chloride; the amine hydrochloride which is formed crystallises out, and reaction ceases. The hydrochloric acid concentration is so decisive that variation in the relative proportions of the starting materials has no effect on the course of the reaction.

Reaction of *o*-phenylenediamine with phthalic anhydride at higher temperatures yields mainly *o*-benzimidazol-2′-ylbenzoic acid (III). In the presence of one equivalent of hydrochloric acid in water, the amino-compound (II) and traces of the imidazole derivative (III) are at once formed on heating, whereas in methanol the sole reaction product is the amino-compound (II). On further heating, the amount of the compound (III) increases, the proportions of the two compounds being 1 : 1 after 1 h and only compound (III) remaining after 2–3 h.



In the presence of hydrochloric acid under pressure at 180°, the reaction gives no typical maximum yield[90,91] at an optimum hydrochloric acid concentration, in contrast to the preparation of benzimidazole derivatives from *o*-phenylenediamine and monocarboxylic acids. The reaction in water is anomalous, with the formation of *o*-diphthalimidobenzene (VI).

In acetic acid reaction follows the same course as in water. As soon as the boiling point is reached, the initially formed amino-derivative (II) passes quantitatively into the imidazole (III) together with a small amount of 1,2-*o*-benzoylenebenzimidazole (IV) and the bisimidazole derivative (V). Reaction products of the same composition are formed in pyridine. The use of nitrobenzene accelerates the reaction and increases the quantity of 1,2-*o*-benzoylenebenzimidazole (IV) in the final product.

1,2-*o*-Benzoylenebenzimidazole (IV) is obtained from (II) and (III) by fusion at 250–290° or boiling in acetic anhydride. In contrast to 1,2-*peri*-naphthoylenebenzimidazole, which is readily formed when *o*-phenylenediamine and naphthalic acid are heated in acetic acid, the reaction of *o*-phenylenediamine with phthalic anhydride terminates under these conditions with the formation of the imidazole (III), the compound (IV) being present in the mixture in very small amount. Closure of the second five-membered ring requires great deformation of the molecule, which can be achieved under severe conditions.

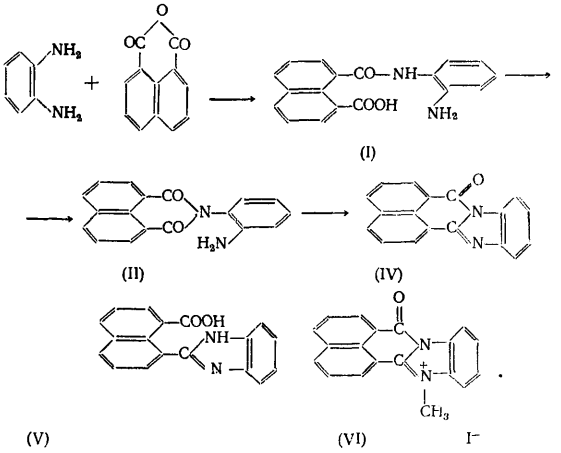
Examination of the rearrangement of *o*-phthalimidoaniline (II) to *o*-benzimidazol-2'-ylbenzoic acid (III) revealed that the hydrochloride of the amino-compound remains unchanged even after heating in methanol for several hours, and the same result is obtained after adding various quantities of either hydrochloric acid or sodium carbonate. In water rearrangement occurs quantitatively after 2–3 h, and hydrochloric acid has no effect on the course of the reaction. High-boiling organic solvents (pyridine, acetic acid, nitrobenzene) accelerate the rearrangement, but the reaction product also contains 1,2-*o*-benzoylenebenzimidazole. Rearrangement leading to the formation of the imidazole derivative is, of course, facilitated by raising the temperature, and probably involves an intermediate stage of formation of 1,2-*o*-benzoylenebenzimidazole (IV), which in aqueous medium, however, is almost immediately hydrolysed to *o*-benzimidazol-2'--ylbenzoic acid (III).

If the process takes place in anhydrous medium (in acetic anhydride or on fusion), reaction stops at the first stage. In high-boiling solvents, partial hydrolysis by water formed in the reaction occurs. On the basis of the above results, the following mechanism has been suggested for the reaction.

5. Mechanism of Interaction of Naphthalic Acid with *o*-Phenylenediamine

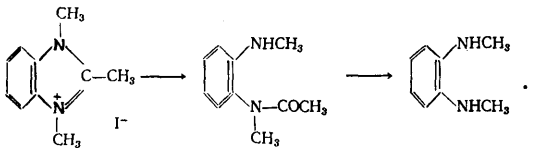
Products of the interaction of naphthalic acid with *o*-phenylenediamine do not possess properties analogous to those of the benzene derivatives. These compounds have been described in less detail, and probably not always entirely correctly. Bistrzycki and Risi[118] obtained from *o*-phenylenediamine and naphthalic anhydride the amide (I), which on being heated to 230–240° was converted into 1,2-*peri*-naphthoylenebenzimidazole (m.p. 189°). Both compounds were later obtained by the same method by Chakravarti[119], who also described 8-benzimidazol-2'--ylnaphthoic acid (V). The 1,2-*peri*-naphthoylenebenzimidazole prepared in a similar manner[120,121] melted at 206°. Krasovitskii and Matskevich[122] obtained negative results for the reaction of naphthalic acid with *o*-nitroaniline, but by simultaneous reduction they isolated[123] *N*-*o*-aminophenylnaphthalimide (II) together with 1,2-*peri*--naphthoylenebenzimidazole (m.p. 189°). It is interesting that papers on the hydrolytic cleavage of benzimidazole derivatives make no mention of the possibility of the cleavage of naphthoylenebenzimidazole, although the analogous benzoylenebenzimidazoles are extremely labile to hydrolysis.

In a study of the interaction of *o*-phenylenediamine with naphthalic acid, Arient and Marhan established that the temperature of the medium has a decisive influence on the direction of the reaction[124]. At temperatures up to 60° in various solvents, the amide (I) is gradually formed, and from it *N*-*o*-aminophenylnaphthalimide (II). In all cases the final reaction product is the imide (II), containing a minute amount of 1,2-*peri*-naphthoylenebenzimidazole (IV).



The undoubted formation of the amino-compound (II) is not consistent with results obtained for the reaction of *o*-phenylenediamine with phthalic anhydride. In the latter case not only amino-compounds of types (I) and (II) but also *o*-benzimidazol-2'-ylbenzoic acid and *o*-bisbenzimidazol-2'-ylbenzene are formed under analogous conditions. The proportions of these products are decisively affected by the content of hydrochloric acid in the reaction mixture.

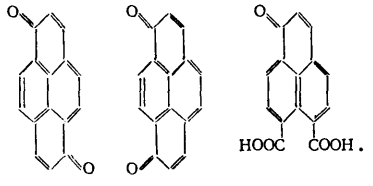
When naphthalic acid is used, analogous benzimidazole derivatives are not formed with the most varied changes in reaction medium.



Interaction at higher temperatures leads to the formation of 1,2-*peri*-naphthoylenebenzimidazole. Reaction occurs very readily, especially in boiling acetic acid, and with a quantitative yield, as well as when *N*-*o*-aminophenylnaphthalimide or the starting materials are heated. The course of the reaction is not affected by additions of various quantities of hydrochloric acid, which is the effective agent in the synthesis of benzimidazole derivatives.

The 1,2-*peri*-naphthoylenebenzimidazole obtained is very stable, and does not undergo cleavage on prolonged boiling or heating at higher temperatures under pressure, either in acid or in alkaline medium. This distinguishes it significantly from the analogous 1,2-*o*-benzoylenebenzimidazole, which is so readily hydrolysed that the final reaction product from *o*-phenylenediamine and phthalic anhydride is *o*-benzimidazol-2'-ylbenzoic acid. An absolutely anhydrous medium is required for the preparation of 1,2-*o*-benzoylenebenzimidazole. The great stability of 1,2-*peri*-naphthoylene-1',2'-benzimidazole means that the reaction of *o*-phenylenediamine with naphthalic acid does not proceed beyond the stage at which it is formed, and the postulated imidazole derivative (V) cannot be obtained.

The following reaction mechanism has been suggested on the basis of the above results



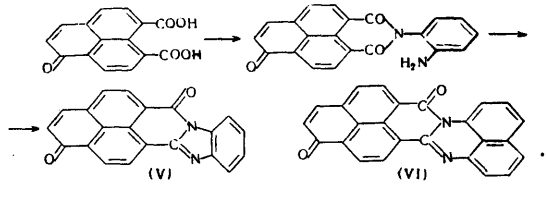
Several methods have been developed for cleaving the imidazole ring in benzimidazole derivatives, among which the most convenient is in most cases alkaline hydrolysis of the 1,2,3-trialkyl derivatives[125-127]

1,2-*peri*-Naphthoylenebenzimidazole forms with methyl iodide a methiodide (VI). Even in this case, however, the naphthoylenebenzimidazole derivative behaves differently from simple benzimidazoles. This compound (VI) is as stable as the original 1,2-*peri*-naphthoylenebenzimidazole, and is not cleaved by any of the usual methods.

## VII. DYES BASED ON PYRENIC ACID

The oxidation of pyrene yields naphthalene-1,4,5,8--tetracarboxylic acid, a necessary intermediate for the synthesis of several vat dyes. A mixture of pyrene-1,6- and -1,8-quinones (I) and (II) can be isolated as intermediate oxidation products, together with 1-oxophenalene--6,7-dicarboxylic acid (III), which is termed pyrenic acid in the literature.

(I) (II) (III)



Pyrenic acid was first obtained by Hintz[128], and isolated in pure form by Goldschmiedt[129], its structure later being determined by Bamberger and Philip[46]. More recently its preparation has been mentioned in a paper by Vollmann et al.[130] The only method available for preparing pyrenic acid is that given by Bamberger and Philip, who oxidised pyrene in aqueous suspension with a slight excess of chromic mixture (6 instead of 5.3 moles calculated as chromium trioxide). Oxidation is not complete. Pyrenic acid was isolated from the reaction products by extraction with dilute sodium carbonate solution at 50°. The residue remaining after extraction was again subjected to further oxidation. Complete oxidation of the pyrene was achieved after six repetitions of the oxidation process. The yield of the unpurified acid is 20.6%. Our results indicate that, apart from resinous impurities, this acid still contains ~20% of naphthalene-1,4,5,8-tetracarboxylic acid. The pyrenic acid is purified by several recrystallisations from acetic acid. The yield of the pure acid was not indicated in the early work[46]. Its anhydride, obtained by prolonged heating above 100°, does not melt, but chars at 260°. Vollmann gives for it m.p. 174°. In a more detailed study of the oxidation of pyrene to pyrenic acid in aqueous suspension, Arient and Dvořák established that the low yield of the acid is due to the fact that a large proportion of the pyrene is oxidised to compounds which dissolve readily in water, or to carbon dioxide.

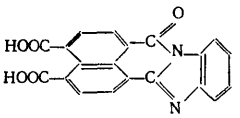
A method was developed for the identification of naphthalene-1,4,5,8-tetracarboxylic acid which consisted in treating it with *o*-phenylenediamine to form a scarlet aroyleneimidazole dye. Pyrenic acid, which gives a yellow spot on a chromatogram, is converted into a brownish-orange dye by reaction with *o*-phenylenediamine.

Bromination of pyrenic acid in acetic acid yields a monobromo-derivative. Neither increasing the excess of bromine nor prolonging the duration of reaction produces further bromination. The bromine is probably present in position 2 in pyrenic acid, by analogy with the bromination of pyrenequinone, in which the bromine enters positions 2 and 7, and also from the fact that oxidation of the brominated pyrenic acid with alkaline hypochlorite solution yields naphthalene-1,4,5,8-tetracarboxylic acid containing no bromine.

Reaction of pyrenic acid or its bromo-derivative with *ortho*- or *peri*-diamines of the benzene or naphthalene series in glacial acetic acid gives an almost theoretical yield of aroyleneimidazole (V) or naphthaloperinone (VI) dyes[117].

A mixture of *cis* and *trans* isomers can theoretically be formed by the reaction. However, the compounds obtained could not be separated into two isomers either by the usual methods or chromatographically. The dyeing properties also indicate that the dyes are single compounds. It may be suggested that, under the influence of the keto--group in the nucleus of pyrenic acid, the electron density will decrease on the carbonyl carbon nearer to the keto--group, which after initial formation of the corresponding imide will take part preferentially in formation of the imidazole ring:

Unlike the products obtained from naphthalic acid, these substances are vatted with *ortho*- or *peri*-diamines. Some of the dyes of this type and their characteristic properties are listed in the accompanying Table.



Bromination of the dye obtained from pyrenic acid and *o*-phenylenediamine yields monobromo- and dibromo--derivatives. The first bromine atom enters the ring containing the keto-group, probably at position 4. The monobromo-derivative is identical with the product of the interaction of 4-bromopyrenic acid and *o*-phenylenediamine. Oxidation of the monobromo-derivative with hypochlorite or with alkaline potassium permanganate solution gives naphthoylenebenzimidazole-*peri*-dicarboxylic acid, which contains no halogen.

The second bromine atom enters the benzene ring of the imidazole. Oxidation with hypochlorite yields naphthoylenebenzimidazole-*peri*-dicarboxylic acid (VII) containing one bromine atom in the molecule. More severe oxidation with chromium trioxide in acetic acid forms a tetracarboxylic acid containing no bromine, to which the structure (VIII) has been assigned on the basis of the work of Bamberger and Berlé[131] and of Efros and his coworkers,

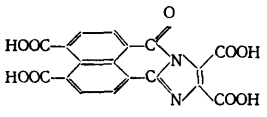


TABLE.

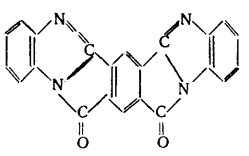
| Acid | Diamine | Colour of dye | Colour of vat | Shade |
|---|---|---|---|---|
| Pyrenic | *o*-phenylene-diamine | yellowish brown | orange with green fluorescence | brownish orange |
| » | 4-chlorophenyl-ene-1,2--diamine | ditto | ditto | reddish brown |
| » | 4-ethoxyphenyl-ene-1,2--diamine | reddish brown | » | pure brown |
| » | naphthylene--1,2-diamine | dark brown | orange | violet-brown |
| » | naphthylene--1,8-diamine | blue-black | red | khaki |
| Monobromo-pyrenic | *o*-phenylene-diamine | brownish orange | orange with green fluorescence | orange-brown |

and which forms with *o*-phenylenediamine orange-coloured reaction products.

(VII)

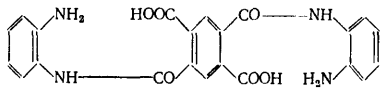


(VIII)

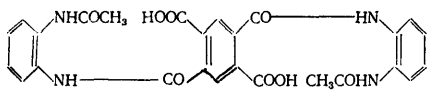
The aroylenebenzimidazole or aroyleneperinone dyes obtained give interesting and brilliant shades on cotton from a vat, but these are less fast to washing than shades obtained with available vat dyes.

## VIII. DYES BASED ON BENZENE-1,2,4,5-TETRACARBOXYLIC ACID

Benzene-1,2,4,5-tetracarboxylic acid has attracted the attention of chemists because of the possibility of obtaining dyes analogous to those of the aroyleneimidazole series from naphthalene-1,4,5,8-tetracarboxylic acid. Little work has been done on the reactions of pyromellitic acid, apart from the formation of functional derivatives. The preparation of complex compounds with thiourea has been described[132], and also the use of pyromellitic anhydride with 2-methylquinoline for the synthesis of benzoindanones[133].



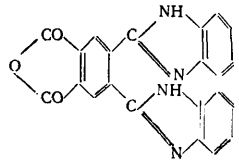
The only mention of the reaction of this acid with aromatic diamines is contained in a Swiss paper of 1941, which describes also 1,2,4,5-benzoylene-1′1′,1″,2″-dibenzimidazole[134]. The paper describes the preparation of the *trans* isomer of terephthaloylenebisbenzimidazole (I) by fusing pyromellitic anhydride with the appropriate quantity of *o*-phenylenediamine. The structure of this compound was postulated without further explanation, and was supported by elementary analysis.



(I)

Formation of the *trans* isomer would be of great interest for the dye industry, since by using various substituted *o*-phenylenediamines it would be possible to obtain a range of dyes which could be vatted and would be of interest as disperse dyes.

Arient and Havlíčková have obtained the compounds (II) and (III) together with a mixture of other products by the reaction of *o*-phenylenediamine with pyromellitic acid in acetic acid[135].



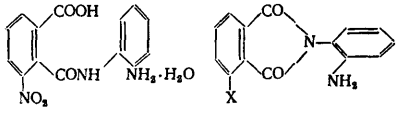
(II)

(III)

Reaction of *o*-phenylenediamine with pyromellitoyl tetrachloride in chlorobenzene gave a mixture of two compounds, which were separated by means of their solubility difference. One of them could be vatted in ammoniacal medium, from which it colours cotton an orange shade; this is the *trans* isomer of terephthaloylenebisbenzimidazole (I). The second substance could not be vatted, melts above 400°, and has the structure (IV).

(IV)

## IX. DYES BASED ON PHTHALIC ACID



The mechanism of the interaction of *o*-phenylenediamine with monocarboxylic and *ortho*- or *peri*-dicarboxylic acids presupposes the initial addition of the lone pair of electrons on the amino-nitrogen to the carbonium ion formed by protonation of the carboxy-group. According to this mechanism a carboxy-group having a diminished electron density on the carbon atom will react preferentially. The magnitude of the electron density on the carboxy-carbon will depend on the nature and position of substituents in the aromatic ring of the carboxylic acid. Krasovitskii et al.[136] point to the formation of a single isomer of naphthoylenebenzimidazole when 4-nitronaphthalic acid reacts with *o*-phenylenediamine. On the above considerations this isomer was assumed to be 1,2-(4-nitronaphth-1,8-oylene)benzimidazole. A similar conclusion was drawn by Arient and Marhan when discussing the results of the reaction of various nitronaphthoic acids with *o*-phenylenediamine and of nitro-*o*-phenylenediamine with naphthalenedicarboxylic acid[87,116].

Nitro- and acetamido-groups present in phthalic anhydride should exert different effects on the formation of nitro- and acetamido-benzoylenebenzimidazoles respectively: 3-nitrophthalic anhydride should yield 1,2-(6′-nitrobenz-1′,2′-oylene)benzimidazole (VII), and 4-nitrophthalic

anhydride the corresponding 4'-nitro-derivative (XIII) or the corresponding intermediate products. The acetamido--group should have the opposite effect: 3-acetamidophthalic anhydride should give 1,2-(3'-acetamidobenz--1',2'-oylene)benzimidazole (XXIII), and 4-acetamidophthalic anhydride the corresponding 5'-acetamido--derivative (XXV).[152]

Paper chromatography indicates that four compounds are formed by the reaction of 3-nitrophthalic anhydride with *o*-phenylenediamine. Among them have been identified 2-benzimidazol-2'-yl-3-nitrobenzoic acid (V), 1,2-bisbenzimidazol-2'-yl-3-nitrobenzene (IX), and the hydrate of 2-*o*-aminophenylcarbamoyl-3-nitrobenzoic acid (I). The fourth compound could be neither isolated nor identified. The corresponding 1,2-(6'-nitrobenz-1',2'--oylene)benzimidazole (VII) was obtained by subliming the benzimidazolylbenzoic acid (V) or boiling it in acetic anhydride.

Reduction of (V) and (IX) followed by acetylation of the resulting amino-derivatives effected the synthesis of 3-acetamido-2-benzimidazol-2'-ylbenzoic acid (VI) — together with 1,2-(6'-acetamidobenz-1',2'-oylene)benzimidazole (VIII) — and 3-acetamido-1,2-bisbenzimidazol--2'-ylbenzene (X).

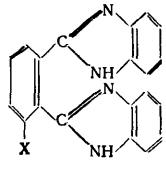
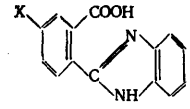
(II)

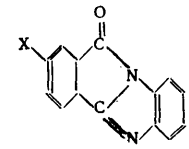


(II) X=$NO_2$;
(III) X=$NH_2$;
(IV) X=$NHCOCH_3$

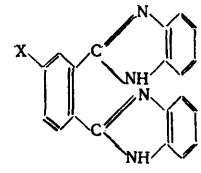
(V) X=$NO_2$;
(VI) X=$NHCOCH_3$;



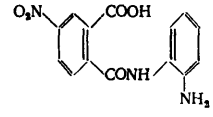
(VII) X=$NO_2$;
(VIII) X=$NHCOCH_3$.



(IX) X=$NO_2$;
(X) X=$NHCOCH_3$.

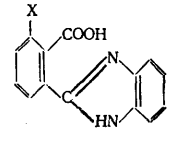


All three compounds formed by the reaction of 4-nitrophthalic anhydride with *o*-phenylenediamine — 2-benzimidazol-2'-yl-5-nitrobenzoic acid (XI), 1,2-bisbenzimidazol-2'-yl-4-nitrobenzene (XVI), and 2-*o*-aminophenylcarbamoyl-5-nitrobenzoic acid (XIX) — have been identified. 1,2-(4'-Nitrobenz-1',2'-oylene)benzimidazole (XIII) is formed only when the benzimidazole (XI) is sublimed or is boiled in acetic anhydride; it was not detected among the initial reaction products. Reduction of the diimidazole (XVI) followed by acetylation gave 4-acetamido-1,2-bisbenzimidazol-2'-ylbenzene (XVIII); reduction of the benzimidazole (XI) gave the amino-derivative (XII), which on being boiled in acetic acid was converted into 1,2-(4'-acetamidobenz-1',2'-oylene)benzimidazole (XV). The same substance was obtained also by the acetylation of (XIV), synthesised from the amino-acid (XII) by sublimation.

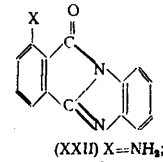


(XI) X=$NO_2$;
(XII) X=$NH_2$;

(XIII) X=$NO_2$;
(XIV) X=$NH_2$;
(XV) X=$NHCOCH_3$.



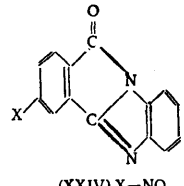
(XVI) X=$NO_2$;
(XVII) X=$NH_2$;
(XVIII) X=$NHCOCH_3$.



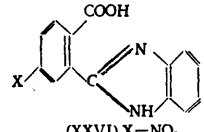
(XIX)

Reaction of 3-acetamidophthalic anhydride with *o*-phenylenediamine yields seven compounds — 1,2-(3'-aminobenz--1',2'-oylene)benzimidazole (XXII) and its *N*-acetyl derivative (XXIII), 2-amino-6-benzimidazol-2'-ylbenzoic acid (XX) and its *N*-acetyl derivative (XXI), 3-acetamido--1,2-bisbenzimidazol-2'-ylbenzene (X), 3-amino-*N*-*o*--aminophenylphthalimide (III), and 3-acetamido-*N*-*o*--aminophenylphthalimide (IV).

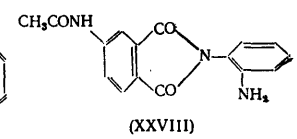
Hydrolysis of the acetyl group is observed not only on reaction in dilute hydrochloric acid under pressure but also under milder conditions, even in methanol.



(XX) X=$NH_2$;
(XXI) X=$NHCOCH_3$



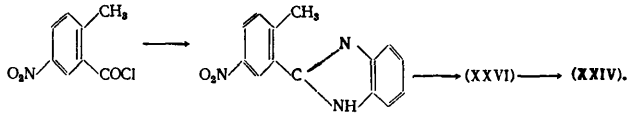
(XXII) X=$NH_2$;
(XXIII) X=$NHCOCH_3$



Paper chromatography indicates that six compounds are formed by the interaction of 4-acetamidophthalic anhydride and *o*-phenylenediamine, but of these only 4-acetamido--*N*-*o*-aminophenylphthalimide (XXVIII) could be isolated. From a chromatographic comparison of the reaction products with known specimens, the structure 4-amino--1,2-bisbenzimidazol-2'-ylbenzene (XVII) was assigned to the compound having $Rf$ = 0.6 and yellow fluorescence, the structure of its *N*-acetyl derivative (XVIII) to the compound having $Rf$ = 0.62 and green fluorescence, and the structure of 4-amino-2-benzimidazol-2'-ylbenzoic acid (XXVII) to the compound having $Rf$ = 0.89.

(XXIV) X=$NO_2$
(XXV) X=$NHCOCN_3$

(XXVI) X=$NO_2$
(XXVII) X=$NH_2$

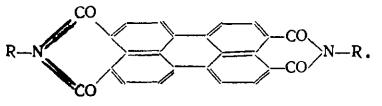


(XXVIII)

Comparison of the ultraviolet spectrum of 1,2-(6'-acetamidobenz-1',2'-oylene)benzimidazole (VIII), prepared by

reducing the 6'-nitro-derivative (VII), with that of the 3'-acetamido-derivative (XXIII) has demonstrated unequivocally that the nitro-group and the acetamido-group exert differently directed effects on the reaction of *o*-phenylenediamine with the corresponding substituted phthalic anhydrides.

The structure of 1,2-(4'-nitrobenz-1',2'-oylene)benzimidazole is supported by the difference between its ultraviolet spectrum and that of the 5'-nitro-derivative (XXIV), synthesised by the scheme



Reaction of 3- and 4-nitrophthalic anhydrides with *o*-phenylenediamine leads to the formation of intermediate products, which on subsequent treatment give 6'- and 4'-nitro-1,2-benz-1',2'-oylenebenzimidazole (VII) and (XIII) respectively. The acetamido-group, on the other hand, yields the opposite results, reaction of 3- and 4-acetamidophthalic anhydride with *o*-phenylenediamine giving 1,2-(3'-aminobenz-1',2'-oylene)benzimidazole (XXII) and 4-amino-2-benzimidazol-2'-ylbenzoic acid (XXVII).

## X. DYES BASED ON PERYLENE-3,4,9,10-TETRACARBOXYLIC ACID

Perylene-3,4,9,10-tetracarboxylic acid does not, on reaction with *ortho*-diamines, form compounds having desirable dyeing properties. With aliphatic and aromatic monoamines, however, interesting red dyes are obtained, which can be applied as vat dyes[137-139] or pigments[140].

Among vat dyes are known Indanthren Red 2G (R = $CH_3$) and Indanthren Scarlet R ( R = *p*-$CH_3OC_6H_4$).

Brilliant red vat dyes are obtained by introducing other vattable groups into the molecule[141,142]. Small changes in shade can be achieved by also introducing substituents into the dye, e.g. by chlorination or nitration[143,144].

The only dyes which differ in colour from the wide range of red dyes are those obtained by the reaction of perylene-3,4,9,10-tetracarboxylic acid with acrylonitrile and with aminopropionitrile, which are very good grey vat dyes[145].

A well-known pigment used for the colouring of plastics, especially poly(vinyl chloride)[140], is PV Fast Red B,[146] the bis-3,5-dimethylphenylimide of perylenetetracarboxylic acid, which is used for the mass coloration of poly(vinyl chloride)[140] and polyamides. It is employed under the name Permanent Red B Extra[147] for oil varnishes and cellulose nitrate varnishes.

## XI. DYES BASED ON VARIOUS DICARBOXYLIC ACIDS

Mainly browns have been obtained from other carboxylic acids which are capable of giving aroyleneimidazole dyes with *ortho*-diamines. The patent literature gives many such examples, but it is most likely that none of these dyes has yet been produced on an industrial scale. The most promising representatives of this group are dyes based on benzanthrone-3,4-dicarboxylic[148] and anthraquinone-2,3-dicarboxylic[125,149,150] acids. Dyes obtained from these acids can apparently be applied as vat and disperse dyes.

## XII. REACTIVE AROYLENEIMIDAZOLE DYES

Reactive yellow and red dyes have been obtained by reaction with cyanuryl chloride of both vattable and non-vattable aroyleneimidazoles of the naphthalene and perylene series containing an amino-group[126,127].

## XIII. AROYLENEIMIDAZOLE DYES FORMED ON THE FIBRE

In 1956 a process was patented for producing aroyleneimidazole dyes directly on the fibre[151]. A di- or tetracarboxylic acid is mixed with a diamine and a substance which will promote the reaction (a relatively non-volatile organic acid, e.g. lactic acid), the resulting paste is printed on cotton cloth, and the dye is developed by steaming the cloth or heating it to 120–130°.

4. Addition of ammonia to alkenes 847
5. Synthesis of amines and diamines by hydrogenation of nitriles 848
6. Other methods of preparing amines 850

## I. INTRODUCTION

The chemistry of amines has long attracted the attention of research workers. In particular there are numerous papers on the chemistry of the aromatic amines, but during the past decade more and more papers on the aliphatic and alicyclic amines and on catalytic methods of synthesising them have appeared. These compounds have been the object not only of theoretical investigations but also of a number of investigations connected with the solution of important scientific and technical problems. Information on the aliphatic and alicyclic amines has not been unified and there are no review papers on this important branch of chemistry in recent literature. The well known review paper of Emerson[1] appeared in 1949 and, of course, does not contain material published later.

Aliphatic amines were first discovered by Würtz in 1849 [2] in distilling isocyanates with potassium hydroxide:

$$R{-}N{=}C{=}O + 2KOH \longrightarrow RNH_2 + K_2CO_3.$$

At present there are a number of general and particular methods of synthesising amines. Catalytic methods are the most widely used. The methods are very diverse both with regard to the starting materials and to the catalysts employed; by changing the reaction conditions the yield of primary, secondary, and tertiary amine can be altered as required. Alcohols, ethers, halogen derivatives, aldehydes, ketones, nitrogen-containing compounds, and unsaturated hydrocarbons are used as starting materials for the synthesis of amines. Catalysts have been proposed with the aid of which some amines may be converted into others. Because of the extensive literature on this problem, we considered it expedient to deal only with problems connected with amines proper and not consider amino-derivatives with other functional groups.

Amines are produced in large tonnages by the basic organic synthesis industry. They are used in the production of plastics, explosives, dyes, artificial fibres, and in a number of other branches of industry. For example, vinylamines are used as inhibitors in the polymerisation of vinyl acetylene [3] and also as accelerators in vulcanisation [4] and in the dyeing of polyacrylic fibres [5]. Primary, secondary and tertiary amines are used as addition compounds with boranes in the reduction of organic compounds [6]. Secondary aliphatic amines are used in the synthesis of enamines, the polymerisation and copolymerisation of which yield auxiliary materials used in the textile industry and in the production of plastics [7]. Some higher primary amines, for example, palmitylamine and stearylamine, give auxiliary materials for the textile industry when condensed with hydroxymethylamides [8]. Primary and secondary aliphatic amines are used for the preparation of aminoacroleins [9]. Aliphatic amines with 2 to 20 carbon atoms in the molecule are used as additives to bind metallic impurities in the distillation of alcohols obtained by the hydroformylation of alkenes and subsequent reduction of the aldehydes formed by hydrogen on a nickel catalyst [10]. In connection with reports that some high-molecular primary alkylamines suppress the development of the tubercule bacillus, 1-aminododecane, 2-aminotridecane, and 3-aminotridecane have been synthesised and show the maximum activity *in vitro* [11]. It has been shown that primary amines containing no more than five carbon atoms in the molecule ignite on mixing rapidly with highly concentrated nitric acid and can be used as fuel for liquid reaction engines; branching of the hydrocarbon chain in the amine molecule reduces the rate of ignition [that is, increases the ignition delay (Ed. of Translation)]; on the other hand, an increase in the number of alkyl groups attached to the amino-group increases it. A solution of triethylamine in 2,6-xylidine was used by the Germans under the name "Tonka 250" as a fuel for rocket engines. A mixture of stereoisomeric 2,7-diaminooctanes is used for the preparation of polyamides from adipic acid. In the polycondensation, polyamides with a molecular weight of ~ 50 000 are formed [12]. The secondary diamines

$$C_2H_5NHCR_2(CH_2)_n\,CR_2NHC_2H_5$$

(where R = $CH_3$ or $C_2H_5$ and $n$ = 2–7) have been synthesised for tests of ganglionolytic activity; the greatest activity is found when $n$ = 4 and R = $C_2H_5$. [13] Aliphatic amines of the type $(CH_3)_2NH$ etc. are used for the synthesis of some ethanolamines with spasmolytic properties. For example,

4-methoxy-ω-chloroacetophenone and dimethylamine yield the effective 4-hydroxy-ω-dimethylaminoacetophenone[14].

Midzhoyan and coworkers[15] carried out investigations in the field of amines and their derivatives with the object of preparing some chloroacetamides and urethanes. Compounds of the general formula

$$p\text{-}ROC_6H_4CH_2CH_2NHCOCH_2Cl$$

where R = $CH_3$, $C_2H_5$, $C_3H_7$, iso-$C_3H_7$, $C_4H_9$, iso-$C_4H_9$, have been synthesised by the following scheme:

$$p\text{-}ROC_6H_4CH_2Cl + NaCN \longrightarrow p\text{-}ROC_6H_4CH_2CN,$$
$$p\text{-}ROC_6H_4CH_2CN + H_2 \longrightarrow p\text{-}ROC_6H_4CH_2CH_2NH_2;$$
$$p\text{-}ROC_6H_4CH_2CH_2NH_2 + ClCH_2COCl \longrightarrow p\text{-}ROC_6H_4CH_2CH_2NHCOCH_2Cl.$$

Changes in the anticonvulsant action of compounds of the type $p$-$ROC_6H_4CH_2CH_2NHCOCH_2Cl$ have been studied. With R increasing, amines of the type $p$-$ROC_6H_4CH_2CH_2NH_2$ have also been used for the synthesis of some urethanes of interest because of their cancerolytic activity.

Khorlin and coworkers synthesised tertiary aliphatic amines with ganglionolytic activity. The amines obtained were subjected to pharmacological examination[16].

Kyo Fujie[17] synthesised seven derivatives of 2-(diphenylmethoxy)ethylamine and six derivatives of 3-(diphenylmethoxy)propylamine and tested them for papaverine-like anticonvulsant activity. The tests were carried out on smooth muscle from the rat uterus, the mouse intestine, and tracheal muscles of the guinea-pig.

Bonvicino and coworkers synthesised the hypnotics xanthene- and thioxanthene-$\Delta^{9\gamma}$-propylamines and related compounds[18].

Ryan and coworkers synthesised halogenoethyl-derivatives of acetyleneamines and carried out pharmacological tests on rats[19]. The greatest activity was found in compounds having the t-butyl group on a nitrogen atom and also having a methyl group.

Björn[20], in a search for new anaesthetics and a study of the effect of structure on physiological activity, prepared s-butylaminoacetanilides. It was shown that the introduction of a methyl-group on the α-C-atom in the amine part of the molecule does not always increase the anaesthetic activity, but it always increases the toxicity; it was shown that replacement of the isopropyl by a s-butyl group on the nitrogen, with the remainder of the molecule unchanged, increases both the anaesthetic activity and the toxicity.

In the presence of small quantities of orthoboric acid, polyamides are obtained from diamines (trimethylenediamine, etc.) and high-molecular-weight fatty acids; these are used as antioxidants for plastics[21]. Resin amines are used for the preparation of effective inhibitors of the corrosion of steel and other metals[22]. *N*-Substituted acrylamides, required for polymerisation and copolymerisation, are obtained by the dehydration of *N*-substituted hydracrylamides, which are synthesised by the reaction of β-propiolactone with amines in the presence of water[23]. Some amines, for example methylamine, are used technically for condensation with *l*-acetylphenylmethanol in the presence of a platinum catalyst[24]. Amines are also used for the stabilisation of sorbic acid salts[25]. 1,4,7-Triazaheptane is used with ethylene oxide for the preparation of polyhydroxyethylated polyamino-compounds (1,11-dihydroxy-3,6,9-triazaundecane-*NN'N''*-triacetic acid) which form water-soluble complexes with the metals calcium, barium, strontium, magnesium, iron, cobalt, nickel, copper, zinc, manganese, and aluminium. The iron complex is used in agriculture for supplying iron to citrus plants growing on calcareous soil[26]. Accelerators for the dyeing of acrylonitrile fibres with anionic dyes are obtained by the reaction of acrylonitrile with mono-, di-, and poly-amines[27]. New complexes are synthesised from isocyanates and tertiary amines[28]. Diaminoalkenes are used commercially as additives to fuel to increase the rate of combustion[29]. Methylamines are used in the leather industry, for the preparation of rubber vulcanisation accelerators, and for the production of explosives, bactericides, and pharmaceutical preparations[30]. Cyclohexylamine is used in making emulsifiers, anticorrosion coatings, rubber vulcanisers, etc.[31] The literature cited on the uses of amines is not exhaustive, but it illustrates the great diversity of uses for amines in different branches of the economy.

## II. METHODS OF SYNTHESISING ALIPHATIC AMINES

The methods of synthesis of aliphatic amines and the conditions for the preparation of these reactive and labile compounds are very diverse. The methods differ substantially according to the nature of the starting materials and for this reason the methods are arranged here according to the nature of the materials being aminated.

### 1. Amination of Alcohols

Baum[32] considers that of all the dehydrating catalysts for the preparation of amines from alcohols or ethers the best catalyst is aluminium oxide. He studied the amination of n-propyl, n-butyl, isobutyl, and isopentyl alcohols and n-dibutyl ether at 220–550°. It was found that the optimal temperature lies within the range 200–350° for primary alcohols, 300–530° for secondary, and 400–550° for tertiary alcohols. The ratio of the quantity of ammonia to alcohol has a substantial effect on the relative amounts of amines formed. If primary amines are to predominate, the molar ratio alcohol:ammonia should be 4:1; for the formation of secondary amines from normal alcohols this ratio should be 2:1 or 3:1; and for iso-alcohols it should be 1:1. The contact time has a considerable effect on the amine yield. On the basis of his interpretations of the mechanism of catalytic amination, the author recommends that a small quantity of water should be introduced into the alcohol–ammonia or ether–ammonia system. It was found that this addition increases the yield of primary amines without affecting the total yield of amines. At temperatures up to 400° the aluminium oxide catalyst retains its activity practically indefinitely.

Goschorn[33] synthesised amines by the vapour-phase amination of aliphatic alcohols or ethers at 300–400° with a catalyst of oxides of metals of Groups II, III, or IV of the Periodic System, or silica gel on which oxides of metals of Groups V, VI, VII, or VIII have been deposited. Most frequently he used oxides of chromium, nickel, or cobalt. In a second patent[34], he obtained 24.9% of primary and 29.2% of secondary butylamine by the catalytic amination of butanol at 347° with a 1:4 molar ratio of butanol to ammonia. In a third patent[35], he aminated butanol at 320° in the presence of a catalyst based on ammonium molybdate, which enabled the reaction to be carried out at a lower temperature. The yield was 32.6% of primary and 23.6%

of secondary butylamine. Smith[36] recommends aluminium oxide as a catalyst in the reaction of methanol with ammonia at 450°; formation of trimethylamine may be kept to a minimum by the addition of 1–2 moles of water vapour.

Taylor and Raynolds[37] obtained amines from aliphatic alcohols with 2 to 13 carbon atoms in the molecule. Alcohol vapour together with ammonia and hydrogen was passed over a hydrogenation catalyst at 140–230°; the catalyst was an element of Group VIII of the Periodic System.

Doyvis and coworkers[38] proposed a method of preparing amines from aliphatic primary and secondary alcohols with 2–9 carbon atoms in the molecule or the corresponding aldehydes or ketones: the alcohol vapour with ammonia and hydrogen at 10–25 atm is passed over a copper catalyst at 240–300°.

Fowler[39] synthesised 1,2-diaminopropane from 1-aminopropan-2-ol by heating the latter with ammonia in the liquid phase at 150–250° and a pressure of 28–140 atm in the presence of a hydrogenation catalyst consisting of finely divided nickel or cobalt.

A Swiss patent[40] describes a method of preparing mono-, di-, and tri-alkylamines from primary and secondary aliphatic alcohols in the presence of a copper or aluminium/barium hydroxide catalyst at 240–300° and a pressure of 10–25 atm.

A French patent[41] describes a method of preparing primary amines from aliphatic alcohols in two stages. First alcohol vapour and excess of ammonia are passed over a catalyst of iron oxides at 360–420°. After the excess of ammonia has been removed from the condensate obtained, the latter is passed over a nickel hydrogenation catalyst at 100–130° and a pressure of 100–150 atm.

Popov and Shuikin[42] studied the amination of alcohols and were unable to confirm the views of Baum that aldehydes, ketones, ethers, or unstable compounds of alcohol with the catalyst are formed in this reaction. In their opinion amines are formed by the direct elimination of the elements of water from the molecules of alcohol and ammonia when they collide on the active surface of the catalyst.

Kozlov and Panova obtained aliphatic amines in high yield by the catalytic amination of ethers[43]. The vapour of dibutyl ether or diisobutyl ether was passed over alumina or thoria/alumina in a stream of ammonia under a pressure of 1–9 atm;[43] optimal results were obtained at 370–375° and a pressure of 9 atm; after distillation of the catalysate, mixtures of butylamine with dibutylamine and isobutylamine with diisobutylamine were obtained.

Bel'chev and Shuikin catalytically aminated n-butyl alcohol on a mixed oxide catalyst[44]; in the presence of 85% aluminia and 15% iron(III) oxide, which was the most active catalyst, at 405° and a volume flow of 0.75, amines were obtained in 42.8% yield (17.5% primary, 20.5% secondary, and 4.8% tertiary).

Kozlov and Panova[45] aminated butyl alcohols at 250–400° and a pressure of 1–10 atm in the presence of alumina. n-Butyl alcohol gave 89.9% of amines (62% primary, 29.8% secondary, and 8.2% tertiary); under the same conditions isobutyl alcohol gave 68.8% of amines and t-butyl alcohol gave 25.3%.

In a French patent[46] it is proposed to aminate primary or secondary aliphatic alcohols by gaseous ammonia on reduced metal catalysts (nickel, cobalt, copper, platinum, or palladium) in the presence of a hydrogen acceptor (the aldehyde or ketone corresponding to the alcohol). The yield of amines reaches 85%.

Rice and Kohn developed a method of preparing secondary and tertiary amines[47]; primary or secondary aliphatic amines are alkylated with alcohols in the presence of Raney nickel. Butylamine and anhydrous ethanol gave $C_2H_5N(n\text{-}C_4H_9)_2$ in 54% yield. Dibutylamine and anhydrous ethanol gave $C_2H_5N(n\text{-}C_4H_9)_2$ in 42% yield. Noeske and Kolling obtained amines from aliphatic alcohols through nitriles[48]. At first alcohol vapour and excess of ammonia were passed over an iron catalyst at 300–470°. After the excess of ammonia had been removed, the condensate obtained was hydrogenated on a nickel catalyst at 80–160° and a pressure of 100–150 atm. The yield of primary amines was 75–85%, and the yield of secondary and tertiary amines 5–15%.

Patnak and Rao synthesised methylamines, starting from methanol at 425° in the presence of alumina[49]. The yield was 50% of $CH_3NH_2$, 25% of $(CH_3)_2NH$, and 25% of $(CH_3)_3N$.

Bashkirov and coworkers[50] developed a method for the reductive amination of aliphatic alcohols or aldehydes at 230° and 100 atm pressure on $Fe_3O_4$ ($V_2O_5$). The yield of amines was 95–97%.

Bel'chev and coworkers[51] carried out the vapour-phase amination of primary alcohols (butyl and pentyl) on alumina and mixed catalysts; the highest yield of butylamines (80%) was obtained in the presence of 5% titanium dioxide/alumina.

Kochetkov and coworkers[52] synthesised secondary amines with a branched chain of the general formula:

$$C_2H_5NHCR_2[CH_2]_nCR_2NHC_2H_5,$$

where R = $CH_3$ or $C_2H_5$ and $n$ = 2–7. Diols of the type $HOCR_2[CH_2]_nCR_2OH$ were used as starting materials.

Kagan and coworkers[53] studied the amination of higher aliphatic alcohols in the presence of a promoted fused iron catalyst under the pressure of hydrogen. Using the amination of octyl alcohols as an example, they found the effect on this process of pressure, temperature, volume flow, composition of the starting gas, and also the effect of the structure of starting alcohols. In the amination of octan-1-ol when the temperature is raised from 230° to 270° the total degree of conversion is increased from 89.5 to 96.5% but the yield of by-products increases by a factor of 3; at 240–250° and 100 atm pressure the yield of amines passes through a maximum of 86%. In the amination of octan-2-ol the yield of primary amines increases to 92%. Branching of the carbon chain sharply reduces the yield of amines and leads to a reduction in the yield of secondary and tertiary amines in the catalysate. Thus, 2-methylheptan-4-ol is converted into amines with only 71.0% yield; the yield from octan-4-ol is 85.0%, that from 2-ethylhexan-2-ol 75%, and that from octan-1-ol 90%.

Kozlov[54] aminated primary, secondary, and tertiary aliphatic and alicyclic alcohols under pressure in the presence of alumina at 370–380°. Increasing the pressure of the ammonia to 8–10 atm suppresses side-reactions and in some cases increases the yield of amines to 90% of the theoretical, based on alcohol reacting.

## 2. Amination of Carbonyl Compounds

Carbonyl compounds as possible starting materials for the synthesis of amines difficult to obtain from other compounds have attracted the attention of a number of workers.

Grigorovskii and Margolina[55] studied the reductive amination of butanal in the liquid phase with finely divided nickel as catalyst. The yield of butylamine was 74–80%.

Olin and McKenna[56] studied the vapour-phase amination of aldehydes at 175–180° in the presence of hydrogen on nickel or cobalt. The yield of amines was 87.7–90.9%.

Bami and coworkers[57] carried out the reductive amination of ketones on finely divided nickel (5–10%). The yield of amines was over 80%. 2-Aminobutane, 2-aminopentane, 2-aminoheptane, 2-aminooctane, 3-aminopentane, and 2-aminohexane were obtained.

Alexander and Misegades[58] obtained primary amines by the reductive amination of ketones under pressure. They used platinum as a catalyst and they noted that the addition of ammonium chloride increases the yield of amines.

Popov and Shuikin[59] studied the possibility of aminating acetone under the action of hydrogen and ammonia in the gas phase in the presence of platinised silica gel. They found that acetone at 240° under these conditions gives up to 37.1% of primary amine.

In a later paper, Popov and coworkers[60] studied the effect on the yield of amines in catalytic amination of the nature of the hydrocarbon radicals in different ketones. It was found that aliphatic ketones with the same hydrocarbon groups are more easily aminated than ketones with different groups. Lengthening the carbon chain in one of the groups leads to a reduction in the yield of amines and the greater the difference between the number of carbon atoms in the two groups the greater will be the reduction in yield.

Hentrich and Kaiser[61] proposed a method for the preparation of aliphatic amines from unsaturated ketones and ammonia or a primary amine. The reaction is carried out in the presence of a nickel–manganese–iron catalyst at 120° and 80 atm.

Iffland and Yen Teh-Fu[62] obtained aliphatic amines by the reduction of the corresponding ketoximes on a Raney nickel catalyst at 20° and 4 atm. The yield of amines was 51–85% (2-aminopentane 85%, 2-aminooctane 51%, 2-aminoheptane 45%).

Teter[63] gives directions for preparing an amination catalyst for use in suspensions; it contains 30–70% of cobalt on a kieselguhr carrier with a small amount of alumina.

Skita and coworkers[64] recommend a method for preparing tertiary aliphatic amines by the catalytic reduction of carbonyl compounds in a liquid phase in a solution close to neutral at normal temperature and high pressure. In the presence of $Pt/BaSO_4$ at 20° and 3.4 atm, triethylamine, tributylamine, and other amines were obtained from an aqueous alcoholic solution of ammonium acetate and the corresponding aldehydes.

Reppe and coworkers[65] synthesised secondary and tertiary aliphatic amines (diethylamine, diethylisobutylamine, etc.) by interaction of aldehydes or ketones with ammonia or amines for 24 h in the presence of water at 160° and the introduction of carbon monoxide under a pressure of 120–200 atm in a stainless steel autoclave.

Treszczanowicz and coworkers[66] synthesised ethylamine from acetaldehyde, hydrogen, and ammonia in the presence of a dehydrating catalyst. Comparative studies were done in the presence of two different catalysts: (1) 1–7.9% nickel, 2.1% chromium(III) oxide and 90% pumice, and (2) 4.9% nickel and 51% alumina. The yield of amines was 58.7 and 64.5%.

In a British patent[67] a method of producing aliphatic or cycloaliphatic amines is based on the interaction of aldehydes with ammonia or amines in the presence of nickel or cobalt. The reaction is carried out in the liquid phase with a low-boiling solvent (alcohol, hydrocarbons). Subsequent hydrogenation is carried out at elevated temperature under pressure.

Schade and coworkers[68] have patented a method for the preparation of pure n-butylamine from commercial butyraldehyde containing ketones and ethers as impurities. The formation of dibutylamine depends on the amount of ammonia introduced into the reaction and the presence of ketones in the starting aldehyde; the reaction is carried out in the presence of 50% nickel on alumina.

Schade and Sperling[69] developed a method of converting mono- and tri-ethylamine into diethylamine. The mono- and tri-ethylamine are brought into reaction with one another at 150–180° in the presence of nickel/alumina and, hydrogen and ammonia under a pressure of 2–3 atm. The mixture of mono- and tri-ethylamine is formed as a by-product in the preparation of diethylamine by the reductive amination of acetaldehyde.

Tindall[70] obtained secondary aliphatic amines by hydrogenating a mixture of aliphatic ketones with anhydrous ammonia or primary amines containing from 1 to 8 carbon atoms. The reaction is carried out in the presence of cobalt on calcium or barium sulphate at 160° and a pressure of 70–105 atm. Diisopropylamine is obtained in 73% yield.

Rauch[71] has proposed a method for the preparation of alkylidenealkenylamines from isobutyraldehyde and ammonia at 200° with the use of a manganese–cobalt oxide catalyst on pumice (7.5% manganese and 1.5% cobalt). Isobutylideneisobutylenamine is obtained in 97.4% yield.

For the preparation of diethylamine from acetaldehyde, hydrogen, and ammonia, Treszczanowicz and coworkers[72] used a catalyst of 49% nickel on alumina reduced by hydrogen at 320°. The yield of diethylamine was 54.2%, based on acetaldehyde.

In a further patent, Treszczanowicz and coworkers[73] propose that the preparation of amines from aldehydes, ammonia, and hydrogen[68] should be improved by evaporating at ~40° before it is mixed with the hydrogen; this prevents the formation of resins and significantly lengthens the life of the catalyst.

Günter and Jutta[74] hydrogenated polyenealdoximes on Raney nickel under pressure and obtained the corresponding higher primary n-alkylamines in good yield; decylamine was obtained in 90% yield from decatetraenealdoxime.

Morris and coworkers[75] developed two methods of preparing cycloheptylamine. In the first method, cycloheptanone oxime is hydrogenated in methanol at 60° and 0.75–1 atm in the presence of rhodium on alumina; the yield is 80%. In the second method, cyclopentanone in a mixture with liquid ammonia and alcohol is hydrogenated at 70° and 100 atm; the yield is 61%. Saito Atsudzi[76] obtained hexamethylenediamine in 72% yield from hydroxyadipaldehyde; the aldehyde reacts with ammonia and hydrogen for 6 h with a small amount of alcohol in the presence of Raney nickel at 220–240°.

### 3. Amination of Halogen Derivatives

The synthesis of amines by the catalytic amination of halogen derivatives seems very attractive and promising in the first place because the haloalkanes are produced on a large scale and form a cheap raw material. Moreover, it should be borne in mind that at present it is possible to obtain haloalkanes of practically any given structure and therefore a great diversity of amines can be obtained from them.

Nekrasova and Shuikin[77] studied the catalytic alkylation of ammonia by halogen derivatives of alkanes and cyclanes in the vapour phase at atmospheric pressure. Chloroalkanes were aminated at 310° in contact with a catalyst based on magnesium oxide. The yield of amines in the catalysate changed from 60 to 78.6% as the length of the chain was increased from $C_4$ to $C_{10}$. Chlorocyclopentane, chlorocyclohexane, and bromocyclohexane were aminated at 340°;[78] the effect of the nature of the halogen and its position in the molecule on amination was also studied. The greatest yield of amines was obtained by amination of the chloro-derivative and the least by amination of the iodo-derivatives. The position of the halogen in the haloalkanes has a considerable effect on the yield of amines.

Brown and Lester[79] set out to synthesise primary alkylamines with a long carbon chain and also with different arrangements of the amino-group in the carbon chain. The amines were synthesised in three ways: by Hofmann's reaction, by Leuckart's reaction, and by the reduction of amides in ether in a Soxhlet apparatus. The yield of amines by the first method was 60–78%. The amines were prepared by Leuckart's reaction from the corresponding ketones in 50–63% yield. In the third method the amines were obtained by the reduction of amides with lithium aluminium hydride in ether in a heated Soxhlet apparatus; the yield varied between 50 and 62%.

Schulte and Goe[80] synthesised primary aliphatic amines with a triple bond from 1-haloalkynes and hexamethylenetetramine in chloroform with subsequent decomposition of the quaternary hexaminium salt by alcoholic solution of hydrogen chloride. The effect of chain length and the position of the triple bond was studied. The quaternary hexaminium salt readily forms at ~ 20° in 90% yield from 1-haloalk-2-ynes independently of the chain length. The quaternary hexaminium salt is not formed from 1-haloalk-1-ynes in the cold or with heating. The stability of the quaternary hexaminium salt decreases with increasing chain length.

Tkaczynski and Kotelko[81] obtained ethylenediamine in 45% yield by the reaction of dichloroethane with ammonia; at the same time 1,4,7-triazaheptane (34%) and 1,4,7,10-tetrazadecane (12%) were separated. Tkaczynski obtained 1,2-diaminopropane and other diamines in an analogous manner, starting from dihalo-derivatives[82].

Hennion and Hanzel[83] prepared amines that were difficult to synthesise for steric reasons. Primary and secondary amines were alkylated with t-alkynyl chlorides. *N*-Isopropyl-1,1-dimethylprop-2-ynylamine was obtained from isopropylamine and 3-chloro-3-methylbut-1-yne at 20° after 7 d; the yield was 58%. The alkynamines were reduced to the corresponding allyl and saturated amines. Thus, *N*-isopropyl-1,1-dimethylprop-2-ynylamine in petroleum ether containing 0.01 g 10% palladium on carbon was reduced under pressure over 7 h at 20°, and *N*-isopropyl-1,1-dimethylprop-2-enylamine was obtained in 71% yield.

Nelson and coworkers[84] obtained $ClC(R)(R')CH=CHCl$ by the interaction of $HOC(R)(R')C\equiv CH$ with HCl; with the appropriate amines this gives $R''NHC(R)(R')CH=CHCl$ in 10–35% yield. Dehydrohalogenation of the compound $R''NHC(R)(R')CH=CHCl$ leads to $R''NHC(R)(R')C\equiv CH$ in 50–70% yield.

### 4. Addition of Ammonia to Alkenes

The considerable development of the petrochemical industry in the past decade has led to alkenes becoming bulk raw materials in the basic organic synthesis industry. This is the main reason why, in the search for uses for alkenes, the addition of ammonia to alkenes to form amines was investigated.

Teter[85] has proposed nickel or cobalt on a carrier as a catalyst in the amination of unsaturated compounds or their conversion into nitriles. With this catalyst, propene reacts with ammonia at 343–427° and high pressure. He has also patented[86] a method for the preparation of a cobalt catalyst with the addition of magnesium silicate for the amination of unsaturated compounds. The addition of 1% magnesium oxide as a promoter to the cobalt catalyst suppresses side-reactions and prevents the formation of carbon. He has also proposed[87] a method for the preparation of a new catalyst for the conversion of alkenes into amines. For this purpose a reduced nickel or cobalt catalyst is prepared on bentonite clay; it contains 40–50% of metal. Teter also investigated the catalytic amination and cyanation of alkenes in the presence of a cobalt catalyst[88,89].

The use of sodium as a catalyst for the synthesis of amines from alkenes and ammonia is described in a British patent[90]. For example, when isobutylene is heated to 250–265° with liquid ammonia under a pressure of 650–700 atm in the presence of metallic sodium, t-butylamine is obtained.

Tindall[91] has proposed a method of preparing amines by the reduction of nitroalkenes of the type $R-CH=C(NO_2)-R'$, where R is alkyl or aryl and R' is alkyl. The reaction is carried out in the presence of Raney nickel catalyst under pressure in an inert organic solvent and in the presence of an organic acid with a dissociation constant between $1.86\times 10^{-5}$ and $1.1\times 10^{-3}$.

Thurston[92] prepared amines from alkenes containing a double bond inside or at the end of the carbon chain and an alkyl group on the second hydrogen atom. The alkenes are first brought into reaction with cyanogen chloride or cyanogen bromide in the presence of an acid catalyst in the liquid phase; the reaction mixture is then subjected to hydrolysis and amine separates.

Graf[93] synthesised aliphatic amines by condensing alkenes with hydrogen cyanide in the presence of a strongly acid catalyst and hydrolysing the reaction product. Thus, 3-formylamino-3-methylheptane is obtained by the condensation of 2-ethylhex-1-ene with hydrogen cyanide in the presence of concentrated sulphuric acid and hydrolysis of the reaction product with sodium hydroxide; hydrolysis of the 3-formylamino-3-methylheptane with concentrated sulphuric acid gives 3-amino-3-methylheptane. Octylamines, 4-aminoheptane, a mixture of dodecylamine isomers, 2-aminodecane, etc. are obtained in a similar way.

Howk and coworkers[94] have proposed a method for the catalytic amination of alkenes under the influence of alkali

metals. It has been shown that ammonia, primary amines, and secondary amines are converted into *N*-alkyl derivatives by reaction with ethylene, propene, 2-methylbut-1-ene, but-2-ene, hex-1-ene, butadiene, and cyclohexene in the presence of sodium, potassium, or lithium. The reaction is carried out in a steel autoclave at 200° and 800–1000 atm and the yield reaches 70%.

Urry[95] recommends a method of alkylating primary, secondary, and heterocyclic tertiary amines at the $\alpha$-carbon atom with the aid of alkenes. The reaction is initiated by alkyl peroxides at 90–130°, or under irradiation at 30–50°. When gaseous alkenes are used the reaction is carried out under pressure.

The alkenylamines are interesting compounds in their chemical possibilities, but there are only a few papers on this type of organic compound.

Engelhardt developed a method of preparing allene and acetylene amines by the interaction of 25% aqueous solutions of methylamine, diethylamine, morpholine, or n-butylamine with vinylacetylene under high pressure at a temperature of ~ 100°.[96]

Hasek and coworkers[97] synthesised allene amines by the following scheme:

$$(CH_3)_2CHCHO + NH_3 \longrightarrow (CH_3)_2CHCH[N{=}CHCH(CH_3)_2]_2 + H_2O$$
$$\downarrow$$
$$(CH_3)_2C{=}CHN{=}CHCH(CH_3)_2 + NH_3.$$

Nelson and coworkers[98] have proposed a method for the preparation of secondary alkynylamines by the interaction of $\alpha$-chloroalkynes and aliphatic amines in the presence of bronze at a temperature below 40°; the yield is 10–21%, depending on the nature of the hydrocarbon radical of the primary amine.

5. Synthesis of Amines and Diamines by Hydrogenation of Nitriles

a. Synthesis of amines. The synthesis of amines from nitriles is effected under conditions close to those used in the amination of alcohols and haloalkanes, but not quite identical. As a rule, the hydrogenation of nitriles is carried out in the presence of catalysts based on Group VIII elements under increased pressure of 10–60 atm and at temperatures of 150–300°. Since in the reduction of nitriles, especially dinitriles, a complex mixture of products may be formed, it is important to select those conditions under which the reaction will go mainly in the desired direction. It is possible to find the necessary conditions for the synthesis of amines from nitriles by making a rational selection of catalyst, temperature, and pressure and, in a number of cases, by introducing ammonia into the reaction zone. For example, the synthesis of hexamethylenediamine from adipodinitrile is carried out on an industrial scale in many countries.

Pratt and Norris[99] obtained lower secondary and tertiary amines by the action of hydrogen on a mixture of nitrile with aldehyde, ketone, or alcohol at 200–300° in the presence of pure copper, iron, cobalt, or nickel, or with the addition of oxides of thorium, silicon, aluminium, chromium, or cerium. Pumice, silica gel, or bauxite may be used as a carrier. The molar ratio of the nitrile to the other component depends on whether primary or secondary amines are desired. From acetonitrile and acetaldehyde with excess of hydrogen on a nickel catalyst at 200–230° 98% of amines is obtained, consisting of 12% monoethylamine, 24% diethylamine, and 62% triethylamine.

In a patent by Mell[100], a method is proposed for the preparation of primary, secondary, and tertiary amines by the cyanation of alcohols with ammonia at 200° in the presence of nickel on kieselguhr; immediately after this the reaction mixture is passed over a hydrogenating copper or nickel catalyst at 100–180°. A mixture of primary, secondary, and tertiary amines is obtained in close to 100% yield.

A patent of Hoffman recommends the preparation of primary amines from nitriles by the action of liquid ammonia and hydrogen at elevated pressure in the presence of nickel on kieselguhr or Raney nickel[101].

A method for the preparation of primary amines from nitriles of aliphatic acids with ten or more carbon atoms has been patented[102]. These nitriles are converted into the corresponding primary amines by the action of hydrogen and ammonia at 210° and high pressure in the presence of Raney nickel.

A method of preparing high-molecular-weight primary amines from nitriles of higher fatty acids (stearic, etc.) is described in a patent[103]. Hydrogenation is carried out at a pressure up to 20 atm in the presence of nickel and with the addition of a small amount of barium hydroxide solution, caustic alkalis, or a quaternary ammonium base; under these conditions 93.5% of primary octadecylamine is obtained from stearonitrile.

A method of preparing primary aliphatic amines with six or more carbon atoms is described in a patent[104]. The nitriles of the fatty acids of coconut and cottonseed oils are hydrogenated at 130–150° and 15 atm in the presence of ammonia and Raney-nickel catalyst. An aqueous solution of ammonia or sodium hydroxide is introduced into the reaction mixture in quantity sufficient to maintain an alkaline medium during the whole hydrogenation process; the yield of primary amines is 77.4%.

Sakakibara and coworkers[105] catalytically reduced nitriles of higher fatty acids in the presence of bases. Lauronitrile and stearonitrile were hydrogenated on Raney nickel in the presence of liquid ammonia, sodium hydroxide, methylamine, or furfurylamine. The reaction products were separated into primary and secondary amines. In the reduction of nitriles without the addition of bases 19% of secondary amines were obtained with the primary amines; the presence of any of the bases mentioned suppressed the formation of secondary amines.

Renfrew and Warner[106] developed a method for the preparation of aliphatic amines from nitriles containing 8 to 22 carbon atoms, which were hydrogenated at 110–170° and 10.5 atm. A nickel hydrogenation catalyst was used and 0.5 to 10% (based on nitrile) of aliphatic alcohol was introduced together with ammonia.

Komori Saburo and coworkers[107] synthesised saturated and unsaturated aliphatic amines containing 8 to 22 carbon atoms by the reduction of nitriles obtained from natural fats; the reduction is carried out in the presence of nickel on silica gel and liquid ammonia at 90–150° under a hydrogen pressure of 10–200 atm. The presence of ammonia suppresses the formation of secondary amines and increases the yield of primary amines; under these conditions the yield of primary amine is 73.5% and of secondary amine 26.5%.

Suganuma Tokumasa and coworkers[108] obtained a mixture of secondary and tertiary aliphatic amines from aliphatic nitriles containing 8 to 18 carbon atoms in the molecule; the nitriles were reduced at 150–300° at high pressure in the presence of saturated $C_1$ to $C_{18}$ alcohols and a nickel catalyst. A mixture of secondary and tertiary amines, depending on the quantity of alcohol, is formed according to the following scheme:

$$RCN + R'OH \xrightarrow{H_2} RCH_2NHR';$$
$$RCN + 2R'OH \xrightarrow{H_2} RCH_2NR'_2.$$

Tertiary amines with 20–30% of secondary amines are mainly formed by this method.

Sommers and Aaland[109] synthesised aliphatic amines by reduction of Schiff bases in the presence of lithium tetrahydroaluminate instead of a hydrogenation catalyst.

Kozlov and Panova[110] aminated carboxylic esters in the presence of alumina at 370°. The corresponding nitriles are formed as intermediates in the reaction.

Freifelder[111] synthesised primary amines of the type $R[CH_2]_n.CH_2NH_2$ by the catalytic reduction of the corresponding nitriles on a Raney rhodium–aluminium (Al–5%Rh) catalyst which is used in amounts 10–20% of the weight of nitrile. The reaction is carried out at 20° and 2–3 atm. The high selectivity of the catalyst is worthy of note. The reduction is carried out in the presence of ammonia to avoid the formation of secondary amines.

Yakushkin[112] hydrogenated a $C_8$–$C_{13}$ fraction of nitriles to the corresponding primary amines in the presence of Raney nickel. The reaction was carried out at 120–200° and a hydrogen pressure of 20–60 atm; it was noted that as the temperature was raised the yield of primary amines diminished. The hydrogenation of $n\text{-}C_5H_{11}CN$ showed that the addition of ammonia and absolute alcohol increases the yield of hexylamine.

In a patent Denis[113] describes the synthesis of primary amines by the catalytic hydrogenation at 200° of aliphatic nitriles containing from 6 to 22 carbon atoms. Selective hydrogenation catalysts, $Cr_2O_3$, ZnO, $ZnO(Cr_2O_3)$ with the addition of CuO are proposed; alumina and aluminosilicate are used as carriers. The yield of amines varies within the range 60–71.2%.

Gould and coworkers[114] studied the hydrogenation of nitriles in the presence of Raney catalysts (nickel, nickel–chromium, cobalt) in acetic anhydride with basic additives. When sodium acetate was added, the activity of the catalyst decreases after three cycles; with sodium hydroxide the catalyst retains its activity for a longer period and the rate of reduction is higher, but the reaction is strongly exothermic. The yield of amines reaches 100%.

b. Synthesis of diamines. In this section other methods are presented apart from the synthesis of diamines from nitriles.

A method of preparing diamines from dinitriles of higher fatty acids by hydrogenation under pressures up to 20 atm in the presence of a nickel catalyst is described in a patent[103]; a small quantity of aqueous barium hydroxide solution, caustic alkalis, or a quaternary ammonium base is added.

Whetstone and Ballard[115] have proposed a method for the preparation of diamines from aliphatic dialdehydes containing 6 to 12 carbon atoms in the molecule, ammonia, hydrogen, and primary or secondary amines in excess of stoichiometric requirements. The reaction is carried out in the presence of a hydrogenation catalyst. Under these conditions diamines were obtained by the condensation of $\alpha$-hydroxyadipaldehyde at 30–50° and 15–350 atm.

Schryer[116] synthesised 3-methylheptamethylenediamine from 5-methylhex-5-enenitrile. The nitrile was first treated with a mixture of carbon monoxide and hydrogen at 75–200° at a pressure not less than 50 atm in the presence of finely divided cobalt or its naphthenate, oxide, or carbonyl; the 6-cyano-3-methylhexenal obtained under those conditions at 75–250° was treated with a mixture of hydrogen and ammonia to give the diamine.

Roster and Schroeder[117] synthesised diamines by the reaction of the product of ozonization of a mixture of cyclohexene and a lower aliphatic alcohol with amines of the type NHRR′, where R and R′ are hydrocarbon groups with one to seven atoms of carbon; the reaction product was then hydrogenated in the presence of cobalt or nickel. To prepare the diamines (hexamethylenediamine, etc.), not less than two molecules of secondary amine or ammonia are used per molecule of cyclohexene.

Möller and Schröter[118] obtained tetramethylenediamine by the catalytic hydrogenation of succinodinitrile in an autoclave.

Regby[119] synthesised hexamethylenediamine by the reaction of adipaldehyde in solution with the secondary amine R′RNH and hydrogen at 25–150° in the presence of a hydrogenation catalyst; R and R′ are cyclohexyl or alkyl groups containing from 1 to 12 carbon atoms.

Larramona[120] studied the formation of diamines of the type $R''_2NCH_2NR_2$ in the cleavage of $\alpha$-vinylketones, $CH_2{=}CRCOR'$, by the action of secondary amines. The reaction proceeds through the intermediate formation of the $\beta$-aminoketone $R''_2NCH_2CHRCOR'$.

Swerdloff[121] obtained diamines by the catalytic hydrogenation of dinitriles in the presence of anhydrous ammonia and Raney nickel in a stainless steel autoclave.

Schreyer[122] developed a method of preparing di-primary aliphatic diamines. Glycols and aminoglycols containing 6–11 carbon atoms were used as starting materials; these reacted with ammonia at 150–250° and 400–700 atm in the presence of a ruthenium catalyst.

Adam[123] hydrogenated tetramethylenedinitrile in the presence of liquid ammonia and a catalyst containing 20% of cobalt and 0.3% orthophosphoric acid deposited on silicic acid at 85° and a hydrogen pressure of 300 atm. The yield of hexamethylenediamine is 90.9%.

A patent[124] describes the preparation of ethylenediamine from monoethanolamine or ethylene oxide with anhydrous ammonia at 180–210° and 145–150 atm in the presence of a hydrogenation catalyst. The yield of ethylenediamine reaches 80%.

In another patent[125] it is proposed to synthesise ethylenediamine from ethylene oxide or monoethanolamine in the presence of a specific catalyst consisting of finely ground nickel–magnesia. The use of such a catalyst in the proportion of 1–10% of the ethylene oxide or monoethanolamine allows the reaction temperature to be reduced to 150–180°, which reduces the formation of by-products and increases the yield of ethylenediamine.

Wiemann has patented a method of preparing 2,7-diaminooctane from octa-2,7-dione[12]. The reaction is

carried out in an atmosphere of hydrogen in the presence of Raney nickel and 30% ammonium hydroxide. A mixture of stereoisomers of 2,7-diaminooctane is formed.

Jefferson and coworkers[126] developed a detailed formula for the preparation of promoting catalysts based on cobalt oxide for the synthesis of hexamethylenediamine. The catalyst was partially reduced and silica (0.04–1%) and titanium dioxide (0.08–0.18%) were used as promoters.

Indest and Meyer[127] obtained hexamethylenediamine of high purity and in 96 to 99% yield by the continuous catalytic hydrogenation of adipodinitrile. Granulated nickel–aluminium alloy (40–60% nickel) was used as a catalyst. The catalyst retained its activity for 30–60 d, after which it was completely regenerated 7–10 times. The dinitrile was hydrogenated in the presence of a solvent (liquid ammonia, methanol, etc.) at 20–80° and a hydrogen pressure of 100–500 atm. The yield of hexamethylenediamine is 98.7%.

Polkovnikov and coworkers[128] have proposed a method for the preparation of hexamethylenediamine from adipodinitrile by hydrogenating the latter in the presence of cobalt boride at 100° and 130 atm. The yield of hexamethylenediamine is 92.6%.

Nakajima[129] studied the condensation of diethylaminoethanol with various imides; when the condensation product is hydrolysed by heating to 360° *NN*-diethylethylenediamine is formed. The yield is 85%.

Miva Itiro and coworkers[130] obtained diamines in a high degree of purity by the hydrogenation of nitriles in the presence of cobalt or nickel formates at 230° and increased pressure. The yield of hexamethylenediamine is 88.5%.

## 6. Other Methods of Preparing Amines

Bashkirov and coworkers[131] have developed a new method of preparing aliphatic amines in which a mixture (1 : 2) of carbon monoxide and hydrogen is passed with ammonia over a promoted iron catalyst. The yield of amines is 25% and 82–96% of these are primary amines. These workers have improved this method of synthesising amines from carbon monoxide, hydrogen, and ammonia[132]. As a result of the interaction of these gases in the presence of a fused iron catalyst, aliphatic amines, mainly primary, with one to 20 atoms and more in the carbon chain are formed. From one cubic metre of these gases 120 g of material is obtained containing 54% of alkylamines (33% liquid and 21% gaseous amines). n-Butylamine, n-pentylamine, n-hexylamine, n-heptylamine, and n-octylamine have been identified in the products of the synthesis.

Aygen and Wolfgang[133] have proposed a method of preparing primary, secondary, and tertiary amines by the methylation of ammonia, primary amines, and secondary amines with diazomethane. The reaction is carried out in the presence of halogen, halogenoalkyl, and alkoxy-derivatives of boron at -80° to 0° in an inert organic solvent. The yield of amines reaches 82%.

Dose[134] has developed a method of preparing aliphatic amines by the decarboxylation of $\alpha$-amino-acids in the presence of aromatic aldehydes, nitrobenzene, xylene, trichlorobenzene, etc. The presence of solvents in the reaction mixture suppresses the formation of by-products. The reaction is carried out according to the following scheme:

$$CH_3—CH_2—CH(NH_2)COOH \rightarrow CO_2 + CH_3(CH_2)_2NH_2.$$

Bashkirov and coworkers[135] studied the synthesis of amines from carbon monoxide, hydrogen, and ammonia on promoted iron catalysts. The best results were obtained by using a mixture of carbon monoxide 12%, hydrogen 68%, and ammonia 20% with a volume rate up to 100 $h^{-1}$ and temperatures up to 200°. The yield of amines reached 50%.

Johnston[136] synthesised amines from amides by reducing them with sodium tetrahydroborate.

Synthesis of alicyclic amines. There is much less information in the literature on the synthesis of alicyclic amines than on the preparation of aliphatic amines. In principle, the methods of synthesis of amines of these two classes of compounds are similar and differ only in the reaction conditions. Because of the limited amount of material it would not be useful to group it in several sections, as was done for the aliphatic amines; we shall confine ourselves to presenting it in chronological order.

Mousseron[138] obtained 3-methylcyclohexylamine in 60% yield (75% *trans* form) from 3-methylcyclohexanone in the presence of platinum(IV) chloride. 2-Methylcyclohexanone gave only 35% of 2-methylcyclohexylamine. The addition of a small quantity of hydrogen hexachloroplatinate(IV) to Harley's catalyst[138] in the amination of 3-methylcyclohexanone reduces the yield of the *trans* form.

Adkins and Billica[139] used a nickel catalyst and hydrogen under a pressure of 15–45 atm at 25–30° for the conversion of cyclohexanone oxime into cyclohexylamine. The yield is 90%.

Popov and Shuikin[140] studied the catalytic amination of cyclohexanol in the presence of hydrogenating and dehydrogenating catalysts. Of these, platinised silica gel was found to be the most active. In the presence of this catalyst at 320° the yield of cyclohexylamine reached 51.3%, calculated on the cyclohexanol consumed in the reaction.

Popov and Shuikin aminated cyclohexanol in the gas phase by the action of hydrogen and ammonia on platinised silica gel[59]. It was found that cyclohexanone at 200° gives up to 89.6% of primary amine.

Kozlov and Akhmetina[141] studied the catalytic amination of cyclohexanol on aluminium oxide in a flowthrough system at 150–380° and an ammonia pressure of 1–20 atm. At a pressure of 5–10 atm the amination predominates and the dehydration of the cyclohexanol almost ceases. It was established that the optimal temperature range is 260–300°; below this the reaction is extremely slow and at a higher temperature the cyclohexylamine decomposes into ammonia and cyclohexene. The yield of cyclohexylamine reaches 70–74%, based on cyclohexanol taken, or 90–95%, based on cyclohexanol consumed in the reaction.

Cairns and Gilbert[142] have proposed a method of preparing polycyclic tertiary amines. Cycloalkanols containing 5–7 carbon atoms and having at least one methylene group in the $\alpha$-position to the C–O group are used as starting materials.

Popov and Shuikin[143] have synthesised cyclopentylamine by passing a mixture of cyclopentanone with excess of ammonia and hydrogen over nickel on aluminium oxide or pumice. The optimal temperature is 150°; at higher

temperatures resin formation increases and the yield of amines decreases. The best yield of amines on nickel deposited on aluminium oxide was 66.6% (55.6% of cyclopentylamine and 11% of dicyclopentylamine).

Naumov and coworkers[144] studied the reaction for the preparation of cyclohexylamine by hydrogenating aniline on different catalysts in the gas phase at atmospheric pressure. Two reactions were studied:

$$C_6H_5NH_2+3H_2-C_6H_{11}NH_2, \quad (I)$$

$$2C_6H_{11}NH_2 \rightleftarrows NH_3+(C_6H_{11})_2NH. \quad (II)$$

An $Ni/Al_2O_3$ catalyst promotes the second reaction. A mixed CoO/CaO catalyst at 190–200° is active only in the formation of cyclohexylamine. The ease with which reaction (II) proceeds and its reversibility on a nickel–alumina catalyst makes it possible to convert aniline almost completely into cyclohexylamine and dicyclohexylamine.

Noeske and Kolling[145] have patented a method of preparing alicyclic amines. Saturated alicyclic mono- and di-aldehydes, hydroxyaldehydes, and products of the oxo-synthesis containing alicyclic aldehydes may be used as starting materials. Hydrogenation is carried out in the presence of nickel on magnesium oxide with kieselguhr at 120° and 90 atm. The yield of (tricyclodecylmethyl)-amine from tricyclodecylmethylal is 83%.

Kost[146] studied the possibility of using Raney nickel and cobalt catalysts in the synthesis of amines. It was shown that cobalt catalysts are less effective, but more convenient in practice, because the change of colour of the reaction mass enables the end of the hydroamination to be determined. Methods of preparing mono- and di-cyclohexylamine from cyclohexanol by the Leuckart reaction have been studied and it has been shown that dicyclohexylamine is sometimes contaminated with formylcyclohexylamine formed by hydrolysis.

Naumov and coworkers[147] proposed a synthesis of cyclohexylamine by hydrogenating aniline at 120–170° in contact with cobalt(III) oxide or mixed oxides, hydroxides, or carbonates of magnesium or strontium. The maximal yield of cyclohexylamine is 96–98% with an admixture of 2% of dicyclohexylamine.

Ivanova[148] obtained cyclohexylamine in 97% yield by hydrogenating nitrocyclohexane on a Raney nickel catalyst.

Illick and Robinson[149] have proposed the preparation of cyclohexylamine by hydrogenating aniline in the presence of a rubidium catalyst. The yield of cyclohexylamine is 81.6%.

Zienty obtained substituted amines (2-cyclopentyl-1-methylethylamine, 1-cyclopentyl-2-aminopropane, 2-cyclohexyl- and 2-cycloheptyl-1-methylethylamine) by hydrogenating the corresponding carbonyl derivatives of cyclopentyl-, cyclohexyl-, and cycloheptyl-acetone, etc. in the presence of a nickel catalyst (70% nickel)[150].

Nisimura Keidzo synthesised cyclohexylamine by the hydrogenation of aniline and acetanilide in the presence of Raney nickel–aluminium catalyst; the catalyst was prepared by treating an alloy of nickel–aluminium and a metal of variable valency with a solution of sodium carbonate and barium hydroxide[151]. The hydrogenation was carried out at 200° and 70 atm.

Wheaton obtained cyclohexylamine in 50% yield by the reaction of cyclohexane with ammonia under the action of ionising radiation with energy ≥ 15 eV.[152]

McKeever and Washburne[154] have proposed a substantial improvement in a method of preparing 1,8-diaminomenthane[153]. As starting material they used limonene, terpin hydrate, dipentene, etc. Reaction with hydrogen cyanide, sulphuric acid, and water was carried out at 50–55° and the 1,8-diaminomenthane was separated; the yield was 57%, calculated on dipentene.

From the great amount of literature material quoted here it is quite clear that for the synthesis of the simplest amines the greatest attention is being devoted to the development of methods based on the catalytic vapour-phase amination of alcohols or alkyl halides. These methods are most promising from the point of view of both production technology and the use of cheap raw materials available in bulk. As far as the catalytic synthesis of more complex amines is concerned, this is often carried out by aminating nitriles or carbonyl compounds in the liquid phase. Metals of Group VIII of the Periodic Table are widely used as catalysts. In recent years papers have begun to appear on the reductive amination of a number of compounds with the aid of aluminium and boron hydrides, fused iron catalysts, and promoted oxides of an acidic and amphoteric character, for example, vanadium pentoxide.

# PROGRESS IN THE STUDY OF THE AGING OF FIBROUS CELLULOSIC MATERIALS

G.N. Rozmarin

## CONTENTS

1. Introduction 854
2. The durability of paper 854
3. The aging of fibrous materials 856

4. The thermal degradation of fibrous materials 858

5. The photochemical degradation of cellulose 860

## 1. INTRODUCTION

Cellulose is the most common natural organic substance and forms the basis of the cell walls in higher plants. Man uses vast quantities of cellulose (~ 500 million tonnes per annum) in the form of various fibrous materials; this tremendous consumption is compensated annually almost entirely by the process of photosynthesis [1,2].

Cellulose plays an important part in the national economy, and a number of organic manufacturing industries are based on the processing of this natural polymer; cellulose is used to prepare various types of paper, synthetic fibres, cotton fabrics, cine film, lacquers, explosives, etc.

The chief sources of cellulose are wood and cotton. Cellulose obtained from annual vegetation (flax, ramie, hemp, reeds, and straw from various grasses) is also of considerable importance. The technological process of cellulose production and purification may be accompanied by degradation resulting from processing. Certain necessary oxidising operations (for example, the pre-ripening of alkali cellulose in the manufacture of viscose rayon, bleaching, scouring, and dyeing) lead to undesirable and harmful consequences. The continuous degrading action of the atmosphere, heat, light, and moisture is shown spontaneously during the storage or exploitation of fibrous cellulosic materials, leading to premature wear and breakdown. All this introduces into the economy considerable losses, which exceed the losses due to the corrosion of metals [3].

In the chemistry of macromolecular compounds, the term *degradation* signifies the entire range of phenomena leading to a decrease in the length of the macromolecules. The decrease in the length of the molecular chains under the influence of internal or external factors takes place spontaneously and leads to *aging* of the polymer, that is, it leads to a decrease in the mechanical strength of the material and a decrease in its period of serviceability.

Degradation processes are usually complex, since it is difficult to determine the factors directly responsible; in general, these processes are brought about by the action of heat, light, and atmospheric oxygen. These factors operate simultaneously in the form of thermal, photochemical, and oxidative processes. There are several classifications of the different types of cellulose degradation [4,5].

Although the importance of the study of the mechanism of degradation is obvious from the practical and scientific viewpoints, many aspects of this mechanism have not been touched upon, despite the rising increase in the number of papers devoted to this problem. The degradation of cellulose leads to the formation of complex reaction products containing, in addition to the original hydroxyl groups, other non-hydroxyl functional groups produced as a result of oxidative degradation, and a certain number of broken units may be present together with unchanged elementary cellulose units: all these changes labilise the $\beta$-glucoside bonds of the chains and lead finally to a decrease in the length of the macromolecules.

In the study of the chemical changes, use is made of physical, physicochemical, and chemical methods, and also methods of artificial aging, in order to estimate the nature, direction, and intensity of the degradation processes, the durability of the manufactured products, the mechanisms of the reactions, etc.

The aim of the present review is to summarise the progress made in the recognition of the nature and mechanism of the processes involved in the degradation and aging of fibrous cellulosic materials, and also to point out the most rational methods for preventing the degradation of these materials.

## 2. THE DURABILITY OF PAPER

The durability of a fibrous material (paper, cardboard, cellulose fibres, or cotton fabric) is determined by its ability to withstand the action of the internal and external factors bringing about degradation during prolonged storage or under conditions of use, when the material is subjected to various mechanical treatments (folding, crumpling, elongation, etc.)[6]. The durability depends on the ability of the material to withstand the action of the surrounding medium, that is, the action of light, moisture, heat, and harmful atmospheres containing industrial gases. Decrease in the durability of fibrous materials, in particular paper, is usually accompanied by a decrease in the degree of whiteness.

Chemical analysis of the fibrous material (for example, paper) may give interesting information on its durability; the approximate period of resistance to wear shown by papers can be found from the data in Table 1.[7-9] Chemical analysis cannot always characterise the durability, however. For example, old Chinese papers (500–925 years old) and European documents (400 years old) have been found in good condition, although the $\alpha$-cellulose content of these papers amounted to only 65–67%.[11] Thus other factors (for example, pH) play an important part.

The exceptional stability of papers manufactured in ancient times can be attributed to their preparation from an exceptional form of raw material (cotton or flax fibres or rags), the mild digesting conditions, the use of starch and gelatin for sizing, use of the minimum amounts of fillers, bleaching in sunlight, and drying under natural conditions. The change to the production of paper from wood cellulose, with mechanical processing on paper-making machines, led to a sharp decrease in the stability of the paper [12]. Modern forms of paper are not durable, and this is due not only to the use of fibres from wood cellulose but also to other technological factors.

The best method for estimating the durability of paper is apparently by *natural aging* under conditions of prolonged storage. This method is applicable to paper which is many centuries old; for modern papers, use is usually made of *artificial (accelerated) aging* methods, based on the fact that

TABLE 1. Estimation of the durability of papers from data obtained by chemical analysis [10].

| Minimum period of use, a | Minimal $\alpha$-cellulose content, % | Copper number | Minimal resin content, % | pH | Lignin |
|---|---|---|---|---|---|
| 500 | 90 | 1.0—1.5 | 1.0 | 5 | absent |
| 100 | 80 | 2.0—2.5 | 1.5 | 5 | absent |
| 50 | 70 | 3.5—5.0 | 2.0 | 4.5 | absent |
| Less than 50 | no limit | | | | present |

damage to paper under natural conditions is due to the action of atmospheric oxygen, heat, and sunlight (direct or diffuse), the degradation being hydrolytic and oxidative in character. In artificial aging, the same factors as in natural aging are used, but under more severe conditions. The most important methods of artificial aging are given below[13-15].

1. Thermal treatment at 105° for 3 d in a drying oven with natural or controlled circulation of air.

2. Treatment with ultraviolet radiation.

3. Hydrolytic degradation in an atmosphere containing sulphur dioxide.

4. Oxidative aging in an atmosphere of oxygen at 15 atm pressure and 50–60°.

5. Aging in air with relative humidity 45% at 38° for 200 h.

6. Aging in air with relative humidity 75–80% at 30–40° for 45–180 d in the presence of definite quantities of oxygen and sulphur dioxide.

Irrespective of the method used, the change in the same physicochemical properties (tensile strength, number of double folds, elongation, bursting strength, etc.) and physicochemical properties (concentration of $\alpha$-, $\beta$-, and $\gamma$-celluloses, degree of polymerisation, degree of whiteness, concentration of functional groups, etc.) is followed. Of particular importance is the determination of the degree of polymerisation (DP): the higher the molecular weight of the cellulose, other conditions being equal, the more stable the paper prepared from it.

The technological factors decreasing the durability of modern forms of paper include the following[16,17]: (1) the decrease in the DP resulting from digesting, beating, and bleaching; it is possible to develop operating conditions under which the change in DP will be a minimum; (2) sizing in acid medium (coagulation of rosin by aluminium sulphate); of considerable promise in this respect are neutral and alkaline sizing procedures, which give papers with increased durability[18,19]; (3) the addition of fillers, which may facilitate degradation processes, although they

may also, on the contrary, retard these processes[19]. The conditions necessary for the production of papers with increased durability have been described[20-22]. By using alkaline fillers, for example, $CaCO_3$, it is possible to reduce the acidity of paper and increase its durability (Figs. 1–3)[22].

Cellulose fibres can be arranged in the following order of decreasing stability[10]: (cotton, flax, hemp) > (sulphite and soda cellulose) > (esparto and straw) > (wood pulp).

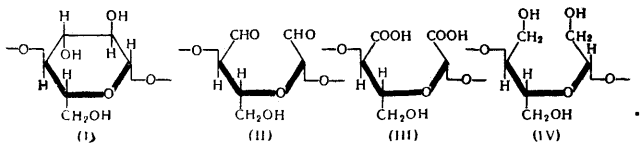
The compositions used in paper manufacture are classified as follows[23] (in order of decreasing stability): (a) pulped rags (100%), (b) pulped rags (50%) + wood cellulose

(50%), (c) wood cellulose (100%), (d) wood cellulose + wood pulp (in different proportions).

Variations of different compositions using cellulose from annual vegetation (reeds and straw) have been put forward[24].

The durability of paper also depends on the conditions of storage and use[25]. Thus during storage, special measures are taken to protect papers from chemical[26], physical[27-29], or biological[30-33] agents.

The literature contains data on the appreciable depolymerisation of cellulose during bleaching, leading to a decrease in the stability of papers[34]. Uchastkina[35] and later Dixon and Nelson[36,37] developed equations for determining the relationship between durability and the physico-mechanical characteristics of the original material. Finally, mention may be made of methods and apparatus for treating old papers for purposes of regeneration[38,39] or methods of chemical modification to increase resistance to heat and light[40].



## 3. THE AGING OF FIBROUS MATERIALS

During storage and use, polymers show a continuous change in a number of variable properties — rigidity, elasticity, durability, and colour — usually referred to as aging[41]. In cellulosic materials, in particular paper, aging is accompanied by a decrease in the degree of whiteness (*yellowing*). The first quantitative observations were made as early as 1918.[42]

The sensitivity of cellulosic fibres to degradation depends on a number of factors. According to certain data[43,44], this is due to the presence of so-called "weak points" in the cellulose structure, appearing as a result of the stresses undergone by, for example, a single macromolecule taking part in the formation of two separate crystalline regions. The number of such weak points may be revealed by oxidative reactions and determined by chemical methods. According to other data[45], these stresses in cellulose appear as a result of repeated drying processes during the technological processing of the material, leading to the irreversible physical phenomena of aging (decrease in viscosity, physiocomechanical characteristics, sorption of dyestuffs, etc.). All these phenomena are described as *internal defects in physical structure*.

Another internal factor is the presence of *defects in chemical structure*. Ivanov and coworkers[46] attribute departures from the normal structure in cellulose to the presence of carboxyl and carbonyl groups, leading to the production of "weak points". Rånby[47] states that some of these non-hydroxyl groups appear as a result of chemical treatment, whereas a certain proportion (one group per 100 glucoside residues) are already present in the wood[47].

Other authors[48,49] have established the following order of stability of the elementary unit in cellulose in degradation processes, for functional groups of different kinds in positions 2 and 3:

The rate of hydrolysis increases in the order I < II < III < < IV.

Korshak and coworkers[50] showed that the resistance of polymers to degradation increases with increase in the length of the macromolecules.

Of the other main factors responsible for aging, *external factors* require emphasis. Cellulose is almost completely stable at room temperature in the dark[51], but with increase in temperature to 100–120° in the presence of air, oxidation processes begin to take place, the rate of these processes increasing in the presence of moisture[52]. Rheological determinations have shown that degradation takes place even at room temperature (the long-chain cellulose macromolecules disappear)[53].

Aging is also favoured by the fact that the weak points referred to above are extremely susceptible to the action of oxygen[54,55], oxidation taking place by a chain reaction[56]. The rate of hydrolysis of cellulose at these "weak points" is 300 times the rate of hydrolytic rupture of an ordinary β-glucoside bond; it should be borne in mind that one weak unit is found for every 400–500 anhydroglucoside units[57]. The rate of hydrolysis of wood cellulose is reduced considerably by preliminary treatment with sodium tetrahydroborate[58].

Mathematical equations describing qualitatively the effect of aging in various grades of paper under the influence of heat, light, or wear have been put forward[59-64]. The rate of these effects, including photo-oxidation or thermal oxidation, is determined by the temperature, the presence of atmospheric oxygen, light, ultraviolet radiation, etc. Thus characteristic features of photo-oxidation are the photochemical initiation of the reactions and the stability of the peroxides formed, whereas characteristic features of thermal oxidation are the chain reactions of peroxo-compounds formed under the influence of heat[65,66].

It has been shown for the example of rubber[67] that aging depends on the number of active reaction centres: degradation under the influence of ultraviolet radiation, despite the superficial nature of the irradiation, is much more intensive than the effect of heat, although with the latter the reaction takes place throughout the entire bulk of the polymer[68-70].

The phenomenon of keratinisation, manifested as a decrease in the reactivity of the fibres as a result of drying above 100°, is observed during the aging of cellulose. Keratinisation is attributed to merging of the fibrils to form characteristic aggregates, with subsequent bonding by hydrogen bonds, leading to a decrease in the physico-mechanical characteristics[71,72].

The aging of various documents or books in libraries in large industrial cities results from the action of the atmosphere, which contains sulphur dioxide. Study of the absorption of sulphur dioxide by papers[73] shows that the reaction of this compound is catalysed by traces of heavy metal ions (Fe, Cu, Cr, V, Co, Ni, or Mn); Na, K, Ca, Ba, and Al ions have no catalytic action. A number of inhibitors (disodium hydrogen phosphate, 8-hydroxyquinoline, or ammonium oxalate) have been proposed for suppressing the action of these metals[74].

The influence of metal ions on the aging of papers has been studied by many workers. Stübchen-Kirchner[75] showed, for example, that the presence of the ions $Fe^{3+}$ > > $Fe^{2+}$ > $Cu^{2+}$ causes yellowing of paper, whereas other ions stabilise the colour of paper, in the following order:

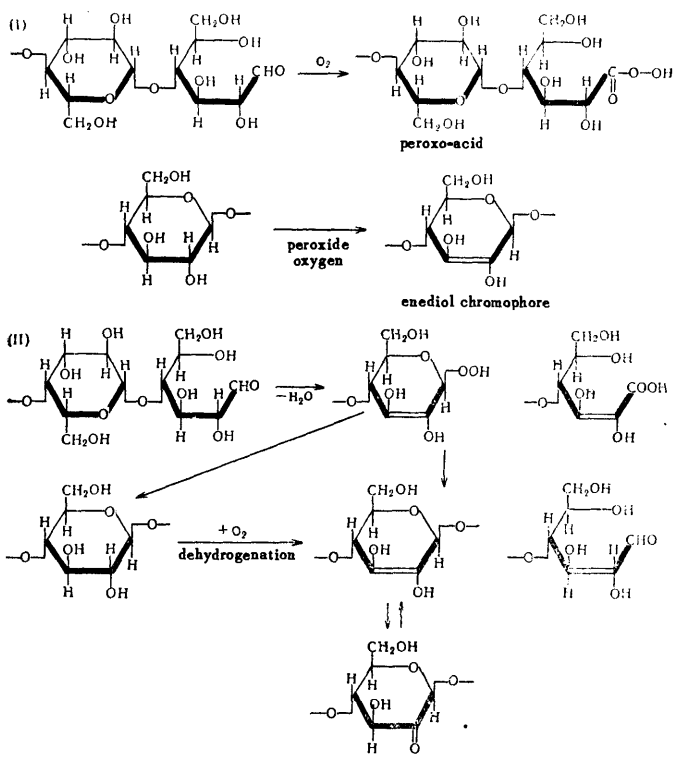
$Cd^{2+} > La^{3+} > Mg^{2+}$. Similar phenomena were observed by other authors [76-79], who emphasise the importance of iron ions in the formation of coloured complexes with rosin during sizing. Similar effects of yellowing in paper have been noted when gelatin and starch were used as sizing agents [80,81].

In the study of the yellowing of monocarboxycellulose under the influence of sodium, calcium, manganese, and aluminium salts, it was established [82] that the free carboxy--groups show a tendency to form anhydrides, lactones, and salts; the formation of salts intensifies the colour. Czepiel [83] arranged metal ions in the following order of decreasing action on the stability of the whiteness of papers: $Fe^{3+} > Fe^{2+} \geq Cu^{2+} > Al^{3+} \geq$ control specimen without ions $\geq$ $\geq Cd^{2+} \geq La^{3+} \geq Mg^{2+} \geq Mn^{2+}$. Manganese salts retard aging. Analogous results were reported by other authors [84-86]. Wultsch and coworkers [87] proposed preliminary treatment of the paper pulp with complex salts of the Trilon B or sodium polyphosphate type (in concentrations of 0.06–0.08%) to remove traces of metals (Fe, Cu, Mn, Co, Al, Cd, and Mg) and increase the whiteness of paper.

The yellowing of paper is an extremely undesirable phenomenon, particularly since paper with a high degree of whiteness can now be produced. The degree of yellowing is defined by the PC number (post colour number). [88] Most authors consider that yellowing is a natural consequence of the accumulation of carbonyl compounds in the cellulose or paper [88-99]. Okada and Ida [99] even established a direct relationship between the degree of yellowing and the quantity of carbonyl groups.

Sikhtol and Virkol [100] made a detailed study of the influence of various functional groups in cellulose on the phenomenon of yellowing, and established that: (1) a formyl group at $C_{(1)}$ in the elementary unit does not cause yellowing, whereas at $C_{(2)}$ and $C_{(3)}$ it favours this process; (2) hydroxyl groups in positions $C_{(2)}$ and $C_{(3)}$ do not cause yellowing; and (3) carboxy-groups in positions $C_{(2)}$ and $C_{(3)}$ bring about the same yellowing effect as formyl groups; the intensity of the yellow colour is greater when these groups are present in the form of the sodium salts, and weaker in the case of the calcium salts.

Sikhtol [100] points out that yellowing is accompanied by a decrease in the DP of cellulose and an increase in the value of the copper number; in the latter case, an increase in the copper number from 5 to 50 has no influence on the yellowing of such celluloses as sulphate cellulose, bisulphite cellulose, cotton cellulose, and hemicellulose.



The yellowing of celluloses decreases with removal of the hemicelluloses, since the presence of the latter facilitates the hydrolytic formation of low-molecular-weight compounds of the oligosaccharide type or even monosaccharides, which condense under the influence of pectic substances and are converted into brown humic products [101-111]. Some authors relate the phenomenon of aging to the concentration of hemicelluloses [112] and, in particular, $\gamma$-cellulose [113].

Celluloses obtained by use of an ammonium hydrogen sulphite cooking liquor undergo yellowing more rapidly than those obtained using a calcium hydrogen sulphite liquor [114]. The stability of the whiteness may also depend on other technological factors, for example, the methods used to bleach the celluloses [115], the best results being obtained by bleaching with chloride dioxide [116]. In all, preliminary treatment with sodium tetrahydroborate can be used to increase the whiteness [117,118].

Roudier and coworkers distinguished two successive stages in the aging and yellowing of papers: (1) *hydrolysis* (as a result of chemical technological treatment or the action of moisture after preparation of the papers), and (2) *degradation* (which is more marked, the higher the concentration of hemicelluloses); the latter also leads to aging [119-122]. Similar conclusions were reached by other authors [123,124].

In an examination of the influence of soluble substances on the increase in the rate of aging of cellulose, Treffers [125] found, among the degradation products, organic acids which have a hydrolytic influence on the separation of hemicelluloses with the formation of free pentoses and oligosaccharides. Under the influence of the same acids, sugars are converted into dark humic products.

Here, mention must be made of an attempt by Kleinert and Marraccini [126] to establish the chemical mechanism of the aging and yellowing of celluloses under the influence of heat. They showed that peroxides are formed during aging [112]. In the presence of air (I), peroxo-groups and enediol compounds are formed, and in the absence of air (II), polyacetal groups are formed; in both cases unsaturated chromophoric groups are produced.

The individual stages of this mechanism were established chromatographically but the scheme is nevertheless fairly speculative.

A similar study was made of the aging of cotton cellulose in 0.5 *N* NaOH in the absence of air at elevated temperatures; the formation of saccharic acids was established chromatographically [127]. Under the influence of atmospheric oxygen and light, cotton cellulose shows a change in DP during ripening in the cotton-plant bolls under conditions of natural and accelerated aging [128]. Different mechanisms of degradation in the presence of oxidising agents of different types have been pointed out [129], together

with the unique part played by the carbonyl groups in this process [130].

In a comparison of natural aging (for 4, 8, 22, and 26 years) with accelerated methods (72 h at 100°), Wilson [131] found good agreement between the results obtained by the two methods for the change in the concentration of $\alpha$-, $\beta$-, and $\gamma$-celluloses, the acidity of the aqueous extract, and the mechanical characteristics of the papers; he established that accelerated aging under the above conditions is equivalent to the effect of natural aging for 25 years. The method of artificial aging has also been used to study the durability of textile fibres [132]. The resistance of fibrous materials to aging is usually established by determining their viscosity [133]; no difference in the concentration of carbonyl and carboxyl groups has been observed for a given DP value [134].

Papers containing wood pulp undergo aging more rapidly because of the increased lignin content. There are reports of a direct relationship between aging and the lignin concentration [135-141]. The phenomenon of aging has also been studied for papers produced from linen and cotton rags [142] and also for papers prepared from wood and straw celluloses [143] or from jute [144]. In all, it was found that aging is accompanied by oxidative and hydrolytic reactions.

## 4. THE THERMAL DEGRADATION OF FIBROUS MATERIALS

Most work on degradation has been carried out by thermal treatment of the cellulose or paper. Yabrova [145] subjected newsprint to thermal aging (at 80° and 20° and a relative humidity of 60%) and observed a decrease in the number of double folds on the fifth day of treatment; at the same time, the solubility of the fibrous material in 7.4% sodium hydroxide solution increased, with a simultaneous increase in the concentration of carboxy-groups.

In a comparison of artificial aging (100° for 72 h) with natural aging, Royen [146] attributed the oxidative degradation of papers to the presence of hemicelluloses. Gluchowska and Winczakiewicz [147] equated the action of thermal treatment under these conditions for different grades of paper prepared from sulphite cellulose to only six years of natural aging (instead of 25 years, as is generally assumed). The presence of carboxy-groups in cellulose leads to a decrease in the heat-resistance of papers [148].

Simionescu and coworkers [19,149] studied the effects of artificial aging for more than 50 grades of writing, printing, and technical papers manufactured in various Roumanian factories, determined the most stable grades, and the technological factors favouring the production of durable paper. The addition, to the fibrous composition of the papers, of cellulose from annual vegetation (reeds and straw) in quantities up to 30–50% in mixtures with spruce cellulose did not lead to any significant intensification in the degradation; this is of practical importance for Roumanian conditions [150].

The most important factors influencing the heat-resistance of cellulose and papers are the DP, the molecular composition of the fractions, and the active acidity of the material; the most stable celluloses are cotton cellulose and sulphate celluloses, and the least stable are bleached (non-purified) sulphite celluloses [151]. The parameters most sensitive to the action of heat are the whiteness, viscosity, and number of double folds [152].

Sulphate cellulose has been shown to have a high heat resistance. In the case of bleached kraft cellulose, it has been established that there is a difference in the behaviour during artificial aging, depending on the temperature and the presence or absence of moisture [153]; other conditions being equal, the presence of lignin and hemicelluloses intensifies degradation [154,155]. Intermediate drying of cellulose for paper-making to a moisture content of 25% leads to a decrease in the mechanical characteristics of the paper [156]. Papers prepared from kraft cellulose, thanks to their heat-resistance, are better than the corresponding grades of paper prepared from rags [157-160], so that they are preferred for work on the restoration of documents [161] or for the production of capacitor papers [162-164]. Fabre [165] recommends chemical methods for the analysis of sulphate papers, in order to examine their aging in electrical transformers.

Cardboard becomes sensitive to the influence of heat only at a relatively high temperature (200°) [166].

Comparison of the aging of cellulosic fibres from cotton [167] or from artificial silk under the influence of heat with that for natural silk [168], and also comparison of the aging of natural fibres [169] with that of synthetic fibres [170], are of practical interest. The heat-resistance of fibres is increased by the addition of antioxidants [171]. In a study of the action of high temperatures (100–160°) on viscose fibres, Agster established that the following stages are involved in the degradation: up to 140° hydrolytic processes predominate, in the range 140–150° oxidative processes predominate, and in the range 150–160° thermal cracking begins [172,173]. At 145° the strength of viscose fibres decreases by 45% relative to the original value [174].

Interesting results have been obtained in the pyrolytic degradation of cellulose. Thus at 172°, [175] a number of gaseous products (CO, $CO_2$, and $H_2O$) were obtained, and saccharic acids, aldehydes, ketones, and glucose were determined by paper chromatography in the residue. In the presence of air, the reactions take place initially in the amorphous regions and then continue in all regions with a simultaneous decrease in the DP to a constant value [176]. At higher temperatures, for example, at 350–375°, a residue containing 55% water, 12.5% laevoglucosan, 15% carbonyl compounds, and 7.5% of various acids is obtained [177].

In the absence of air [178], the thermal degradation of cellulose takes place with an activation energy of the order of 26 kcal mole$^{-1}$. The pyrolysis of fibrous vegetable materials has been studied in the presence of mineral salts [179] under different temperature conditions [180-186]. In all, the formation of laevoglucosan with 1,5 and 1,6 oxygen bridges was established [187]. A relationship was established between the reactivity of celluloses and their behaviour during pyrolytic degradation [188]. In the degradation of cellulose with a molecular weight of approximately one million for 10 h at 130°, one chain unit in every 18 units underwent a change, even in the absence of air [189]. Analogous data on the degradation of various native celluloses have been given by other authors [190-193].

An important contribution to the study of various aspects of thermal degradation has been made by Golova and coworkers. On the assumption that $\beta$-glucose is an intermediate product in the formation of laevoglucosan [194,195], they showed [196] the possibility of the direct formation of the latter from cellobiose [197,198], pectic substances [199], and polygalacturonic acids [200] by splitting at the 1-4-$\beta$-glucoside

bond and isomerisation of the chain fragments. The yield of laevoglucosan depends on the original structure of the cellulosic material[201], high yields being obtained where the density of packing of the molecular chains is high. Similar conclusions were reached by other authors[202,203].

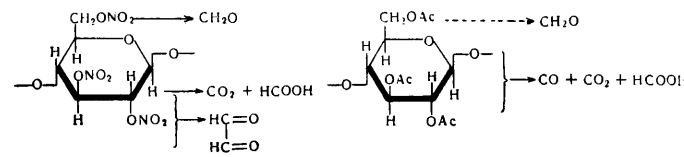
The extent of degradation depends not only on temperature but also on the duration of treatment, the degree of polymerisation of the cellulose, and the composition and nature of the medium in which the degradation takes place. For example, moderate heating (up to 120°) is accompanied by depolymerisation, but at elevated temperatures (240°) dehydration begins with a subsequent change in the chemical composition of the elementary unit[204].

A review by Sergeeva[205] gave data obtained in a study of the changes and degradation undergone by wood vegetable fibres, and also the macromolecular components of wood, under the influence of thermal treatment. In particular, it was reported that the degradation of the cell walls of holocellulose takes place in stages: degradation of the hemicelluloses and the loose regions of the cellulose takes place at 155–260°, degradation of the secondary layer of cellulose begins at 280–285°, and at 280–300° the secondary layer of cellulose decomposes completely and degradation of the cellulose of the cambial layer begins; under these conditions, only the cellulose of the tertiary layer remains stable.

The degradation of cellulose has been carried out in various liquid media. For example, cellulose has been heated in petrol, benzene, pyridine, dioxan, and various alcohols, for 3 h at 200°; a decrease in the DP was observed[206]. Depolymerisation is more extensive in non-polar liquids (kerosene, benzene) than in polar liquids[207-209]. Heating for 1 h at 240° in anhydrous glycerol leads to an increase in the density of packing of the cellulose (the density of the specimen changed from 1.531 to 1.551). This led Sharkov and Shchleglova[206] to establish a direct relationship between the changes in the density of cellulose specimens and the changes in the infrared spectra of the specimens in the range 3000–3600 $cm^{-1}$. Usmanov and coworkers[210] established that thermal treatment of cotton cellulose leads to a decrease in the integral heat of wetting, and that a unique type of structural change takes place, leading to an increase in the ability to undergo changes in packing and an increase in molecular packing. The action of pure water on cellulose at elevated temperature has also been studied[211,212]; on treatment with water, the concentration of carboxy-groups increases, the water becomes acidic, and the cellulose undergoes extensive depolymerisation.

Degradation has been carried out in sodium hydroxide solutions at 170°,[213,216] sodium hypobromite solutions[214], liquid paraffin, superheated steam, sulphuric acid, and salt solutions in the range 130–250°, in order to establish the approximate mechanism of degradation[217].

The changes undergone by cotton cellulose during thermal degradation were described by Aubry[218]. Thus at 90° there is a moderate decrease in such parameters as the moisture content, mechanical strength, degree of whiteness, and DP, after treatment for only 4 h; at 110° these characteristics also decrease slightly (from the start in this instance), the rate of decrease in these characteristics increasing considerably only at 130–150° (the DP decreases from 3000 to 1200); the same rates are observed for the change in solubility in sodium hydroxide, the acidity of the aqueous extract, the copper number, the degree of whiteness, and the concentration of carboxyl groups in the cellulosic material. Hydrocellulose is distinguished by an increased heat-resistance; this is attributed to a difference in the number of "weak points" (one per 1000 glucoside residues for cotton fibre and one per 500 or 250 glucoside residues respectively for hydrate cellulose)[219-221].



Significant changes are also observed in the X-ray diffraction patterns for native and mercerised cellulose as a result of thermal treatment; at moderate temperatures there is a change in the reflections corresponding to the (002) planes, and the (101) and (10$\bar{1}$) planes show irreversible broadening; in the case of cellulose-II the reflections of the (101) plane show gradual fogging[222]. At 300° the texture of both celluloses disappears completely from the X-ray diffraction patterns[224].

When the degradation of cellulose is carried out by increasing the temperature gradually (5.5 deg $min^{-1}$), dehydration is observed at 200–230°, and at 300° the water is removed completely and structural changes begin, with partial loss of carbon; above 300° combustion begins, with partial decarbonisation and formation of amorphous carbon[224].

The thermal decomposition of cellulose in a vacuum is accompanied by the production of carbonyl and carboxyl groups, with a simultaneous change in elemental composition[225]. Structural changes resulting from thermal treatment have also been described for mercerised cellulose[226,227].

The method of thermal degradation has been extended to cellulose derivatives. Thus the thermal decomposition of nitrocellulose[228,229] (which takes place by a chain reaction), cellulose acetate[230-234], ethylcellulose[235], or cellulosic fibres thermostabilised by partial acetylation[236] or cyanoethylation[237-239] has been described. Acetylcellulose was found to be more stable under conditions of thermal aging than other derivatives, its thermal stability being several times that of cellulose[240].

The thermal decomposition of nitrocellulose leads to the formation of oxides of nitrogen, volatile organic substances, carbon dioxide, carbon monoxide, formic acid, formaldehyde, glyoxal, and hydrogen cyanide[241]. On the basis of data obtained using tracer atoms, the following schemes were proposed for the degradation of cellulose nitrate[100] and cellulose acetate[235]:

It should be emphasised that in the last scheme the degradation products appear chiefly as a result of the rupture of the pyranose ring, and not by removal of the acetyl (Ac) groups of the macromolecule, as was previously generally accepted.

Thermal degradation, as a method of studying the structure of cellulose, provides extensive factual material and gives additional information on the overall mechanism of the decomposition. Different versions of the method are still used by many authors.

## 5. THE PHOTOCHEMICAL DEGRADATION OF CELLULOSE

During use, cellulosic materials always undergo aging under the direct influence of *sunlight.* Diffuse light (day--light, the light from "white" incandescent lamps or fluorescent sources) also leads to aging, although it rarely contains appreciable proportions of the ultraviolet range of the spectrum [242,243].

The influence of sunlight on cellulose fibres during the bleaching of flax and hemp in bleaching greens has been known for long: this action was attributed to the influence of heat and light [244,245]. The prolonged action of sunlight on various grades of paper (exposure for 5-120 d) produced different changes in the concentration of $\alpha$-cellulose and in the value of the copper number [246,247]. Yellowing has been attributed to the presence of rosin size [248-251]. The bleaching of paper under the influence of sunlight filtered through window-glass has also been noted [252]. The aging of papers from bisulphite bleached and unbleached celluloses exposed to sunlight depends on the concentration of lignin present [253]. Since the spectrum of sunlight contains radiation with wavelength from 290 m$\mu$ to 700 m$\mu$, it should be noted that cellulose absorbs radiation with $\lambda < 400$ m$\mu$; [254,255] the presence of lignin [256-259] displaces the absorption to the range 280–400 m$\mu$; the use of rosin as size intensifies the absorption in the range 330–440 m$\mu$. [260]

Marini [261] compared the action of sunlight in the yellowing of papers with that of illumination by a mercury lamp; the results of exposure to the two different light sources are different, due to the difference in the energy distribution of the spectra. Analogous experiments were carried out by others [262].

Photochemical degradation is generally studied using *ultraviolet irradiation.* Under the influence of this illumination, simple sugars decompose with the formation of volatile products. Fructose [263] gives carbon dioxide, carbon monoxide, formaldehyde, methanol, and various acids; aqueous solutions of glucose and fructose gave carbon monoxide, methane, hydrogen, carbon dioxide. The rate of decomposition of fructose is seven times that of glucose [264]. In the case of cellulose irradiated in a vacuum ($\lambda$ = 253.7 m$\mu$ at 40°), liberation of a gas mixture with characteristic composition (87.5% $H_2$ + 8.2% CO and 4.3% $CO_2$) is also observed; [265] depolymerisation (DP 1710 → 690) and an increase in the concentration of nonhydroxyl functional groups takes place simultaneously. The degradation is attributed to the conversion of alcoholic groups into carbonyl groups, accompanied by the liberation of hydrogen: a stoichiometric relationship was established between the number of broken glucoside bonds and the number of carboxy-groups.

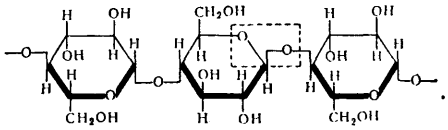
The effects of ultraviolet irradiation on cellulose and paper depend on the wavelength. Irradiation with narrow ranges of the ultraviolet spectrum established a difference between the behaviour of papers with high lignin content (from wood pulp) and that of papers containing almost no lignin. Liberation of gases was observed always [266]; after an interval, the liberation of gases stopped, as a result of the screening effect of the carbonyl groups [267]. Radiation with wavelength 290–395 m$\mu$ was most effective [60,268]; according to data obtained by other authors, the active radiation is displaced towards 250 m$\mu$. [269] A systematic study by Spinner [270] of the dependence of the degradation on the spectrum of the ultraviolet radiation showed that a unique part in the photodegradation is played by lignin, the moisture content of the medium, atmospheric oxygen, and the temperature of the medium. The phenomena of photolytic after-effects are also observed. These data are given in Table 2.

Emphasising the importance of physical bonds between the components of paper for the development of durable grades, Richter and Wells [273] developed a method of artificial aging by ultraviolet irradiation. Ultraviolet radiation was also used to determine the degree of decomposition of sulphite and sulphate celluloses and to establish the nature of fillers and contaminants [274].

McClaren and coworkers [275] studied the action of ultraviolet radiation ($\lambda$ = 253.7–365.4 m$\mu$) on paper prepared from bisulphite kraft celluloses, and established that rapid yellowing of the specimens takes place in the initial stages of exposure. A curious feature is that according to the results of these authors, the behaviour of the materials is independent of the humidity of the atmosphere or the presence of carbon dioxide or sulphur dioxide; the effect of exposure is restricted to a depth of 0.15 mm. According to the results of other authors [276], the light sensitivity of paper depends on the method of bleaching: papers bleached with sodium tetrahydroborate were found to be most stable, and celluloses bleached with calcium hypochlorite were found to be most sensitive to the action of heat and light.

The light sensitivity of bleached celluloses is closely related to the nature of the fibrous raw material, the method of digestion, and the use to which the material is put. Rozmarin and Simionescu [277] studied the chemical changes undergone by different celluloses under the influence of ultraviolet radiation, and established that for chemical celluloses the concentration of $\alpha$-cellulose decreases with a marked increase in the concentration of hemicelluloses and a simultaneous decrease in the degree of whiteness. It was noted that the rate of formation of keto-groups is greater than the rates of formation of aldehyde and carboxyl groups. Papermaking grades of cellulose show an approximate analogous change in chemical composition. The degradation of cellulose from beech and reeds is more intensive than that of cellulose from spruce.

Spectroscopic study of photodegradation confirmed these conclusions; under the influence of ultraviolet radiation, cellulose and its derivatives undergo chemical and structural changes (new absorption bands due to carbonyl groups appear in the range 1720–1760 $cm^{-1}$, and the 3400 $cm^{-1}$ band corresponding to the hydroxyl groups is displaced towards smaller wave numbers). These results also show that the oxidative changes involve the direct participation of atmospheric oxygen [277].



Cellulose can be regarded as transparent to radiation with $\lambda > 200$ m$\mu$. Carboxy-groups absorb radiation of

TABLE 2. Influence of ultraviolet irradiation on cellulose.

| Wavelength of radiation $\lambda$, m$\mu$ | Action on cellulose or paper containing no lignin | Action on cellulose or paper containing appreciable quantities of lignin | References |
|---|---|---|---|
| 200–300 | *Yellowing*: the presence of water inhibits the process; yellowing may begin during the after effect; temperature has no direct effect on the process | *Yellowing*: more intensive in the presence of air, moisture, and heat; moderate in their absence | 266, 267 |
| 300–400 | *Bleaching*: appreciable in the presence of moisture and air; heat causes yellowing | *Yellowing*: bleaching takes place in the absence of moisture and heat | 258, 268, 271, 272 |
| 400–500 | – | Bleaching may take place | 258, 270 |

very short wavelength, whereas the C–O–C group does not absorb radiation with $\lambda > 220$ mμ.[278-280] Sippel[60] established that the energy corresponding to radiation with $\lambda = 350$ mμ, equal to 82 kcal mole$^{-1}$, is quite sufficient for the rupture of chemical bonds in polymers. It has been established that other wavelengths also correspond to appreciable energies[281].

From the above data it follows that the splitting of the $C_{(1)}-C_{(2)}$ and $C_{(1)}-O$ bonds of the elementary unit of cellulose may take place in different ways under the influence of ultraviolet radiation. Chromatographic determination of the corresponding cellulose degradation products confirmed, in particular, the mechanism of labilisation of these bonds, as shown below[282]:

By measuring the polydispersity, Page[283] proved that significant changes are undergone by cellulose subjected to ultraviolet irradiation for a prolonged period (500–2000 h). Recently, Rozmarin and Simionescu[284] established that appreciable changes take place in the polydispersity of celluloses as a result of shorter exposures (100–240 h); in all cases the maximum of the differential molecular-distribution curves was displaced towards lower DP values (papermaking celluloses acquire a more regular molecular composition under the influence of irradiation, but chemical celluloses, with more regular initial fraction composition, show a much greater increase in the degree of polydispersity). These changes are illustrated schematically in Fig. 4.

The above data confirm the theory (put forward as early as 1943[285]) that photolytic splitting of the cellulose chains takes place under the influence of ultraviolet radiation, with simultaneous photo-oxidation phenomena[286]. On the other hand, for cellulose and its derivatives, Tichener[287] found no relationship between the polydispersity and the course of the photolytic reactions.

Photochemical degradation involves free-radical chain reactions[288]. This was proved for cellulose by Simionescu and Poppel[289], who observed that solutions of hydroquinone and gallic acid inhibit the photodecomposition completely; this revealed that the reaction involved free radicals[19,290]. Zapol'skii[291] also confirmed this suggestion for the case of Cellophane, on the basis of spectroscopic data.

A mathematical method has been developed for calculating the number of cellulose chains split during photolysis from the concentration of aldehyde groups formed and the quantity of hydrogen liberated during the reaction[292].

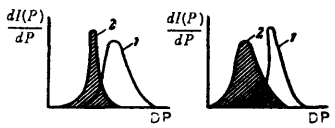


Fig. 4. Change in the molecular composition of paper-forming (left) and viscose (right) celluloses under the influence of ultraviolet radiation.
1) Control specimens; 2) irradiated specimens.

Flieder[293] used the ultraviolet light from bactericidal lamps to bleach old papers, and Belaya[294] used the same light to determine the durability of grades of paper used for printing. Simionescu and Poppel[295,296], on the basis of the artificial aging of papers by ultraviolet irradiation, recommended the use of kauri gum for the preservation of papers. A large number of versions of new methods of bleaching, using chlorine dioxide, sodium tetrahydroborate, sodium peroxide, and hydrogen peroxide, have been proposed, to increase the stability of the whiteness of papers[297] and reduce the effects of photodegradation[298,299].

Centola[300] established the following order of photo-stability for cellulosic materials: cotton > flax > hemp > > jute and linter > spruce viscose cellulose > spruce papermaking cellulose > spruce cellulose > sulphate cellulose > spruce semi-chemical cellulose > straw cellulose.

Using the numerical criterion of Geller and Meskin[301] for determining the degree of polydispersity, Rozmarin and Simionescu[284] gave another version of the order of photo-stability of bleached celluloses: spruce papermaking kraft cellulose > spruce bisulphite papermaking cellulose > > viscose sulphate cellulose from reeds > papermaking sulphate cellulose from reeds > viscose bisulphite spruce cellulose.

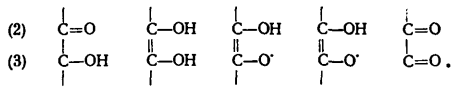
It has been shown that lignin facilitates the photodecomposition of cellulose, although it has also been reported[302] that lignin is able to retard oxidation processes. Papers sized with natural rosin are less stable to the action of light than papers sized with completely saponified rosin[303]. No appreciable yellowing effect is observed for cardboard[304].

Titanium dioxide fillers have a catalytic action. Atomic oxygen is formed, according to the reaction[305]:

$$2TiO_2 + h\nu = Ti_2O_3 + O,$$

and this oxidises hydrated cellulose[306] or cellulose derivatives[307] (for example, acetate rayon) preferentially. Under the influence of ultraviolet light, titanium dioxide acts an an oxidising agent on disaccharides (maltose, lactose, saccharose, and cellobiose) with the formation of the corresponding acids, but no splitting of the heterocyclic rings or acetal bonds was observed[308].

The presence of hemicelluloses and oxycelluloses does not play any significant part in the photolytic yellowing of cellulose from jute[309,310].



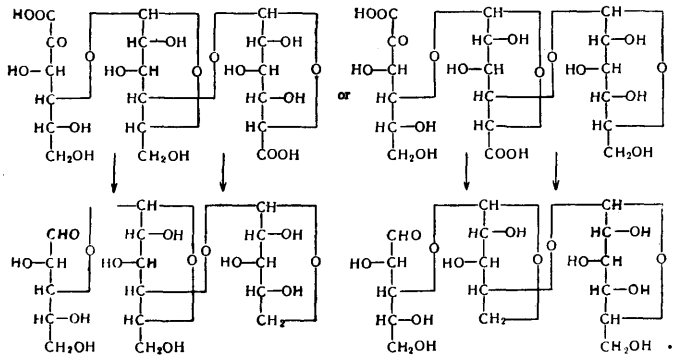
Zinc oxide increases the sensitivity to photochemical reactions, but glycerol, glucose, benzidine, etc. have a retarding influence[302]. More than 1% titanium dioxide may exert a protective influence on cellulosic materials[311-313]. A catalytic action is shown by Fe, Cu, Cr, Mn, U, Ti, and Mg ions[314]. Similar observations were made for synthetic[315,316] and artificial[311-313] fibres and on mixed fibres from cotton and Lavsan [Dacron, Ed. of Translation)][317].

Mention must be made of work on the influence of photodecomposition on the formation of cellulose ethers[318], which established a decrease in the reactivity of cellulose and also work on cellulose nitrate[319-321] and cellulose acetate[322].

Various schemes for the mechanism of the photodecomposition of cellulose have been proposed. Mention has already been made of the theories of Wilson and coworkers[265-267], Beelik and Hamilton[282], and Simionescu and coworkers[18,19,277,284,289,296]. In the opinion of these authors, ultraviolet radiation has a *photolytic* action on

the bonds formed by the carbon atoms in positions 1 and 2[282] and an *oxidative* action on the carbon atoms in positions 2, 3, and 6[265,277]. The reactions take place with the participation of atmospheric oxygen[277] by oxidative chain reactions[19,289].

Work by other authors has confirmed these suggestions. Schurz and coworkers[323] studied the ultraviolet absorption spectra of the soluble products of the yellowing of celluloses and found the following chromophoric groups in positions 2 and 3 of the elementary unit:



These groups undergo a number of changes, leading finally to splitting of the $C_{(2)}-C_{(3)}$ bond and the pentylene oxide bond 1–5 with the formation of brown products.

Zapol'skii[324] subjected Cellophane to the action of ultraviolet light and established an increase in the concentration of carboxy-groups as a result of the oxidation of primary alcoholic groups. On the basis of a study of the infrared absorption spectra, he suggested the following mechanism of photodegradation:

On the basis of data obtained by chromatographic separation of the products of the photodecomposition of cellulose, Bera and coworkers[325,326] concluded that cellulose decomposes to monosaccharides (xylose, arabinose, and glucose), cellobiose, and oligosaccharides (cellotriose and cellotetrose), which are converted into simple sugars by decarboxylation and splitting of the glucoside bonds:

The formation of xylose, arabinose, and glucose proves that photolysis of the β-glucoside bond takes place initially; the products are oxidised by atmospheric oxygen and decarboxylated under the influence of irradiation. It is difficult, however, to explain the formation of dark brown decomposition products by this scheme.

---o0o---

The above published data indicate the considerable interest shown by scientists in the study of the degradation of cellulose under the influence of a variety of factors. The phenomenon of aging, which accompanies degradation processes, has also attracted the attention of research workers. Examination of the above results makes it possible to determine the progress made in each branch of the study of the degradation of cellulose and to establish the nature of the problems requiring further examination.

It follows from this review that in thermal degradation and photodegradation, cellulose exhibits dual behaviour: oxidation and depolymerisation. The heat- and light--stability of cellulosic materials depends on the nature of the cellulosic raw material, the processes of digestion and bleaching, and the conditions of use. It may also be taken as established that the two types of degradation (under the influence of heat and light) differ essentially only in the superficial action of light and the bulk action of heat. In both, the decomposition involves chemical changes in the cellulose macromolecules (under the influence of atmospheric oxygen or the oxygen atoms of the molecules itself) and rupture of the chains.

The mechanisms proposed by different authors for the decomposition of cellulose have thrown light on a large number of individual aspects of the chemical changes undergone by cellulose but all possibilities in this field have not yet been exhausted. In the solutions of these problems, use must be made of the more promising methods of study, for example, chromatographic and spectroscopic methods.

Among methods leading to an improvement in the durability of cellulosic materials, particular attention should be paid to the development of milder conditions for the technological processes involved in the preparation, purification, bleaching, and finishing of cellulose. Mention may be made, for example, of the harmful effects of beating, bleaching, and sizing in acid medium in the manufacture of paper. Methods involving the addition of various inhibitors to prevent the degrading action of air, heat, and light, and also methods for the chemical partial modification of celluloses[327] appear promising.

Finally, it should be noted that in the study of artificial aging, the contradictory results which have been obtained can be attributed to the fact that the conditions of humidity and temperature have not been strictly controlled. In this field it is necessary to determine the factors responsible for the decrease in the whiteness of cellulosic materials, to develop standard methods of accelerated aging, and to establish the part played by non hydroxyl functional groups. In this connection the development of accurate methods for determining the different functional groups of cellulose is of considerable importance.

VIII. Reasons for the stabilising action of NSAS 879
IX. The use of NSAS for emulsion polymerisation and for increasing the stability of lattices 880

## I. INTRODUCTION

The production of non-ionic surface-active substances (NSAS) began in 1929–1935, when for the first time products were obtained by the addition of ethylene oxide to organic compounds containing at least one reactive hydrogen atom, such as the higher aliphatic acids, their amides, higher aliphatic alcohols, thiols, alkylphenols, amines, etc. These products are characterised by the number of ethylene oxide groups attached to one mole of the organic substance. It should be noted that the oxyethylene chains in the compounds are almost never of equal length, their distribution with respect to dimensions being described by a classical Poisson curve[1,2]. At the present time, methods are available for separating a mixture of polymer-homologues into individual products[3] and also for obtaining certain individual NSAS using particular chemical reactions[4].

As a result of the slightly hydrophilic character of ethylene oxide, the addition products usually have a higher solubility in water than the original substances. A significant advantage of oxyethylated substances is the possibility of controlling their hydrophilic nature by altering the quantity of attached ethylene oxide, and also the number of carbon atoms in the hydrophobic chain. This makes it possible to obtain substances with optimal properties for any given field of application. Another important characteristic feature of oxyethylated substances is that they cannot form salts, so that they are stable in hard water and can be used in combination with both anion-active and cation-active SAS.

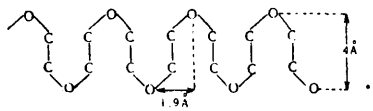
TABLE 1. Main classes of NSAS.[10]

| Type | Chemical structure | Trade name and firm** |
|---|---|---|
| Oxyethylated aliphatic acids and products of the oxyethylation of tall oil* | $R-CO[OC_2H_4]_nOH$ | Soromine SG<br>Emulsifier A<br>Sterox CD (Monsanto)<br>Prevocel (Buna) |
| Oxyethylated amides | $R-CON\begin{matrix}[C_2H_4O]_xH\\[C_2H_4O]_yH\end{matrix}$ | Dionyl (Hulz) |
| Oxyethylated alcohols | $R-[OC_2H_4]_nOH$ | Peregal O, Bunegal O (Buna) |
| Oxyethylated alkylphenols |  | Igepal C and W, Sapal (Buna) |
| Sulphonated oxyethylated alcohols | $R-[OC_2H_4]_m-OSO_3Na$<br>R = alkyl or alkylphenyl<br>$m = 2-8$ | Alipal<br>Igepal B |
| Esters of sorbitan and aliphatic acids |  | Span |
| Oxyethylated esters of sorbitan and aliphatic acids | the same, polyglycol ester | Tween |
| Monoethanolamides | $R-CO-NH-C_2H_4OH$ | Ninol |
| Diethanolamides | $R-CON\begin{matrix}C_2H_4OH\\C_2H_4OH\end{matrix}$ | Ninol |
| Oxyethylated poly(propylene glycol)s | $H[OC_2H_4]_x-[OC_3H_6]_n-[OC_2H_4]_y-OH$;<br>$R-[OC_3H_6]_n-[OC_2H_4]_xOH$ | Pluronic |
| Oxyethylated (ethylenediaminopolypropylene glycol)s | $CH_2-N\{[C_3H_6O]_n-[C_2H_4O]_xH\}_2$<br>$CH_2-N\{[C_3H_6O]_n-[C_2H_4O]_xH\}_2$ | Tetronic |
| Dialkyldihydroxyacetylene |  | Surfynol |
| Esters of saccharose and aliphatic acids | R–CO–(saccharose) | Sacrodet |
| Saccharose alkylurethanes | R–NH–CO–(saccharose) | |

* Tall oil is a by-product of sulphate cellulose production, containing chiefly a mixture of aliphatic and resin acids.

** See Ref. 10.

The combination of valuable technical properties shown by NSAS and the continuous decrease in the cost of their production has recently led to their extensive application in many branches of technology, including the textile industry, the manufacture of wetting agents[5], the processing of petroleum[6], etc.



As well as increased production of these substances, the production of oxyethylated substances of the block copolymer type – oxyethylated poly(propylene glycol)s[7,8] and oxyethylated ethylenediaminopoly(propylene glycol)s[8,9] – has been developed in recent years.

Since 1935, NSAS of the sorbitan ester, ethanolamide, saccharose–aliphatic acid ester, dialkyldihydroxyacetylene, etc., type have been prepared in addition to oxyethylated NSAS. Some of the most commonly encountered classes of NSAS are listed in Table 1.

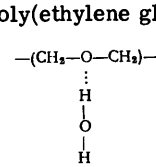
The aim of the present review is to summarise data on the properties of oxyethylated non-ionic surface-active substances and to indicate some of their fields of application.

## II. STRUCTURE OF NON-IONIC SURFACE-ACTIVE SUBSTANCES (NSAS)

In a study of the structure of polyoxyethylene chains, Staudinger[11] suggested that the retarded increase in chain length with increase in the number of oxyethylene groups can be explained by assuming that the polyoxyethylene chain has a winding shape (caterpillar shape):

The winding shape of the polyoxyethylene chain is generally assumed to be due to the mutual attraction of the oxygen atoms in the chain to one another. The chain strives to become shorter under the influence of the forces of attraction. At a low degree of polymerisation, these forces are insufficiently strong to lead to a decrease in the length of the chain, and the chain retains its usual zigzag shape[12].

Comparison of the observed and calculated specific viscosities of polyoxyethylene diacetates established that the chains have a zigzag shape up to a degree of polymerisation of 9 and that they acquire a winding shape only at higher degrees of polymerisation.



Many studies have been made of the structure of the polyoxyethylene chain[13–16]. Rösch[16] explains the winding shape of the polyoxyethylene chain on the basis of the general concepts of valency theory. He represents the structure of the polyoxyethylene chains as a zigzag structure, in which, because of the presence of $CH_2-CH_2-O$ and $CH_2-O-CH_2$ groups, oblique-angled and equilateral triangles alternate in the ratio 2:1. Each ethylene oxide group forms a dipole with a moment of 1.88, in which the $CH_2$ is the positive pole and the O the negative pole. The distance between the dipoles is 2.3 Å. The $CH_2$ groups of the ethylene oxide repel one another and the oxygen atoms attract neighbouring $CH_2$ groups. This produces stresses which increase with increase in the length of the zigzag chain. When the degree of oxyethylation reaches 9–11, the magnitude of the stresses becomes sufficiently high to produce a change in structure, and the zigzag shape is converted into the winding shape. The change in the structure leads to contraction of the oxyethylene chain.

In aqueous solutions of oxyethylated substances, as a result of the formation of polyoxonium complexes, an increase in the polarisation of the CO bond takes place and this may also lead to a change in structure.

Uchida and coworkers[17], on the basis of the dipole moments in dioxan solution, established that the polyoxyethylene chain consists of a mixture of both structures, although the winding shape of the chain predominates in aqueous solution.

## III. SOLUBILITY AND TEMPERATURE OF APPEARANCE OF TURBIDITY IN SOLUTIONS

The solubility of oxyethylated substances in water is due to the formation of hydrates as a result of the production of hydrogen bonds between the water molecules and the ether oxygen atoms of the poly(ethylene glycol) residue:

With increase in the number of oxyethylene groups, there is an increase in the number of water molecules attached to the ether oxygen atoms, and the hydrophilic

nature of the oxyethylated substance increases. Thus the polyoxyethylene chain can be regarded as "sheathed" with water molecules throughout its length. One or more of these water molecules may take up a proton from the surrounding solvent, with the formation of a hydroxonium ion. When this is so, each molecule of the oxyethylated substance is surrounded by an electrical double layer of ions. The ethylene oxide oxonium group can be represented as follows:

$$[-(CH_2-\underset{\displaystyle H_3O}{\underset{|}{O}}-CH_2)]^+OH^- .$$

The formation of charged groups increases the hydration of the substance. The presence of the charge was confirmed indirectly by the analytical studies of Wurzschmidt[18], who showed that in aqueous solutions, oxyethylated substances behave as weakly cation-active polyoxonium compounds. Only a small proportion of the ether oxygen atoms usually form oxonium salts. Studies by Schick[19], however, showed that oxonium salt formation increases on acidification, and that in strongly acidic media every ether oxygen atom forms an oxonium ion.

Scheller[5] established a rule which makes it possible to find the relationship between the number of carbon atoms in the hydrophobic fraction of oxyethylated substances and the number of oxyethylene groups necessary to make these substances soluble in water. If the hydrophobic fraction contains $n$ carbon groups, $n/3$ oxyethylene groups are required to give minimum solubility in water, $n/2$ oxyethylene groups are required to give moderate solubility in water, and between $n$ and $3n/2$ oxyethylene groups are required to give ready solubility in water.

According to the ideas of Cohen and Smith[20], one hydroxyl group or one ether oxygen atom is sufficient to overcome the hydrophobic character given to a substance by three methylene groups. Since the ethylene oxide molecule contains two $CH_2$ groups, the oxyethylated substance should contain one oxyethylene group in the hydrophilic fraction for every $CH_2$ group in the hydrophobic fraction if the substance is to dissolve in water. Thus a substance with general formula $H[CH_2]_x[OCH_2CH_2]_yOH$ is soluble in water if $y \geq x - 3$.

Shakhovskii[5] prepared oxyethylated $C_4-C_{12}$ alcohols and established that the substances obtained dissolved in water when they contained $M/44.05$ oxyethylene groups, where $M$ is the molecular weight of the aliphatic alcohol.

The solubility of oxyethylated substances in water decreases with increase in temperature, and since the energy of the hydrogen bond is low (7 kcal mole$^{-1}$), dehydration takes place so that the non-ionic substance loses its ability to dissolve in water. With decrease in temperature, the hydrate is reformed and the substance dissolves. The solubility of oxyethylated substances in water at elevated temperatures is characterised by the temperature at which turbidity appears in the solution (the cloud point). This temperature provides an important analytical indication of the degree of polyoxyethylation of the product and to some extent makes it possible to characterise NSAS. If the poly(ethylene glycol) residue contains a sufficiently large number of $CH_2-CH_2-O$ groups, the ability of these compounds to undergo hydration is so great that their aqueous solutions do not become cloudy even on boiling. Table 2 gives the cloud points of aqueous solutions of polyoxyethylated poly(propylene glycol)s.

TABLE 2. Cloud points ($t_c$) of 10% aqueous solutions of Pluronics[6].

| Pluronic symbol | Characteristics of Pluronic | Mean molecular weight of polyoxypropylene taken for oxyethylation | % polyoxyethylene in Pluronic molecule | $t_c$, °C |
|---|---|---|---|---|
| L-62 | liquid | 1750 | 20 | 20 |
| L-64 | liquid | 1750 | 40 | 70 |
| L-44 | liquid | 1200 | 40 | 78 |
| F-68 | flakes | 1750 | 80 | 100 |

Table 2 shows that the longer the oxyethylene chain, the greater the degree of hydration and the higher the temperature necessary for dehydration of the non-ionic molecules of the substance. The properties of Pluronics have been described in detail[21].

Raphael[5] determined the dependence of the cloud points of oxyethylated alcohols and octylcresols on the degree of oxyethylation at different concentrations. He showed that increase in the degree of oxyethylation leads to a linear increase in the cloud point, and that for a given degree of oxyethylation the cloud points are higher in concentrated solutions.

The cloud point depends on the chain-length distribution of the oxyethylene chains. If the oxyethylated substance contains a large proportion of low-molecular-weight products, the cloud point is low, whereas substances with a narrow distribution are more hydrophilic and have high cloud points[22].

The addition of certain electrolytes to solutions of oxyethylated substances leads to a marked decrease in the solubility and cloud points. Thus Knowles and Krupin[23], in a study of the cloud points of aqueous solutions of nonylphenols with different degrees of oxyethylation in the presence of electrolytes, obtained the results given in Table 3.

The influence of electrolytes involves chiefly a dehydrating action resulting from rupture of the hydrogen bonds. Sometimes, however, electrolytes exhibit a stabilising action related to the cation-active nature of the oxyethylated substances. Hydrochloric acid raises the cloud point (Table 3). This is due to the fact that in acid medium there is an increase in the possibility of formation of oxonium ions and hence in the hydration. Sulphuric acid has a very weak dehydrating action, since the increase in hydration resulting from oxonium ion formation is compensated by the desolvating action of the bivalent $SO_4^{2-}$ anion. Bases bring about particularly extensive dehydration. The cation-active nature of NSAS is also shown by the fact that the solubility is little influenced by the nature of the cation but is influenced to a marked extent by the nature of the anion[24].

TABLE 3. Influence of electrolytes on the cloud point of oxyethylated nonylphenols[28].

| Degree of oxyethylation of nonylphenol | Cloud point, °C | | | | | | |
|---|---|---|---|---|---|---|---|
| | distilled water | 3% NaCl | 3% $Na_2CO_3$ | 3% NaOH | 3% HCl | 3% $H_2SO_4$ | 3% $Na_3PO_4$ |
| 9 | 55 | 45 | 32 | 31 | 60.5 | 51 | 43 |
| 10.5 | 72 | 61 | 48 | 45.5 | 78 | 69 | 60 |
| 15 | 98 | 84.5 | 70 | 67 | 100 | 96 | 83.5 |
| 20 | 100 | 95 | 78 | 73 | 100 | 100 | 92 |

Doscher and coworkers[25] showed that salts of the alkaline earth metals, for example, calcium, have no dehydrating action and even facilitate the dissolution of NSAS. The $Ca^{2+}$ ions are strongly hydrated and the dipoles of the water are orientated around the $Ca^{2+}$ ions with their positive pole directed outwards. This orientation favours the formation of a coordinate bond between the hydrated ions and the negative ether oxygen atoms, leading to an increase in the hydration of the NSAS. This may explain the high efficiency of non-ionic wetting agents in hard water.

The addition of small quantities of anionic surface-active substances increases the cloud point by 10–20 deg. Maclay[26] attributed this phenomenon to the formation of mixed micelles of anionic and non-ionic SAS. At the cloud points, the non-ionic detergents are solubilised in these micelles.

The addition of aromatic or polar aliphatic substances (benzene, phenol, aniline) leads to a marked lowering of the cloud point[26–28]. The lowering of the cloud point in the presence of polar additives is attributed to the fact that these substances are solubilised in the micelles of non-ionic detergent and, as it were, increase the relative part played by the hydrophobic fraction of the detergent, with a consequent decrease in hydration and lowering of the cloud point.

## IV. SURFACE ACTIVITY AND SURFACE FILMS

It has been shown for the case of oxyethylated aliphatic alcohols[5,29], alkylphenols[5,30], and Pluronics[31] that within a given series, the minimal surface tension of the aqueous solutions increases with increase in the degree of oxyethylation and decreases with increase in the number of carbon atoms in the hydrophobic chain. The change in surface activity shows qualitative agreement with Traube's rule, that is, the surface activity increases with increase in the number of carbon atoms in the hydrophobic chain. The surface activity decreases with increase in the degree of oxyethylation. Data for Pluronics, confirming these general features, are given in Table 4.

With increase in temperature, the minimal surface tension of aqueous solutions of NSAS decreases and the surface activity of the non-ionic substances increases. This characteristic feature is related to the dehydration of the NSAS molecules with increase in temperature.

Crook and coworkers[30] recorded the surface tension isotherms for *p*-t-octylphenols with normal distribution and for individual *p*-t-octylphenols prepared by special methods[4]. Using these isotherms, they determined the dependence of the minimal surface tension $\sigma_{c_k}$ and the areas occupied by the molecules in a layer with maximum

TABLE 4. Dependence of the surface tension (dyn $cm^{-1}$) of a series of Pluronics at 30° on the concentration of the aqueous solutions[31].

| Pluronic symbol | Concentration, % | | | |
|---|---|---|---|---|

saturation on the degree of oxyethylation (Figs. 1*a* and 1*b*). It can be seen from Fig. 1*a* that the surface tension corresponding to $c_k$ for the individual products is greater than that for the mixtures with normal distribution, since in the latter case preferential adsorption of the more highly surface-active components with lower degree of oxyethylation takes place at the solution–air boundary.

On the basis of a comparison of the surface activity of oxyethylated substances of different classes, Schönfeldt concluded that oxyethylated alcohols and phenols exhibit the highest surface activity. Wrigley and coworkers[31] studied the surface tension of 1% solutions of oxyethylated aliphatic acids and aliphatic alcohols with oxyethylated chains of different length. With equal numbers of carbon atoms in the hydrophobic fraction and equal numbers of oxyethylene groups in the hydrophilic fraction, the surface tension is greater for the oxyethylated alcohols. For example, the values of the surface tension (dyn $cm^{-1}$) for hexadecanol specimens with degree of oxyethylation equal to 15, 20, and 30, are 36.4, 38.2, and 40.2 respectively, whereas the values for palmitic acid specimens with the same degree of oxyethylation are 34.2, 35.8, and 38.4.

To determine the nature of the orientation of non-ionic surface-active substances at an air–water boundary, a number of workers have studied surface films of aqueous solutions of polyoxyethylated aliphatic alcohols[32] and alkylphenols[19,28,33–36].

The nature of the packing and orientation of the polar groups in these surface films was established from the surface tension and surface potentials, and also by recording two-dimensional phase diagrams for the films[32]. Schick[33] used the Gibbs equation and surface tension isotherms to establish the dependence of the area of the adsorbed surface film on the surface pressure $\pi$ for two homologous series of oxyethylated NSAS.

The areas occupied by the molecules in the adsorbed films at $\pi = 20$ dyn $cm^{-1}$ are given in Table 5. This table also gives the data obtained by Lange[35] for a saturated adsorbed film, and Schick's data for insoluble surface films of the same NSAS. It can be seen from Table 5 that the area occupied by a molecule of oxyethylated n-dodecanol and n-octadecanol is much greater than the cross-sectional area of aliphatic hydrocarbons (20 Å²) or the benzene

TABLE 5. Areas occupied by the molecules in the surface films of non-ionic detergents.

| Hydrophobic group | Degree of oxyethylation | Area occupied by a molecule, Å² | | |

| | 14 | 94 | — | 160 |
| | 100 | 150 | — | 960 |

ring (25 Å²) and increases with increase in the length of the oxyethylated chain. Thus vertical orientation of the oxyethylene chain is excluded. Changes in the structure of the hydrophobic groups at constant molar concentration of ethylene oxide have little influence on the area occupied by the molecule. On the basis of these results, two possible configurations can be suggested for the NSAS molecules in adsorbed surface films: the molecules are orientated in such a way that the hydrophobic groups lie above the interface, and the oxyethylene groups either lie on the surface of the phases or form coils in the aqueous phase. In order to select one of the two possible orientations, a comparison was made of the molecular areas occupied by the molecules of non-ionic detergents in adsorbed surface layers and the corresponding molecular areas in insoluble surface films[35]. In the latter, the substrate consisted of a saturated solution of sodium nitrate or 29% sodium chloride solution.

In both homologous series, the areas occupied by the molecules at comparable surface pressures increase with increase in the length of the oxyethylene chain, whereas the difference in the structures of the hydrophobic groups at constant degree of oxyethylation has little influence on the areas of the molecules in the saturated films. From this it should have followed that the hydrophobic groups are orientated above the interface, and the oxyethylene chains lie on the surface. The molecular areas in insoluble surface films, however, are very much greater than the corresponding values in adsorbed surface films, so that the horizontal orientation is also excluded. These considerations led the authors to the conclusion that the molecules of the surface-active substance are orientated at the air–water interface with their hydrophobic groups above the interface and with the oxyethylene chains forming coils in the aqueous phase. The dimensions of the coils increase with increase in the number of segments in the oxyethylated chain.

These conclusions were confirmed and extended in a study of the surface potentials for polyoxyethylated n-dodecanols and n-octadecanols containing oxyethylated chains of different length[19].

It was found that the increase in surface potential and hence the increase in the dimensions of the coils decreases with increase in the degree of oxyethylation. This is related to the polymeric nature of the oxyethylene chain. Figure 1*b* gives the dependence of the area occupied by a molecule of *p*-t-octylphenol on the length of the oxyethylene chain. The increase in area is non-linear, although

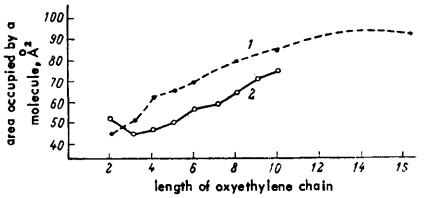

Fig. 2. Dependence of the area occupied by a molecule at the solution–isooctane boundary on the chain length of individual OP SAS (2) and mixtures with normal distribution (1).[39]

the deviation from linearity is slight in the range from 3 to 10 oxyethylene groups. On the basis of the assumption that the hydrated molecules of oxyethylated substances in adsorption layers form statistical configurations, Van Voorst-Vader[37] concluded that the area of the molecule at saturation is proportional to $\sqrt{m}$, where $m$ is the degree of oxyethylation. This was confirmed for the case of oxyethylated alkylphenols. Lange[32] obtained the same relationship for oxyethylated dodecanol.

By measuring the interfacial tension at the interface between isooctane and an aqueous solution of NSAS, Crook[30] determined the dependence of the area occupied by a molecule at the interface on its degree of oxyethylation (Fig. 2). For individual substances, the areas occupied by a molecule on the solution–hydrocarbon boundary are close to the corresponding values for a solution–air boundary. For mixtures with normal distribution, the area of the molecule at the solution–air boundary (Fig. 1*b*) is smaller, and the area at the solution–hydrocarbon boundary (Fig. 2) greater, than the value for the corresponding individual products. As already described, the former is due to the preferential adsorption of the more highly surface-active components of the mixture at the solution–air boundary. The second result is due to the fact that for mixtures with normal distribution it is necessary to make allowance for the specific solubility of the different components of the mixture in isooctane. Since the components with lower degree of oxyethylation are more soluble in isooctane, they are concentrated in the hydrocarbon phase, so that the average molecular weight of the NSAS dissolved in water increases, leading to an increase in the area of the molecule at the interface. Becher[34] put forward suggestions regarding the orientation of non-ionic surface-active substances at an oil–water interface for the polyoxyethylated lauryl alcohols and nonylphenols, and the part played by hydrogen bonds in this orientation.

## V. MICELLE FORMATION. THE SHAPE AND DIMENSIONS OF MICELLES

Micelle formation by NSAS has been fairly fully studied. The studies have been carried out chiefly using oxyethylated aliphatic alcohols and alkylphenols. Several methods have been used to determine the critical concentration of micelle formation ($c_k$) of non-ionic surface-active substances: the surface tension method[38-43], the dye solubilisation method, a method based on the change in the absorption spectrum[40,43-50], the light scattering method[40,41,50-55], and the viscosity method[51,55].

Unlike the case of ionogenic surface-active substances, in which the hydrophilic fraction of the molecule is much

TABLE 6. $c_k$ and the micellar weights of non-ionic detergents in aqueous solutions[56].

| Hydrophobic groups | Degree of oxyethylation | Number of C atoms in the hydrophobic fraction | $c_k$, μmole litre$^{-1}$ | Micellar weight × $10^{-3}$, $M_m$ | Degree of association (n) |
|---|---|---|---|---|---|
| Nonylphenol (branched) | 10 | 10.5 | 75 | 182 | 276 |
| | 15 | | 110 | 70 | 80 |
| | 20 | | 140 | 68 | 62 |
| | 30 | | 185 | 67 | 44 |
| | 50 | | 280 | 48 | 20 |
| n-Dodecanol | 7 | 12 | 50 | | |
| | 14 | | 55 | 100 | 125 |
| | 23 | | 60 | | |
| | 30 | | 80 | 82 | 55 |
| n-Octadecanol | 14 | 18 | 60 | 330 | 370 |
| | 100 | | 20 | 465 | 100 |

smaller than the hydrophobic fraction, the hydrophilic fraction may be greater than the hydrophobic fraction in non-ionic oxyethylated substances. With non-ionic substances, the absence of electric charge facilitates micelle formation, so that $c_k$ for NSAS is much lower than $c_k$ for ionic surface-active substances, as can be seen from Table 6, which gives the values of $c_k$ for several homologous series of non-ionic detergents in aqueous solutions. For comparison, it may be noted that for sodium dodecyl sulphate, $c_k$ = 8100 μmole litre$^{-1}$.[5]

From the results obtained it follows that $c_k$ increases with increase in the length of the oxyethylene chain, that is, increase in hydration or solubility hinders the aggregation of the non-ionic surface-active substances. The low values of $c_k$ for n-octadecanol-100, compared with those for n-octadecanol-14, can be attributed to the decrease in the solubility of the oxyethylene fraction of the chain at very high degrees of oxyethylation. Thus with increase in the length of the oxyethylene chain, the overall solubility of non-ionic detergents passes through a maximum. It has been shown[38,39] that the increase in $c_k$ with increase in the length of the oxyethylene chain is given by the equation

$$\ln c_k = BR + K \qquad (1)$$

where $R$ is the average number of oxyethylene groups in the chain, $B$ a constant which depends on the nature of the hydrophobic group and decreases with increase in the length of the hydrophobic chain, and $K$ a constant which depends on the nature and concentration of the electrolyte present.

For oxyethylated nonylphenols in water, $B$ = 0.056 and $K$ = 3.87. It then follows from formula (1) that the value of $c_k$ is doubled when $R$ increases by 12. Approximately the same relationship is applicable for oxyethylated substances of other classes (Fig. 1c)[39].

For oxyethylene chains of constant length, the values of $c_k$ for NSAS, like those for ionogenic detergents, decrease with increase in the length of the hydrocarbon chain, due to the increase in the interaction between the hydrocarbon chains, facilitating aggregation. According to recent work by Schinoda[57], the influence of the length of the hydrocarbon chain on $c_k$ is given by the formula

$$\log c_k = -\frac{m\omega}{kT} + \text{const}, \qquad (2)$$

where $m$ is the number of carbon atoms in the chain and $\omega$ the change in cohesion energy for the transfer of one methylene group from aqueous solution into the micelle.

The values of $c_k$ are approximately doubled when the hydrophobic chain is reduced by one $CH_2$ group. Thus the influence of 12 ethylene oxide groups on $c_k$ is equivalent to that of one methylene group.

The influence of temperature on $c_k$ for NSAS solutions is opposite to the usual influence of temperature on micelle formation. Since thermal movement hinders micelle formation, the latter should decrease with increase in temperature, and the values of $c_k$ should increase. This is the usual relationship observed, with certain exceptions, in solutions of ionogenic SAS. For NSAS, $c_k$ decreases with increase in temperature, that is, micelle formation shows negative thermal effects.

Schick[58] used the Clausius–Clapeyron equation to determine the enthalpy change on micelle formation ($\Delta H_m$) from the temperature dependence of $c_k$. The dependence of $\log c_k$ on $1/T$ for oxyethylated alcohols is shown in Fig. 3. As shown in Fig. 3 and in other papers[41,59,60], this relationship is strictly linear for NSAS, and the enthalpy increases on micelle formation. The fact that the Clausius–Clapeyron equation is applicable to micelle formation means that in NSAS solutions this process must be regarded as involving phase separation. This approach is also applicable to ionic detergents in the presence of salting-out electrolytes[60,61]. From the conditions for equilibrium at $c_k$, it follows that the free energy change $\Delta\bar{G}_m$ is equal to zero, and the entropy of micelle formation can be calculated from the equation

$$\Delta\bar{S}_m = \frac{\Delta\bar{H}_m}{T}. \qquad (3)$$

The quantity $\Delta\bar{H}_m$ is positive, so that the entropy change on micelle formation in NSAS solutions is also positive. A positive entropy change means an increase in disorder. Since it cannot be that aggregation of monomeric detergent molecules to form micelles is accompanied by an increase in the disorder of the system, it is necessary to find other reasons for the positive change in entropy. Studies have shown[33,56,58,62] that the chief reason for the increase in entropy on micelle formation may be the desolvation of the NSAS molecules on aggregation. This is confirmed by the data in Table 7.

The greater the concentration of electrolyte and hydration of the anion ($CNS^- < Cl^- < SO_4^{2-}$), the greater the increase in entropy. The part played by dehydration can

| n-Dodecanol | 30 | 0.86 M $^1/_2Na_2SO_4$ | 9.1 | 30.2 |

* Values obtained in the range 1–55°.

also be seen by comparing the values of $\Delta\bar{S}_m$ for substances with different hydrophilic character (n-dodecanol-30, n-dodecanol-7, and n-hexadecanol-30). The greater the hydrophilic character, the more difficult the process of dehydration and the smaller the increase in entropy on aggregation.

In addition to desolvation, another factor increasing the entropy may be an increase in the configurational entropy of the hydrocarbon chain of the detergent molecule inside the micelle[36,64]. To counterbalance this, the configurational entropy of the oxyethylene chain in the outer sheath of the micelle is smaller than its entropy in solution. Since the experimentally-observed entropy change is positive, the decrease in entropy taking place on aggregation of the molecules of non-ionic detergents is compensated by desolvation and to some extent by an increase in the entropy of the hydrocarbon chain.

Tables 6 and 8 give values of the micellar weights and corresponding values of $c_k$ for non-ionic detergents in aqueous solutions, obtained by the light scattering and ultracentrifuge methods[54]. Similar results were obtained by Mankowich[65], Dwiggins and coworkers[66-68], and Elworthy and Macfarlane[55].

Low values of $c_k$ correspond to the highest values of the micellar weights, and vice versa, as is usually the case in micellar solutions. The degree of association or the number of molecules in the micelle is defined as the ratio of the micellar weight to the molecular weight of the surface-active substance. No allowance is made for the degree of hydration since this is unknown.

It can be seen from Table 6 that when the degree of oxyethylation is constant (for example, 14 or 15 $CH_2-CH_2-O$ groups), the micellar weights and degree of aggregation increase with increase in the chain length of the hydrophobic fraction of the molecule. With increase in the number of oxyethylene groups, however (Tables 6 and 8), the micellar weights decrease, and for substances with a low degree of oxyethylation, small changes in the ethylene oxide content bring about the most marked changes in the micellar weights. Study of a mixture of fractions with different degree of oxyethylation showed that the change in the micellar weight for fractions with high ethylene oxide content is much greater than that for fractions with low degree of oxyethylation. Thus change in the conditions of preparation of polyoxyethylated surface-active substances may have a marked influence on their micellar weight in solutions.

TABLE 8. Average micellar weights and degree of association of oxyethylated lauryl alcohol and nonylphenols[53].

| Hydrophobic fraction | Degree of oxyethylation | $10^3 c_k$, g litre$^{-1}$ | Micellar weight × $10^{-3}$, $M_m$ | Degree of association, $n$ |
|---|---|---|---|---|
| Lauryl alcohol | 8 | 59 | 68.2 | 123 |
| | 12 | 65 | 58.9 | 81 |
| | 18 | 80 | 50.6 | 51 |
| | 23 | 110 | 48.9 | 40 |
| Nonylphenol | 10 | 64 | 66.3 | 100 |
| | 15 | 77 | 45.0 | 52 |
| | 30 | 236 | 29.7 | 19 |

The degree of association decreases with increase in the length of the oxyethylene chain. With n-octadecanols (Table 6), the degree of association also decreases with increase in the length of the oxyethylated chain, but the micellar weight increases, due to an increase in the molecular weight of the surface-active substance. Becher[53] found a linear relationship between the degree of association and the degree of oxyethylation. For derivatives of lauryl alcohol and nonylphenol, the equations for the straight lines are of the form

$$n = 1025/R - 5.1 \quad (4)$$

and

$$n = 1215/R - 22.5 \quad (5)$$

respectively, where $n$ is the degree of association and $R$ the number of oxyethylene groups in the chain.

A decrease in the degree of association with increase in the length of the oxyethylene chain was also observed by Kushner et al.[69] for polyoxyethylated isooctylphenols and by Stauff and Rasper[70] for polyoxyethylated dodecanol. This work[69,70] was carried out with fractionated specimens, however, and since the polymer distributions are different in the fractionated specimen and in the industrial product with the same average molecular weight, these results are of mainly theoretical importance.

Work by Balambra and coworkers[54] and Mankowich[47] showed that the micellar weights increase exponentially with increase in temperature.

A number of authors have put forward suggestions regarding the shape of the micelles in NSAS solutions[53,56,71-74]. As for ionic detergents, the existence of spherical, lamellar, and cylindrical micelles has been suggested. On the basis of calculations of the surface area of micelles of different types for oxyethylated nonylphenols and lauryl alcohol, Becher[53] showed that the cylindrical shape is the most probable.

Ermilov[48] suggests that there exist two critical concentrations for micelle formation: $c'_k$, at which small spherical micelles are formed, and $c''_k$, at which large lamellar micelles are formed. Levitskii and coworkers[49], however, consider that only the spherical micelles postulated by Hartley exist at $c'_k$ and $c''_k$, but that the quantity of these micelles is smaller at $c'_k$ and greater at $c''_k$. The final equilibrium distribution of the structural units of different type (molecules and micelles), both in the bulk of the micellar solutions and between the bulk and the adsorption layers, is established at $c''_k$, and this distribution remains unchanged over a wide concentration range until another form of micelle is produced in the solution.

Schick and coworkers[56] determined the shape of micelles formed by non-ionic surface-active substances, by the light-scattering method and from the rate of sedimentation. They suggest that in the micellar weight range 45 000–100 000 the micelles are most probably spherical, whereas

at higher micellar weights they have the shapes of discs and rods. Similar results were obtained by Gorkill[74].

The addition of electrolytes influences $c_k$ and the dimensions of the micelles in solutions of non-ionic detergents. This influence is analogous to the influence of electrolytes on $c_k$ for ionic SAS, established by Corrin and Harkins[75] and Klevens[76]. Addition of electrolytes leads to a decrease in $c_k$ and an increase in the micelle dimensions. The influence of electrolytes on $c_k$ for non-ionic detergents has been studied in detail by Hsiao and coworkers[39], Becher[38], Kuriyama[77], and Schick[33].

It can be seen from Table 9 that increase in the NaCl concentration leads to a marked increase in $c_k$ for solutions of polyoxyethylated nonylphenols in water (the increase is greater than that for ionic surface-active substances).

In a study of the influence of added electrolytes on micelle dimensions for oxyethylated derivatives of lauryl alcohol, nonylphenol, and tridecanol in the presence of Na and Ca chlorides, Na sulphate, and Na citrate $Na_3C_6H_5O_7$, Becher[38] showed that replacement of the univalent $Na^+$ cation by the bivalent $Ca^{2+}$ cation has no significant influence on the micelle dimensions or degree of association; change in the anion, however, has a more marked influence on these quantities. The anions can be arranged in the following order of decreasing activity:

sulphate > citrate > chloride.

TABLE 9. Influence of electrolyte concentration on $c_k$ for solutions of polyoxyethylated nonylphenols[33].

| NaCl concentration, M | Decrease in $c_k$, $\mu$mole litre$^{-1}$ | |
|---|---|---|
| | nonylphenol + $+15CH_2CH_2O$ | nonylphenol + $+50CH_2CH_2O$ |
| 0.43 | 45 | 80 |
| 0.86 | 55 | 130 |
| 1.29 | 65 | 180 |

The data which they obtained on the influence of electrolytes are given in Table 10. The micellar weights $M_m$ were calculated from the Debye equation, and the degree of association $n$ was calculated from the micellar weight and the average molecular weight of the surface-active substance. The increase in the degree of association is due to the decrease in the hydration of the oxyethylene chain resulting from the desolvating action of the electrolytes. It can be seen from Table 10, however, that this influence of electrolytes is shown only in solutions of substances with low degree of oxyethylation. For substances with a high degree of oxyethylation, the addition of electrolytes sometimes leads to a decrease in the degree of association, although the addition of electrolytes leads to a decrease in $c_k$ even at high degrees of oxyethylation, as can be seen from Table 9. Becher suggests that the effect of electrolytes involves not only their action on the hydrophilic nature of the polyoxyethylene chain but also their action on the charge of the micelles resulting from the formation of the hydroxonium ion.

## VI. FORMATION OF MIXED MICELLES. SOLUBILISATION

Kuriyama and coworkers[78] determined the micellar weight for mixtures of non-ionic and ionic surface-active substances in 0.2 M sodium chloride solution at different temperatures. The results are given in Table 11.

The micellar weight of non-ionic surface-active substances increases with increase in temperature, whereas that of ionic surface-active substances decreases.

In mixtures of non-ionic and ionic surface-active substances, the increase in the micellar weight of the non-ionic detergents is suppressed with increase in the quantity of ionic SAS added. When the quantity of added ionic SAS exceeds a definite value (~20%), the micellar weights decrease with increase in temperature. This relationship was explained as follows[78]. The formation of micelles in solutions of non-ionic surface-active substances is determined by two factors: the forces of cohesion between the oleophilic groups and the affinity of the hydrophilic groups

TABLE 10. Influence of electrolytes on the micellar weight ($M_m$) and average degree of association ($n$).[38]

for water molecules. At a given temperature, a corresponding balance is established between the forces of hydration and cohesion, and micelles with definite dimensions are formed. In the case of ionic SAS, the formation of micelles is associated with a balance between the electric forces of the ionised groups and the forces of cohesion of the hydrocarbon chain.

In mixtures of ionic and non-ionic detergents in solution, mixed micelles are formed. The balance between the electric forces and the forces of cohesion and hydration may be altered in either direction with increase in temperature, depending on the ratio of the quantities of ionic and non-ionic detergents. It follows from the results obtained (Table 11) that the micellar weights increase with increase in temperature until a definite composition is reached in the mixture of ionic and non-ionic SAS, after which the micellar weights decrease.

The ionogenic substances added to a solution of non-ionic detergents may influence the equilibrium between the forces of cohesion and the electric forces in two ways: (1) by penetrating into the micelle and altering its structure, and (2) by dissolving in the aqueous phase and thus altering the medium surrounding the micelles[25].

The solubilisation of n-decane and n-decanol in solutions of oxyethylated decanols with general formula $C_{10}H_{21}[OC_2H_4]_nOCH_3$, where $n$ = 8 or 12, at different temperatures, was studied by Kuriyama[79,80]. The solubilisation was estimated from the change in micellar weights, as shown in Table 12.

| | | 10.18 | 7.5 | 62.9 | 86 | 37 |
| | | 17.12 | 6.3 | 12.2 | 158 | 113 |

With n-decane, the micellar weights increase with increase in its solubilisation up to a definite saturation limit and then remain unchanged. The data obtained indicate that the increase in micellar weights is due not to simple introduction of the molecules of the substance being solubilised into existing micelles but also to an increase in the number of molecules of surface-active substance making up the micelle. Thus the solubilisation process is associated with a change in the structure of the micelles. These results agree with data given by Mattoon[81].

Mankowich[47], in a study of the micellar solubilisation of oxyethylated alkylphenols, found that the temperature dependence of this process is exponential.

## VII. HYDROPHILIC-LIPOPHILIC BALANCE (HLB)

Of decisive importance for the surface and bulk properties of the non-ionic SAS described in the preceding sections and hence for their application, is the relative efficiency of the two opposed groups of the molecule — the hydrophilic and hydrophobic (or lipophilic) groups — the so-called hydrophilic-lipophilic balance (HLB). Unlike the case of ionic SAS, whose HLB depends to a marked extent on the concentration of electrolytes in the medium, the HLB of non-ionic SAS is comparatively constant and depends only on the structure of the molecule.

An empirical quantitative characterisation of the HLB was derived in 1949 by Griffin[82] and this has been used extensively in the last decade as a guiding principle in the preparation of emulsions and for other applications of SAS. The HLB system was described briefly by Schönfeldt[5] and in more detail by Jalina and Goǒjila[83]. According to Griffin's classification, each SAS is characterised by a definite value for the HLB number, which may vary from 1 to 40. The higher the HLB number, the greater the hydrophilic character of the SAS. The smallest HLB number, 1, is shown by oleic acid, and the highest, 40, by Na lauryl sulphate. The HLB number determines the range of application of the SAS, as follows:

| HLB number | Application |
|---|---|
| 3–6 | water/oil emulsions |
| 7–9 | wetting agents |
| 8–18 | oil/water emulsions |
| 13–15 | wetting agents |
| 15–18 | solubilising agents |

It should be emphasised that the value of the HLB number, which determines the range of application of the SAS, does not characterise its efficiency sufficiently completely. SAS with different chemical structures, some of which are more effective than others, may have the same HLB number. The HLB system makes it possible to define the parameter required for a given process and thus to limit the range of substances studied. The HLB number is determined from the emulsifying action. Here it must be borne in mind that the HLB number characterises not only the emulsifier but also the "oil" being emulsified. The so-called necessary HLB number of the "oil" is taken as the value of the HLB number of the emulsifier which forms the most stable emulsion with this oil. To determine the necessary HLB number of the "oil", use is made of the fact that the change in HLB number, when a mixture of two SAS is used, is additive. If a series of emulsions of a given "oil" is prepared, using as emulsifiers a mixture of two SAS for both of which the HLB numbers are known, and the stability of the resulting emulsions is determined, it

is possible to calculate the HLB number of the optimal mixture (the necessary HLB number of the "oil") using the formula:

$$HLB_1X + HLB_2(1-X) = HLB_0\dagger, \quad (6)$$

where $X$ is the weight fraction of the first emulsifier in the mixture.

By emulsifying an "oil" with known necessary HLB number $HLB_o$, using a mixture of two emulsifying agents, for one of which the value of the HLB number $HLB_1$ is known, while that of the other requires to be determined, it is possible to find the optimal ratio of these emulsifying agents and to calculate from formula (6) the value of the HLB number $HLB_2$ in which we are interested. The values of the experimentally determined HLB numbers for various emulsifying agents and oils are given in Table 13.

Griffin's procedure for determining HLB numbers is very tedious, so that a method for the rapid determination of the HLB numbers of emulsifying agents and the necessary HLB of "oils", using a centrifuge, has been proposed[84].

In the experimental determination of HLB numbers by these methods, use is made of a high concentration of emulsifying agent (5% of the total volume of the disperse phase and dispersion medium) so that this number makes allowance for the influence of the structure of the molecule of the emulsifying agent and the nature of the disperse phase on the stability of the emulsion but it does not characterise the influence of the emulsifying agent concentration.

In later work, using different pairs of NSAS for the emulsification of the same oil, Griffin[85] was able to show that in all the experiments, maximum stability is observed at the same weight percentage of hydrophilic substance in the mixture. Thus the HLB of NSAS is essentially a function of the weight fraction of the hydrophilic part of the molecule. On the basis of this observation, it was possible to derive formulae for calculating HLB numbers; these were found to be different for substances of different chemical character. For example, the HLB number of esters is calculated from the formula

$$HLB = 20\left(1 - \frac{s}{A}\right), \quad (7)$$

where $s$ is the saponification number and $A$ the acid number.

TABLE 13. HLB numbers[82].

| Emulsifying agent | HLB No. | Oil | HLB No. |
|---|---|---|---|
| Na oleate | 18 | Carbon tetrachloride | 9 |
| K oleate | 20 | Paraffin | 9 |
| Oleic acid | 1.8 | Kerosene | 12.5 |
| Span 80 | 4.3 | Cetyl alcohol | 13 |
| Span 60 | 4.7 | Dimethyl phthalate | 15 |
| Span 20 | 8.6 | *o*-Phenylphenol | 15.5 |
| Tween 81 | 10.0 | Stearic acid | 17.0 |
| Tween 60 | 14.9 | | |
| Tween 80 | 15.0 | | |
| Tween 20 | 16.7 | | |
| Oxyethylated nonylphenol-7 | 9.9 | | |
| Oxyethylated nonylphenol-15 | 16.1 | | |

† In this and all subsequent formulae, the symbol HLB denotes the HLB number of the corresponding substances.

For oxyethylated products, whose hydrophilic fraction consists of ethylene oxide, the following formula is applicable:

$$HLB = \frac{E}{5}, \quad (8)$$

where $E$ is the wt. % of ethylene oxide groups.

A paper by Davies[86] gave a convenient method proposed by Griffin for calculating HLB numbers from chemical composition by means of so-called group numbers. The calculation uses the formula

$$HLB = \Sigma N_{\text{hydrophilic}} - nN_{CH_2} + 7, \quad (9)$$

where $\Sigma N_{\text{hydrophilic}}$ is the sum of the group numbers of the hydrophilic groups, $n$ the number of $CH_2$ groups in the molecule, and $N_{CH_2}$ the group number for $CH_2$. The values of the group numbers are given in Table 14.

The numbers given are not suitable for very large molecules of oxyethylated substances; in practice, a degree of oxyethylation equal to 20 represents the upper limit of the value of the HLB number for these molecules. The values of the HLB number calculated from formula (9) for a number of substances show good agreement with the values found experimentally. Sometimes[87], instead of the HLB numbers, the so-called approximate HLB number is calculated. The approximate HLB number is the ratio of the number of ethylene oxide groups in the hydrophilic chain to the number of carbon atoms in the straight chain of the hydrophobic group. In these calculation a benzene ring is taken as equivalent to 3.5 carbon atoms. It should be borne in mind that an unsatisfactory feature of all the formulae used for the calculations is that they are based on the stoichiometric composition and make no allowance for isomerism.

A large number of papers have been devoted to establishing the relationship between the empirical HLB number characterising the range of application of SAS, and their physicochemical properties, such as the solubility in water and other solvents[5], the distribution between the two phases of an emulsion[86], the formation of insoluble complexes[88], the cloud point[4], the surface tension and interfacial tension[89,90], $c_k$,[42] the hydration energy, and the electric potential[86].

Table 15 shows that the solubility in water is an extremely approximate characteristic of the HLB. It has been pointed out[90] that there is no direct relationship between solubility and the HLB number. Two emulsifying agents with the same HLB number may exhibit different solubilities.

TABLE 14. Group numbers for calculating HLB numbers[86].

| Groups | Group No. | Groups | Group No. |
|---|---|---|---|
| Hydrophilic groups | | Lipophilic groups | |
| $-SO_4Na^+$ | 38.7 | $-CH-$ | −0.475 |
| $-COOK^+$ | 21.1 | $-CH_2-$ | −0.475 |
| $-COONa^+$ | 19.1 | $CH_3-$ | −0.475 |
| N (tertiary amines) | 9.4 | $CH-$ | −0.475 |
| Ester group (sorbitan ring) | 6.8 | | |
| Ester group | 2.4 | Complex groups | |
| $-COOH$ | 2.1 | | |
| Hydroxyl | 1.9 | $-(CH_2-CH_2-O)-$ | 0.33 |
| $-O-$ | 1.3 | $-(CH_2-CH_2-CH_2-O)-$ | −0.15 |
| Hydroxyl (sorbitan ring) | 0.5 | | |

TABLE 15. Approximate values for the HLB numbers of SAS with different solubilities in water.

| Solubility in water | HLB No. |
|---|---|
| Not dispersed | 1–4 |
| Slightly dispersed | 3–6 |
| Milky dispersion formed after vigorous shaking | 8–10 |
| Spontaneous formation of milky dispersion | 10–13 |
| Transparent solutions | 13 |

‡ The solubility of water in a mixture of organic solvents, for example, dioxan and benzene, is altered in the presence of NSAS. The water number characterises the number of millilitres of distilled water which must be added to a mixture of solvents containing NSAS until a permanent turbidity is produced. The water numbers of SAS mixtures are algebraically additive and directly proportional to the HLB numbers for the given class of substance. The coefficients in the equations of the straight line are different for different classes of substance.

The HLB of individual SAS can also be characterised by the distribution constant $R_f$ for distribution between a stationary aqueous phase and a mobile organic phase for chromatography on paper or on paper which has been made hydrophobic[90]. There is a direct relationship between $R_f$ and the HLB number. Unfortunately, this method is not suitable for a mixture of emulsifying agents, since separation into individual components takes place[2].

In an examination of the relationship between the rate of coalescence of an emulsion of oil in water and an emulsion of water in oil, the HLB number, and the solubility of the emulsifying agent in each of the emulsion phases, Davies[86] concluded that the HLB number is related to the distribution of the emulsifying agent between the two phases by the expression

$$\text{HLB} - 7 = 0.36 \ln \frac{c_w}{c_o}, \qquad (10)$$

where $c_w$ and $c_o$ are the solubilities of the emulsifying agent in water and oil.

If the emulsifying agent dissolves preferentially in water, the HLB number is greater than 7, and if the emulsifying agent dissolves preferentially in the oil, the HLB number is less than 7.

The methods used by Karabinos and Jutaka Tanaka to characterise the HLB, described in a paper by the latter[88], are based on the fact that when aqueous or alcoholic solutions of NSAS are titrated with a phenol solution, an insoluble complex of these two substances is formed and the solution becomes cloudy. The quantity of phenol solution used up at the end of the titration is called the cloud number. The cloud numbers increase with increase in the length of the oxyethylene chain. An interesting feature is that Jukata Tanaka's cloud number is directly proportional to the HLB number, irrespective of the class of compound. The equation of the corresponding straight line is

$$\text{HLB} = 0.89A + 1.11, \qquad (11)$$

where $A$ is the cloud number.

‡ The beginning of this paragraph is missing from the Russian text (first two lines of preceding paragraph repeated instead) (Ed. of Translation).

For a given class of compounds, the HLB may be characterised by the cloud point, which is higher, the greater the hydrophilic character of the substance.

It might be suggested that the necessary HLB number of an oil is equal to the HLB number of the emulsifying agent which produces the greatest decrease in the interfacial tension. Wachs and Reusche[90] studied the stability of emulsions of undecane in water in the presence of mixtures of emulsifying agents with HLB from 2 to 17 and the interfacial tension at the boundary between the undecane and solutions of the corresponding mixtures of emulsifying agents, and found that the optimal value of the HLB number was equal to 9.5, irrespective of the composition of the mixture of emulsifying agents. In some systems the interfacial tension at this value of the HLB number passes through a minimum. In others, however, the interfacial tension changes continuously with change in the HLB, without passing through extreme values. Becher[34] obtained the same results in a study of the dependence of the interfacial tension on the degree of oxyethylation. Thus the interfacial tension is not the only factor determining the stability of an emulsion and the necessary HLB number of the oil. Ross and coworkers[89] concluded that the influence of the interfacial energy on the energetic balance in the formation of emulsions cannot be denied. Low interfacial tension, however, is a necessary but insufficient condition for stability. Another condition for stability in an emulsion of the type formed by oil in water is that the spreading coefficient $S_1$ should have a low negative value (from 0 to -5). The spreading coefficient indicates the way in which the oil spreads over the surface of a 1% solution of the emulsifying agent in water, and is calculated from the formula

$$S_1 = \sigma_{\text{solution}} - (\sigma_o + \sigma_{i.f.}), \qquad (12)$$

where $\sigma_{\text{solution}}$ is the surface tension of the solution of the emulsifying agent in water, $\sigma_o$ the surface tension of the oil, and $\sigma_{i.f.}$ the interfacial tension at the boundary between the oil and the solution of the emulsifying agent in water.

It follows from Ross's data that the spreading coefficient is directly proportional to the HLB number of the emulsifying agent. The results for the boundary between castor oil and an aqueous solution of an emulsifying agent are given in Fig. 4. This makes it possible to replace

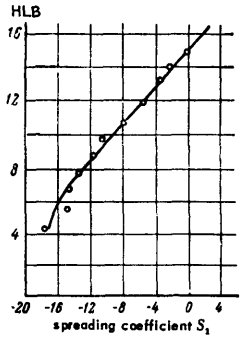

Fig. 4. Spreading coefficient $S_1$ for castor oil on the surface of 1% solution of SAS with different HLB.[99]

the tedious and sometimes inaccurate method of determining the HLB number of an emulsifying agent by measurements of the physicochemical constants of the system formed by the disperse phase with a solution of the emulsifying agent in the dispersion medium.

Wachs and Hyano[42] found experimentally for the monoesters of saccharose and saturated aliphatic acids that the HLB of this class of compound is directly proportional to the logarithm of $c_k$. These authors derived the same equation by calculation based on a comparison of the above equations used by Griffin[85] for calculating the HLB, on the one hand, with the empirical equation (2) giving the dependence of $c_k$ on the length of the hydrocarbon chain, on the other hand. This showed the applicability of Griffin's equation. The observed relationship between the HLB number and $c_k$ makes it possible to determine the HLB numbers of the stereoisomers of the monoesters; as pointed out above, this cannot be done using the calculation formulae.

In a paper presented at the Second Congress on Surface-Active Substances in London, Davies[86] tried to provide a quantitative kinetic basis for the HLB system. Davies' conclusion was based on the suggestion put forward by Rebinder[92] that both oil/water and water/oil emulsions are formed during emulsification, the nature of the final emulsion depending on which of the emulsions formed undergoes more rapid coalescence. Davies considered the rate of coalescence ($R_1$) of two drops of oil separated by water, and the rate of coalescence ($R_2$) of two drops of water separated by oil in the presence of the emulsifying agent. He assumed that the rate $R_1$ depends on a hydrodynamic factor $A_1$, an energy barrier related to the electric potential $\psi_0$, and an energy barrier $\Sigma\epsilon_h$, equal to the sum of the energies of hydration of the polar groups, which must be overcome in order to remove the hydration layers of water from the surface. In general, the rate of coalescence of oil drops decreases both as a result of charging and as a result of hydration, and the equation is of the form

$$R_1 = A_1 e^{-\frac{0.24\psi_0^2 - \theta\Sigma\varepsilon_h}{RT}}, \qquad (13)$$

where $\theta$ is the fraction of the surface occupied.

The opposite system consisting of two drops of water in a non-polar oil will undergo coalescence if the intermediate layer of oil is squeezed out as the drops of water approach one another. The rate of coalescence $R_2$ will depend on a hydrodynamic factor $A_2$, the barrier created by each $CH_2$ group on movement into water (equal to 300 cal[93]), the number $n$ of $CH_2$ groups, and the proportion $\theta$ of the surface occupied by the emulsifying agent

$$R_2 = A_2 e^{-2n\theta\frac{300}{RT}}. \qquad (14)$$

By combining Eqns. (13) and (14) and assuming that $A_1 = A_2$ (i.e. that the viscosities and phase volumes of the oil and water are equal), we obtain the equation

$$RT\ln\frac{R_2}{R_1} = 0.24\psi_0^2 + \theta\Sigma\varepsilon_h - 600n\theta. \qquad (15)$$

Separating $n$ from Eqns. (9) and (15) and comparing the right-hand sides of the resulting equations term by term, Davies arrived at a system of three equations:

$$\ln\frac{R_2}{R_1} = 2.2\theta(\mathrm{HLB} - 7), \qquad (16)$$

$$\Sigma N_{\substack{\text{hydrophilic}\\ \text{hydrated}}} = \frac{\Sigma\epsilon_h}{1260}, \qquad (17)$$

$$\Sigma N_{\substack{\text{hydrophilic}\\ \text{charged}}} = 1.9\times10^{-4}\frac{\psi_0^2}{\theta}, \qquad (18)$$

where $\Sigma N_{\substack{\text{hydrophilic}\\ \text{hydrated}}}$ is the sum of the group numbers of the hydrophilic hydrated groups, and $\Sigma N_{\substack{\text{hydrophilic}\\ \text{charged}}}$ the sum of the group numbers of the hydrophilic charged groups.

These equations show that the HLB system has a firm kinetic basis. The HLB determines the rate of coalescence. For oil/water emulsions the HLB numbers are greater than 7 and for water/oil emulsions the HLB numbers are less than 7. For an HLB number equal to 7 or values of $\theta$ close to zero, neither of the emulsions is stable. Eqns. (17) and (18) show the part played by the hydration energy and charge in the characterisation of the HLB of surface-active substances. It can be seen from Eqn. (18) that the HLB of a charged group depends on $\psi_0$, and the latter changes with even a small change in the concentration of electrolytes in the system. Thus the contribution made by the charged groups to the HLB numbers of anion-active and cation-active SAS, as already noted, is not strictly constant, so that the HLB numbers are not constant. In the case of non-ionic SAS, the values of the HLB numbers are less dependent on the electrolyte concentration.

Deryagin[94], in the discussion of Davies' paper, pointed out that it is incorrect to express the influence of the hydrophilic groups of the emulsifying agents on the stability of an emulsion of oil in water as the simple sum of the hydration energies of these groups. In actual fact, the action of the hydrophilic groups is determined by the forces of repulsion produced under the general influence of these groups in the aqueous polymolecular layers surrounding the surface of the drops.

These studies make it possible to estimate the part played by the HLB as a factor characterising the relationship between the structure of the molecule of the emulsifying agent and its affinity for the disperse phase and the dispersion medium of the emulsion. It should be emphasised that the HLB numbers of SAS, as shown at the start of the present section, play an important part not only in emulsification, but also in other processes taking place in dispersion systems. For example, Schick and Beyer[87] showed that the HLB number of a non-ionic stabiliser characterises the stability of foams. In each homologous series of NSAS, the stability of the foams passes through a maximum at a certain critical value of the HLB number. This is due to the fact that the resistance to rupture shown by the film of stabiliser depends on the magnitude of the cohesion of the adsorbed molecules, and the latter passes through a maximum with increase in the degree of oxyethylation.

Examples of the use of HLB numbers for the selection of emulsifying agents for emulsion polymerisation have been given[95]. A study was made of the dependence of the stability of the latices, the dimensions of the particles, the viscosity, and the rate of conversion on the HLB numbers for the emulsion polymerisation of styrene and vinyl acetate. An anionic emulsifying agent (an alkyl aryl sulphonate), non-ionic emulsifying agents (polyoxyethylated esters of oleic, lauric, steric, palmitic, and other acids), and their mixtures were used for this purpose. A high rate of conversion and the most stable polystyrene emulsions were obtained using polyoxyethylated stearate, with HLB

number equal to 15. With mixtures of anionic and non-ionic SAS, the greatest stability of the emulsions lies at HLB numbers of about 14–15. With vinyl acetate, this range is broader and extends from 16.2 to 17.5.

## VIII. REASONS FOR THE STABILISING ACTION OF NSAS

When NSAS are used, the stabilising action cannot be due to the electrical double layer. In this case, other thermodynamic stability factors are operating, such as hydration of the molecules of stabiliser, the entropy factor[96], and the associated splitting pressure. In addition to these thermodynamic factors, the structural-mechanical properties of the adsorption layer may be of considerable importance for the aggregate stability[97,98].

It has been shown[99,100] that dispersion systems stabilised by non-ionic SAS may exhibit a small electrokinetic potential. For example, 1% polychloroprene latices stabilised by the oxyethylated products OP-4, OP-7, and OP-10, at pH 9, had electrokinetic potentials from -35 mV to -55 mV. The magnitude of the electrokinetic potential decreased with increase in the degree of oxyethylation. Butadiene–styrene latices stabilised with the SAS OP-7, OP-10, and OP-18, and prepared with precautions to reduce the concentration of electrolytes in the system, showed much smaller electrokinetic potentials. The potential varied from -9 mV for the latex stabilised by OP-7 to -5 mV for the latex stabilised by OP-18. These results show that here the electrokinetic potential is due to the selective adsorption of anions which are present, for one reason or another, in the system. The negative charge produced by the adsorption of anions may be partly neutralised by adsorbed molecules of oxyethylated SAS, exhibiting cation-active character. The longer the chain, the greater the extent to which the negative charge of the globules is reduced. None of the resulting latices coagulated when electrolytes were added, although the electrokinetic potential decreased to zero. The aggregative stability of the polychloroprene latices in the isoelectric state decreased slightly relative to that of the original latices. These results confirm the part played by non-electric stability factors, for example, according to the authors cited, hydration of the adsorption layers.

The importance of hydration of the stabiliser and its affinity for the dispersion phase of the emulsion was examined by Davies[86] and was reflected in the HLB system. As shown above, however, this examination did not make allowance for the possibility that hydration of the hydrophilic groups of the stabiliser molecules leads to the formation of polymolecular hydrate sheaths and the production of a splitting pressure when the particles approach one another. The splitting pressure is positive, that is, it prevents approach, if the interaction between the hydrophilic groups of the stabiliser molecules and the molecules of the solvate layer is greater than the interaction between the molecules of the solvate layer and the molecules of the medium, Duyvis and Overbeek[101] showed that for foam films formed by solutions of NSAS of the type OP-7, OP-10, and OP-20 in the presence of an electrolyte (NaCl), there exist two ranges of equilibrium film thickness: one very small, of the order of 100 Å, which is close to twice the length of the stabiliser molecule, and the other much greater, observed only at NaCl concentrations less than $10^{-4}$ *N*. The first thickness corresponds to the repulsion caused by steric hindrance, whereas the second is related to the splitting pressure. Analogous results were obtained by Sheludko and coworkers[102], who also worked with free liquid films. On the basis of the existence of equilibrium film thicknesses of the order of 100 Å, with stability related to the steric hindrance arising in the interaction of the adsorption layers, it was concluded that in order to obtain thermodynamically stable films, it is necessary that the adsorption monolayer have a sufficiently high stability (an arbitrary term denoting the presence of adequate tangential forces of cohesion in the monolayer).

Deryagin and coworkers[103] studied free films of solutions of the NSAS OP-10 and oxyethylated di-t-butylphenol at an NaCl concentration of $10^{-2}$ *N*. The equilibrium film thickness, equal to approximately 120 Å, is independent of the electrolyte concentration and temperature. The observed splitting pressure, which prevents further decrease in the thickness of the film, was attributed to interaction between the adsorbed monolayers and adjoining water layers with a thickness of 10–20 molecules. If, however, these results are compared with the results obtained by Duyvis and Overbeek, the phenomena observed by Deryagin and coworkers must be attributed not to the splitting pressure but to steric hindrance provided by the adsorbed molecules of the monolayer. The splitting pressure associated with the polymolecular hydrate layers apparently could not be observed in this work because of the relatively high concentration of electrolytes in the system. The absence of a splitting pressure due to hydration is also confirmed by the fact that the observed effects were independent of temperature, whereas increase in temperature should have a dehydrating action.

The existence of a splitting pressure in stabilisation by non-ionic SAS can be related not only to hydration in the true sense of the term, but also to osmotic forces developing during the swelling of the adsorbed layer of stabiliser, as suggested for protective colloids by Bromberg[104]. This possibility is confirmed by the above results obtained by Schick[58], from which it follows that the oxyethylated chains are present in the form of a coil in the dispersion medium, so that they exhibit the properties of a flexible polymeric chain capable of undergoing micro-Brownian movement. The micro-Brownian movement, which causes the dispersion medium to be forced into the space between approaching particles, can also be regarded as the entropy component of the splitting pressure (the entropy stability factor). The mobility of a chain usually increases with increase in temperature, but here the mobility decreases with increase in temperature, since dehydration takes place, causing the oxyethylene chains to adhere to one another with a consequent loss of mobility. Thus increase in temperature should lead to a decrease in both the hydration and the entropy components of the splitting pressure. The same influence on the splitting pressure should be shown by the addition of electrolytes. The part played by hydration as a factor influencing the stability of dispersion systems in the presence of NSAS is confirmed by the fact that dehydration, produced for example by an increase in temperature, leads to separation of the phases and, in the case of latices, to gelatinisation. This last result was shown by Panich and coworkers[100] for the case of butadiene–styrene latices stabilised by the non-ionic oxyethylated products OP-7, OP-10, and OP-18. Work by Orr and coworkers[105,106] showed that the addition of a non-ionic stabiliser to latices containing an anion-active soap leads to a decrease in the area occupied by a molecule of the latter. This was attributed to a decrease in the electrostatic repulsion of the soap ions as a result of the presence of the molecules of

the non-ionic stabilising agent between the ions in the adsorption layer. Sometimes, however, non-ionic soaps produce the opposite effect. Van Voorst-Vader[37], in a study of a solution—air interface, showed that the area occupied by the molecule of an ionic soap increases in the presence of non-ionic soaps. He attributed this phenomenon to the fact that in the presence of two different hydrophilic groups, the water molecules may be orientated in such a way that the ionic soap is more readily hydrated. This leads to attraction of the ionic soap into the water, increases the area occupied by the molecule, and thus decreases the affinity of the soap for the surface. Thus the addition of NSAS to disperse systems containing ionic soaps may either increase or decrease the affinity of the ionic soap for the dispersion phase with a corresponding influence on the aggregative stability of the system.

Neiman and coworkers[107] showed that the addition of NSAS of the OP type to an adsorptively unsaturated latex stabilised by an ionic soap increases its stability to the action of electrolytes until saturation of the adsorption layer takes place. Further addition of NSAS has no influence on the stability. The results obtained are readily explained by the fact that on the addition of NSAS, an important part begins to be played by the non-electric latex--stability factor, and the influence of electrolytes becomes less marked.

Aleksandrova and coworkers[108] studied the influence of NSAS on the stability to mechanical treatment shown by adsorptively saturated and unsaturated polystyrene latices stabilised by an ionic emulsifying agent (sodium oleate) and found that the addition of non-ionic emulsifying agents leads to an increase in the aggregative stability only for the adsorptively saturated latex. With the unsaturated latices, the addition of non-ionic surface-active substances is accompanied by a decrease in the aggregative stability until adsorptive saturation of the surface of the latex globules takes place, after which the stability increases, as for the adsorptively saturated latices. The observed phenomena were explained as follows. When small quantities of NSAS are added to adsorptively unsaturated latices, the molecules of the non-ionic emulsifying agents are distributed on the free areas of the surface of the polymeric globules, screening the sodium oleate molecules and leading to a deterioration in the protective properties of the adsorption monolayer. Increase in the quantity of NSAS leads to an even sharper decrease in stability as a result of the formation of a fragile saturated monolayer consisting of alternating associates of NSAS and sodium oleate. A sharp increase in stability is observed only when the excess of NSAS is sufficient for the formation of a single--layer protective sheath. The theory that a polymolecular protective sheath is formed on the surface of the latex globules is not undisputed. Kuznetsov and Lebedev[109] showed, on the basis of viscosity measurements, that soaps of aliphatic acids form a monomolecular interfacial layer on the surface of globules of butadiene–styrene latex.

Shits and Trapeznikov[110] studied the structural-mechanical properties of adsorption layers of the NSAS Xylital O-10, OP-7, OP-10, OP-20, Tween-20, and OS-20 at the boundaries with air and styrene. They found that only OS-20 forms a stable adsorption film at the boundary with air. At the boundary with styrene, in the initial period of existence of the interfacial surface, the SAS studied do not produce a high surface viscosity. The process of solubilisation, accompanied by the spontaneous formation of a styrene micro-emulsion, takes place gradually and facilitates structure-formation in the volume adjoining the interface on the aqueous-solution side.

Taubman and coworkers[111] studied the stability of adsorption layers of non-ionic stabilisers (OP-10 and Pluronic L-64) at the boundary with xylene, and also the stability of emulsions of xylene in water and the stability to freezing shown by polystyrene latices in the presence of the same substances. The stability of the emulsions and latices was greatest when protective layers of high stability were formed. High stability of the protective layers is associated with the formation, at the interface, of two liquid phases consisting of complex supermolecular structures in the form of fairly thick multi-layer films. It has been shown[112-114] that these structures are formed as a result of a hydrodynamic effect associated with the surface turbulence and convection leading to unidirectional transfer of the hydrocarbon phase into the aqueous phase in the form of an ultramicro-emulsion. It can be seen that Taubman and coworkers[111] studied not the structural--mechanical properties of the adsorbed films but the structure-mechanical properties of the supermolecular structures. The formation of the latter represents a particular case and cannot be taken into account in the development of a general theory of the stability of disperse systems. This was confirmed by Sonntag and Klare[115], who pointed out particularly that in the characterisation of the specific protective action of SAS, it is necessary to consider only those concentrations at which the interfacial tension is greater than the critical value, and at which spontaneous emulsification does not take place.

## IX. THE USE OF NSAS FOR EMULSION POLYMERISATION AND FOR INCREASING THE STABILITY OF LATICES

As noted in the Introduction, extremely varied use is made of NSAS in the modern economy. The use of NSAS in various branches of technology was examined in detail in the well-known monograph by Schönfeldt[5], to which the reader is referred. In this section we shall review briefly only the application of NSAS as stabilisers in emulsion polymerisation and for increasing the stability of latices — the fields which are of greatest interest to the authors of the present review.

Polymerisation in emulsions has found extensive application in industry, since it has a number of important advantages over other methods of polymerisation under the influence of free radicals. The high rates of the processes compared with those in homogeneous systems, the wider temperature range in which the polymerisation processes can be carried out, and the possibility of varying the nature and concentration of emulsifying agents are of considerable importance for the control of the polymer properties.

A large number of papers[116-120] have been devoted to the problems of studying the complex heterogeneous process represented by emulsion polymerisation. Several recently published papers have dealt with the problems of studying the characteristic features of the mechanism of emulsion polymerisation in the presence of non-ionic emulsifying agents. Thus French[121] studied the emulsion polymerisation of vinyl acetate with the non-ionic emulsifying agent Pluronic F-68 (a block copolymer of ethylene oxide and propylene oxide) in the presence of potassium persulphate. Parts and Moore[122] studied the polymerisation of

vinyl stearate with oxyethylated octylphenol as emulsifying agent. Neither of these papers, however, give any conclusions regarding the characteristic features of this process.

The problems of selecting different emulsifying agents (anionic, cationic, and non-ionic) for emulsion polymerisation were examined by Helin and coworkers[123], who recommended a number of emulsifying agents and their mixtures on the basis of a study of the kinetics of polymerisation and stability of latices.

Gritskova and coworkers[124-126] studied the emulsion polymerisation of styrene in aqueous solutions of non-ionic emulsifying agents (Pluronic F-68 and oxyethylated octylphenol and octadecanol) and point out a number of characteristic features distinguishing these processes from the analogous processes taking place "in bulk" and in the presence of ionic emulsifying agents.

NSAS are often used as additives to latices for increasing their stability to the action of electrolytes. This is particularly important in the production of latex pigments. Many grades of NSAS are produced especially for this purpose[5]. It has been shown[5,110] that NSAS added to latices increase their stability to low temperatures. Finally, NSAS can be used for the thermo-sensitisation of latex mixtures[127]: the NSAS give the latices stability at low temperatures, whereas with increase in temperature they separate as an individual phase, are solubilised in the adsorption layers of the ionogenic stabiliser and decrease their protective properties, leading to gelatinisation of the latices.

# MECHANISM AND KINETICS OF TOPOCHEMICAL REACTIONS TAKING PLACE WITH DECREASE IN THE VOLUME OF THE SOLID PHASES

E. S. Vorontsov

CONTENTS

I. Introduction 883

II. Diffusion inside the crystal lattice of the initial phase 884

III. Mechanism of the formation of a new phase 885

IV. Development of the process and peculiarities of its mechanism and kinetics 888

## I. INTRODUCTION

There is a large class of reactions which can be described by the equations:

$$A(solid) = B(solid) + D(gas), \quad (1)$$

$$A(solid) + C(gas) = B(solid) + D(gas), \quad (2)$$

in which the volume of the newly formed solid phase B is less than the volume of phase A which is undergoing the conversion. This very important condition, which brings about the distinctive features of the mechanism and kinetics of the process, can be expressed by the inequality:

$$V_B < V_A. \quad (3)$$

Such reactions include: the dissociation of carbonates, oxides, sulphates; the reduction of most commercially important metals from their oxides by gaseous reductants; the dehydration of crystal hydrates; and many other processes.

Relation (3) usually leads to the appearance of a finely disperse, very porous, new solid phase. It is well-known that the dissociation of massive calcite yields calcium oxide with a very porous, finely disperse structure, and in the production of iron by the reduction of crystals of its oxides "sponge" iron is produced. Metals reduced at moderate temperatures can be pyrophoric. These facts already suggest that in processes (1) and (2) the formation of the new phase B is accompanied by its continuous breaking-away or scaling off from the initial material.

The general theory of the nucleation and growth of a new phase from an old one was created by Gibbs and developed in the works of Fol'mer, Frenkel', Stranskii, Danilov, Roginskii, and others[1-5].

It must be noted that this theory starts from the existence of ideal contact between the disappearing and the growing phases. It is completely applicable, for example, to the simplest interaction of two phases in a one-component system, that is, to the changes of state and phase transformations when drops of liquid or crystallites are formed in supersaturated vapour, crystallites or bubbles of vapour in a liquid, and so forth:

$$A_{\Phi.I} \rightarrow A_{\Phi.II}. \quad (4)$$

Here the symbol $A_{\Phi.I}$ denotes the existence of a component in a certain phase state, and $A_{\Phi.II}$ that in another phase state.

Certain general features of this theory are also correct for reactions of types (1) and (2), as is usually stressed in contemporary literature[6-9]. However, the unusualness of these processes necessitates considerable modification of the theory in analysing their mechanism. Jacobs and Tompkins[10] attempted to develop the theory applicable to this class of change.

To make more precise current views about the mechanism and kinetics of formation of a new phase in topochemical reactions of types (1) and (2), we will attempt to systematise the principal differences between the features of the reactions now being considered and those of processes (4). These differences impose certain features on the thermodynamic analysis and particular attention must be paid to them in the kinetic analysis of the changes being compared (see Table 1).

The extension of Gibbs' theory to the class of topochemical reactions now under consideration led to the conclusion that a peculiarity of these crystal chemical transformations is the existence of two crystalline phases with a boundary surface, which acts as a reaction surface. The development of the process is shown in the growth and changes of this surface.

It must also be remembered that the extension of the theory of the nucleation and growth of a new phase,

TABLE 1. Most characteristic differences between processes (1), (2), and (4).

| (4) | (1) and (2) |
|---|---|
| Reaction of two phases in a one-component system. Ideal contact is maintained between the phases. | Three phases take part in the process. Forced formation of product B is brought about during contact of phases A and D or A and C. |
| Accumulation of the product does not hinder the course of the process, which takes place at the phase separation boundary, but, on the contrary, facilitates its development. | Accumulation of the product can spatially separate phase A from the gas and retard the process. |
| The formation of heterofacial fluctuations, which are nuclei of a new phase, is connected with the movement of the particles, bringing about consolidation and rarefaction in micro-volumes. | The formation of heterofacial fluctuations, leading to the appearance of new phase B, is linked with the removal of material from the bulk of the initial phase. |
| With the same temperature throughout the whole volume of the initial phase the fluctuations are distributed in it according to statistical laws. | With the same temperature throughout the whole volume of the initial phase the distribution of the fluctuations depends on the rate at which the gaseous substance leaves them. |
| The formation of nuclei of a new phase leads to the appearance of an interfacial surface. Work must be expended in the creation of this surface. | The formation of nuclei of a new phase can, by virtue of relation (3), lead to breaking-away from the old phase from separate parts of the surface. Work is required for the deformation of the crystal lattices at the point at which the phases meet and for their breaking away, that is, work on the reproduction of another two separation surfaces: A – gas and B – gas. |
| The growth of the new phase is connected with the supply to it of material from the initial feed medium. | The disappearance of the old phase is accompanied by the accumulation of material in the two growing phases. |
| The growth of the new phase is not accompanied by breaking of its contact with the old. | The growth of the new phase can bring about its rupture from the old. |
| The newly formed, growing, solid phase is usually compact and free from porosity. | The growth of phase B is usually accompanied by the great development of porosity in its bulk. Subsequent recrystallisation and sintering can complicate the course of the process. |

loped mainly for processes (4), to reactions (1) and (2) without essential modifications to it can be considered unjustified in the light of the differences given in Table 1.

Let us consider in more detail some aspects of the mechanism and kinetics of reactions of interest to us.

## II. DIFFUSION INSIDE THE CRYSTAL LATTICE OF THE INITIAL PHASE

The essence of processes (1) and (2) is the removal of material from the crystal lattice of the old phase and its subsequent reconstruction into a new phase. Therefore there is great interest in explaining the problems of the diffusion of $CO_2$ in carbonates, of $O^{2-}$ and $S^{2-}$ ions in oxides and sulphides during their decomposition, and also of $O^{2-}$ ions in oxides during the reduction of the metals, etc.

### 1. Diffusion of $CO_2$ in the Calcite Lattice

The appearance of CaO nuclei in the depths of the $CaCO_3$ phase precedes the formation of a supersaturated solution of B in A. Its formation is linked with the departure of $CO_2$ molecules from the crystal lattice of the carbonate. Therefore the investigation of the diffusion of $CO_2$ in $CaCO_3$ is of considerable practical interest. Such an investigation[11] was made using the carbon isotope $^{13}C$. From the decrease in the concentration of "labelled" carbon in the gas phase in contact with the calcite the coefficient of self-diffusion of $CO_2$ in $CaCO_3$ at 692–848° was found. The temperature dependence:

$$D = D_0 \exp\left(-\frac{58\,000}{RT}\right),$$

was determined and the entropy of activation of the self-diffusion of $CO_2$ was calculated:

$$\Delta S^* = R \ln\left(\frac{D_0}{d^2\nu}\right) = 4.7 \text{ cal deg}^{-1} \text{ mole}^{-1},$$

where $D_0 = 4.5 \times 10^{-4}$ cm$^2$ s$^{-1}$, $d = 4.04$ Å is the distance between the carbon atoms in the calcite lattice, and $\nu = 3 \times 10^{-12}$ s$^{-1}$ is the frequency of their vibration.

But it must be noted that there is a substantial difference between the self-diffusion of $CO_2$ in the stable $CaCO_3$ lattice and diffusion under the conditions of dissociation of the carbonate. The first process can be hindered by an absence (or insignificant proportion) of $CO_2$ vacancies in the crystal lattice. In the surface layers of calcite the second process can be greatly facilitated by the disintegration of the anionic sublattice. The elimination of molecules of $CO_2$ and the formation of $O^{2-}$ ions instead of $CO_3^{2-}$ can be considered as the production of vacancies for the diffusion of $CO_2$ in the lattice of the carbonate. These vacancies can be propagated into the depth of the crystal lattice.

Hence the diffusion media for both types of migration will be different and the energy characteristic obtained ($E$ = 58 000 cal mole$^{-1}$) and the value of $\Delta S^*$ scarcely give a correct representation of the difficulty of carrying out the removal of $CO_2$ from the $CaCO_3$ lattice during the dissociation of the carbonate.

### 2. Diffusion of Oxygen in an Oxide Lattice

The removal of oxygen from the crystal lattice of the oxides is the main aim in the reduction of metals. Moreover, the part played by oxygen diffusion in such processes is still uncertain.

Many oxides of commercially important metals (Zn, Cu, Fe, Ni, etc.) are either reduction semiconductors (ZnO) or oxidation semiconductors ($Cu_2O$, FeO, NiO) in which the cations have a higher mobility than the anions. This experimental fact, together with the results from investigations of the transport numbers of ions in oxide crystals, gives basis for considering the process of scale formation often as a preferential transfer of cations in the presence of a rigid network of the oxygen (or in the more general case, anion) sublattice.

Actually, in many experiments neutral particles on the surface of copper, nickel, or iron form a scale during high-temperature oxidation, by appearing closer to the metal–oxide boundary and not the oxide–gas boundary. Experiments on the sulphiding of silver[12] and copper[13] showed the incommensurably greater mobility of the metal cations compared with the sulphur anions.

All this provided a basis for some investigators to carry too far the analogy in the mechanisms of high-temperature oxidation and reduction. For example, in an analysis of the mechanism of reduction of iron[14,15] the preferential diffusion of the cations is considered in detail and no attention is paid to the possible movement of the anions, although without a corresponding removal (departure) of oxygen atoms it is difficult to understand the formation of three-dimensional metallic nuclei, the zonality of the process, the reconstruction of the oxygen sublattice in phase transformations, and other phenomena. In this, the preferential diffusion of the cations is "confirmed" by such experimental results as could equally well be explained by two-way diffusion of the cations and anions and even by the preferential motion of the latter.

Direct reduction of iron from oxides[16] is also treated as a process in which the diffusion of oxygen does not take place. But in addition the authors had to suggest that after the filling of the last cationic vacancies in the wüstite lattice and the formation of three-dimensional metallic nuclei further reduction proceeds by diffusion of oxygen along the metal–oxide interface. The problem of how three-dimensional metallic nuclei can appear without the corresponding exit of oxygen atoms, why these atoms should "await" the complete filling of all the cationic vacancies in the wüstite, why the reductant should invariably react with the oxygen which is diffusing from the deep zones along the metal–oxide interface and not react with the oxygen atoms which are nearer and more accessible for reaction, etc. was left completely unresolved.

Such a biased treatment of the mechanism of the reduction processes was due, evidently, to the fact that until quite recently nothing was known about the diffusion of oxygen in oxides. However, many recent studies have established the diffusion of oxygen in various oxides. For example, Barzakovskii and Volkov's review[17] gave the data in Table 2.

Calculation of the diffusion coefficients for oxygen by the formula:

$$D = D_0 \exp\left(-\frac{E}{RT}\right),$$

TABLE 2. Diffusion of oxygen in oxides†.

| Oxide | Temperature range | $D_0$, $cm^2 s^{-1}$ | $E$, kcal $mole^{-1}$ | $\Delta S^*$, cal × × $mole^{-1}$ $deg^{-1}$ |
|---|---|---|---|---|
| BeO | 1600—1900 | $5.2 \cdot 10^{-7}$ | 4.29 | — |
| $Cu_2O$ | 1030—1120 | $6.5 \cdot 10^{-3}$ | 39.3 | −3.4 |
| $UO_2$ | 550— 800 | $1.2 \cdot 10^{+3}$ | 65.3 | — |
| $TiO_2$ | 860—1030 | 1.1 | 73 | +12 |
| CdO | 640— 820 | $8 \cdot 10^{6}$ | 93 | +43 |
| ZnO | 1100—1300 | $6.5 \cdot 10^{11}$ | 165 | +59 |

† $D_0$ is the pre-exponential factor in the equation for the temperature dependence of the diffusion coefficient $D$, $E$ the activation energy, and $\Delta S^*$ the entropy of activation of the process.

from the results of Table 2 suggests that at high temperatures (800–1400°) the rate of motion of the oxygen often becomes close to the similar quantity for the cations of the metals. Barzakovskii and Volkov[17] concluded that it may be necessary to take into account the mass transfer of oxygen in reactions between solid oxides.

It must be specially emphasised that these results were obtained under conditions where the oxides are stable. The usual method of studying self-diffusion of oxygen in oxides involves the observation of the isotopic exchange between the gaseous oxygen labelled with the isotope $^{18}O$ and the oxide crystal. Knowing the surface area of the powder and the fall in concentration of the isotope, the diffusion coefficient can be calculated.

The data in Table 2 are not readily comparable with one another, since the experiments for different oxides were performed in different temperature ranges. However, it is evident that the quantities $D$ and $E$ vary within very wide limits, which, finally, depend on the nature of the oxide, the presence of lattice defects (in particular, oxygen vacancies), the diffusion mechanism, and other factors.

In this connection, attention must be paid to the fact that in high-temperature reductions which take place with irreversible disordering of the oxygen sublattice, the conditions for the diffusion of oxygen from the deep layers of the crystal to its surface should be incomparably more favourable than for the stable existence of the oxides. Here the analogy with the destruction of the anionic sublattice during the dissociation of carbonates is completely relevant.

In a conductimetric investigation[18] it was concluded that during the reduction of metals by diffusion of oxygen, in the surface layers of the oxides at least, the process can be preferred to the migration of cations in a positive direction both from the thermodynamic and from the molecular-kinetic points of view.

It has been noted[19,20] that in the reduction of wüstite a dense film of iron can be formed on its surface. Examination of this film under the electron microscope showed the complete absence of pores. Moreover, the reduction of wüstite continues, although very slowly. It can proceed here only by diffusion of oxygen through the compact layer of iron. The calculated[20] activation energy for this diffusion is 53 000 ± 4000 cal per g-atom of oxygen.

Hence, when the diffusion of oxygen through a compact film of iron in the reduction of wüstite is considered, then the possibility of the movement of oxygen in oxides with breakdown of the oxygen sublattice in process (2) cannot be doubted.

Evidently the time has come to reconsider the part played by diffusion of oxygen in the reduction of iron and other metals from their crystalline oxides. The theoretical or experimental evaluation of the rates of diffusion of anions under the conditions of breakdown of the anionic sublattice would be a considerable achievement.

## III. MECHANISM OF THE FORMATION OF A NEW PHASE

### 1. Nature of a Solid Solution of B in A

It must be assumed that the production of nuclei of a new phase precedes the formation of a solid solution of component B in A. Whereas from a thermodynamic viewpoint such a solution can be considered as an excess of MO in $MCO_3$ or of M in MO and MS as compared with the stoichiometric formulae of the carbonates, oxides, and sulphides, from the viewpoint of its formation mechanism two treatments are possible.

On the one hand the formation of the solution can be considered as the introduction of metal cations and oxide anions during the dissociation of carbonates or of metal cations during the reduction and dissociation of oxides and sulphides into the crystal lattice of the initial phase.

On the other hand, the departure of $CO_2$ molecules, oxygen atoms, or sulphur atoms from the initial substance A in the processes under consideration creates an unstable transition structure in the surface layer, which can be considered to be a solid solution. It is completely clear, however, that its nature will be quite different in comparison with the solution which is obtained by contact saturation of the carbonate with oxide, or of the oxide and sulphide with the metal.

The solubility of oxides in carbonates is apparently negligible. Thus, Gel'd and coworkers[21] could not detect it, and concluded that the solubility of the components could not exceed 0.06%, that is, the accuracy of the measurements.

As regards the solubility of metals, such a definite conclusion cannot be drawn for even the lower oxides and sulphides. The oxide and sulphide phases can have an excess of the metal or the non-metal[22] and their homogeneity region can be rather broad. Metals can be dissolved in the oxide by introduction between the sites of the crystal lattice. The filling of vacancies is evidently more correctly considered as chemical reaction, and not as dissolution, because this act is connected with the redistribution of electrons in the crystal.

A feature of the reactions we are considering is that the appearance of a new phase is associated with the loss of material from the old, and therefore here the greatest interest will relate to unstable transition structures arising during processes (1) and (2) and not to solutions formed by contact saturation of phases A and B.

The instability of the transition structure is linked with the degree of departure of the system from equilibrium and from the thermodynamic standpoint can be treated as chemical supersaturation of the solid solution of B in A. The onset of this supersaturation in the surface layer, in some of, or in the whole volume will evidently depend (at a

temperature) on the rate of removal of material from the initial phase.

For example, the very rapid removal of $CO_2$ from the carbonate lattice and the replacement of $CO_3^{2-}$ anions by $O^{2-}$ can comparatively easily bring about the formation of oxide in the micro-volumes of the surface layer. On the other hand, it can be thought that the removal of some $CO_2$ molecules still does not bring about the reorganisation of the old lattice into the new and when conditions for the equilibrium redistribution of particles throughout the whole volume are created by withdrawing negligible amounts of $CO_2$, then supersaturation can be attained throughout the whole piece of carbonate. Hence the smaller the piece the easier it is to reach supersaturation throughout it (less time is required for this). From this viewpoint it is understandable why the stepwise nature of the process during the reduction of oxides can be followed more easily the smaller the dimensions of the grains being reduced and the lower the rate of conversion.

A thermodynamically necessary condition for the supersaturation is that the chemical potential of the substance in the new phase should be less than its value in the solid solution:

$$\mu_2 < \mu_1, \tag{5}$$

Esin and Gel'd[8] proposed that for the dissociation of carbonates $\mu_2$ should be considered to be the chemical potential of the pure oxide and $\mu_1$ that of the oxide in the solid solution. By analogy with this it can be assumed that in the dissociation of oxides and their reduction $\mu_2$ will be the potential of the pure metal and $\mu_1$ that of the metal dissolved in the oxide. For a thermodynamic evaluation of the supersaturation it does not matter how this difference in chemical potentials arises: by the dissociation of an oxide or its reduction. But from the standpoint of the practical realisation of the process, it is known how difficult it is to create chemical supersaturation in order to bring about dissociation, for example, of the lower oxides of copper, iron, nickel, chromium, and other metals (at least, at the temperatures of ordinary pyrometallurgical processes), and how it is reached comparatively easily in the high-temperature reduction of these metals.

The magnitude of the chemical supersaturation expresses the probability of formation of a new phase, and with the aid of the latter, the rate of the process, thus connecting in this way a thermodynamic quantity with a kinetic characteristic.

A feature of the transformations being considered is that the supersaturation of the solid solution is connected in a definite way with the extent of the departure from equilibrium of the system as a whole. The way of writing:

$$\Delta G = \mu_2 - \mu_1 \tag{6}$$

ignores the thermodynamic properties of the gas which actively participates in the process of establishing the new condensed phase. Therefore it is evidently more correct to take for the characteristic of the method of reaching supersaturation in the "solution" the probability of the formation of nuclei, not the difference (6) but the magnitude of $\Delta G_i$ based on the occurrence of reactions (1) and (2):

$$\Delta G_1 = \mu_D + \mu_B - \mu_A \tag{7}$$

or

$$\Delta G_2 = \mu_D + \mu_B - \mu_C - \mu_A. \tag{8}$$

In Eqn. (6) $\Delta G$ is the change in free energy of the system due to the appearance of the new solid phase B, and $\Delta G_1$ and $\Delta G_2$ are the changes in potential of the system brought about by the course of reactions (1) and (2); $\mu_i$ are the chemical potentials of each of the substances taking part in the reaction.

When D is absent from system (1), then $\mu = \infty$, so that:

$$\mu_D = \mu_D^0 + RT \ln P_D, \tag{9}$$

where $P_D$ is the pressure of gas D in the system and $\Delta G_1 = -\infty$. The thermodynamic probability of the formation of phase B in this system should be very great.

From these relations, in a comparative investigation of the rates of oxidation of iron and of its reduction from oxides[23] the probability of formation of nuclei of a new phase was linked with the quantity $\Delta G_2$.

## 2. Heterofacial Fluctuations

Variations in density exist in carbonates, oxides, and sulphides, as in all other thermodynamic systems. However, the heterofacial fluctuations which can become the stable nuclei of new phase B also arise as the result of a chemical process — the essential difference in the mechanism of formation of a new phase in changes (1) and (2) as compared with processes of type (4).

Thus, in the dissociation of carbonates the chemical act of detachment of $CO_2$ from the complex anion $CO_3^{2-}$ and also the diffusion of $CO_2$ lead to the replacement of the $CO_3^{2-}$ anions by the monatomic $O^{2-}$. This destroys the symmetry of the force fields and distorts the carbonate crystal lattice, creating an unstable transition structure, within which the formation of heterofacial fluctuations is possible — the nuclei of the new phase MO.

In the dissociation or reduction of oxides or sulphides the chemical act is the transfer of electrons to the metal cations, which, together with the departure of oxygen or sulphur from the crystal lattice, also leads to the appearance of a transition structure, a "solid solution".

When the oxides or sulphides have cationic vacancies, then during the course of the reaction it is possible for monatomic particles of metal to migrate to the unfilled lattice sites[24]. But when the rate of production of anionic vacancies is so great that the rate of diffusion of oxygen or sulphur surpasses the intensity of movement of metal in the bulk of the oxide or sulphide, which is evidently so in real technological processes, then the "solution" will be none other than unfilled anionic places in the lattice of phase A. Its supersaturation provokes the appearance of stable heterofacial fluctuations which can become the nuclei of the new phase.

The instability of the transition structures is also connected with the replacement of the pair $M^{2+}-CO_3^{2-}$ by $M^{2+}-O^{2-}$ or $M^{2+}-O^{2-}$ by M–M, which are characterised by a lesser distance between the particles and a tendency to approach one another.

From this position it is easy to explain the appearance of three-dimensional nuclei of product B and also the appearance of zonality during the reduction of an oxide. Rostovtsev and Rudenko[25] discussed the problem of whether atomised iron is present at the interfacial surface. Each iron ion is in an environment of oxygen anions. In the defect sites of the oxide surface there are evidently almost

"gaseous" metal atoms, which can easily be reduced to the metallic state. But such atoms can hardly become stable nuclei of the new phase.

A heterofacial fluctuation can appear in any part of the volume of phase A, but its appearance in the surface layer is the most probable. When the process is proceeding intensively the fluctuations arising on the surface do not extend through the whole volume of the initial phase; their "concentration" in the surface layer becomes high. Under such conditions the coagulation (merging) of small fluctuations into coarser and more stable ones is even possible. The formation of nuclei of a new phase on the surface, but not in the volume, becomes predominant.

It is assumed that the processes of dissociation and reduction start from active centres, which are the most distorted sites of the crystal lattice, surface defects of the crystals: here the bond between particles can be weakened and the initial act of removal of oxygen or carbon dioxide is more probable [26]. In this connection it should be noted that the origination of heterofacial fluctuations (the three-dimensional nuclei of a new phase) is not only connected with the removal of individual oxygen atoms of oxygen, sulphur, or molecules of carbon dioxide from the crystal surface, but also with the probability of their departure from the bulk of the external layer of phase A.

From the diagram (Fig. 1) it is easy to see that this probability is quite dissimilar for particles situated on the protuberances and in the depressions. Points *a* and *b* are equally removed from the crystal surface, but whereas the first has more than one shortest path to the surface, the second has only one. Therefore the probability of fluctuations arising at the vertices of a cube will be greater than on an edge; at the latter, greater than around a face, and at a face greater than around the corner of a depression.

If it is assumed that the crystal surface is ideal and does not have defect sites, then again the probability of the occurrence of the elementary act of removal of a particle at its individual points will be unequal, because of the different energetic states of the ions. There will always be individual particles which are energetically more prepared for the completion of the elementary chemical act than the others.

## 3. The Formation of Nuclei of a New Phase

In phase transformations (4) at least one of the phases is mobile and this ensures ideal contact between the phases. When in a one-component system there is interaction between two solid phases with only a slight difference in specific volumes, then contact between them can also be very enduring and stable.

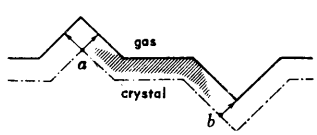

Fig. 1. Mechanism of loss of material from defect places of a crystal surface.

Relation (3) is responsible for the appearance of specific features in the mechanism of formation of nuclei of a new phase. It is clear that in processes (1) and (2) the contact between solid phases A and B can be very imperfect and in individual parts even completely destroyed. The existence of submicroscopic porosity in the products has also received direct confirmation [19,27].

Since the crystallites of the new phase should exhibit their intrinsic properties and have corresponding lattice parameters, its formation as a result of the operation of inequality (3) should be accompanied by detachment from the matrix medium A, if not along the whole interfacial surface, then at least partly. The formation, for example, of nuclei of calcium oxide in calcite should lead to the appearance in their vicinity of a "free" volume, approaching ~ 117% of the volume of the nucleus itself.

This circumstance should be reflected even in the initial equation for the change in free energy for formation of heterofacial fluctuations:

$$\Delta G = (\mu_2 - \mu_1)n + \alpha\sigma n^{2/3}, \qquad (10)$$

where the first term reflects the change in $G$ due to the difference in the chemical potential of the particles in the new (2) and old (1) states, and the second term the work in the creation of the interfacial surface A–B.

Recently it was even noted that the quantity $\sigma$ should not be treated as interfacial tension for changes (1) and (2) [10,23].

The directed action of the atomic forces at the contact surface of the two crystal lattices or the internal stresses should cause corresponding deformations or changes in the lattice parameters, which requires a definite amount of work. This was studied in a review [10] by Jacobs and Tompkins [10], where instead of $\sigma$, the quantity $\gamma$ is introduced, the energy of the stress associated with unit surface of separation:

$$\Delta G = \Delta G_i n + \alpha\gamma n^{2/3}. \qquad (11)$$

It is not difficult to see that the nature of processes (1) and (2) is not reflected completely here either, since relation (3) is not obeyed.

For reactions of type (1) and (2) the second term in Eqns. (10) or (11) should also take into account the work of breaking away of the new phase from the old, which can be done by the introduction of a third term:

$$\Delta G = \Delta G_i n + x\alpha\gamma n^{2/3} + y\alpha\varepsilon n^{2/3}, \qquad (12)$$

where $\alpha$ is a numerical factor depending on the geometrical form of the fluctuations which arise; $\gamma$ the energy of the stress, $\epsilon$ the work of adhesion (if the nuclei break away from the initial phase) or cohesion (if the nucleus itself ruptures), $x$ the fraction of interfacial surface A–B, $y$ the fraction of interfacial surface A–gas or B–gas, and $n$ the number of particles.

Evidently $x + y = 1$. But it must be remembered that the areas of the A–gas and B–gas surfaces for nuclei can be somewhat different by virtue of ratio (3).

Apparently instances are possible when either $x$ or $y$ can be neglected and the more general Eqn. (12) takes the form of the partial equations (10) and (11).

$\Delta G_i$ can be determined by Eqns. (7) and (8). It must then be remembered that in Eqn. (12) it relates to a single elementary particle; in the formation of a metallic nucleus, to one atom of the metal; in the formation of oxide from carbonate, to one pair of ions $M^{2+}$–$O^{2-}$.

## IV. DEVELOPMENT OF THE PROCESS AND PECULIARITIES OF ITS MECHANISM AND KINETICS

### 1. Role of the Gaseous Phase

In reactions (1) and (2) the new phase can appear only as a result of the interaction of the initial phase and the gas. Therefore the process always starts at the A–D or A–C boundary. The appearance of reaction product B complicates the course of the process, since it separates the reagents spatially.

This is well evident from the following examples. Almost all the metals (with the exception of palladium, iridium, platinum, and gold) are unstable under ordinary atmospheric conditions and should be changed into the ionic state[28]. But it is well known that most of them do not oxidise under these conditions, since the very thin oxide film formed separates the metal from the oxygen of the air. According to current views[29] the time for the formation of the film on iron in an atmosphere of air is 0.05 s. Often the reaction of carbonation also ceases almost completely because of the formation of a compact film of carbonate on the crystalline oxide.

These two examples relate to the reverse course of reactions (1) and (2), in which a relation opposite to inequality (3) holds. The direct course of these processes is usually aided by the new phase being very porous. This leads to the conclusion[19,30] that the formation of the product does not lead to the breaking of the A–gas contact between the reagents. But in the very investigations, on the basis of which these conclusions were made, it was observed that when a dense and pore-free product is obtained the process is sharply retarded. It is still possible only owing to the diffusion of elementary particles through the crystal lattice of the reaction product. In this the operation of the chemical reaction no longer takes place at the (initial phase)–gas boundary, but at the (new phase)–gas boundary or the surface of separation of the solid phases.

Thus in the oxidation of a metal the initial reaction proceeds owing to its contact with the oxidant gas, and then (after the formation of a film) is continued either owing to the movement of cations to the oxide surface, where they react with oxygen, or by diffusion of oxygen through the oxide layer to the metal surface.

In the reduction of oxides with the formation on them of a compact film of metal, the place of that reaction also moves from the oxide–gas-reductant boundary to the metal–gas separation surface, to which oxygen diffuses, there reacting with the reductant[19,20].

Hence the chemical reaction and the phase transformation can be spatially separated. This shows that the mechanism of changes (1) and (2) is more complicated than that for transformations (4).

Consequently, in these reactions the formation of products which block the surface of reagent A can sharply retard the course of the process. On the other hand, the breakdown of this blockade owing, for example, to cracking of the scale during the high-temperature oxidation of metals, or the formation of pores and cracks in the product during the dissociation of carbonates and the reduction of oxides can greatly accelerate the process, both as a result of the renewal of the (phase A)–gas contact, and also as a result of the great shortening of the diffusion paths of the elementary particles.

Note that in many investigations the rate of reactions (1) and (2) are usually considerably greater than the rate of the back reactions, when they relate to the same physical and geometrical conditions of the experiment. For example conductimetric investigation of the rates of oxidation and reduction of copper and iron wires[18] showed that under the same conditions reduction requires ten times less time than oxidation. The dissociation of carbonate is incomparably more rapid and more complete than carbonation[31].

### 2. Rate of Formation of Nuclei and Their Growth

The thermodynamic stability of the heterofacial fluctuations — the nuclei of the new phase — is determined by Eqn. (12), from which it is evident that even when the first term is negative the positive values of the last two terms can affect the absolute magnitude more than the first term, and the fluctuations then become unstable.

Since for a given degree of departure of the system from equilibrium (or for a definite chemical supersaturation) the first term in Eqn. (12) grows more rapidly than the sum of the second and third terms with increase in the number of particles $n$, $\Delta G$, as a function of $n$, has a maximum. The value of $\Delta G_{max}$ corresponds to that critical value of $n$ at which the growth of the nucleus can occur spontaneously, because it is accompanied by a fall in $\Delta G$.

$$\frac{\partial(\Delta G)}{\partial n}=\Delta G_i+\frac{2}{3}\varkappa\alpha\gamma n^{-\frac{1}{3}}+\frac{2}{3}y\alpha\varepsilon n^{-\frac{1}{3}}. \qquad (13)$$

Equating this derivative to zero, we find $n_{crit}$:

$$n_{crit}=\frac{8}{27}\alpha^3\frac{(x\gamma+y\varepsilon)^3}{(-\Delta G_i)^3}. \qquad (14)$$

An analysis of this equation shows that not only the energy of deformation of the crystal lattice, but also the work of formation of the primary submicroscopic particles should affect the value of $n$. From Eqn. (14) it follows that the necessary condition for the formation of critical nuclei is the inequality:

$$\Delta G_i<0, \qquad (15)$$

since if the reverse of (15) holds we obtain $n_{crit}<0$, which has no physical significance. For reactions (1) and (2) it is very important to emphasise that when, during its formation, the crystallite of the new phase is separated from the initial phase and the possibility of its further growth is excluded, then it can be thermodynamically stable only under the condition $\Delta G<0$. Note that if the nuclei in reactions (1) and (2) cannot grow at their points of detachment from phase A by the addition of elementary particles, the possibility of their growth by mutual cohesion is obviously not excluded (especially when there is great chemical supersaturation in the system).

The probability ($p$) of the formation of the nuclei depends not only on $\Delta G$, but also on the mobility of the atoms, since the formation of the new phase requires the reconstruction of the crystal lattice, which is impossible without corresponding movement of the particles. Starting from this consideration, $p$ is determined by the relation:

$$p=C\exp\left(-\frac{U+\Delta G}{KT}\right), \qquad (16)$$

and the rate of formation of nuclei ($v$):

$$v=A\exp\left(-\frac{U+\Delta G}{KT}\right), \qquad (17)$$

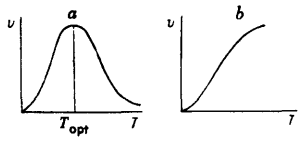

Fig. 2. Rate of formation of three-dimensional nuclei ($v$) as a function of temperature ($T$): $a$) for crystallisation from a melt; $b$) for the dissociation of carbonates, oxides, and sulphides.

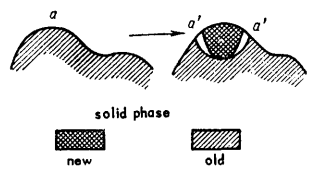

Fig. 3. Scheme for the reproduction of "defect" places — active centres of reaction.

where the energy factor $U$ is identified with the activation energy of diffusion, $A$ and $C$ are proportionality coefficients, and $K$ is Boltzmann's constant.

During crystallisation from the melt, $\Delta G$ increases with temperature but $U$ falls. There is therefore a temperature at which the rate of formation of the nuclei will be maximal (Fig. 2$a$).

For dissociations (1), there may not be an optimal temperature. At constant pressure, increase in $T$ should decrease both $\Delta G$ and $U$. Therefore the rate of formation of the nuclei will be an increasing function of temperature (Fig. 2$b$). It is necessary to mention this because in recent monographs[7,8], in discussing the above mechanism and kinetics of the dissociation of carbonates in terms of the theory of the formation and growth of a new phase and in fixing the position of the optimal temperature on the $v-T$ curve, for some reason it was not observed that there could not be one for the processes considered.

As regards reduction processes, there is evidently always a decrease in $U$ and rise in temperature affects $\Delta G$ differently. For example, in the reduction of magnetite and wüstite to iron by hydrogen, $\Delta G$, as well as $U$, is a decreasing function of temperature and therefore extremal values cannot be expected on the $v-T$ curve. But in the reduction of the same compounds with carbon monoxide there is one, for $\Delta G$ is an increasing function of temperature.

In real technological processes changes (1) and (2) are carried out at great degrees of chemical supersaturation and high rates. Under such conditions the rate of nucleation of the new phase is extremely high and the conditions for their growth can appear very unfavourable. The following features of the reactions being considered hinder the growth of the nuclei.

1. Whereas in processes (4) the supply of material is effected comparatively readily, in changes (1) and (2) the growth of the nuclei of the new phase is complicated by the slowness of the diffusion of the elementary particles in the crystal lattice.

2. The formation of a crystallite of the new phase should be accompanied — if not by complete — then at least by partial detachment of it from the initial substance, because of relation (3) (see, for example, Fig. 3). The gaps formed in the neighbourhood of the crystallite will be insurmountable obstacles for the diffusion of particles to the surface of the nucleus.

3. If the attachment of the nucleus of the new phase to the old is not coherent but has a distinct boundary, then its motion should bring about movement of the nucleus, since $v_B < v_A$. But with the condition of intensive formation of nuclei, their free movement is excluded (not for a gas and not for a liquid). The crystallites press one another and even their insignificant formation at the interfacial boundary should lead to fracture of the phase.

Obviously the growth of the crystallites is strongly connected with the processes of coalescence, sintering, and recrystallisation, which will be the more successful and occur at lower temperatures the smaller, and consequently the more active and more mobile the nuclei themselves; to a lesser extent the growth occurs by the attachment of elementary particles. This obviously also explains the possibility of obtaining pyrophoric metals in the low-temperature reduction of the oxides[30].

What has been stated agrees well with the ease of obtaining very finely dispersed and porous products B during reactions (1) and (2), which is observable in practice.

It is worth noting that very few results of investigations of the physical and chemical properties of the products of reactions of type (1) and (2) (for example, properties such as density, electrical conductivity, mechanical strength, adsorptivity, chemical activity, etc.) have been published. Such investigations are extremely desirable since they can give additional information about the mechanism of the process.

## 3. Pore Formation

In the mechanism of the changes which we are analysing, a special place is occupied by the formation of pores and their part in the development of the reaction. The origination of pores can often be considered to be the same result of a process as the formation of a product. Therefore the size of the relative porosity (the volume of pores compared with the volume of the lump of carbonate, oxide, or sulphide) can even serve as a measure of the completion of the process.

In several investigations, for example, that of Edström[30], it was noted that the dimensions of lump specimens either did not change at all or changed insignificantly during dissociation and reduction, although the difference in the volumes of phase A and B can be very considerable. If therefore the change in dimensions of single-crystal or polycrystalline specimens during the conversion be neglected, then it is not difficult to calculate the limiting value of the overall porosity ($\pi_p$, %) corresponding to complete conversion of the old phase into the new.

For example: $CaCO_3 \rightarrow CaO + CO_2 + \text{pores}$

$$\pi_p = \left(1 - \frac{2.8 \times 56}{100 \times 3.4}\right) \times 100 = 54\%,$$

where 100 and 56 are the molecular weights of $CaCO_3$ and CaO respectively, and 2.8 and 3.4 their densities in g cm$^{-3}$.

Similarly, it is possible to calculate that the reduction of $Fe_3O_4$ to FeO requires the appearance in the product of

a relative porosity of ~15%: $Fe_3O_4$ to Fe ~52%; FeO to Fe ~40%.

Then the ratio of porosity $\pi$ corresponding to a definite stage in the process, to its limiting value $\pi_p$ provides a criterion of the degree of completion of process A:

$$(\pi/\pi_p) \times 100 = A\%. \quad (18)$$

The difference between the value thus found for A and the real value is usually due to sintering or recrystallisation.

It has often[23,32-34] been observed that the sintering of a layer of products can even bring about some decrease in the rate of the process with rise in temperature, which explains why obstacles to diffusion arise with densification of the layer. In this connection, there is great interest in investigating not only the overall, but also the differential, porosity and also the true surface of the reagents.

Tatievskaya and Chufarov[27] found that from 65 to 90% of the pores formed as a result of the reduction of haematite and magnetite at temperatures up to 500° are very fine capillaries with a radius not exceeding $50 \times 10^{-7}$ cm. An increase in temperature to 800° leads to the almost complete disappearance of fine pores with a radius less than $200 \times 10^{-7}$ cm.

In a later investigation[19] of the reduction of wüstite at temperatures between 600 and 870° the fraction of pores with radii up to $1.3 \times 10^{-5}$ cm varied accordingly from 42.8 to 56.3%. It was found that the relative surface of the products decreased from 23 540 to 13 910 $cm^2\ cm^{-3}$.

These experimental results suggest that submicropores appear in the products of reactions (1) and (2) during the formation of the crystallites of the new phase as a consequence of the inequality (3).

The formation of pores leads to the reestablishment of the contact between the initial solid and gaseous phases, considerably facilitating the course of reactions (1) and (2) in comparison with the back reactions. In the latter the products should be compact and pore-free, since its volume is greater than the volume of the solid substance entering into the reaction. True, in the processes which are the reverse of the reactions which we are analysing pores can be formed in the internal layers of the product (for example, in the high-temperature oxidation of metals) but for another reason — due to the Kirkendall effect[35].

Hence the change from the oxidation of metals to their reduction significantly changes the mechanism of the process: the transport of the reagents in oxidative reactions is realised almost exclusively by mass transfer of them through the crystal lattice of the product, but in reductions, by motion along the micropores, that is, by Knudsen diffusion.

## 4. "Autocatalysis"

The following feature is characteristic for changes (1) and (2): there is a maximum on many rate–time graphs. This phenomenon is termed autocatalysis, since as the reaction develops it accelerates itself. The explanation is that the main place at which the reactions proceed is the surface separating phases A and B. The interfacial boundary grows during the process, but since the reaction is heterogeneous and its rate is proportional to the surface, this rate must also increase and reach a maximal value.

The many investigations of Chufarov, of Rostovtsev, and others[36-39] provide an experimental basis for the autocatalytic theory applicable to the processes we are considering.

Chufarov developed the adsorption-autocatalytic theory for the reduction of a metal; this theory has been widely recognised and extended. It is the leading theory in the contemporary educational literature on the theory of metallurgical processes.

Many papers have considered in detail the adsorption nature of reduction processes[40-42].

However, it must be noted that some aspects of the adsorption-autocatalytic theory are not satisfactory. Thus in Lyuban's monograph[43] it is stated that as the temperature is raised the role of adsorption in the reduction processes must necessarily be diminished. But here it must be remembered that chemical adsorption of gases can occur at comparatively high temperatures. Thus, oxygen is adsorbed on graphite even at 1200°.

The adsorption side of the theory was criticised in Manchinskii and Shkodin's review[44], where it was shown that in many experiments which provide an experimental basis for the theory and from which quite important conclusions were drawn about the nature and mechanism of the reactions being studied, the use of a vacuum could change the process in the diffusion, but not in the kinetic, region, notwithstanding the opinions of their authors.

It is noted that from the standpoint of the adsorption theory, in criticising the baseless analogies between equilibrium and kinetic characteristics in the "two-stage" hypothesis on the mechanism of the reduction of metals, they themselves tolerate a similar error, by explaining the difference in the rates of reaction of metals with hydrogen and carbon monoxide in terms of the equilibrium values of adsorption of these gases. These values are extrapolated into the region of high temperatures without sufficient reason. Furthermore, adsorption relates not to unit volume of the adsorbent but to its unit surface and the true surface of the solid phases in the experiments was not estimated. The authors unfortunately did not discuss the question of how the adsorption in real processes departs from its equilibrium values.

The "autocatalytic" mechanism for the processes being analysed also needs considerable refinement.

It is now thought[7-9] that, after the formation of the nuclei of the new phase, reactions (1) and (2) are localised on the surface of separation A–B, that is, in those places where their operation is complicated by the above three circumstances. This starts from the fact that the process of building up a new phase is easier (from the energetic point of view) than its initial formation.

Here, evidently, the difficulties of the reactions proceeding on the surface of separation between two solid phases are partly understated and the difficulties of formation of three-dimensional nuclei (which cannot be so great at high chemical supersaturations) are exaggerated to a certain extent.

As a sharp separation surface between the solid phases is necessary for catalysis, first of all it is necessary to settle the question as to whether such a surface is always present in the changes being studied.

Starting from the analysis given above of the nature of the "solid solution" it is expected that there can also be

continuous — coherent change between A and B. It is interesting in this connection to note that some authors confirm the accelerating action of the reaction product[45,46] whereas others do not[47-49].

Furthermore, if reaction (3) is obeyed, then both the initiation and the growth of the new phase can lead to the disappearance of the A–B surface of separation and to the production of A–D and A–C contacts. Then the main place for the reaction to take place can become the surface of separation of the initial solid phase from the gas. But then the explanation of the maximum on the atuocatalytic curves in terms of the growth of the A–B interfacial surface does not seem very convincing.

With the exception, for example, of such processes as the formation of a condensed phase from saturated vapour, of a crystallite from a melt, etc., the mechanism of which can prove to be quite different from that in reactions (1) and (2), where three phases interact, the genesis of an interfacial surface, which brings about the separation of the reagents, may not only accelerate but also complicate and retard the change. The essence of the latter is that loss of material from initial reagent A is hindered by the appearance of the product and boundaries separating the solid phases.

Hence the phenomenon of "autocatalysis" can be explained by the change in the A–B interfacial surface only when good contact is maintained between the phases which are interacting and there is a distinct separation surface between them.

In accordance with what has been stated other possible reasons for the appearance of a maximum on the rate–time curves must be considered.

1. When as a result of inequality (3) there is detachment of the new phase from the old, then this can bring about extensive renewal of an A–gas separation surface. This has a limit. As reagent A is consumed a moment is reached after which the occurrence of the reaction is accompanied by a decrease in this surface.

At high degrees of chemical supersaturation and almost continuous covering of phase A by the nuclei of phase B the surface of contact between the initial substance and the gas very rapidly reaches a maximal value and subsequently can only decrease, which agrees well with experiment.

2. The nuclei of the new phase are formed mainly in defect sites on the surface of the crystallites. Even partial rupture of a crystallite of B from the initial substance A signifies renewal of the defect sites, which can also accelerate the process. This can be represented, for example, by the scheme shown in Fig. 3. Here it is evident that instead of one active centre $a$, the sharp edge $a'$–$a'$ of a crater is formed and on this there will be many defect sites.

The appearance of the descending branch of the autocatalytic curve is due not only to the decrease in the reaction surface and the number of defects but also the growth in the thickness of the layer of product, which hinders the supply or removal of gaseous reagents and the heat exchange.

Hence the advances in general and physical chemistry in the investigation of the processes analysed in the present review make it possible to build up a mechanism for them from new points of view. These advances also enable us to hope that in the near future essential modifications will be made to the theory of nucleation and growth of a new phase in topochemical changes of the type considered here.

We think that the following are the most interesting features of the mechanism and kinetics of these reactions.

1. Processes (1) and (2) are complex heterogeneous interactions which include at least six stages: (a) the chemical reaction itself; (b) reconstruction of the crystal lattice of the initial phase A into that of the new phase B; (c) transport of the gaseous reagents and products between the reaction surface and the centre of the gas stream; (d) diffusion of the gases into the pores of the initial crystalline phase; (e) the diffusion of gases into the pores (capillaries) of the solid reaction products; and (f) the diffusion of particles (atoms, ions, molecules) in the crystal lattices of the solid phases.

Each of these stages can be rate-limiting — it depends on the particular conditions under which the process is carried out.

2. The formation of the solid product B leads to spatial separation of the reagents and to difficulties in carrying out the process.

3. The difference (3) between the volumes of the solid phases originating and disappearing during the course of the interaction leads to the development of porosity, to the spatial drawing together of the reagents, and even to renewal of their contact, which in turn facilitates the course of the reaction, in distinction, for example, from the back reaction.

4. The interaction of these two tendencies (those mentioned in paragraphs 2 and 3) bring about the peculiar features of the kinetics of the processes analysed here, sometimes causing their acceleration and sometimes their retardation.

The reaction rate at a given temperature and degree of chemical supersaturation can be affected by: (a) the topography of the surfaces of the solid phases and the renewal of defect places; (b) the disordering of the crystal lattices and the formation of transition structures during the transformation; (c) the formation of electrical fields and the possibility of their penetration in connection with the development of porosity in the depth of the crystal of the solid phase; (d) the sintering (recrystallisation) of the reaction products and the hindering (or facilitation) of capillary diffusion of the gaseous reagents, and also the supply or removal of heat necessary for the course of the reaction.

5. Many experimental results show that the solid product of reactions of the type considered are usually obtained finely disperse with a strongly developed surface and consequently high chemical activity. The production of coarsely crystalline and single-crystal products is greatly hindered by the operation of inequality (3). Crystal growth is evidently mainly brought about by their sintering and to a lesser extent by the addition of elementary particles.

# QUANTITATIVE ASPECTS OF GAS-PHASE CHEMICAL KINETICS

V. N. Kondrat'ev

Chemical kinetics has long been, by its very nature, a quantitative science, concerned mainly with measuring the rates of chemical reactions. However, measurements of the reaction rates under a given set of conditions (temperature and pressure, initial composition, presence or absence of an inert diluent) give no indication at all of the rate of the same reaction under arbitrarily prescribed conditions. Yet the main value of kinetic investigations lies, both from the theoretical and especially from the practical point of view, in the ability to predict the rate of a given chemical reaction over a wide range of different conditions. A knowledge of the reaction mechanism and of the rate constants of (at least) all the main elementary processes involved is an invariable prerequisite.

At present, the mechanism of the oxidation (combustion) of hydrogen, and of reaction in hydrogen–halogen systems, among those of complex gas-phase reactions, have been studied in some detail, as has the mechanism of the oxidation (combustion) of carbon monoxide (but far from exhaustively); the mechanism of chemical changes in the nitrogen–oxygen system has been examined in broad outline; and individual steps in the oxidation of hydrocarbons and in various other complex reactions have been elucidated. Studies of the mechanism of a variety of chemical reactions, vigorously pursued over a wide front by physical chemists of many countries, are steadily adding to the number of reactions whose mechanism is understood. However, we are still at a relatively early stage, and a large number of reaction mechanisms (including those of technically important reactions) still remain to be investigated and made more precise.

In spite of the many studies devoted to measurements of the rate constants of elementary processes, and in spite of the very large number of kinetic constants which have now been measured, our existing fund of constants is far from adequate for a prediction of the rates of chemical reactions under prescribed conditions. Even in the rare instances where the reaction mechanism is known, and the rate constants of all the main elementary processes have been measured, the precision of the constants is often found to be inadequate. This is particularly true when it becomes necessary to extrapolate to high temperatures the values of these constants measured at relatively low temperatures (a problem which present-day practice often puts to chemical kineticists).

Before discussing the present state of the problem of the rate constants of elementary chemical processes, we shall review briefly some modern experimental methods of measurement.

The experimental methods used to measure rate constants of elementary chemical processes can be divided into two groups: in the first, the constants are measured in the course of the reaction itself, whilst in the second group a single process (often the primary process for the particular experimental conditions) is artificially isolated from the many concomitant elementary processes. The second group of methods is often used to measure the rate constants of processes in which atoms and free radicals interact with molecules or with each other, the atoms and radicals being generated thermally, photochemically, or electrically. Generation can be effected either in the reaction zone or elsewhere. Thus, the photochemical generation of active reaction centres is most frequently carried out in the reaction vessel, whereas when the active centres are generated electrically they appear in a region of electrical discharge, and they are led to the reactor, through a jet, by the flowing gas.

The method of crossed molecular beams is ideal for studying a single, isolated elementary process, but its application has so far been severely limited by the difficulty of measuring the reaction rates.

Among the first group of methods should be listed the shock tube method and the related method of adiabatic compression. The problem of measuring the dissociation constants of diatomic molecules, when the progress of the reaction is usually monitored from the change in concentration of the experimental gas (e.g. by absorption spectroscopy), is solved most easily by the shock tube method. The main difficulty, arising from insufficient accuracy in the measurements, is encountered in the analytical presentation of the measured rate constant. In using the expression from classical collision theory for the dissociation rate constant[1]

$$k_d = c\sqrt{T}\left(\frac{D}{RT}\right)^n e^{-D/RT} \qquad (1)$$

(where $c$ is a constant factor, $D$ the dissociation energy, and $n$ the number of internal degrees of freedom involved in activation of the dissociating molecule), a value of $n$ is usually chosen such that the experimentally observed temperature variation of the constant $k_d$ is described as accurately as possible by formula (1). The extent to which such choice can vary (as a direct consequence of the low precision of the measurements) can be assessed from Table 1.

One important result from the shock tube method for measuring $k_d$ has been to verify the correctness of the expression

$$K = \frac{k_d}{k_r}, \qquad (2)$$

where $K$ is the equilibrium constant and $k_r$ the rate constant for recombination of the atoms (the reverse of the molecular dissociation process).

Measurements of the dissociation rate constants of polyatomic molecules are usually complicated by the great variety of secondary processes which follow the primary process. Thus, all stages of cracking, as far as carbon, have been demonstrated in the thermal decomposition of methane:

$$CH_4 \rightarrow C_2H_6 \rightarrow C_2H_4 \rightarrow C_2H_2 \rightarrow C.$$

However, the initial stage of the reaction can be isolated by restricting the reaction time. In this way, formulae for the dissociation rate constant in which the dissociation energy and the preexponential factor have closely similar values have been reported in three independent studies[8-10] of the decomposition of methane.

To interpret the experimental results from this type of work correctly, it is essential to ascertain correctly whether the primary process involves dissociation of the methane molecules by the mechanism $CH_4 \rightarrow CH_3 + H$ or by the mechanism $CH_4 \rightarrow CH_2 + H_2$, and whether this process follows first-order or second-order kinetics.

The first of these two questions can now be said to have been resolved in favour of the process $CH_4 \rightarrow CH_3 + H$. A strong argument in its favour was the identity of the activation energy measured for the primary process with the dissociation energy of the $H_3C-H$ bond, and also the fact that $CH_3$ radicals have been detected, by the Paneth mirror technique [by the formation of $(CH_3)_2Te_2$] in the gas stream issuing from the region of methane cracking, whilst no $CH_2$ radicals were detected (absence of $CH_2Te$).[11]

The problem of the order of reaction has been analysed in a previous paper[10], which showed that the process $CH_4 \rightarrow CH_3 + H$ is a first-order reaction (at least, under the experimental conditions of the adiabatic compression method[12]). Thus, the statistical theory of unimolecular decomposition[13] gives for the rate constant of the second-order process $CH_4 + Ar = CH_3 + H + Ar$ the formula

$$k_{d,2} = 10^{21} e^{-E/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1},$$

correct to an order of magnitude at temperatures below 1860°K. Furthermore, the same theory shows that decomposition will occur by a first-order law if

$$k_{d,2}[Ar] > k_{d,1}, \qquad (3)$$

where $k_{d,1}$ is the first-order dissociation constant, and [Ar] the concentration of argon. (The reactions occur in methane diluted with 20–100 times its volume of argon.) Substituting in this inequality the formula obtained[10] for $k_{d,1}$

$$k_{d,1} = 10^{15} e^{-E/RT} \text{ s}^{-1},$$

and [Ar] = $10^{-3}$ mole cm$^{-3}$ (degree of adiabatic compression = 20) we obtain $10^{21} \times 10^{-3} = 10^{18} \gg 10^{15}$, showing that the condition for unimolecular decomposition by the first-order law is satisfied.

Studies of the thermal decomposition of polyatomic molecules in shock tubes sometimes lead to an Arrhenius formula for the decomposition rate constant in which the activation energy $E$ is considerably lower than the dissociation energy. Thus, the following formulae have been obtained[14-17] for the rate constant of the thermal dissociation of $CO_2$:

$$k_d = 3 \times 10^{11} \sqrt{T}\, e^{-86\,000/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1}, \quad M = Ar, \quad T = 2500\text{–}3000^\circ K,^{14}$$

$$k_d = 1.5 \times 10^{14} e^{-87\,000/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1}, \quad M = CO_2, \quad T = 3000\text{–}5500^\circ K,^{15,16}$$

$$k_d = 2.9 \times 10^{11} \sqrt{T}\, e^{-74\,700/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1}, \quad M = Ar, \quad T = 3500\text{–}6000^\circ K,^{17}$$

$$k_d = 2.5 \times 10^{11} \sqrt{T}\, e^{-74\,500/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1}, \quad M = N_2, \quad T = 3500\text{–}6000^\circ K,^{17}$$

whereas the dissociation energy of $CO_2$ into CO and O is $D$ = 125.75 kcal mole$^{-1}$. The $k_d$ constants measured in this work can also be represented by formulae of the type of Eqn. (1):

$$k_d = 1.2 \times 10^2 \sqrt{T} \left(\frac{D}{RT}\right)^{7.11} e^{-D/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1},^{14}$$

$$k_d = 3 \times 10^7 \sqrt{T} \left(\frac{D}{RT}\right)^{6} e^{-D/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1},^{15,16}$$

$$k_d = 5.8 \times 10^{10} \sqrt{T} \left(\frac{D}{RT}\right)^{4.56} e^{-D/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1},^{17}$$

$$k_d = 2.0 \times 10^{10} \sqrt{T} \left(\frac{D}{RT}\right)^{4.72} e^{-D/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1}.^{17}$$

TABLE 1. Temperature dependence of the preexponential factor in the expression for the rate constant of the dissociation of the $O_2$ molecule ($O_2 + O_2 = 2O + O_2$), as reported by various workers ($D$ = 118 000 cal mole$^{-1}$).

| $k_d e^{D/RT}$, cm$^3$ mole$^{-1}$ s$^{-1}$ | $T$, °K | Ref. |
|---|---|---|
| $7.4 \cdot 10^{11} \sqrt{T} (D/RT)^{1.5 \pm 0.2}$ | 6000—7000 | 2 |
| $2.25 \cdot 10^{12} \sqrt{T} (D/RT)^{1.5}$ | 3000—8000 | 3 |
| $5.5 \cdot 10^{11} \sqrt{T} (D/RT)^{3}$ | 2800—3900 | 2, 4 |
| $5.4 \cdot 10^{10} \sqrt{T} (D/RT)^{3}$ | 3000—5000 | 5 |
| $5.1 \cdot 10^{10} \sqrt{T} (D/RT)^{3}$ | 4000—7000 | 6 |
| $4.6 \cdot 10^{9} \sqrt{T} (D/RT)^{4}$ | 2600—7000 | 7 |

Since the exponent of the term $D/RT$ cannot exceed 5 when M = Ar, and therefore the number 7.11 has no physical significance, Brabbs et al.[14] assumed that the thermal dissociation of carbon dioxide occurs in the two steps

$$CO_2(^1\Sigma) + Ar = CO_2^*(^3\Pi) + Ar,$$
$$CO_2^*(^3\Pi) \rightarrow CO + O,$$

of which the first is rate-determining†. These authors[14] interpret the glow (characteristic of the CO flame) which is observed during the thermal dissociation as evidence for the participation of electronically excited $CO_2^*$ molecules. They base one of their two methods for measuring the rate constant of the dissociation of $CO_2$ on measurements of the intensity of this glow.

According to Davies[17], however, the glow is a secondary process, associated with the recombination of CO + O leading to the formation of electronically excited $CO_2^*$ ($^3\Pi$) molecules; while the dissociation of $CO_2$ occurs in a single step, $CO_2 + M = CO + O + M$ (in Davies' formulae $n < 5$).

To establish the true mechanism of the thermal dissociation of $CO_2$ it is very important to determine the difference in energy between the $^3\Pi$ and $^1\Sigma$ levels, which is not known at present. It is interesting to note that in the thermal dissociation of carbon disulphide, for which the activation energy $E$ is also smaller than the energy required to break the SC–S bond, but for which the excitation energy of the $^3\Pi$ level is known from spectroscopic data, the value of $E$ agrees[18] with the energy difference between the $^3\Pi$ and $^1\Sigma$ levels. This is convincing evidence in favour of the two-stage mechanism for the reaction.

Two-stage thermal decomposition has been established also in the case of $SO_2$, for which the activation energy calculated from the formula

$$k_d = 10^9 \sqrt{T} \left(\frac{E}{RT}\right)^3 e^{-E/RT} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1},$$

coincides with the excitation energy of the triplet state[19] of the $SO_2$ molecule. The dissociation process in this case occurs according to the scheme

$$SO_2 + M = SO_2^* + M - 73.6 \text{ kcal mole}^{-1},$$
$$SO_2^* + SO_2 = SO_3 + SO + 25.6 \text{ kcal mole}^{-1},$$

where M denotes any species.

The thermal ionisation of the inert gases has also been shown to be a two-stage process. Thus, the ionisation of xenon in a shock tube proceeds according to the scheme[20,21]

$$Xe + M = Xe^* + M,$$
$$Xe^* + M = Xe^+ + e^- + M.$$

Whereas measurements of the rate of decomposition of saturated molecules, needed in order to determine rate constants, present no special difficulties, measurements of the rates of reactions involving atoms and free radicals, formed in the reaction itself or generated externally, present a much more difficult problem. To determine the rate constants in these cases, the concentration of active centres taking part in the reaction must be measured, or else the rate constant of another reaction involving the same active species must be known.

† The second stage can be written

either $CO_2^*(^3\Pi) + Ar = CO + O + Ar$ or $CO_2^*(^3\Pi) + CO_2 = 2CO + O_2$.

Without attempting to list existing methods of measuring concentrations of atoms and free radicals, we shall only state that the electron spin resonance (e.s.r.) method, recently included among these methods on account of its potentialities, now appears to be the most effective and the most promising. Kinetic investigations of reactions involving H and O atoms, halogen atoms, and OH radicals have already been successfully carried out with the help of the e.s.r. method.

An example of this is the recent work of Panfilov[22], who has measured the rate constants of twelve reactions of the type $H + RH = H_2 + R$, as well as of the reaction $H + O_2 = OH + O$ in low-pressure oxyhydrogen flames (500–600°C, 3–6 mmHg) containing small quantities of the compound RH, the concentrations of H atoms being measured by e.s.r. spectroscopy.

The measurement of the rate constant of one reaction from the known rate constant of another reaction usually relies on the change in the combustion limits[23–30]. The basis of this method can be understood by considering the hydrogen–oxygen flame. With fairly rich hydrogen–oxygen mixtures (the lower combustion limit is set by the removal of H atoms at the walls), if a small amount of a substance M with which H atoms can react is present in the gas mixture, the displacement (in pressure) of the lower limit $\Delta p_1$ can be expressed by the formula

$$\frac{\Delta p_1}{p_1^0} = \frac{k[M]}{k_0}, \quad (4)$$

where $p_1^0$ is the pressure at the lower limit in the absence of the additive, $k$ the rate constant of the reaction between H atoms and the substance M (for example, the rate constant of the reaction $H + RH = H_2 + R$, if M = RH), and $k_0$ the rate constant for the heterogeneous removal of H atoms.

Nalbandyan and his coworkers[31] have tried, by appropriate treatment of the walls of the reaction vessel, to induce the reaction to occur in the diffusion region, where the constant $k_0$ can be calculated very accurately in terms of the diffusion coefficient. Thus, from a knowledge of $k_0$ combined with measurements of the relative displacement of the lower combustion limit $\Delta p_1/p_1^0$ at various values of [M], they calculated the constant $k$ as the slope of the linear plot of Eqn. (4). A common drawback of the method of limit displacement is the fact that the temperature range over which reliable results are obtained is relatively narrow.

The method of "competing reactions", extensively used by Steacie, and also by Trotman-Dickenson, Noyes, and others to study the reactivity of methyl radicals, also relies on measuring the rate constant of one reaction in terms of the rate constant of another reaction.

In the simplest case, when only one substance (e.g. acetone) is present in the system initially, thermal or photochemical decomposition generates $CH_3$ radicals, which proceed to recombine or to react with acetone molecules, splitting off an H atom. The kinetic equations for this system lead to the relationship

$$\frac{R_{CH_4}}{\sqrt{R_{C_2H_6}}} = \frac{k[CH_3COCH_3]}{\sqrt{k_r}}, \quad (5)$$

where $R_{CH_4}$ and $R_{C_2H_6}$ are the rates of formation of methane and ethane respectively, $k$ is the rate constant of the reaction $CH_3 + CH_3COCH_3 = CH_4 + CH_2COCH_3$, and $k_r$ is the recombination constant of methyl radicals. Thus, formula (5) allows the rate constant $k$ to be calculated from measurements of $R_{CH_4}$ and $R_{C_2H_6}$ if the constant $k_r$ is known.

At this stage, we must make the following observation. The constant $k_r$ is often assumed to be independent both of temperature and of pressure. Thus, for example, Trotman-Dickenson and Steacie adopt a value of $7 \times 10^{13}$ cm$^3$ mole$^{-1}$ s$^{-1}$ for the constant $k_r$ in their paper[32] on the reactions of the methyl radical with acetone and with hydrocarbons; Brinton[33] takes $k_r$ to be $4.5 \times 10^{13}$ cm$^3$ mole$^{-1}$ s$^{-1}$ in his work on the reactions of the $CH_3$ radical with various imines; Gray and Thynne[34] studied reactions of the type $CH_3 + CH_3NH_2 = CH_4 + CH_3NH$ or $CH_4 + CH_2NH_2$, and adopted the value $k_r = 2.2 \times 10^{13}$ cm$^3$ mole$^{-1}$ s$^{-1}$; and so on. All these workers calculate the value of $k_r$ from data obtained in Kistiakowsky's laboratory[35,36], or from the same data, corrected by refinements of the theory of the sector method[37]. Yet it was shown[38] in Kistiakowsky's own laboratory that at low pressures of acetone vapour the constant $k_r$ varies with pressure (in the temperature range 180–240°C) approximately as

$$k_r = \frac{k_{r,2}}{1 + \frac{3.6}{p}}, \qquad (6)$$

where $p$ is the pressure of acetone vapour in mmHg. Lossing and his coworkers have demonstrated[39,40] a dependence of $k_r$ upon helium pressure. By comparing the results of these workers with those already mentioned we conclude that helium is approximately one-fifteenth as effective as acetone in the role of the species M in the reaction

$$CH_3 + CH_3 + M = C_2H_6 + M.$$

Lossing and his coworkers also reported a temperature dependence of the third-order recombination constant (in the range 434–1087°K). When interpreted by means of an Arrhenius expression, these results lead to an activation energy of $E = -1.5 \pm 0.5$ kcal mole$^{-1}$; when substituted in a power law ($\propto T^{-n}$) they give $n = 1.0$–$1.5$. On analysing all available data on the recombination constant of methyl radicals, we conclude that the second-order (high-pressure) recombination constant should be expressed by the formula

$$k_{r,2} = 1.1 \times 10^{12} \sqrt{T} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1},$$

and the third-order (low-pressure) recombination constant should be expressed by the formula

$$k_{r,3} = 4.3 \times 10^{19} e^{(1500 \pm 500)/RT} \text{ cm}^6 \text{ mole}^{-2} \text{ s}^{-1}$$

for $M = CH_3COCH_3$, and by

$$k_{r,3} = 2.9 \times 10^{18} e^{(1500 \pm 500)/RT} \text{ cm}^6 \text{ mole}^{-2} \text{ s}^{-1}$$

for M = He. The identical temperature dependence of the constant $k_{r,3}$ when $M = CH_3COCH_3$ and when M = He is based on the assumption[39,40] that it is mainly due to the increase in probability of dissociation of the complex $[CH_3 \cdot CH_3]^*$ with increase in temperature.

Thus, it is evident that rate constants calculated in terms of the recombination rate constant of methyl radicals on the assumption that the latter is independent of both temperature and pressure stand in need of revision.

We shall discuss next the method of measuring rate constants in which active species are produced in an electrical discharge and are led by the gas stream into the reaction vessel, where they interact with various substances. This method was used in Steacie's early work, and also by Avramenko, Kaufman, Schiff, and others. Its most extensive application is found in the work of Avramenko[41].

In the simplest case, when the discharge produces active particles of a single kind (atoms of A), which react with the added molecules of M by a single path to give the reaction product P, the kinetic equations can be written

$$-\frac{d[A]}{dt} = (k_0 + k[M])\ [A],$$

$$\frac{d[P]}{dt} = k[M]\ [A],$$

where $k$ is the rate constant of the reaction $A + M \rightarrow P$ and $k_0$ the rate constant for the disappearance of A atoms. If the atoms are removed by a first-order process (e.g. by adsorption on the walls), $k_0$ is independent of the concentration of A atoms. In this case, assuming negligible consumption of the substance M and replacing [M] by the initial concentration $[M]_0$, and making the further assumption that the gas stream emerging from the reaction vessel contains practically no A atoms, the above kinetic equations can be solved to give

$$\frac{1}{[P]} = \frac{1}{[A]_0} + \frac{k_0}{k[M]_0[A]_0}. \qquad (7)$$

If the reciprocal of the measured concentration of reaction product is plotted (vertically) against the reciprocal of the initial concentration of M for various values of $[M]_0$ (with $[M]_0 - [M] \ll [M]_0$, and $[A]_0$ constant), Eqn. (7) leads to a linear plot whose parameters yield the ratio of the constants $k/k_0$.

Avramenko obtained the constant $k_0$ from measurements of the relative concentrations of A at different points in the reaction vessel. This, in conjunction with the ratio of $k/k_0$ obtained from the linear plot of Eqn. (7), allows the constant $k$ to be calculated.

However, this simple method demands great care to ensure that the underlying assumptions are satisfied. Thus, when the rate constant of a homogeneous process is being measured, it must be quite certain that A and M do not interact on the walls of the reaction vessel. Nevertheless, the relatively low pressures normally used in the experiments by the electrical discharge method greatly increase the probability of heterogeneous reaction. Furthermore, we must know that the constant $k_0$ is unaffected by the presence or absence of the substance M. Since at low pressures and low concentrations the active particles are usually lost at the walls, on which they become adsorbed, there is likely to be an effect of impurities on the adsorption properties of the walls. It is also necessary to check that the value of $[A]_0$ remains constant at different values of $[M]_0$. Further complications are introduced by the possibility of reactions between A and M by two or more paths, when formula (7) is replaced by

$$\frac{1}{\Sigma[P_i]} = \frac{1}{[A]_0} + \frac{k_0}{\Sigma k_i [M]_0[A]_0}, \qquad (7')$$

or, if the yield of only one of the products ($P_1$) is monitored, by the formula

$$\frac{1}{[P_1]} = \frac{\Sigma k_i}{k_1}\frac{1}{[A]_0} + \frac{k_0}{k_1[M]_0[A]_0}. \qquad (7'')$$

It is easy to see that formula (7′) allows only the sum of the rate constants $\Sigma k_i$ for the interaction of A and M to be determined. From formula (7″), on the other hand, we can obtain the rate constant of a single process $k_1$ if the initial concentration of A particles is measured independently.

We have assumed that the reaction products whose concentration is measured during the experiment are obtained by direct interaction between A and M. However, the primary products of an interaction of this type are often certain intermediates, which undergo further transformation to give the products whose yield is taken as a measure of the rate of interaction of A and M by a particular path. Thus, for example, when we measure the rate constant of the reaction $O + H_2 = OH + H$ from the yield of water, we must be absolutely certain that the rate of this reaction and the rate of formation of water are either identical or interrelated in a specific (and known) way.

It follows from what has been said that the rate constants of elementary chemical reactions measured by the electrical discharge method can be considered reliable only if all possible factors affecting the course of the reaction have been carefully weighed and evaluated.

We will now turn to the photochemical method of producing atoms and free radicals, whose rates of interaction with various substances it is desired to measure. This method has been used extensively by Steacie, Noyes, Cvetanović, Nalbandyan, and others. One of its advantages over the electrical discharge method is the fact that chemical reactions can be studied at relatively high pressures, when heterogeneous processes may be ignored.

However, the photochemical method also presents one very important disadvantage, which compels us to regard with the greatest caution the rate constants measured by this method. This drawback arises from the possibility of producing "hot particles", whose reactivity is higher than that of similar particles having an equilibrium (or close to equilibrium) energy distribution.

The possibility of obtaining hot particles in photochemical reactions, and their role in the reaction, were pointed out[42] as early as 1934 (although the concept of "hot particles" came later). In that investigation, the proportion of hydrogen iodide which was oxidised was measured by irradiating a mixture of $HI + O_2$ in Uviol ($\lambda > 2800$ Å) and quartz ($\lambda > 2000$ Å) vessels near room temperature. Since in the first case the maximum energy of the H atoms produced by the primary process $HI + h\nu = H + I^*$ did not exceed 10 kcal mole$^{-1}$, whilst in the second case it reached 20 kcal mole$^{-1}$ ($\lambda = 2537$ Å) or more, the approximate doubling of the amount of HI oxidised, observed when the Uviol vessel was replaced by a quartz vessel, was ascribed to the high reactivity of the intermediate $HO_2$ radical, formed by the reaction between a fast ("hot") H atom and an $O_2$ molecule. An alternative explanation was also put forward: in the presence of fast H atoms, a different intermediate process becomes possible, namely $H + O_2 = OH + O - 16.7$ kcal mole$^{-1}$, and this can lead to an increase in the fraction of HI which is oxidised.

The formation of hot H atoms in the photolysis of HI has recently been confirmed by Dzantiev et al.[43], who studied the photochemical reaction in mixtures of HI and ethylene at temperatures between 0° and 250°C. They showed that the main product of this reaction is ethane, and that its yield is independent of temperature over the experimental temperature range (curve *a*, Fig. 1), is practically unaffected by dilution with argon (curve *a*, Fig. 2), and decreases sharply when the mixture is diluted with helium (curve *b*, Fig. 2). The mixture diluted with helium showed a variation in yield of ethane of the Arrhenius type (curve *b*, Fig. 1), corresponding to an effective activation energy of 3.5 kcal mole$^{-1}$.

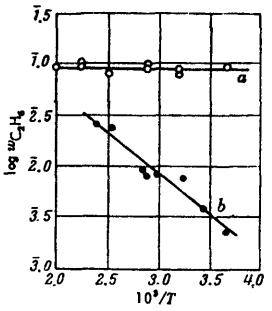

Fig. 1. Variation of the rate of formation of ethane (cm$^3$ min$^{-1}$) with temperature: *a*) $HI : C_2H_4 = 9 : 1$; *b*) $HI : C_2H_4 : He = 9 : 1 : 40$.

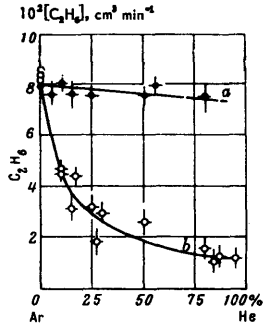

Fig. 2. Variation of the yield of ethane on dilution with: *a*) argon; *b*) helium.

These results were interpreted by postulating that the hot H atoms, which are mainly consumed by the reaction $H + HI = H_2 + I$, can react also with ethylene to some extent, forming "hot" $C_2H_5^*$ radicals which then react with HI according to the scheme $C_2H_5^* + HI = C_2H_6 + I$. Dilution with helium brings about thermal equilibration of the hot H atoms, as evidenced by the lower yield of $C_2H_6$ and by the appearance of a temperature dependence of the reaction rate.

Whereas in this work the hot $C_2H_5$ radicals are formed through the agency of the primary hot H atoms, many instances are known of the formation of hot radicals in the primary photochemical act. We shall mention only one example[44], which showed that the photolysis of azomethane $CH_3NNCH_3$ produces a certain proportion of hot $CH_3^*$ radicals. Until they have reach thermal equilibrium, these radicals can easily abstract H atoms from hydrocarbon molecules at room temperature. As in the work on the oxidation of hydrogen iodide, the activity of the $CH_3$ radicals was found to decrease with increase in wavelength (since the relative yield of methane decreases).

The problem of hot particles, and in particular of the particles formed during photolysis, cannot as yet be considered fully solved. However, in view of the above and other similar observations, it is evident that great caution must be exercised in the quantitative interpretation of kinetic results obtained under conditions admitting the formation of hot particles and their participation in the reaction.

The conclusion to be drawn from this discussion of the methods for measuring the rate constants of chemical processes is that each method has some unsatisfactory features, and that a critical approach is imperative in dealing with quantitative data based on these methods. The lack of a duly critical attitude, particularly on the part of the authors themselves (who do not always attach due weight to the errors in their measurements), is often responsible for the large discrepancies found between the quantitative results obtained by different authors using different or even the same methods.

The results given above (Table 1) for the rate constant of the dissociation of oxygen serve to illustrate the large errors involved in measurements of this type. Further simple examples are given below.

Table 2 lists the rate constants for the reaction $H + O_2 + H_2 = HO_2 + H_2$ reported by various workers. It can be seen that the extreme values differ by a factor of $10^4$.

The values of the constant $k_r$ obtained by different workers from measurements of the second combustion limit of hydrogen in the neighbourhood of 800°K do not differ by more than a factor of 2, averaging[48,53] about $10^{16}$ cm$^6$ mole$^{-2}$ s$^{-1}$. Since the temperature dependence of the recombination constant is usually expressed by a formula of the type

$$k_r = aT^{-n}, \qquad (8)$$

where $1 \leqslant n \leqslant 2$, extrapolation to 300°K gives $k_r = 2.6 \times 10^{16}$ for $n = 1$ and $k_r = 7.0 \times 10^{16}$ for $n = 2$. Comparing these values with those set out in Table 2 we conclude that the only admissible value is[48] $4 \times 10^{16}$. Of all the data given in Table 2, this can be considered the most reliable.

Table 3 gives data for the reaction $H + CH_4 = H_2 + CH_3$. With one exception, the activation energy and the preexponential term increase with temperature. We may conclude that the large scatter of the rate formulae obtained by different authors is due essentially to a large error in the measurement of the temperature variation of the constant $k$. The correctness of this conclusion is confirmed by the almost identical values given by three of the five formulae at a constant temperature (800°K). We may therefore adopt as the most reliable formula for the constant

$$k = 10^{13.17} \exp(-11\,200/RT) \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1},$$

obtained as the geometric mean of the three formulae.

TABLE 2. Rate constant of the reaction $H + O_2 + H_2 = HO_2 + H_2$ at room temperature.

| $k_r$, cm$^6$ mole$^{-2}$ s$^{-1}$ | Method | Ref. |
|---|---|---|
| $6.9 \times 10^{15}$ | electrical discharge; concn. of H determined from ortho–para conversion | 45 |
| $3.3 \times 10^{14}$ | photochemical oxidation of HI | 46 |
| $4.3 \times 10^{14}$ | electrical discharge; rate of formation of $HO_2$ determined from yield of $H_2O_2$ | 47 |
| $4.0 \times 10^{16}$ | electrical discharge; concn. of H determined from HNO glow | 48 |
| $1.8 \times 10^{17}$ | Hg photosensitisation of $H_2 + O_2$ reaction | 49 |
| $2.9 \times 10^{17}$ | electrical discharge; products estimated mass-spectroscopically | 50, 51 |
| $6.1 \times 10^{17}$ | Hg photosensitisation of $H_2 + O_2$ reaction | 52 |

TABLE 3. Rate constant of the reaction $H + CH_4 = H_2 + CH_3$.

| $k$, cm$^3$ mole$^{-1}$ s$^{-1}$ | $T$, °K | $k$(800°K) | Ref. |
|---|---|---|---|
| $10^{10.0} \exp(-4500/RT)$ | 372–436 | $10^{8.77}$ | 54 |
| $10^{12.5} \exp(-9000/RT)$ | 403–503 | $10^{10.03}$ | 55 |
| $10^{13.925} \exp(-14\,100/RT)$ | 773–873 | $10^{10.06}$ | 22 |
| $10^{13.08 \pm 0.35} \exp(-10\,600 \pm 1000/RT)$ | 843–933 | $10^{10.18}$ | 56,57 |
| $10^{14.3} \exp(-11\,500 \pm 1500/RT)$ | 1100–1900 | $10^{11.15}$ | 58 |

The formulae obtained by different authors for the reaction $OH + HCHO = H_2O + HCO$ show even greater scatter, as can be seen in Table 4. Measurements obtained in Refs. 59–61 are described accurate to a factor of 3 by the formula

$$k = 10^{12} \exp(-6300/RT) \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1}$$

(see Fig. 3).

The formulae obtained by different authors for the reaction $OH + H_2 = H_2O + H$ are presented in Table 5. We see that there is close agreement between the first three formulae, obtained by different methods, whereas in the last three formulae the activation energy differs considerably. This is due to the difference between the measured value[65] of the rate constant at 310°K — $(4.3 \pm 1.0) \times 10^9$ cm$^3$ × × mole$^{-1}$ s$^{-1}$ — and the values extrapolated to that temperature by means of the first three formulae of Table 5, amounting to 2–3 orders of magnitude.

It is interesting to note that a value of 5 kcal mole$^{-1}$ has been obtained[68] for the difference $E_{OH+H_2} - E_{OH+CO}$. Hence, with $E_{OH+H_2} = 10$ kcal mole$^{-1}$ we find that $E_{OH+CO} = 5$ kcal mole$^{-1}$, a value consistent with measurements by various authors (ranging from 3.4 to 10.3 kcal mole$^{-1}$), whereas if $E_{OH+H_2} = 5.9$ kcal mole$^{-1}$ we obtain ~1 kcal × × mole$^{-1}$ for the activation energy of the process $OH + CO = CO_2 + H$. Further experimental work is needed to solve the problem of the true activation energies of the reactions $OH + H_2 = H_2O + H$ and $OH + CO = CO_2 + H$.

TABLE 4. Rate constant of the reaction $OH + CH_2O = H_2O + HCO$.

| $k$, cm$^3$ mole$^{-1}$ s$^{-1}$ | $T$, °K | Ref. |
|---|---|---|
| $1.2 \cdot 10^{13} \exp(-900/RT)$ | 346–489 | 59 |
| $5.1 \cdot 10^{14} \exp(-3650/RT)$ | 798–923 | 60 |
| $5 \cdot 10^{13} \exp(-13\,000/RT)$ | 1250–1400 | 61 |

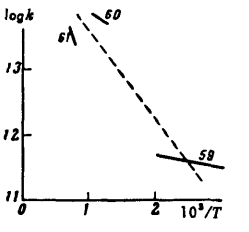

Fig. 3. Rate constant of the reaction $OH + CH_2O = H_2O + HCO$ according to different workers.

TABLE 5. Rate constant of the reaction OH + + $H_2$ = $H_2O$ + H.

| $k$, $cm^3$ $mole^{-1}$ $s^{-1}$ | $T$, °K | Ref. |
|---|---|---|
| $2.3 \cdot 10^{14} \exp(-1100/RT)$ | 900—1400 | 62 |
| $1.4 \cdot 10^{14} \exp(-10\,400/RT)$ | 380—490 | 63 |
| $2.5 \cdot 10^{14} \exp(-10\,000/RT)$ | 1660—1850 | 64 |
| $10^{13.9 \pm 0.7} \exp(-5900 \pm 1000/RT)$ | 310 and 1500 | 65 |
| $10^{13.48} \exp(-5500 \pm 600/RT)$ | 310 and 915 | 66 |
| $10^{13.6} \exp(-5700/RT)$ | 1500—2600 | 67 |

From these examples, to which many more could be added, it is evident that the present situation regarding the problem of the rate constants of elementary chemical reactions is unsatisfactory. This introduces great difficulties in the practical application of kinetic data.

In view of the difficulties in every experimental method of measuring the rate constants of chemical reactions, various theoretical or semi-theoretical indirect methods are often used with success. The statistical method for calculating second-order rate constants for the thermal dissociation of molecules must be mentioned first (see Ref. 13, p. 25). The method relies on the formula

$$k_d = Z g_s(E_0) \exp(-E_0/RT)/F(s-1), \quad (9)$$

where $Z$ is the collision factor of the kinetic theory of gases ($Z \simeq 10^{14}$ $cm^3$ $mole^{-1}$ $s^{-1}$),

$$g_s(E_0) = \left(\frac{E_0 + E_z}{h\bar{\omega}}\right)^{s-1} \frac{1}{(s-1)!},$$

$E_0$ is the dissociation energy, $E_z = \frac{1}{2}\Sigma h\omega_i$ is the zero-point vibrational energy, $\bar{\omega}$ is the mean vibration frequency, defined as

$$\bar{\omega} = \left(\prod_i \omega_i\right)^{1/s},$$

$s$ is the total number of vibrational degrees of freedom, and $F(s-1)$ is the vibrational partition function. The $k_d$ constants calculated from formula (9) agree with experiment to within an order of magnitude [69].

We have shown above (p. 894), using the thermal decomposition of methane as an example, that the order of a reaction can be ascertained from approximate calculations of the rate constant. The recombination constant of H + $O_2$ provides another example of this. Direct measurements of this constant at room temperature gave widely divergent values (see Table 2): we can calculate it through the dissociation constant and the equilibrium constant $K$ from the formula

$$k_r = \frac{k_d}{K}. \quad (2')$$

If we calculate the constant $k_d$ for 800°K and 300°K from formula (9) and adopt tabulated values [70] for the $H + O_2 \rightleftharpoons HO_2$ equilibrium constant at these temperatures, we obtain $k_r = 9 \times 10^{15}$ and $1.5 \times 10^{16}$ $cm^6$ $mole^{-2}$ $s^{-1}$ for the respective temperatures. Since it is assumed, in evaluating the number of vibrational degrees of freedom $s$, that the particle M is an atom, we can obtain values of the constant $k_r$ for M = $H_2$ by multiplying the above values by 5, it having been shown [71] that the relative efficiencies of $H_2$ and Ar in the reaction H + $O_2$ + M = $HO_2$ + M at 800°K are in the ratio 5 : 1. This gives $k_r = 4.5 \times 10^{16}$ (800°K) and $k_r = 7.5 \times 10^{16}$ (300°K). These values are only slightly higher than the experimental value of $k_r$ reported above (p. 898) for 800°K and the value measured [48] at 300°K. We should note that the two experimental values of $k_r$ differ by a factor of 4. Since the ratio of the temperatures (800° and 300°K) is 2.7, we may tentatively conclude that $k_r \propto 1/T^{3/2}$.

We shall discuss one more example. Szwarc [72] measured the rate constant for the unimolecular decomposition of hydrazine, and interpreted it as a first-order constant:

$$k_d = 4 \times 10^{12} \exp(-60\,000/RT)\ s^{-1}.$$

However, Gilbert [73] has since shown that the decomposition of $N_2H_4$ under Szwarc's experimental conditions should obey a second-order law, and he has reinterpreted Szwarc's data to give the following formula for the second-order dissociation constant

$$k_d \simeq 10^{19} \exp(-60\,000/RT)\ cm^3\ mole^{-1}\ s^{-1}.$$

Since this formula agrees exactly with that calculated by Nikitin and Sokolov [69], Gilbert's views appear to be correct.

It is important to note that the theoretical formula (9) for the constant $k_d$ implies that the temperature dependence of the preexponential factor in $k_d$ is different at low and at high temperatures respectively. In the low-temperature region ($T < h\omega/k$, where $\omega$ is the lowest vibrational frequency of the dissociating molecule) the vibrational partition function $F(s)$ is practically unity, and the temperature dependence of the preexponential factor $A$ becomes indistinguishable from that of the collision factor $Z$ of the kinetic theory of gases: i.e. $A \propto \sqrt{T}$. In the limit at fairly high temperatures, however, when $F(s)$ is expressed as $\prod_i (kT/h\omega_i)$, the temperature dependence of the preexponential factor takes the form

$$A \sim T^{1.5s-s}. \quad (10)$$

It follows that it is impossible, in principle, to express the dissociation rate constant $k_d$ by a formula of the type

$$k_d = A \exp(-E_0/RT), \quad (11)$$

in which the preexponential factor $A$ is either constant or of the form $A = A_0 T^{-n}$ ($n$ remaining constant over a wide range of temperatures). Another important test of the correctness of the interpretation of experimental kinetic results could be to calculate the preexponential factor in the expression for the bimolecular rate constant from the activated complex theory. Unfortunately, however, this method still lacks adequate theoretical development, and has been used in relatively few instances (see, for example, Refs. 53 and 74–78).

Application of the Polanyi–Semenov rule can also be of some value when testing the results of direct measurements. With a few exceptions, the linear relation

$$E = a - bQ \quad (12)$$

between the activation energy $E$ and the heat of reaction $Q$ is approximately obeyed in series of chemical reactions of similar type. Fig. 4 shows the variation of $E$ with $Q$ for the reactions H + RH = $H_2$ + R (curve $a$) and O + RH = OH + + R (curve $b$), where R = $CH_3$, $NH_2$, OH, and F. It is evident that the Polanyi–Semenov rule can be applied satisfactorily to both types of reaction within the limits of experimental error‡.

‡ In this plot the average of all measured values of $E$ has been taken, and the mean deviation calculated accordingly. The error in the values of $Q$ is determined by the inaccuracy of the corresponding thermochemical data.

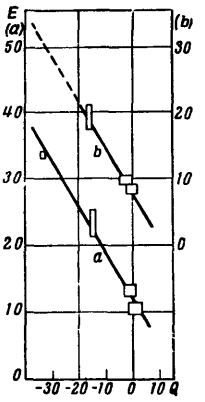

Fig. 4. Test of the Polanyi-Semenov rule for the reactions:
*a*) H + RH = $H_2$ + R;
*b*) O + RH = OH + R (R = $CH_3$, $NH_2$, OH, F).

The unsatisfactory state of our understanding of kinetic constants, which has been stressed in this review, exists also, to a greater or lesser degree, in other fields of science. In view of the vast and annually growing store of experimentally determined constants, presented with an almost complete lack of critical assessment, we are faced with an urgent need to rationalise the whole problem.

At the moment, the necessary measures are being taken (or planned) in many countries. Committees and organisations responsible for the compilation of tested and critically assessed quantitative data are being set up. In the Soviet Union, this is the responsibility of the State Committee for Standards, Measures, and Measuring Apparatus, which has begun to plan and develop efforts to produce and keep up to date exhaustive compilations of the best, most reliable, critically selected data in various fields.

As far as is known, in the USA the selection of reliable data has been undertaken by the National Bureau of Standards. The programme known as the National Standard Reference Data System [NSRDS], described in a paper by E. L. Brady of the Bureau of Standards, may be mentioned in this context.

It is obvious, however, that the critical evaluation and selection of the most reliable data should be organised on an international basis. To this end, the International Council of Scientific Unions (ICSU), acting on a report by the foreign secretary of the National Academy of Sciences of the USA, Dr. Harrison Brown, established in June 1965 a special group including representatives from many countries, charged with studying the problem of international cooperation in the preparation of international critical tables. This group will report its findings to the next session of the Executive Committee of the ICSU.

## I. INTRODUCTION

Selenocyanates find practical use as sensitisers in photographic emulsions and for the preparation of organic derivatives of selenium. The use of selenocyanates is very promising for the production of metal selenides, which are of great value in electronics. It may also be assumed that the selenocyanates will find use in analytical chemistry, especially in various titrations in non-aqueous solutions and also in the separation of selenium and tellurium with the object of obtaining these elements in a high state of purity.

Investigation of the selenocyanates is also of great theoretical significance in connection with the more profound elucidation of the chemical individuality of selenium. Nevertheless, there are no reviews on the selenocyanates. Only the dissociation constants of silver, mercury, and cadmium selenocyanates are given in a handbook[1]. Even the book by Williams[2] on cyanogen and its compounds with various elements gives only general information about a few metal selenocyanates.

The present paper is the first attempt to systematise published information on the selenocyanates.

## II. SELENOCYANOGEN AND ITS PROPERTIES

Selenocyanogen has been prepared by a method similar to that used for the preparation of thiocyanogen[3], an ethereal solution of iodine being allowed to act on silver selenocyanate[4]:

$$2AgSeCN + I_2 = 2AgI + (SeCN)_2.$$

Selenocyanogen is a yellow powder soluble in light petroleum, chloroform, and carbon tetrachloride. It decomposes when dissolved in water. In the solid state it keeps well under a vacuum. Its structure may be represented as two isomers N≡C–Se–Se–C≡N and Se=C=N–N=C=Se.

By analogy with thiocyanogen, selenocyanogen can combine with metals and also form compounds with some non-metals. For example, a compound with selenium is known; this consists of an unbranched chain with three atoms of bivalent selenium in the middle and CN groups at the ends. The distances between the atoms in $Se(SeCN)_2$ have been found[15] to be Se–Se (2.33 Å), Se–C (1.83 Å), and C–N (1.05 Å). The Se–Se–Se valence angle is 101°.

Caesium trisselenocyanate $Cs(SeCN)_3$, which may be regarded as a polyhalide type of compound, has been obtained by the action of an ethereal solution of selenocyanogen on an alcoholic solution of caesium selenocyanate. Caesium trisselenocyanate consists of reddish brown monoclinic prisms stable in air; it is soluble in alcohol but is decomposed by water[6]. It has been shown that the compounds $KNCSeI_2$, $K(NCSe)_2I$, and $K(NCSe)_3$ are formed in the potentiometric titration of KNCSe with iodine solution.

Selenocyanic acid HNCSe was obtained by Crookes by the action of hydrogen sulphide on $Pb(SeCN)_2$ suspended in water[7]:

$$Pb(SeCN)_2 + H_2S = PbS + 2HNCSe.$$

HNCSe is known only in solution. It dissolves iron and zinc with liberation of hydrogen and displaces carbon dioxide from carbonates.

## III. ANALYTICAL CHEMISTRY OF THE $SeCN^-$ ION

The quantitative analysis of selenocyanate solutions may be carried out by the usual argentometric titration with diphenylcarbazone[8], and also by potentiometric titration of the appropriate solutions with silver nitrate[19] or mercury perchlorate[10].

In the analysis of small quantities of selenocyanates, good results may be obtained by argentometric determination of the selenium[11]. The selenocyanate ion is converted to selenite by the action of nitric acid; an excess of silver nitrate and crystalline hydrazinium sulphate are added to the acid solution. Part of the silver is converted into silver selenide. The excess of silver nitrate is titrated against ammonium thiocyanate.

The concentration of selenocyanates soluble, or even slightly soluble in water, may be conveniently determined as selenium. The selenocyanates are decomposed with hydrochloric acid:

$$KNCSe + HCl = KCl + HCN + Se.$$

The selenium that separates is filtered off, dried at 100–110°, and weighed. This method gives good results in the analysis of salts in which the selenocyanate ion is not strongly bound. Apart from selenocyanates of the alkali and alkaline-earth metals, the salts of cadmium, cobalt, nickel, and even lead may be analysed by the method. The selenocyanates of silver, mercury, copper, and platinum are not completely decomposed by hydrochloric acid, part of the selenium appearing to be precipitated as selenide.

In recent years highly sensitive methods for the determination of selenium with the use of organic reagents have been developed[12–14]. These methods have been reviewed by Ryabchikov and Nazarenko[15]. The reagents may also be used in the analysis of selenocyanates.

## IV. SIMPLE SELENOCYANATES AND THEIR PROPERTIES

The most studied compound of this series is potassium selenocyanate, first obtained by the fusion of selenium with potassium hexacyanoferrate(II).[16] It may be assumed that this reaction proceeds in the same way as the reaction of sulphur with potassium hexacyanoferrate(II):

$$6Se + 2K_4Fe(CN)_6 = 6KNCSe + FeK_2Fe(CN)_6.$$

White crystals of KNCSe are obtained when the melt is extracted. Since the selenocyanate ion is easily decomposed in the presence of water, absolute alcohol has replaced water in the extraction[7].

Later, methods for the preparation of KNCSe were proposed in which selenium was dissolved in a concentrated aqueous solution of KCN[4,17] or fused with potassium cyanide[18], the melt being subsequently extracted with water[19].

A very pure product was also obtained by boiling a suspension of selenium and potassium cyanide in absolute alcohol[20]. However, because of the interaction of the selenocyanate ion with alcohols and the formation of volatile evil-smelling alkyl selenides, this method is also inconvenient. A very unpleasant odour is also noticed in the extraction with alcohol of the product obtained by sintering selenium with potassium cyanide or potassium hexacyanoferrate(II). It is therefore more convenient to use acetone in the extraction[21]. A perfectly pure preparation of KNCSe was obtained by the reaction of selenium with potassium cyanide in liquid ammonia[22].

There are reports in the literature on the preparation of sodium selenocyanate by boiling red selenium with sodium cyanide in absolute alcohol[20]. Sodium selenocyanate may be obtained in good yield also by fusing selenium with sodium cyanide[21]. The density of sodium selenocyanate is 2.490 and that of potassium selenocyanate 2.347 g $cm^{-3}$.[20]

Caesium selenocyanate is also mentioned in the literature[6], but nothing is said about the properties of this salt. Ammonium selenocyanate was first obtained by Crookes by neutralising HNCSe with ammonia[7]. Later this salt was prepared by double decomposition between $(NH_4)_2SO_4$ and KNCSe in absolute alcohol[23], and its very poor stability noted.

Recently a communication was published on hydrazinium selenocyanate[24]. The tendency of this salt to isomerise was noted:

$$N_2H_5NCSe \rightleftharpoons H_2N–CSe–NH–NH_2.$$

Equilibrium in this reaction is rapidly reached in the presence of acetone and corresponds to 35% conversion of hydrazinium selenocyanate into the semicarbazide.

The selenocyanates of the alkaline-earth metals were first described by Crookes[7]. Since the salts he obtained were only analysed qualitatively, some caution must be used in dealing with his results. This refers particularly to the simple formulae for the salts put forward by Crookes. All the salts of the alkaline-earth metals and magnesium were obtained by the action of selenocyanic acid on the corresponding carbonates, with subsequent evaporation of the solutions over sulphuric acid in a vacuum desiccator.

As far as the properties of this group of compounds are concerned, there is more or less complete information in the literature on potassium selenocyanate. This is a colourless compound crystallising in the form of white acicular crystals, which deliquesce in air and are readily decomposed by acid vapours. When heated in a sealed vessel, potassium selenocyanate melts without decomposition; when heated in air, it decomposes at 100°. It dissolves readily in water, producing an appreciable reduction in temperature. The aqueous solution is alkaline; when the pH of the solution is reduced to 5, the salt begins to decompose.

Potassium selenocyanate behaves differently in the presence of foreign ions. As Lodzinska has pointed out, introduction of the ions $Na^+$, $K^+$, $Mg^{2+}$, $Ca^{2+}$, and $Ba^{2+}$ has no effect on decomposition pH of the salt[25]: in the presence of these cations, potassium selenocyanate begins to decompose, when hydrochloric acid is added, at pH 5.5–4.9. In the presence of the cations $Cd^{2+}$, $Hg^{2+}$, $Zn^{2+}$, $Pb^{2+}$, $Fe^{3+}$, and $Cr^{3+}$, however, decomposition begins somewhat earlier, at pH > 6. The cations $Ni^+$, $Co^{2+}$, and $Cu^{2+}$ decompose the selenocyanate ion still earlier, at pH > 7. According to Lodzinska, even at concentrations of cobalt, nickel, or copper cations of $10^{-4}$ g-ion litre$^{-1}$ decomposition of $SeCN^-$ begins at a hydrogen-ion concentration of $10^{-8}$ g-ion litre$^{-1}$.

The electrical conductivity of aqueous solutions of potassium selenocyanate has also been studied; according to Birckenbach, the equivalent conductivity at infinite dilution is 119.5 at 18° and 138.2 at 25°.[26] The decomposition voltage of KNCSe was found to be 1.10 V.[6,27].

From a study of decomposition voltages and also calculation of the electron affinity of atoms and groups of atoms, Birckenbach concluded that the selenocyanate ion has properties closely similar to those of the halide ions. According to this worker, the selenocyanate ion should be placed before the iodide ion in the sequence of halide and pseudohalide ions:

$SeCN^-$, $I^-$, $SCN^-$, $CN^-$, $Br^-$, $N_3^-$, $Cl^-$, $OCN^-$, $CNO^-$, $F^-$.

## V. SELENOCYANATES OF HEAVY METALS†

Selenocyanates of heavy metals that were sparingly soluble in water were obtained before other selenocyanates. They were prepared by the action of a solution of potassium selenocyanate on the corresponding salt of the metal. Thus, Crookes obtained silver selenocyanate as a slightly soluble white compound[7]. Later silver selenocyanate was isolated by other workers[4,20], who found its density to be 4.602[20] and its solubility product to be $4.0 \times 10^{-16}$ at 18–20°.[27] Crookes noted that when potassium selenocyanate was added to salts of bivalent copper a brown precipitate was formed. He assumed that this was copper selenocyanate. However, the compound was not obtained in the pure state. Attempts to obtain the selenocyanate of univalent copper was also unsuccessful for a long time[28].

We have prepared the salt CuSeCN from acetone solution[29]: a solution of KNCSe is saturated with copper(I) chloride, and CuSeCN is precipitated by the introduction of a small quantity of water. The salt obtained in this way is a white powder, sparingly soluble in water, alcohol, and acetone. The solubility product of CuSeCN, measured potentiometrically at 20°, is $1.82 \times 10^{-10}$.

Crookes mentions the preparation of $Zn(SeCN)_2$ by dissolving zinc or its oxide in selenocyanic acid, but he gives no analytical results on the salt and says nothing about its properties[7].

Cadmium selenocyanate is obtained much more easily than the zinc salt from aqueous solution because of its lower solubility[30]. $Cd(SeCN)_2$ is obtained by mixing solutions of cadmium nitrate and potassium selenocyanate, rapidly filtering the solution, and drying the product[30]. This salt is also obtained from non-aqueous solutions. The solubility product of $Cd(SeCN)_2$ at 20° is $1.93 \times 10^{-5}$.[30] The salt is sparingly soluble not only in water but also in alcohol and acetone; it dissolves readily in the presence of an excess of selenocyanate or iodide ions.

Mercury selenocyanate, which was prepared by Cameron and Davy by the action of KNCSe on mercury(II) acetate solution, is very similar to the cadmium salt[23]. It was also obtained by Rosenheim and Pritze, using $HgCl_2$ and KNCSe as starting materials[31]. $Hg(SeCN)_2$ separates from water as a white mass; it is sparingly soluble in water, and readily soluble in the presence of selenocyanates, iodides, and cyanides of the alkali metals.

With its poor solubility in water, mercury(II) selenocyanate is very similar to the iodide and the thiocyanate. Cadmium selenocyanate, however, differs markedly from the iodide and the thiocyanate. Being sparingly soluble in water, in contrast to the latter, cadmium selenocyanate closely resembles the mercury salts. In solubility and thermal stability, $Hg(SeCN)_2$ is more reminiscent of the iodide than of the other halides. There is a still greater similarity in this respect between the salts of univalent mercury. Cameron and Davy also obtained mercury(I) selenocyanate by the action of potassium selenocyanate on mercury(I) nitrate[23]. The salt $Hg_2(SeCN)_2$, like $HgI_2$, has an olive green colour.

Of the elements of Group III of the Periodic System, only thallium selenocyanate is known; this was obtained by the action of potassium selenocyanate on an aqueous–alcoholic solution of thallium acetate[20], a yellow precipitate of TlSeCN, sparingly soluble in water, being formed. The specific gravity of TlSeCN is 5.462.[20]

Lead selenocyanate was obtained in the same way as the thallium salt[7,20,32]. Spacu prepared the salt Pb(OH)SeCN.[33] The compound $Pb(SeCN)_2$ is a finely crystalline pale yellow powder with a density of 4.694.[20,32] It turns red on exposure to sunlight. When heated, lead selenocyanate decomposes at a temperature somewhat above 100°, without reaching the melting point. At 20° a saturated aqueous solution of lead selenocyanate has a concentration of 0.00239 M.[32] It is practically insoluble in acetone and

† The term "heavy metal" is used by the Reviewers to include such transition metals as copper and zinc (Ed. of Translation).

alcohol. The solubility product of $Pb(SeCN)_2$ at 20° is $3.34 \times 10^{-7}$ (ionic strength of solution ~ 4.[32]

The problem of preparing selenocyanates of the transition metals — iron, cobalt, nickel, etc. — is considerably more complicated. Spacu showed that $Co(NCSe)_2$ exists in solution, but he dod not succeed in obtaining the compound in the solid state[34].

Crookes tried to prepare iron(II) selenocyanate by the action of HNCSe on FeO, but only free selenium was obtained[7]. Attempts to prepare iron selenocyanate by the action of aqueous solutions of potassium selenocyanate on an iron(II) salt solution were also unsuccessful.

## VI. COMPLEXES BASED ON METAL SELENOCYANATES

Because of the poor stability of the $SeCN^-$ ion, and because many cations become more stable when converted from hydrates to ammines, most work on the preparation of selenocyanato-complexes has been devoted to compounds containing ammonia or various organic amines in their structure.

Spacu and his coworkers studied compounds of this type. They succeeded in obtaining the following compounds with pyridine (Py)[34]: $MPy_4(NCSe)_2$ (with $Co^{2+}$, $Ni^{2+}$, $Mn^{2+}$, $Zn^{2+}$, $Cd^{2+}$, $Fe^{2+}$), $MPy_2(NCSe)_2$ (with $Cd^{2+}$ and $Zn^{2+}$), and $NiPy_6(NCSe)_2$. The salt $CoPy_4(NCSe)_2$ was converted into $CoPy_2(NCSe)_2$ when kept in a vacuum at 70°.

Besides pyridine, Spacu introduced hexamethylenetetramine (Hex) as a ligand and obtained the salt $MHex_2(H_2O)_4 \cdot (NCSe)_2$, where M = $Co^{2+}$, $Ni^{2+}$, $Mn^{2+}$, $Zn^{2+}$, or $Fe^{2+}$.[34] A large number of compounds were obtained with ethylenediamine[36-38]. The selenocyanates of nickel, cobalt, copper, cadmium, and manganese also form complexes with toluidine, benzidine, ammonia[33], and phenylhydrazine[39]. Quite recently the salt $Cu(NH_3)_4(NCSe)_2$ has been obtained from aqueous solution[40].

Other compounds containing amines are the complex salts $[(CH_3)_4N]_2[Co(NCSe)_4]$ and $[Et_4N]_2[Co(NCSe)_4]$, where $Et_4N$ is tetraethylammonium[41].

Spacu compared selenocyanates with the corresponding thiocyanates, and found little difference in their properties; salts containing amines with the SeCN group are somewhat less soluble than analogous salts with the SCN group.

Some molecular selenocyanates separate from liquid ammonia when selenium acts on metal cyanides[22]: magnesium, aluminium, and zinc selenocyanates have been obtained in this way. Zinc selenocyanate $Zn(SeCN)_2 \cdot 4NH_3$ melts with slight decomposition when heated in a vacuum to 100°. Magnesium selenocyanate $Mg(NCSe)_2 \cdot 4NH_3$ decomposes when heated to 135°. When heated in a vacuum to 70° $Al(NCSe)_3 \cdot 5NH_3$ loses 2–2.5 molecules of ammonia, but at 75° it decomposes completely.

By analogy with ammine complexes, it would appear that many selenocyanates, unobtainable under ordinary conditions, might be obtained from ketone and ether solutions. This applies in particular to salts of the transition elements. This hypothesis has been partially confirmed in the case of cobalt and nickel selenocyanates with dioxan, which will be discussed below.

## VII. COMPLEX FORMATION INVOLVING THE SELENOCYANATE ION AS LIGAND AND AS CENTRAL ION

Potentiometric study of the $Ag^+$–$SeCN^-$–$H_2O$ system has demonstrated the existence of $Ag(SeCN)_3^{2-}$ complexes with a dissociation constant of $1.3 \times 10^{-14}$.[28,42] With a higher concentration of KNCSe in aqueous solution, $Ag(SeCN)_4^{3-}$ is formed. Under conditions such that the solubility method in aqueous solution is applicable, it can be shown that AgSeCN is formed[42].

The salt $KAg_2(SeCN)_3$ has been obtained when aqueous solutions of potassium selenocyanate are saturated with silver selenocyanate[43]. This salt is stable in air and sparingly soluble in water. Colourless crystals of $KAg(SeCN)_2$ separate from aqueous solution as regular cubes, in addition to crystals of $K_3Ag(SeCN)_4$ and finely acicular colourless crystals of $K_2Ag(SeCN)_3$. The last salt is better prepared from alcoholic and acetone solutions[43]. It has also been shown by the solubility method in aqueous solution that the mixed complexes $Ag(SeCN)_2 \cdot SCN^{2-}$[44] and $AgI(SeCN)_2^{2-}$[45] are formed. The salts $K_2Ag(SeCN)(SCN)_2$, $KAg_2(SeCN)_2(SCN)$,[44] and $KAg_2(CNSe) \cdot I_2$[45] have been obtained crystalline; the complexes $AgI_3(SeCN)^{3-}$ and $Ag(SeCN)_3(SCN)^{3-}$ have been detected potentiometrically[45].

Both in the character of complex formation and in stability the selenocyanato-complexes are reminiscent of iodo- and thiocyanato-complexes[46,47]. They are, however, more stable than the thiocyanato-complexes. It is for this reason that silver forms comparatively readily mixed selenocyanatothiocyanato- and halogenoselenocyanato- - complexes[45].

It has also been found that selenocyanates, like halides and thiocyanates[48-51], form silver complexes of cationic type[52]. A study of the solubility of AgSeCN in aqueous solutions of $AgNO_3$ and $AgClO_4$ has shown that the complexes $Ag_2SeCN^+$, $Ag_3SeCN^{2+}$, and $Ag_4SeCN^{3+}$ are formed[52]. It is interesting to note that the solubility of AgSeCN at corresponding concentrations of $AgNO_3$ is very close to the solubility of silver iodide[51]. However, in contrast to the selenocyanate system, the iodide system has no complex with coordination number 4.[49-51]. Crystalline $[Ag_3SeCN] \cdot (NO_3)_2$ and $[Ag_2SeCN]ClO_4$ are obtained from aqueous solution. These salts are stable in air but are decomposed to AgSeCN by water[52].

It is also possible that some other metals form selenocyanato-complexes with a central anion. Thus, it may be assumed that similar complexes with mercury ($Hg_2SeCN^{3+}$) and even cadmium ($Cd_2SeCN^{3+}$) exist.

The formation of a cadmium complex $Cd(SeCN)_4^{2-}$ with a dissociation constant of $2.5 \times 10^{-4}$ has been demonstrated polarographically[28]. A potentiometric study of aqueous and aqueous–acetone solutions has revealed the existence not only of $Cd(SeCN)_4^{2-}$ but also of other complexes — $Cd(SeCN)_6^{4-}$, $Cd(SeCN)_5^{3-}$, $Cd(SeCN)_3^-$, $Cd(SeCN)_2$, and $Cd(SeCN)^+$ — the dissociation constants of which have been calculated[30].

As with the halides, mercury forms more stable selenocyanates than cadmium. Thus, the dissociation constant of $Hg(SeCN)_4^{2-}$ is $2.8 \times 10^{-30}$, and that of $Hg(SeCN)_3^-$ is $3.8 \times 10^{-27}$.[28]

The complexes $Hg(SeCN)Cl$, $Hg(SeCN)_2$, $Hg(SeCN)_3^-$, and $Hg(SeCN)_4^{2-}$ have been detected by the conductometric titration of an aqueous solution of $HgCl_2$ with KNCSe solution[53].

Some mercury selenocyanates have been obtained in the solid state[31]. The salt Hg(SeCN)Cl and also the salt $KHg(SeCN)_3$, which is sparingly soluble in cold water and alcohol, have been obtained from aqueous solution. The latter salt was previously obtained by Cameron and Davy[23]. Potassium tetrakisselenocyanatomercurate, readily soluble in water and alcohol, was obtained in the form of large amber-yellow plates. With the use of an aqueous solution of this salt the sparingly soluble compounds $MHg(SeCN)_4$, where M = Zn, Co, Pb, or Cu, have been isolated[31,53]. According to Swinarski and Lodzinska, the solubility of the $MHg(SeCN)_4$ salts in water, acetone, and aqueous alcohol decrease in the order Cd > Co > Zn.[54] The solubility product of $CuHg(SeCN)_4$ in aqueous solution is $1.59 \times \times 10^{-10}$.[55] The lattice parameters and the coefficient of thermal expansion of $CoHg(SeCN)_4$ crystals have been determined[56].

Formation of the sparingly soluble $M[Hg(SeCN)_3]_2$, where M = Zn, Pb, or Cu, has been demonstrated, and the double salt $4Co[Hg(SeCN)_3]_2.Co(CH_3COO)_2$ has also been prepared[53].

Complex mercury salts of mixed type $KHg(SeCN)(CN)_2$ and $KHg(SeCN)Hal_2$ were obtained by Cameron and Davy[23]; they were prepared by the action of mercury halides on an alcoholic solution of KNCSe.

The selenocyanate complexes of lead have been studied only recently. A potentiometric study of aqueous solutions has shown that $Pb(SeCN)_6^{4-}$ ($K_6 = 1.41 \times 10^{-4}$ at 20°) is formed[57]. This complex was also detected in a study of the heterogeneous $Pb(SeCN)_2$–KNCSe–$H_2O$ system by the solubility method[32]. The salt $K_4Pb(SeCN)_6$, which is sparingly soluble in water and acetone, was obtained from an aqueous–acetone (7 M with respect to acetone) solution of KNCSe by saturating it with lead selenocyanate[32].

The selenocyanates of the transition metals have been little studied. We have been able to demonstrate the existence of $CoNCSe^+$ and to calculate its dissociation constant ($K = 0.063$) by spectrophotometry[58]. The existence of the nickel complex $NiNCSe^+$ has been demonstrated in the same way[59,60].

Ablov and Samus' obtained dimethylglyoximatocobalt(III) complexes containing the selenocyanato-group[61]. Fine plates of the potassium salt and rhombic prisms of the ammonium salt $M[Co(DH)_2(NCSe)_2]$, where M = K or $NH_4$ [and DH = HON : C(CH$_3$).C(CH$_3$) : NO– (Ed. of Translation)], were obtained from an aqueous–alcoholic solution. A solution of the latter salt gives characteristic precipitates with $Cd^{2+}$, $Fe^{2+}$, $Co^{2+}$, $Ni^{2+}$, and $Mg^{2+}$ cations. When hydrochloric acid is added to solutions of $K[Co(DH)_2(NCSe)_2]$, the acid $H[Co(DH)_2(NCSe)_2]$, which is sparingly soluble in water, is obtained; the action of alkali gives $[Co(DH)_2.(NCSe)H_2O].H_2O$.

When an alcoholic solution of potassium selenocyanate acts on $H_2PtCl_6$, a red-brown precipitate is formed, and when this is recrystallised from alcohol, it gives very fine hexahedral plates of $K_2Pt(SeCN)_6$[62,63]. If the preparation is carried out in aqueous solution, potassium hexakisselenocyanatoplatinae is obtained as a crystalline dihydrate[64]. Recrystallisation of this product from alcohol yields the anhydrous salt. Ammonium hexakisselenocyanatoplatinate $(NH_4)_2Pt(SeCN)_6$ is obtained as black rhombic crystals[65].

## VIII. SELENOCYANATO-COMPLEXES IN NON-AQUEOUS SOLUTIONS

As has been mentioned above, the selenocyanates are very sensitive to acids, and even to water. This appears to be due to the instability of the Se–C bond and also to the hydration of selenocyanate ions.

When it is considered that the introduction of non-aqueous solvents promotes a reduction in the hydration of ions[66], increased stability of the selenocyanates of many metals may be expected even in mixed solvents. The stability of the selenocyanate ion, and of complexes formed from it, is still more noticeably improved in solvents not capable of entering into solvolysis reactions with various salts. For this reason, even selenocyanates of the alkali metals are more stable in acetone and some other solvents than in water or alcohols. This is why the formation of copper(I) selenocyanato-complexes has been established in acetone by a study of the CuCl–KNCSe–$CH_3COCH_3$ system by the solubility method[29]. The salt KCu(SeCN)Cl is obtained as colourless crystals on crystallisation of the corresponding solution; it is decomposed by water and by alcohol with separation of CuSeCN[29]. Mixed selenocyanatothiocyanato-complexes of copper can also be shown to exist in acetone[44].

Copper(I) selenocyanate is very soluble in an acetone solution of KNCSe. It may be supposed that in this case, as with thiocyanates[67], the complex salts $K_2Cu(SeCN)_3$ and $K_3Cu(SeCN)_4$ are formed. However, the exact structure of the complexes formed on dissolution of CuSeCN has not been established, because the system undergoes rapid decomposition.

Reduction in the hydration of ions by the introduction of non-aqueous solvents, other conditions being similar, leads to the formation of higher complexes[66]. This is illustrated by silver selenocyanates. In aqueous solution the complex $Ag(SeCN)_3^{2-}$ is formed, but in a solution 7 M with respect to acetone, at the same concentrations of $NCSe^-$ ions, the complex $Ag(SeCN)_4^{3-}$ is formed[42]. A similar effect is observed in aqueous–methanolic and aqueous–dioxan solutions[68,69]. The complex $Ag(SeCN)_4^{3-}$ is mainly formed in high concentrations of methanol and in pure methanol[68].

From an alcoholic solution of potassium selenocyanate and gold(I) chloride, Clarke obtained fine, dark red crystals that rapidly decomposed[62]; he considered that these crystals corresponded to the salt $KAu(SeCN)_2$ (Au found 48.31%, compared with 43.94% calculated).

The interaction between potassium and cadmium selenocyanates in methanolic solution has been studied by electrical conductivity measurements, and the complex $Cd(SeCN)_3$ detected[30]. The salts $KCd(SeCN)_3.3CH_3COCH_3$, $K_2Cd(SeCN)_4.2CH_3COCH_3$, $K_2Cd(SeCN)_4$, $K_4Cd(SeCN)_6$, and also a number of cadmium halogenoselenocyanates have been obtained from acetone solution[70].

The dependence of the solubility of lead selenocyanate on the concentration of potassium selenocyanate in acetone solution has been studied, and formation of the complex $Pb(SeCN)_3^-$ demonstrated[32]. When the acetone solution is evaporated, the salt $KPb(SeCN)_3$ is obtained in fine silky yellowish green needles. The salt is readily soluble in acetone, but is decomposed by water[32].

We have studied the selenocyanato-complexes of cobalt and nickel in acetone and methanol solutions[58–60]. The formation of complexes from $MSeCN^+$ to $M(NCSe)_6^{4-}$, where

M = Co or Ni, has been demonstrated in these solutions by spectrophotometric and conductivity methods, and the dissociation constants of these complexes have been calculated.

The formation of nickel selenocyanato-complexes in dimethylformamide has also been studied. It has been shown that in this solvent complexes from $NiNCSe^+$ to $Ni(NCSe)_4^{2-}$ are formed. A comparison of the dissociation constants of nickel selenocyanates in different solvents shows that these complexes are most stable in acetone[71].

Complex selenocyanates of nickel and cobalt have been prepared from acetone solution[58-60]. Information on the composition, stability, and preparation of cobalt and nickel selenocyanates indicates that they are very similar to the thiocyanates[72,73].

Selenocyanates of manganese, cobalt, and nickel of composition $M(DMF)_4(NCSe)_2$ have been separated from dimethylformamide[40].

## IX. COMPLEX-FORMING CHARACTERISTICS OF THE $SeCN^-$ ION

The selenocyanate ion behaves as a pseudohalide ligand in complex-forming reactions. To determine the position occupied by this ion in the sequence of its analogues, we shall examine some selenocyanato-complexes and compare then with iodo-and thiocyanato-complexes.

From the dissociation constants of silver complexes of analogous composition with different ligands, it is easy to see that the selenocyanate ion is very close to the iodide ion in its complex-forming power[46,47]. The selenocyanato--complexes of silver are, however, more stable than the thiocyanato-complexes. In comparison with the latter, the selenocyanates separate more easily from solutions in equilibrium with a precipitate of the simple salt. Moreover, silver selenocyanates are easily formed as dinuclear complexes, which are reminiscent of iodo-complexes. Therefore, in their complexing power for silver ions selenocyanate and thiocyanate ions may be arranged in the series $I^- \geqslant NCSe^- > NCS^-$.

An analogous series is established on comparing the dissociation constants of thiocyanato-[74,75], iodo-[66,76], and selenocyanato-[36,57] complexes of lead, mercury, and cadmium.

It would seem that the above sequence of complex-forming power should be observed also in other cases. However, this is not so. Cobalt thiocyanates from $CoNCS^+$ to $Co(NCS)_4^{2-}$ are known in aqueous solution[77], but the selenocyanate ion forms only the simplest complex, and iodo-complexes of cobalt have not been detected in water at all. In this case, therefore, the sequence of complex--forming power $I^-$, $NCSe^-$, $NCS^-$ is in the reverse order. This applies to a still greater degree to nickel compounds[60,78].

Copper(II) thiocyanates have been described in the literature, but it appears that copper(II) selenocyanates are not formed[79,80].

## X. THE STRUCTURE OF SELENOCYANATES

The NCS group can be linked to metals through the nitrogen atom (isothiocyanate group), through the sulphur atom (thiocyanate group), and through the nitrogen and sulphur simultaneously (bridge thiocyanate group). It has been shown, for example, that in nickel and cobalt thiocyanato-complexes the ionic character of the M–NCS bond predominates, while in the thiocyanates of mercury, platinum, and silver the covalent character of the bond through sulphur predominates[81-83]. Since thiocyanates and selenocyanates are similar in properties, it is reasonable to suppose that the group NCSe can also form three types of bonds.

Two lines, at 2074 $cm^{-1}$ (2051) and 575 $cm^{-1}$, have been found in the Raman spectrum of aqueous solutions of KNCSe; these can be assigned to C–N and C–Se vibrations[84,85]. From this it was concluded that potassium selenocyanate had an ionic structure, and the structure $Se-C\equiv N$ was assigned to the $NCSe^-$ group. The same conclusion has been reached from study of the infrared spectra of KNCSe[41,86].

Examination of the infrared spectra of the compounds $CoA_2(NCSe)_2$ and $B_2Co(NCSe)_4$, where A is an amine and B is tetraalkylammonium or tetraarylarsonium, has shown that the selenocyanate group is attached to Co through N.[41,87,88].

Since $CoPy_2(NCS)_2$ and $CoPy_2(NCSe)_2$ have the same magnetic moment (5.1 $\beta$), an octahedral structure has been assigned to the latter compound. In solution in polar organic solvents, however, these compounds appear to have a tetrahedral configuration[35].

The compounds $CoHg(SeCN)_4$ and $CoHg(SCN)_4$ have been shown to be isomorphous[89]. Construction of Patterson projections confirmed the identity of the two structures. Therefore, in $CoHg(SeCN)_4$ the NCSe group forms a bridge between Hg and Co [as does the SCN bond in $CoHg(SCN)_4$[90]]; the selenocyanato-ligand is linked to mercury through the selenium, and to cobalt through the nitrogen[89]. The bidentate character of $NCSe^-$ in the $CoHg(SeCN)_4$ complex is obvious from infrared spectra[41,87]. The bridge structure also appears to occur in the silver selenocyanates[41]. In the $K_2Pt(SeCN)_6$ and $K_2Hg(SeCN)_4$ complexes the link between the selenocyanate group and the central atom is effected through the selenium[88].

A detailed study of the structure of the selenocyanates of the transition metals has begun in the Institute of General and Inorganic Chemistry of the USSR Academy of Sciences. Already results have been published of X-ray structure studies on the compounds $MA_4(NCSe)_2$ (where M = Co or Ni and A is dimethylformamide)[91]. These compounds are paramagnetic; the magnetic susceptibility of the cobalt salt is 3.22 $\beta$. X-Ray structure analysis has shown that in $MA_4(NCSe)_2$ the selenocyanate groups enter the inner sphere of the complex $[MA_4(NCSe)_2]$, which has an octahedral *trans*-configuration[91]. The NCSe group is linked to the central atom through the nitrogen, and the M–N=C angle is close to 180°.

A comparison of the stability of selenocyanato-complexes and their structure shows that those compounds in which the NCSe group is linked to the central atom through the selenium are more stable than the corresponding thiocyanates. Compounds in which the NCSe group is linked through the nitrogen, however, are less stable than the thiocyanates.

It will be seen from the above review of the literature that, right up to the 1950's, the number of metals that formed known coordination compounds with $NCSe^-$ ions was extremely small. Attempts to prepare selenocyanates of

a number of metals may have failed because aqueous solutions were used. Only selenocyanates of those metals that form stable complexes with $NCSe^-$ could be studied in water.

The range of existence of selenocyanato-complexes has been considerably extended by the use of non-aqueous solvents. With non-aqueous solutions it has become possible to study more fully both the compounds of the metals that form stable selenocyanates and the salts of such metals as cobalt, nickel, and copper, which do not form selenocyanato-complexes in water.

Comparison of results in the literature on selenocyanato-complexes shows that even metals with identical electron shells differ in their power of coordinating selenocyanate ligands. With the exception of the zinc subgroup, it is impossible in other groups of metals to trace a strict sequence in the stability of their complexes with their atomic number. Thus, in the copper subgroup, silver forms selenocyanato-complexes most easily. In Group III indium should form selenocyanato-complexes more readily than other metals in the tervalent state. Because of the high oxidation potential of $Tl^{3+}$, thallium, like lead, can form selenocyanates only in its lower valency state.

If the metals are compared according to Periods, the following points may be noted. In the Sixth Period the most stable selenocyanates in aqueous solution are formed by quadrivalent platinum and bivalent mercury, in the Fifth Period by silver and cadmium, and in the Fourth Period by cobalt. Therefore, as we go from the Sixth to the Fourth Period, the centre of complex formation is displaced to the left. From this it may be assumed that selenocyanates will be formed by iron, manganese, and other metals in this Period.

It is quite probable that in non-aqueous solvents selenocyanates not only of $Fe^{2+}$, $Fe^{3+}$, $Cr^{3+}$, $Mn^{2+}$, and $Zn^{2+}$, but even of gallium, tin, and other metals can be obtained.

Extension of the number of selenocyanates will permit this class of compounds to be characterised more fully and open the way to their practical use‡.

# STUDY OF THE THERMAL STABILITY OF INORGANIC PEROXO-COMPOUNDS BY THE DIFFERENTIAL THERMAL ANALYSIS METHOD

I. I. Vol'nov

The inorganic peroxo-compounds are special higher forms of oxygen compounds of the elements and every year they acquire new fields of use. The diverse use of the different types of this broad class of compounds is determined not only by their oxygen content, which can be readily released in active form, but also by the singular nature of the bonding to oxygen in their molecules.

The presence of the peroxo-group, the so-called "oxygen bridge" was thought until recently to be sufficient for defining "inorganic peroxo-compounds". A detailed study of the structure and properties of a series of peroxo-compounds, made in the 'thirties of the present century, with the active participation of Soviet scientists, showed that this concept embraces at least nine groups of compounds, which are distinguished by the nature of the bond between the oxygen atoms in the bridge and by the nature of the bond between the oxygen bridge and the atoms of the element forming the peroxo-compounds. Some authors tend to include all the inorganic peroxo-compounds within the framework of complex compounds dividing them into three groups: polyoxides, peroxo-acids, and peroxohydrates. However, the group of polyoxides includes peroxo-compounds with a crystal lattice consisting of metal ions (predominantly of the Ia and IIa subgroups of the Periodic System) and the molecular anions $O_2^{2-}$, $O_2^-$, and $O_3^-$ respectively, which differ both in their structure and in the nature and length of the O–O bond. The bonds of the metal atoms with the oxygen bridge in these compounds are of the ionic type, whereas in other peroxo-compounds the peroxo-group as such or in the form $H_2O_2$ or $HO_2$ is joined to the atom of the element forming the peroxo-compound by a coordinate, not an ionic bond. It is therefore desirable to keep the division of inorganic peroxo-compounds into simple and complex.

The simple inorganic peroxo-compounds can be subdivided into four groups: (1) the hydrogen peroxides, which are characterised by the presence of the hydrogen peroxide ion HO [presumably $HO_2^-$ (Ed. of Translation)]; (2) the peroxides, characterised by the presence of the peroxide ion $O_2^{2-}$; (3) the superoxides, characterised by the presence of the superoxide ion $O_2^-$; (4) the ozonides, characterised by the presence of the ozonide ion $O_3^-$.

The complex peroxo-compounds can be subdivided into five groups: (1) peroxo-acids and their salts, in which the peroxo-group forms part of the complex anion, mono- and poly-nuclear representatives of this group being known; (2) peroxo-complexes which are neither peroxo-acids nor their derivatives, represented by compounds which include in the inner sphere a peroxo-group (peroxo-complexes), or hydrogen peroxide (perhydro-complexes [Russian nomenclature (Ed. of Translation)]), or the hydrogen peroxo-group (hydrogen peroxo-complexes); (3) peroxide hydrates — addition compounds of peroxides with water of crystallisation; (4) peroxohydrates — molecular compounds of

peroxides or salts analogous to crystal hydrates containing hydrogen peroxide of crystallisation; (5) hydrates of peroxohydrates — molecular compounds of peroxides or salts which contain both water of crystallisation and hydrogen peroxide of crystallisation.

Specific properties of compounds of each of the above groups have been described in a monograph[1] and an article[2].

A characteristic property of the peroxo-compounds, whether simple or complex, is the ability to lose oxygen in an active form during thermal decomposition or under the action of chemical agents.

To determine whether it is possible to use inorganic peroxo-compounds as sources of chemically bound oxygen it is necessary to have accurate information on their behaviour on heating.

Up to 1952, with the exception of Kapustinskii and Bayushkina's data[3] on the dissociation temperature of $BaO_2$, obtained by use of an apparatus which was a combination of a Kurnakov thermal analysis apparatus and a Beckmann manostat, and data on the thermal decomposition of several minerals under the action of sodium peroxide, obtained by differential thermal analysis[4], the literature does not contain objective information about the thermal stability of the inorganic peroxo-compounds based on the use of the last method. In the Peroxide Compounds Laboratory of the Institute of General and Inorganic Chemistry of the Academy of Sciences of the USSR since 1952 Makarov, Rode, Mironov, Vol'nov, Dobrynina, Grigor'eva, Firsova, and Chamova have widely used the method of differential recording of heating curves on a Kurnakov recording pyrometer for the thermal characterisation of representatives of the above-mentioned groups of peroxide compounds. It appeared that, depending on the type of peroxo-compound, the nature of the heating curves is different. In recent years the method of differential thermal analysis has been applied to peroxides by several foreign scientists: Margrave, Hoffman, Ghormley, Duval, etc.

It is necessary to note that unlike the manostat-pyrometric method used by Kapustinskii, which, as the author mentioned at the First Conference on Thermography[5] made possible the automation of the investigation of all three variables ($t$, $p$, and $c$), which determine the state of equilibrium of systems which dissociate with evolution of gas (liberation of oxygen, for peroxides), most of the heating curves for peroxo-compounds given in the present paper were recorded at a given external (atmospheric) pressure. Consequently, these curves reflect only the behaviour of the peroxo-compounds on heating under the real conditions of their use as sources of chemically bound oxygen and the value of the decomposition temperature thus obtained cannot be a basis for any rigorous thermodynamic calculations. Nevertheless, since these curves were obtained under comparable conditions, a comparison of them can throw light on the difference in structure of the individual groups of peroxo-compounds.

## STUDY OF THE THERMAL STABILITY OF THE PEROXIDES $M_2O_2$ AND $M^{II}O_2$†

Mironov[6] has widely used the thermographic method in investigating phase transformation diagrams of the $H_2O_2$–$H_2O$ system. Fig. 1 shows low-temperature heating curves

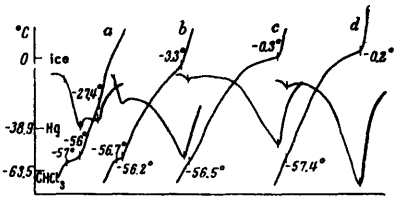

Fig. 1. Low-temperature heating curves of hydrogen peroxide solutions. $H_2O_2$, %: *a*) 77; *b*) 96.1; *c*) 99.3; *d*) 99.8.

for various compositions in this system, which can serve as a criterion of the purity of hydrogen peroxide. From the last curve of the diagram it is evident that thermography enables the presence of up to 0.2 wt.% water to be detected, which it is difficult to do by the usual chemical methods. Mironov[7] also took heating curves of the glassy substance which is formed when the dissociation products of water vapour in a glow discharge are frozen in a trap cooled with liquid air. The originality of the effects which appear on the curves and their difference from the effects obtained at low-temperature recording of solutions of hydrogen peroxide enabled the author to conclude that the glassy substance contained a compound of the type of higher peroxides of hydrogen. This conclusion was later also confirmed thermographically[8,9].

The heating curves for solutions of hydrogen peroxide of different concentrations in the region of positive temperatures [presumably above 0° (Ed. of Translation)] are characterised by the presence of an endothermic effect of boiling (at 151° for 100% $H_2O_2$) with a subsequent exothermic effect for the decomposition into water and oxygen, due to the liberation of heat (23.44 kcal mole$^{-1}$ for 100% $H_2O_2$).

Unlike the decomposition of hydrogen peroxide, the decomposition of alkali and alkaline earth metal peroxides into the oxide and hydrogen is accompanied by absorption of heat, as shown on the heating curves of lithium, sodium, calcium, and strontium peroxides[10–13]. It is not necessary to reproduce all these curves, since the effects characteristic for them also appear on the curves of the peroxide hydrates, which will be given below. It is also necessary to note that the effect at 510° on the heating curve of sodium peroxide[11] (Fig. 2), which was previously ascribed to fusion, really corresponds, according to new

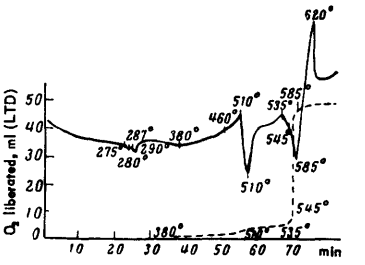

Fig. 2. Differential heating curve of sodium peroxide. Broken line: oxygen liberation curve.

† M denotes metal.

results[14], to the transformation of the hexagonal modification of $Na_2O_2$ (I) into another modification $Na_2O_2$ (II), the symmetry of which has not been determined. According to Tallman and Margrave[14], sodium peroxide melts above 596°.

## STUDY OF THE THERMAL STABILITY OF PEROXIDE HYDRATES, $M_2O_2.xH_2O$

There is considerable interest in the heating curves of the alkali and alkaline earth metal peroxide hydrates, which enable us to judge whether it is possible to obtain the peroxide in the anhydrous state. Fig. 3 shows the differential heating curves of lithium peroxide monohydrate[15] and sodium peroxide octahydrate[16,17]. On heating, lithium peroxide monohydrate loses water at 100–140° and forms the anhydrous peroxide. An endothermic effect, starting at 325°, corresponds to the decomposition of $Li_2O_2$ into $Li_2O$ and $\frac{1}{2}O_2$. On heating sodium peroxide octahydrate, it melts at 68°, dissolving in the water of crystallisation, and loses its active oxygen completely, being converted into sodium hydroxide dihydrate. An effect at 131° corresponds to the boiling off of the solution. Consequently, sodium peroxide cannot be obtained like lithium peroxide by dehydrating the hydrate formed in the oxide hydrate–hydrogen peroxide–water system.

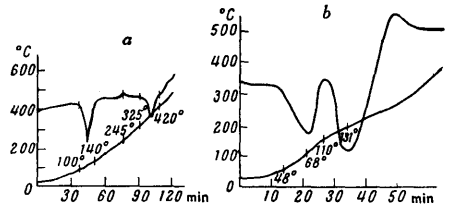

Fig. 3. Heating curves for:
*a*) lithium peroxide monohydrate $Li_2O_2.H_2O$; *b*) sodium peroxide octahydrate $Na_2O_2.8H_2O$.

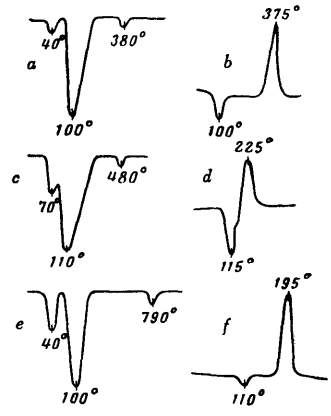

Fig. 4. Differential heating curves for peroxide hydrates of elements of Periodic Group II:
*a*) $CaO_2.8H_2O$; *b*) $MgO_2.xH_2O$; *c*) $SrO_2.8H_2O$; *d*) $ZnO_2.xH_2O$; *e*) $BaO_2.8H_2O$; *f*) $CdO_2.xH_2O$.

A marked difference is apparent on comparing the differential heating curves of calcium[12], strontium[18], and barium[19] peroxide octahydrates with those of the hydrated forms of magnesium[19], cadmium[19-21], and zinc[22] peroxides of gross composition $MO_2.xH_2O$ (Fig. 4). Those of the calcium, strontium, and barium peroxide octahydrates have three endothermic effects, corresponding respectively to incongruent melting, dehydration, and decomposition of the peroxide into the oxide and oxygen. With increase in the atomic weight of the element forming the peroxide, the stability of the latter increases: thermal decomposition starts at 380° for $CaO_2$, 480° for $SrO_2$, and 790° for $BaO_2$. On the heating curves of the hydrated forms of magnesium, zinc, and cadmium peroxides there is no fusion effect. The curves are characterised by the presence of a single endothermic effect within the limits 100–115°, corresponding to the removal of the mother-liquor, and a single exothermic effect, corresponding to decomposition to the oxide with liberation of oxygen and water. In this, with increase in the atomic weight of the element forming the peroxide the decomposition temperature decreases: $MgO_2$ 375°, $ZnO_2$ 225°‡, $CdO_2$ 195°. Owing to this difference and also because the oxides of these metals show less basic properties than calcium, strontium, and barium oxides, it can be suggested that the hydrated forms of magnesium, zinc, and cadmium peroxides are not hydrates of the true peroxides $MO_2$, but belong to a group intermediate between the peroxides of this composition and peroxo-acids. The probable structure of these compounds can be written (HO).M(OOH).$xH_2O$. The infrared spectra recently obtained[23] for these compounds also show the absence of water of crystallisation. If, for example, the magnesium peroxide hydrate had the actual formula $MgO_2.xH_2O$, its heating curve should show, after the removal of water, an endothermic effect for decomposition, as on the heating curve of, for example, $CaO_2.8H_2O$. The heats of the reactions $CaO_2 \rightarrow CaO + \frac{1}{2}O_2$ (-5.8 ± 0.5 kcal mole$^{-1}$) and $MgO_2 \rightarrow MgO + \frac{1}{2}O_2$ (-5.1 ± 1 kcal mole$^{-1}$) are very close.

## STUDY OF THE THERMAL STABILITY OF METAL PEROXIDE–HYDROGEN PEROXIDE ADDITION COMPOUNDS, $M_2O_2.xH_2O_2$, "PEROXOHYDRATES"

Differential heating curves of the alkali and alkaline earth metal peroxide–hydrogen peroxide addition compounds, that is, compounds in which hydrogen peroxide of crystallisation replaces water of crystallisation, are given in Fig. 5.[12,16,18,24-26] They show an exothermic effect of the decomposition of the crystallisation hydrogen peroxide in the range 45–65° with a subsequent endothermic effect of dehydration (with the sodium compound, fusion at 285°) at ~100° and the final endothermic effect of decomposition of the peroxide into the oxide and oxygen. On comparing the heating curves for the hydrated forms of magnesium, zinc, and cadmium peroxides (Fig. 4) with the heating curves of calcium, strontium, and barium peroxide–2-(hydrogen peroxide)s (Fig. 5), then the hypothesis that the first group of compounds contain hydrogen peroxide of crystallisation fails, since the exothermic effect corresponding to their decomposition does not precede the dehydration effect, as is characteristic for peroxide–(hydrogen peroxide) addition compounds.

‡ The report[21] that the decomposition of $ZnO_2$ at 200° is accompanied by an endothermic effect is evidently incorrect.

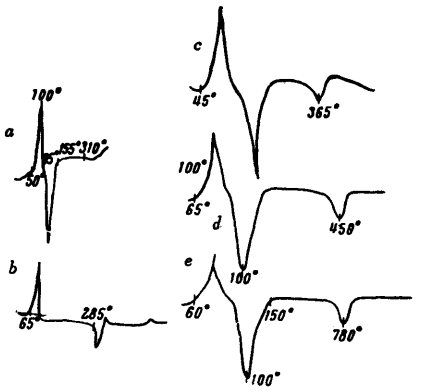

Fig. 5. Differential heating curves of the alkali and alkaline earth metal peroxide–(hydrogen peroxide) addition compounds:
*a*) $Li_2O_2.2H_2O_2$; *b*) $Na_2O_2.H_2O_2$; *c*) $CaO_2.2H_2O_2$; *d*) $SrO_2.2H_2O_2$; *e*) $BaO_2.2H_2O_2$.

## STUDY OF THE THERMAL STABILITY OF THE SUPEROXIDES $M^IO_2$

Only four representatives are known of this group of peroxide compounds: sodium, potassium, rubidium, and caesium superoxides. We have obtained the calcium, strontium, and barium superoxides[27] only admixed with peroxide and hydroxide of the metal. Rode[11,28] has made a detailed study of the behaviour of sodium superoxide on heating. It was found (Fig. 6) that in dry oxygen sodium superoxide starts to decompose at ~120°, in dry, $CO_2$-free air at 80–90°. In oxygen at 250° and in dry, $CO_2$-free air at ~215° it decomposes vigorously and endothermically with formation of sodium peroxide. Rode[29] also confirmed thermographically (Fig. 7) that sodium and potassium superoxides had two low-temperature polymorphic transformations, at -43° and -80° and at -75° and -120° respectively. As for the melting point of potassium superoxide, it must be pointed out that the values of 380°[30] and 440°[31] given in the literature were found over 30 years

ago and were evidently obtained with insufficiently pure material. In the Peroxide Compounds Laboratory of the Institute of General and Inorganic Chemistry a heating curve has been recorded for caesium superoxide prepared in a pure form[45] (Fig. 8); it has an endothermic effect for fusion at 450°. The effect at 475° is due to the reaction of caesium oxide with the glass of the test-tube in which the recording was made. Fig. 9 shows the heating curve obtained by Vol'nov[27] for a preparation containing 16% calcium superoxide as well as calcium peroxide and hydroxide. The interpretation of this curve, together with chemical analysis and magnetic measurements, showed that the exothermic effect at 290° corresponds to the decomposition of

the superoxide and the endothermic effects at 392° and 516° correspond to the decomposition of calcium peroxide and hydroxide to the oxide.

## STUDY OF THE THERMAL STABILITY OF THE ALKALI METAL OZONIDES $M^{I}O_3$

Sokovnin and Matveev[32,33] recorded the heating curves of a new class of inorganic peroxo-compounds, discovered by Kazarnovskii, but obtained by their use of a new method: the reaction of the corresponding superoxides with $O_3$ in a pseudo-liquefied layer created by a current of ozonised oxygen, with subsequent extraction with liquid ammonia. Caesium ozonide with a purity of 92.5% was first obtained by this method[32]. The heating curve of potassium ozonide (Fig. 10), in agreement with the thermodynamic data which show that during the decomposition of the ozonide to the superoxide 5.5 kcal mole$^{-1}$ is released, is characterised by the presence of an exothermic effect for decomposition to $KO_2$ at 60° ± 2° and the endothermic effect of the decomposition of $KO_2$ to $K_2O_2$ at 390°. The oxygen liberation curve shows clearly how the process takes place in two stages[33]. The heating curve of caesium ozonide[32] (Fig. 11) is characterised by the analogous exothermic effect of the decomposition of $CsO_3$ to $CsO_2$ at 70–100°. The exothermic effect at 408° corresponds to the fusion and decomposition of the decomposition products of $CsO_3$. Both effects are confirmed by the nature of the oxygen liberation curve, shown by a broken line in the diagram. A comparison of the heating curves for $KO_3$ and $CsO_3$ shows that the limit of thermal stability rises with the atomic number of the elements.

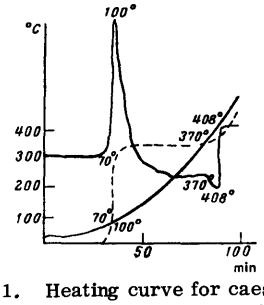

Fig. 11. Heating curve for caesium ozonide. Broken line: oxygen liberation curve.

## STUDY OF THE THERMAL STABILITY OF PEROXO--ACIDS AND THEIR SALTS

Peroxo-acids are quite unstable compounds which are difficult to isolate in the free state. Their salts have a greater thermal stability and can be used as initiators in some polymerisations. Grigor'eva and Selezneva[34] succeeded long ago in isolating crystalline hydrates of metaperoxo-acids of niobium and tantalum. The heating curves of these compounds are given in Fig. 12. The endothermic effects at 75–100° for $HNbO_4.H_2O$ and 100–145° for $HTaO_4.H_2O$ correspond to the decomposition of these compounds to the meta-acid with evolution of active oxygen and water[34]. The heating curves of the sodium salts of peroxoorthoniobic and peroxoorthotantalic acids $Na_3NbO_8$ and $Na_3TaO_8$ (Fig. 13) are characterised by the presence of an exothermic effect of the liberation of all four atoms of active oxygen at 130°.[34] The sodium salt of peroxoorthovanadic acid is decomposed in a similar manner, but at 115°.[35]

Fig. 14 shows the heating curves of several salts of dinuclear peroxo-acids: potassium peroxodicarbonate $K_2C_2O_6$,[36] potassium peroxodisulphate $K_2S_2O_8$,[37] and sodium peroxopyrotantalate $Na_4Ta_2O_{12}$.[35] The endothermic effect on the heating curve of the potassium peroxodicarbonate at

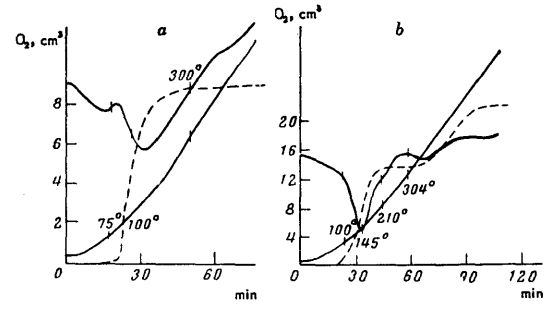

Fig. 12. Heating curve for hydrates of peroxoniobic and peroxotantalic acids:

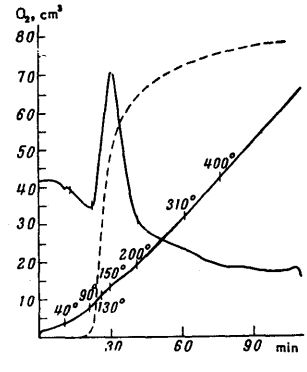

Fig. 13. Heating curves for sodium peroxoorthotellurate $Na_3TaO_8$. Broken line: oxygen liberation curve.

106° corresponds to its decomposition into carbonate with liberation of oxygen and carbon dioxide. The second effect at 198–200° corresponds to the decomposition of $KHCO_3$ impurity. On the heating curve of potassium peroxodisulphate the exothermic effect at 200° corresponds to the decomposition of this salt into pyrosulphate with liberation of oxygen. The endothermic effect at 350° corresponds to the fusion of pyrosulphate and the effect at 470° to the decomposition of the latter to sulphate with the liberation of sulphur trioxide. Sodium peroxopyrotantalate decomposes exothermically at 120° with liberation of all five atoms of active oxygen add the formation of $Na_4Ta_2O_7$. Potassium peroxopyrovanadate $K_4V_2O_{11}$ decomposes in a similar manner, but at 130–145°.[35]

Comparison of the heating curves shown in Fig. 14 suggests that when the decomposition of peroxo-salts is accompanied only by the liberation of active oxygen, this is shown by an exothermic effect (Figs. 14*b* and 14*c*). When the decomposition is more extensive, for example, by the reaction:

$$K_2C_2O_6 \rightarrow K_2CO_3 + CO_2 + {}^1/_2O_2$$

(Fig. 14*a*), the effect is endothermic.

Peroxide complexes which are not derivatives of peroxo--acids have been very little studied. Only one paper, devoted to the so-called uranium peroxide hydrates, has been published[38]. These compounds, which are peroxo--complexes and which contain a peroxo-group and water in the inner sphere, lose active oxygen stepwise on heating, with the formation of $U_3O_8$ finally at ~600°.

## STUDY OF THE THERMAL STABILITY OF SALTS WITH HYDROGEN PEROXIDE AND WATER OF CRYSTALLISATION

The heating curves of salts containing hydrogen peroxide of crystallisation have an exothermic effect for the decomposition of the peroxide into water and oxygen. In several alkali metal carbonate–hydrogen peroxide addition compounds (Fig. 15) this effect, which was studied by Chamova[39] and by Dobrynina[40], is preceded by the endothermic effect of the fusion of a salt in the crystallisation water. When the salt contains water of crystallisation in addition to hydrogen peroxide of crystallisation (the so-called hydrates of peroxyhydrates), the type of curves, as is evident from the example of $Na_2SiO_3.3H_2O_2.H_2O$,[41] is the same as for anhydrous hydrogen peroxide addition compounds (Fig. 16). But sometimes, as for example, on heating $Na_2CO_3.2H_2O_2.H_2O$ (Fig. 17), an endothermic effect, corresponding to the removal of water of crystallisation, precedes an exothermic effect of the decomposition of the

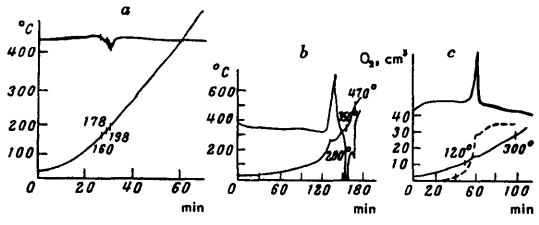

Fig. 14. Heating curves:

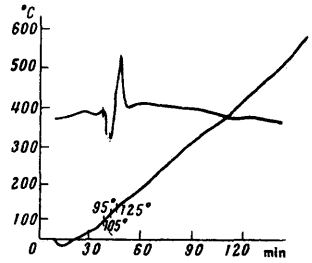

Fig. 17. Heating curve for sodium carbonate–2-(hydrogen peroxide)–water, $Na_2CO_3.2H_2O_2.H_2O$.

hydrogen peroxide of crystallisation. The curve permits the recommendation of temperature conditions for obtaining anhydrous sodium carbonate–hydrogen peroxide, which is widely used as a mild oxidant in the home and in the textile, food, and cosmetic industries. In some other salt–hydrogen peroxide addition compounds, for example, sodium sulphate–hydrogen peroxide[42], the endothermic

effect which corresponds to the incongruent melting of the compound precedes the exothermic effect of decomposition of hydrogen peroxide of crystallisation (Fig. 18).

Some bases – ammonia and urea – are also capable of forming molecular compounds with hydrogen peroxide. Their behaviuur on heating has been studied by Mironov[43], Lebedev[44], and Vol'nov[13]. Release of active oxygen in these compounds is shown on the heating curves by an exothermic effect at 40° and 80° respectively.

The example of several representatives of the groups of inorganic peroxo-compounds has shown that the use of differential thermal analysis in studying their thermal stability permits: (1) the rapid and objective determination of the nature and temperature limits of release of active oxygen: (b) the recommendation of a temperature regime for their production as hydrates, hydrogen peroxide addition compounds, or in the anhydrous state; (c) to recommend a temperature regime for their use in various oxidations; (d) to recommend temperature conditions for their safe storage; (e) to give a preliminary qualitative appraisal of the nature and strength of the bonding of the active oxygen in their molecules.

Depending on the group to which the peroxide compound belong, the heating curves are different:

1. The heating curves of the alkali and alkaline earth metal peroxides have an endothermic effect corresponding to the decomposition $M_2O_2 \rightarrow M_2O + \frac{1}{2}O_2$. With an increase in the atomic weight of the element forming the peroxide, the thermal stability increases. Barium peroxide is the most thermally stable compound of this group; it decomposes into oxide and oxygen at 790°.

2. The heating curves of alkali metal superoxides have successive endothermic effects for decomposition by the sequence $2MO_2 \rightarrow M_2O_2 + O_2 \rightarrow M_2O + \frac{1}{2}O_2$. The thermal stability of these compounds rises in the series Na–Cs.

3. The ozonides are the least stable of the simple (ionic) peroxides. Their heating curves have an exothermic effect for decomposition to superoxides by the reaction $MO_3 \rightarrow MO_2 + \frac{1}{2}O_2$ between 60° and 70°.

Fig. 18. Heating curve for sodium sulphate–3-(hydrogen peroxide), $Na_2SO_4.3H_2O_2$.

4. The heating curves of alkali and alkaline earth metal peroxide hydrates have an endothermic effect for decomposition by the reaction $M_2O_2 \rightarrow M_2O + \frac{1}{2}O_2$, which usually precedes the endothermic effects of incongruent melting and dehydration.

5. Unlike the alkaline earth metal peroxide hydrates, the hydrated forms of magnesium, zinc, and cadmium peroxides have heating curves with an endothermic effect corresponding to the loss of mother-liquor and the exothermic effect of decomposition. This can be explained by ascribing to these compounds the hydrogen peroxide form HO–M–OOH.

6. The heating curves of the salts of peroxo-acids have an exothermic effect at the thermal decomposition by the reaction $M_2E_2O_8 \rightarrow M_2E_2O_7 + \frac{1}{2}O_2$. When they undergo more extensive decomposition at the same time as they lose the active oxygen, there is an endothermic effect on their heating curves. The salts of the peroxo-acids exhibit considerable thermal stability and usually decompose above 130°. The peroxosulphates (~200°) are the most stable thermally.

7. The least stable of the peroxo-complexes are the molecular compounds with hydrogen peroxide – the "peroxohydrates" of peroxides and salts. Their heating curves have the exothermic effect of decomposition at 50–70°.

III. Technology of the production of complex fertilisers with use of urea 922

## I. INTRODUCTION

Urea is a highly concentrated fertiliser containing 46.6% nitrogen, free of inert materials, and is used either independently or in complex fertilisers which contain phosphorus and potassium as well as nitrogen. Furthermore, urea finds use as foodstuff for farm animals, is widely employed in plastics manufacture, in the pharmaceutical industry, and in medicine.

The increase in the demand by agriculture and industry for urea has brought about a considerable increase in the production in the USSR and abroad[1]. The greatest amount of urea is produced in Japan, where 85–90% of the total output is used as a fertiliser, compared with 60–65% in USA, and 20–40% in Europe.

In 1962 urea formed only 8% of the world production of nitrogenous fertilisers; in 1966 [1963 ?] this had grown to 17.5% calculated on nitrogen[2]. The production of urea for industrial purposes is also growing steadily.

In the USSR until recently the use of urea as a fertiliser was quite limited. In 1958 the total fraction of urea in the balance of nitrogenous fertilisers was 1% (calculated on

nitrogen). At the end of 1961 the level of production of the urea in the USSR had increased almost six times in comparison with 1958. In 1962 the USSR occupied third place in the world — after the USA and Japan — as regards output of urea.

According to the latest plan data in the USSR, owing to the improvement in the process the cost per unit of nitrogen in urea exceeds that in ammonium nitrate by 7–15%.[3] With the reduction in the cost of manufacture of urea and the increasing scale of production it is obviously finding wide application in agriculture as a component of fertilisers, both independent and complex.

To choose optimal conditions for carrying out the production of nitrogenous and complex fertilisers employing urea, several equilibrium systems have been studied. This work started in the USSR in the middle of the 'thirties; in recent years there have been further developments.

This article is a review of physicochemical investigations of systems which include urea and compounds containing nitrogen, phosphorus, potassium, and trace elements, and also the commercial methods of preparing fertilisers based on these systems.

## II. PHYSICOCHEMICAL INVESTIGATIONS

### 1. Solubility of Urea in Water and Ammonia

Various investigators have studied the urea–water binary system in detail[4–12]. A summary of the results obtained up to 1935 has been given in a monograph[11]. Soviet investigators subsequently studied the temperature region from complete solidification to 40°.[12–14].

Table 1 gives data on the solution compositions at the cryohydric points and the points of polymorphic transformations.

Various investigators have studied the solubility of urea in liquid ammonia[8,15]. The solubility of urea in liquid ammonia rises considerably with the temperature; starting from ~ 30° the solubility of urea in liquid ammonia exceeds its solubility in water. Urea and ammonia form the compound $CO(NH_2)_2 \cdot NH_3$; it can exist only in solutions containing an excess of ammonia, therefore the solubility curve for urea in liquid ammonia (Fig. 1) has a change in direction at the point $CO(NH_2)_2$ 77.9, $NH_3$ 22.1%, coinciding with the melting point of this compound, 46°.

Fig. 2 shows the $CO(NH_2)_2$–$NH_3$–$H_2O$ system; curves for the vapour pressure over saturated solutions are also given on this diagram.

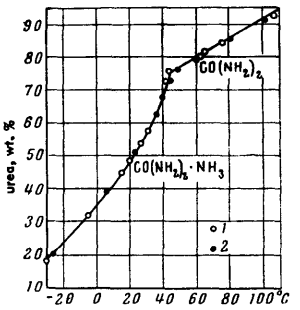

Fig. 1. Solubility curve for urea in liquid ammonia:
1) after Jänecke[8]; 2) after Scholl and Davis[15].

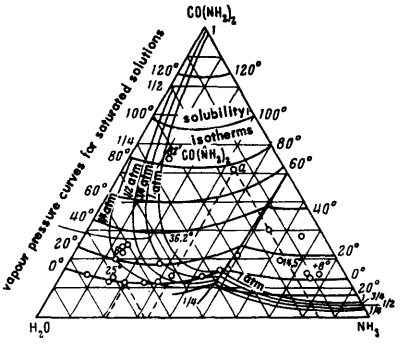

Fig. 2. Equilibrium diagram of the $CO(NH_2)_2$–$NH_3$–$H_2O$ system[8].

### 2. Systems Containing Urea and Nitrates

The $CO(NH_2)_2$–$NH_4NO_3$ anhydrous binary system has been studied by various authors[16,17]. Double compounds are not formed between the components; the eutectic point is at $NH_4NO_3$ 53.5%, 44.6°.[16] Soviet investigators have studied the viscosity and electrical conductivity of this system[18].

The $CO(NH_2)_2$–$NH_4NO_3$–$H_2O$ ternary system has been studied by the visual-polythermal method from 25° to complete solidification (-26.5°)[19] and by the isothermal method at 25°.[20] The polytherm (Fig. 3) is divided into seven crystallisation fields; in addition to the ice field there are three fields each for the polymorphic modifications of urea and ammonium nitrate. The existence of two series of solid solutions in the system has been suggested: urea in ammonium nitrate and ammonium nitrate in urea[19], but in the investigation of this system by the isothermal method solid solutions were not observed in the residues[20].

The electrical conductivity and viscosity of this system at 30° have also been studied[21]. The extrema on the curves in Figs. 4 and 5 are evidence of the formation of the complexes $NH_4NO_3 \cdot CO(NH_2)_2$ and $NH_4NO_3 \cdot 2CO(NH_2)_2$ in the solutions.

The common solubility in the $CO(NH_2)_2$–$NH_4NO_3$–$NH_3$–$H_2O$ system[22] was studied at 30° and 0° and various $NH_3$ : : ($NH_3$ + $H_2O$) ratios. The highest total solubility of the

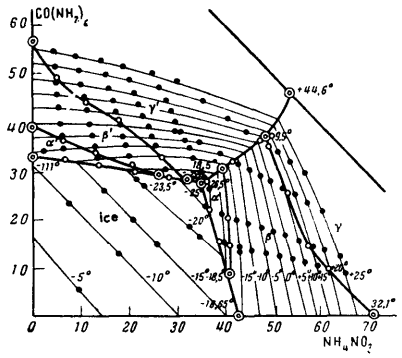

Fig. 3. Polythermal solubility diagram of the $CO(NH_2)_2$–$NH_4NO_3$–$H_2O$ system.

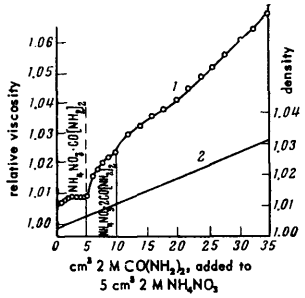

Fig. 4. Viscosity and density curves for the $CO(NH_2)_2$–$NH_4NO_3$–$H_2O$ system at 30°: 1) relative viscosity; 2) density.

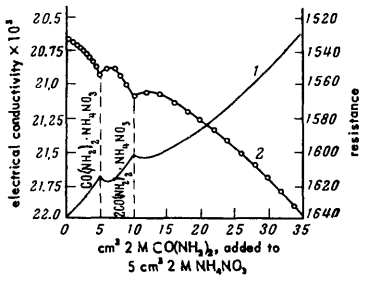

Fig. 5. Electrical conductivity curves for the $CO(NH_2)_2$–$NH_4NO_3$–$H_2O$ system at 30°: 1) electrical conductivity; 2) resistance.

salts at 30° — for 70% $NH_4OH$ and $NH_3$ : ($NH_3$ + $H_2O$) 0.7 — is 96.9%, of which 53.4% comes from the ammonium nitrate.

A complex of urea with ammonia starts to form at 0° and $NH_3$ : ($NH_3$ + $H_2O$) ratios of 0.4–0.5. At the ratio 0.4 the solid phase corresponds to the composition $NH_4NO_3$. $.CO(NH_2)_2$. $0.11NH_3$, at the ratio 0.5 to $NH_4NO_3.CO(NH_2)_2$. $.0.25NH_3$. It is suggested that as the $NH_3$ : ($NH_3$ + $H_2O$) ratio is increased the values of $n$ in the complex formed $CO(NH_2)_2.nNH_3$ will tend to unity.

The solubility of the salts at 30° increases with the $NH_3$ : ($NH_3$ + $H_2O$) ratio. At 0° such a relationship is not observed, owing to the formation of complexes.

On the basis of these results on the mutual solubility the authors [22] recommend for agricultural use a series of ammonia addition compounds, of composition given in Table 2.

Double compounds were not observed in a study of the $CO(NH_2)_2$–$NaNO_3$ anhydrous system [23]. The eutectic point is at $NaNO_3$ 29.5%, 83.9°.

The $CO(NH_2)_2$–$NH_4NO_3$–$NaNO_3$ ternary anhydrous system has been studied [23]. The ternary eutectic point is at $CO(NH_2)_2$ 45, $NH_4NO_3$ 47.5, $NaNO_3$ 7.59%, 37.1°.

The $NaNO_3$–$CO(NH_2)_2$–$H_2O$ three-component system was studied by the visual-polythermal method at temperatures from 40° to complete solidification (-19.55°). [24,25] The formation of an incongruently soluble compound $NaNO_3.CO(NH_2)_2.pH_2O$ was reported [25]. There are six crystallisation fields on the diagram (Fig. 6): ice, three fields of urea ($\alpha$, $\beta$, and $\gamma$ modifications), sodium nitrate, and the compound $NaNO_3.nCO(NH_2)_2.pH_2O$.

It was found that in the $CO(NH_2)_2$–$KNO_3$ binary system the eutectic point is at $CO(NH_2)_2$ 75.7, $KNO_3$ 24.3%, 110°. [26]

Fusion in the $CO(NH_2)_2$–$NH_4NO_3$–$KNO_3$ ternary system was also studied [26]. On the projection of crystallisation surface there is the field of the compound $2NH_4NO_3.KNO_3$, which melts incongruently at 170°. This field narrows to a transformation point at $CO(NH_2)_2$ 48, $NH_4NO_3$ 47, $KNO_3$ 5%, 66°. The ternary eutectic point is at $CO(NH_2)_2$ 44.3, $NH_4NO_3$ 49.9, $KNO_3$ 5.7%, 43° (Fig. 7).

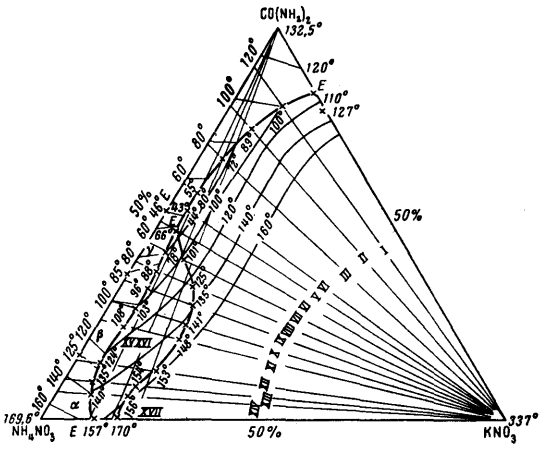

Fig. 7. Equilibrium diagram of the $CO(NH_2)_2$–$NH_4NO_3$–$KNO_3$ system.

Solubility in the $CO(NH_2)_2$–$KNO_3$–$H_2O$ system has been studied by several investigators [27,28]. Fig. 8 shows the diagram of the polytherms of this ternary system [27]; the investigation was by the visual-polythermal method, from 30° to complete solidification. Table 3 gives the compositions corresponding to the eutectic points according to the results of the different investigators.

Fig. 9 shows the 25° isotherm [29] of the $Ca(NO_3)_2$–$CO(NH_2)_2$–$H_2O$ system and the data for the system are also given in Table 4.

The compound $Ca(NO_3)_2.4CO(NH_2)_2$ was first isolated in 1918 by Bosch. A fertiliser of this composition is produced abroad; it has good physical properties, its hygroscopicity being less than that of calcium nitrate.

## 3. Systems Containing Urea and Phosphates

Several papers describe the study of the common solubility of urea and various phosphates. The $CO(NH_2)_2$–$H_3PO_4$–$H_2O$ system was studied by the visual-polythermal and isothermal methods [11,30-32]. However, the information given by various authors on the presence of compounds in this system is contradictory. Matignon and Dodé [30] found the compound $CO(NH_2)_2.H_3PO_4$ and the compound $3CO(NH_2)_2.2H_3PO_4$ has been reported [11]. When solubility in this system was studied by the visual-polythermal method three crystallisation fields were observed: ice, urea, and solid solutions of the type $mCO(NH_2)_2.nH_3PO_4$. [31]

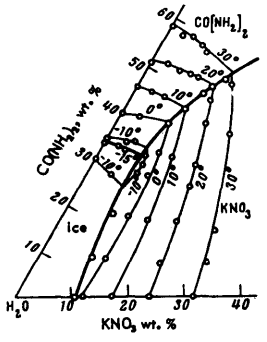

Fig. 8. Polythermal solubility diagram of the $CO(NH_2)_2$–$KNO_3$–$H_2O$ system.

According to recent information, in an isothermal study of solubility at 20° and 40° only urea, uronium phosphate, and their mixtures were observed in the solid phase [32]. Uronium phosphate dissolves congruently (Fig. 10).

The ammonium dihydrogen phosphate–urea–water system has been studied by the visual-polythermal method between -15.3° and 40° [33-35] and by the isothermal method at 25°. [20] It has one ternary point; chemical reaction between the components is not observed (Fig. 11). The cryohydric point is at $CO(NH_2)_2$ 28.8, $NH_4H_2PO_4$ 11.9, $H_2O$ 59.3%, -15.3°.

Solubility in the $(NH_4)_2HPO_4$–$CO(NH_2)_2$–$H_2O$ system was studied at temperatures from -16.6° to 30°. [14] The presence of the crystal hydrate of diammonium hydrogen phosphate $3(NH_4)_2HPO_4.2H_2O$ was confirmed (Fig. 12). Table 5 gives the invariant ternary points in this system.

The same work [14] gives the equilibrium diagram of the $CO(NH_2)_2$–$(NH_4)_2HPO_4$ system. The eutectic is at $CO(NH_2)_2$ 96.3, $(NH_4)_2HPO_4$ 3.7%, 126.7°.

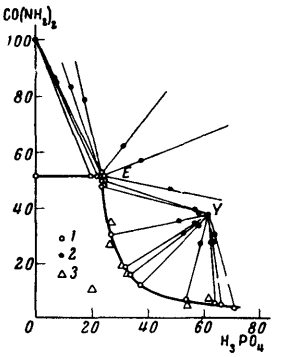

Fig. 10. Isothermal solubility diagram for the $CO(NH_2)_2$–$H_3PO_4$–$H_2O$ system at 20°. Phase compositions: 1) liquid; 2) solid; 3) liquid, calculated from the results of Blidin and coworkers[31]. *E* = uronium phosphate + urea. *Y* = uronium phosphate.

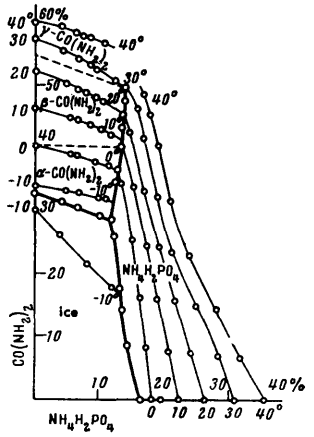

Fig. 11. Polythermal solubility diagram of the $CO(NH_2)_2$–$NH_4H_2PO_4$–$H_2O$ system.

TABLE 5. Invariant ternary points in the $(NH_4)_2HPO_4$–$CO(NH_2)_2$–$H_2O$ system.

| Point No. | Wt. % $CO(NH_2)_2$ | Wt. % $(NH_4)_2HPO_4$ | Wt. % $H_2O$ | per 100 moles dry salts: moles $CO(NH_2)_2$ | per 100 moles dry salts: moles $(NH_4)_2HPO_4$ | Crystallisation temperature, °C | Solid phase |
|---|---|---|---|---|---|---|---|
| 1 | 25.4 | 12.3 | 62.30 | 81.96 | 18.02 | —17.0 | ice + urea + $(NH_4)_2HPO_4.2H_2O$ |
| 2 | 26.7 | 15.90 | 57.4 | 79.87 | 20—13 | —16.2 | urea + $(NH_4)_2HPO_4$ + $(NH_4)_2HPO_4.2H_2O$ |

Solubility in the $KH_2PO_4$–$CO(NH_2)_2$–$H_2O$ system was studied by the visual-polythermal method from 35° to the temperature of complete solidification (-12.9°) [12] (Fig. 13). As the amount of potassium dihydrogen phosphate added is increased the temperature at the transformation point of one modification of urea into another falls from 22.5° to 1°. Evidently there is a region of restricted solid solutions of urea in $KH_2PO_4$ and the formation of compounds between the components is not observed.

## 4. Systems Containing Urea and Sulphates

Solubility in the $CO(NH_2)_2$–$(NH_4)_2SO_4$–$H_2O$ ternary system has been studied from -29° to 40°.[14] The polytherm diagram has six crystallisation fields: ice, solid solutions, the $\alpha$, $\beta$, and $\gamma$ modifications of urea, and the $(NH_4)_2SO_4$. There is one ternary point, at $CO(NH_2)_2$ 20, $(NH_4)_2SO_4$ 32, $H_2O$ 48%, -29°. Along its boundary with the urea field the solid solutions field stretches up to the eutectic of the $CO(NH_2)_2$–$H_2O$ binary system. As the temperature is raised the solid solutions field narrows and shifts to the urea side (Fig. 14).

The solubility of the $K_2SO_4$–$CO(NH_2)_2$–$H_2O$ system was studied by the visual-polythermal method from 25° to the temperature of complete solidification (-13°).[36] The presence of potassium sulphate in the solution has little effect

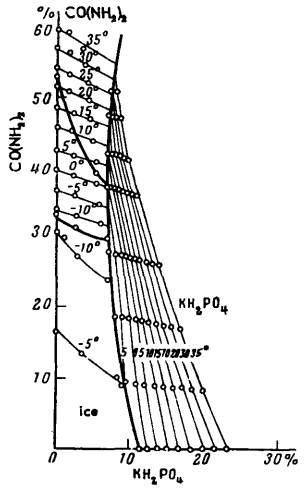

Fig. 13. Polythermal solubility diagram of the $KH_2PO_4$–$CO(NH_2)_2$–$H_2O$ system.

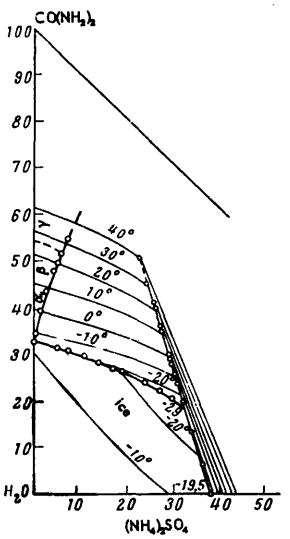

Fig. 14. Polythermal solubility diagram of the $CO(NH_2)_2$–$(NH_4)_2SO_4$–$H_2O$ system.

on the change in solubility of the urea. The ternary eutectic is at $CO(NH_2)_2$ 31.2, $K_2SO_4$ 4.9%, -13°.

The $CaSO_4$–$CO(NH_2)_2$–$H_2O$ ternary system was studied by the isothermal method[37–39] at 0°, 20°, 25°, 40°, and 70°. The compound $CaSO_4 \cdot 4CO(NH_2)_2$ is formed in the system (Fig. 15), and was first studied by Wittaker and coworkers[40].

Solubility in the $MgSO_4$–$CO(NH_2)_2$–$H_2O$ ternary system has been studied by the isothermal and visual-polythermal methods[41–45]. The complex $MgSO_4 \cdot 4CO(NH_2)_2 \cdot H_2O$ exists between 5° and 26° and decomposes at lower temperatures with liberation of urea, and at higher temperatures is converted into $MgSO_4 \cdot CO(NH_2)_2 \cdot 3H_2O$ (Fig. 16). The lower the temperature, the less the influence of urea on the solubility of magnesium sulphate.

5. Systems Containing Urea, Chlorides, and Other Compounds.

The KCl–$CO(NH_2)_2$–$H_2O$ system has been studied by several investigators[13,46,47] from -19.4° to 40°. There is no chemical interaction between the components of the

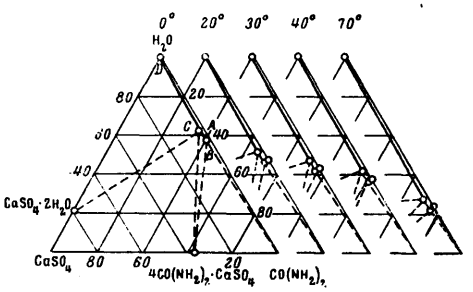

Fig. 15. Isothermal solubility diagrams of the $CaSO_4$–$CO(NH_2)_2$–$H_2O$ system (g per 100 g solution).

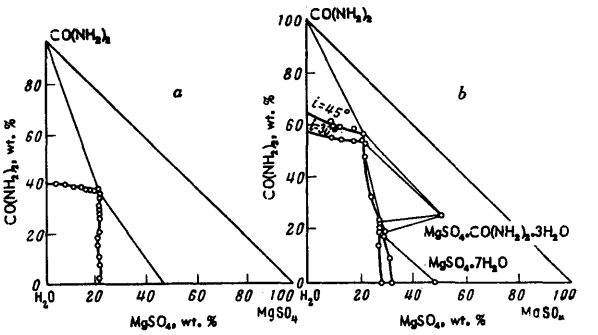

Fig. 16. Isothermal solubility diagrams of the $CO(NH_2)_2$–$MgSO_4$–$H_2O$ system: *a*) 0° isotherm; *b*) 30° and 45° isotherms.

system. The solubility of urea decreases in the presence of KCl. The ternary point of the system is at KCl 13.45, $CO(NH_2)_2$ 26.5%, -19.4°.

Solubility in the KOH–$CO(NH_2)_2$–$H_2O$ system has been studied[48]. Two solubility isotherms (0° and 30°) have been given. At 30° the isotherm has three parts, with the solid phases: $KOH \cdot H_2O$, $KOH \cdot 2H_2O$, and $CO(NH_2)_2$ (Fig. 17).

Several multicomponent systems have been studied to choose optimal conditions for the production of complex fertilisers. The $CO(NH_2)_2$–$NH_4NO_3$–$NH_4H_2PO_4$–$H_2O$ system was studied by the visual-polythermal method from -7° to 50° with $NH_4H_2PO_4$ : $NH_4NO_3$ weight ratios from 0.5 to 4 and total concentrations in the saturated solution of 30, 35, 37, and 40%,[49] and by the isothermal method at 25° and 50°.[20] The composition of the eutonic solution at 25° is: $CO(NH_2)_2$ 40.07, $NH_4NO_3$ 49.03, $NH_4H_2PO_4$ 0.78%.[20] The kinetics of the decomposition of urea in solutions in the presence of ammonium dihydrogen phosphate has been studied[20] at 50°. The 0° solubility isotherm in the $H_3PO_4$–$NH_3$–$CO(NH_2)_2$–KCl–$H_2O$ system has been studied[50]. In pursuing practical objectives, the authors studied restricted regions of this system in accordance with the agricultural requirements for the ratio $N : P_2O_5 : K_2O$ in liquid complex fertilisers. In addition, compositions of solutions for the molar ratios $NH_3 : H_3PO_4$ 1.7, 1.6, and 1.5. A linear relation was also found between the concentration of the total nutrients in solution and the temperature of crystallisation of the solid phase with which this solution is in equilibrium (Fig. 18).

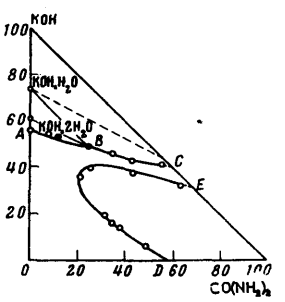

Fig. 17. Isothermal solubility diagram of the KOH–$CO(NH_2)_2$–$H_2O$ system at 30°.

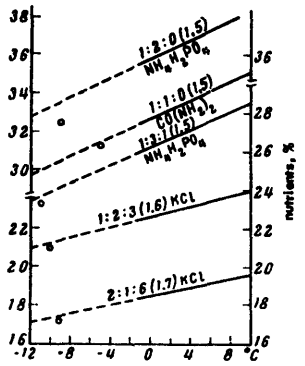

Fig. 18. Circles: measured values. Broken lines: extrapolated values. In parentheses: $NH_3:H_3PO_4$ molar values.

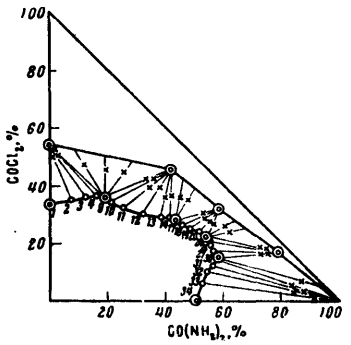

Fig. 20. Isothermal solubility diagram of the $CoCl_2-CO(NH_2)_2-H_2O$ system at 20°.

Solubility in the $CO(NH_2)_2-NH_4NO_3-NH_3-H_3PO_4-KCl-H_2O$ system at 0° was also studied only for selected ratios of the nutrients[50]. Fig. 19 gives a diagram of this system at 0°.

## 6. Systems Containing Urea and Trace Elements

In recent years several systems containing urea and compounds used as sources of trace elements (boron, manganese, copper, zinc, cobalt, etc.) have been investigated.

Mutual solubility in the $CoCl_2-CO(NH_2)_2-H_2O$ system at 20° has been studied[51] (Fig. 20, Table 6).

The 30° solubility isotherm of the $CoSO_4-CO(NH_2)_2-H_2O$ system[42,43] consists of four branches. Two complexes of cobalt and urea are formed in this system: $CoSO_4.2CO(NH_2)_2.4H_2O$ and $CoSO_4.6CO(NH_2)_2$ (Fig. 21).

In studying solubility in the $NiSO_4-CO(NH_2)_2-H_2O$ system[52] compounds analogous to those formed by urea with cobalt sulphate were found: $2CO(NH_2)_2.NiSO_4.4H_2O$ and $6CO(NH_2)_2.NiSO_4$. The system was studied at 25° and 40°.

TABLE 6. Invariant points of the $CoCl_2-CO(NH_2)_2-H_2O$ system.

| Composition of the solution, wt. % | | | Composition of the solid residues, wt. % | | Solid phase |
|---|---|---|---|---|---|

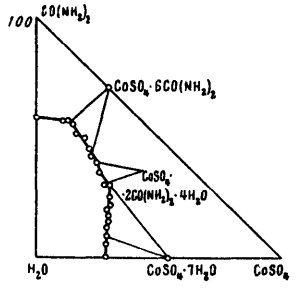

Fig. 21. Isothermal solubility diagram of the $CoSO_4-CO(NH_2)_2-H_2O$ system at 30°.

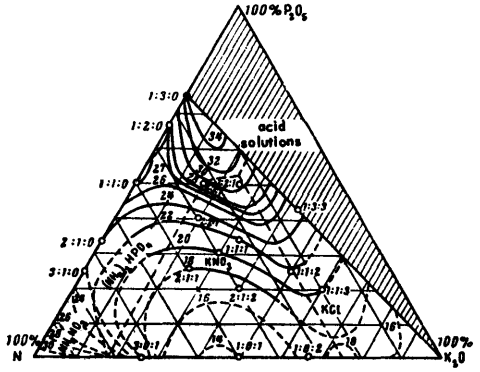

Fig. 19. Isothermal solubility diagram of the $CO(NH_2)_2-NH_4NO_3-H_3PO_4-NH_3-KCl-H_2O$ system at 0°.

The solubility of zinc sulphate in the presence of urea was studied by the visual-polythermal method at temperatures from -20.4° (the temperature of complete solidification) to 25°.[53] The ternary eutectic point is at $ZnSO_4$ 25.4, $CO(NH_2)_2$ 26.2, $H_2O$ 48.4%. Formation of complexes was not observed.

Solubility in the $CuSO_4-CO(NH_2)_2-H_2O$ system was also studied by the visual-polythermal method[42] from -18.4° to 30°. The solutions are viscous. The system tends to give supersaturated and supercooled solutions. The solubility of copper(II) sulphate rises from 12.5% at the eutectic point of the $CuSO_4-H_2O$ binary system to 23% at the ternary eutectic point, which suggests chemical reaction between the components. The concentrations of urea in solutions corresponding to the eutectic points of the binary and ternary systems are almost the same. The ternary eutectic

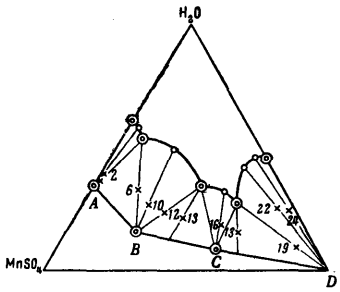

Fig.22. Isothermal solubility diagram of the $MnSO_4$–$CO(NH_2)_2$–$H_2O$ system at 20°: *A*) $MnSO_4.4H_2O$; *B*) $MnSO_4.CO(NH_2)_2.2H_2O$; *C*) $MnSO_4.4CO(NH_2)_2.2H_2O$; *D*) $CO(NH_2)_2$.

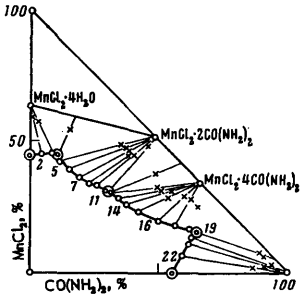

Fig.23. Isothermal solubility diagram of the $CO(NH_2)_2$–$MnCl_2$–$H_2O$ system at 30°.

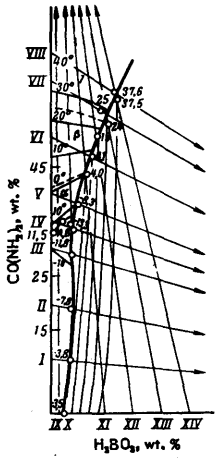

Fig.24. Polythermal solubility diagram of the $H_3BO_3$–$CO(NH_2)_2$–$H_2O$ system.

point is at $CO(NH_2)_2$ 32, $CuSO_4$ 23, $H_2O$ 45%, -18.4°. It has been suggested that two complexes of urea and copper(II) sulphate may be formed, by analogy with cobalt sulphate, in the liquid phase, but complexes have not been observed in the solid phase.

Solubility has been studied [54-56] in the $MnSO_4$–$CO(NH_2)_2$–$H_2O$ system at 10°, 20°, and 25° (Fig. 22).

The solubility in the $MnCl_2$–$CO(NH_2)_2$–$H_2O$ system was studied at 20° and 30° [57] and the specific gravity and viscosity of the equilibrium solutions were measured. Two compounds $MnCl_2.2CO(NH_2)_2.H_2O$ and $MnCl_2.4CO(NH_2)_2$ crystallise at 20° in addition to the two components, and the compounds $MnCl_2.2CO(NH_2)_2$ and $MnCl_2.4CO(NH_2)_2$ at 30° (Fig. 23).

Mutual solubility of the components in the $H_3BO_3$–$CO(NH_2)_2$–$H_2O$ system has been studied at temperatures from -14° (the temperature of complete solidification) to 50°. [58] Formation of compounds was not observed. The ternary eutectic point is at $H_3BO_3$ 3.7, $CO(NH_2)_2$ 36.5, $H_2O$ 59.8%, -14°. The polytherm of the ternary system is divided into three branches: ice, urea, and boric acid. The solubility of urea is almost unchanged in the presence of boric acid, but the solubility of boric acid rises slightly in the presence of urea (Fig. 24).

## III. TECHNOLOGY OF THE PRODUCTION OF COMPLEX FERTILISERS WITH USE OF UREA

The results of the physicochemical investigations were used to choose optimal conditions for various processes for the production of urea-containing fertilisers. Thus the production of the nitrogenous fertiliser, known on the world market under the trade name of "Calurea", is based on the production of a complex of urea and calcium nitrate. The ratio of the components in the compound corresponds to the formula $Ca(NO_3)_2.4CO(NH_2)_2$. This fertiliser displays better physicochemical properties than each of its constituents, that is, lower hygroscopicity and less deterioration on storage. When the calcium nitrate in this fertiliser is in excess then the mixture exhibits a greater hygroscopicity than calcium nitrate alone. The fertiliser is made by dissolving accurately measured quantities of urea in hot concentrated solutions of calcium nitrate (specific gravity 65° Bé) at 80–100°. The compound $Ca(NO_3)_2.4CO(NH_2)_2$ crystallises out on cooling [11]. Many patents have proposed different methods for obtaining fertilisers including $Ca(NO_3)_2.4CO(NH_2)_2$. [11,59-62] The mixtures can include salts of magnesium, calcium, and other metals. Fertilisers have also been patented in which urea is combined with calcium or magnesium basic nitrate, for example $Ca(OH)NO_3.2CO(NH_2)_2$. [63]

The existence of the compound $Ca(NO_3)_2.CO(NH_2)_2.3H_2O$ has been established. In comparison with "Calurea" it contains less urea and is readily granulated [64]. Urea is known to form solid solutions with some fertilising salts (for example, with ammonium sulphate, potassium phosphate, etc.) [12,14].

Several methods for preparing fertilisers containing urea and ammonium sulphate have been proposed [65,66]. Urea is dissolved in sulphuric acid at 80–1000° and the mixture neutralised with an excess of ammonia. Owing to the heat of reaction most of the water is vaporised. Then the mixture is dried and ground [65].

Mixed crystals of urea and $KNH_4HPO_4$ have been suggested for use as a fertiliser [67].

The widest use of urea is in the production of mixed fertilisers, which are composed of simple or double superphosphate, potassium salts, and other compounds. Urea is employed in these fertilisers predominantly as its ammines, often mixed with ammonium nitrate for the ammoniation of superphosphates [68-73].

Urea ammines cause hardly any corrosion of equipment made of ordinary steel.

Solutions obtained at one of the stages in the production of urea — at the exit of the synthesis column or after distillation — have also been suggested for use in the ammoniation of superphosphate. The fertiliser contains about 3.65% N, and 16.3% $P_2O_5$.[70]

Jensen has described[71] a process for the production of complex fertilisers containing urea. The experiments were made on a semi-plant apparatus using a TVA-type† ammoniator–granulator and a horizontal rotating drying drum. Urea ammines were used for the ammoniating solution and simple or double superphosphates and potassium chloride were employed. The author notes that no special difficulties were experienced in granulating complex fertilisers with $N:P_2O_5:K_2O$ ratios of 8:16:16, 10:10:10, or 5:20:20. The duration of the material in the granulator was 10 min, and the temperature of the product at entry 66–93°. It was in the drying drum for 15 min, and the temperature of the product on leaving was 66–121°. The hydrolysis of the urea was negligible.

Phillips[72] studied the conditions for granulating complex fertilisers containing simple or double superphosphate, potassium chloride, ammonium sulphate, etc. in an apparatus similar to that described. Ammoniating solutions of two compositions were used: ammines of ammonium nitrate and urea and ammonium nitrate ammine alone. It was noted that granulation proceeds best in working with solutions containing both ammonium nitrate and urea.

Jewell[74] studied, under laboratory conditions, the granulation of complex fertilisers with $N:P_2O_5:K_2O$ = = 10:10:18, obtained from superphosphate made from Moroccan phosphorite, ammonium nitrate or sulphate, urea, and potassium chloride. The amount of urea introduced into the fertiliser was varied from 2 to 15%. A mechanism has been suggested[74] for the hydrolysis of urea during the production and storage of complex fertilisers, depending on their acidity or alkalinity. The effect of moisture, acidity, and urea content on the stability of complex fertilisers has been determined.

The optimal conditions for obtaining and storing fertilisers so as to retain the stability of the product have been found, namely, entry temperature of product in drying $\geqslant$ 70°, reaching 90° during drying for $\geqslant$ 15 min. Temperature of storage of the fertiliser $\geqslant$ 35°, then the loss of nitrogen is negligible.

Several authors[11,73,75,76] note that to obtain fertilisers with good physicochemical properties, urea must be added in limited amounts. Several Japanese patents propose the manufacture of mixed fertilisers based on urea and superphosphate; the superphosphate should be neutralised without fail, for otherwise the urea reacts with the monocalcium phosphate to form uronium phosphate, dicalcium phosphate, and water[77] by the reaction:

$$Ca(H_2PO_4)_2\cdot H_2O+CO(NH_2)_2=H_3PO_4\cdot CO(NH_2)_2+CaHPO_4+H_2O.$$

Because of the presence of water the mixture becomes greasy, and unsuitable for spreading. Dolomite[78], ammonia[79,80], sodium hydrogen carbonate[81] are among the neutralising additions that have been suggested.

When neutralising additions are made, the monocalcium phosphate is partly or completely converted into dicalcium phosphate by the reaction:

$$CaH_2P_2O_8\cdot H_2O+CaCO_3+H_2O=2CaHPO_4\cdot 2H_2O+CO_2,$$

during which the hygroscopic moisture is converted into the water of crystallisation of the dicalcium phosphate. During the reaction of dicalcium phosphate dihydrate with urea, the latter accelerates the loss of the water of crystallisation[77]. Mixtures of dicalcium phosphate and urea exhibit approximately the same hygroscopicity as urea itself, with the exception of the instances when urea is present in small amounts.

Methods have been developed for making complex fertilisers with use of urea based on the products of the sulphuric acid[82–91] and nitric acid[92–102] treatment of phosphate raw materials. Thus, a Japanese patent proposes the addition of urea to a suspension of phosphogypsum in phosphoric acid, obtained by the decomposition of natural phosphate with sulphuric acid. The reaction is carried out at $\geqslant$ 80°. The suspension is then neutralised with ammonia and the product is dried at 70° to give a fertiliser with the composition (%): $CaSO_4.4CO(NH_2)_2$ 77.48, $NH_4H_2PO_4$ 20.86, $H_2O$ 1.9, $CaHPO_4.2H_2O$ traces, $P_2O_5$ 12.35, N 26.32. $N:P_2O_5$ 2.1:1.

Another Japanese patent[84] recommends the treatment of phosphorite with a mixture of sulphuric acid and urea followed by separation of the reaction products. The decomposition proceeds by the equation:

$$Ca_3(PO_4)_2+3H_2SO_4+12CO(NH_2)_2=2H_3PO_4+3[CaSO_4\cdot 4CO(NH_2)_2].$$

The reaction products contain calcium sulphate–4-urea in the precipitate and phosphoric acid and urea in the solution. Sodium alkylbenzenesulphonate is added to the reaction mixture to facilitate filtration. The yield of $H_3PO_4$ is 95%. Calcium sulphate is known to give a double compound with urea $CaSO_4.4CO(NH_2)_2$[40] which exhibits good physical properties. Apparently when urea is added to the product of the decomposition of phosphatic raw materials with sulphuric acid, which contain calcium sulphate, this double salt is formed. The Japanese investigators investigated the conditions for its production and determined its physicochemical constants and solubility in water[39,86–89].

Several patents recommend the use of phosphogypsum, which is a byproduct in the extraction method of making phosphoric acid, for mixing with urea.

Several articles and patents describe the production of urea-containing complex fertilisers based on the decomposition of phosphates with nitric acid. Japanese investigators published the first studies of the chemistry of the process[92,93]. Depending on the ratio between phosphorite, nitric acid, and urea, various reactions can take place, with the formation of calcium phosphates, uronium phosphate, and calcium nitrate–urea double compound.

An investigation of the hygroscopicity of the fertilisers produced showed that the best results are obtained when 1 mole $Ca_3(PO_4)_2$ takes not less than 4 moles conc. nitric acid (60%) and not less then 9 moles urea. The product contains $P_2O_{5\,tot}$ 9, $N_{tot}$ 24–25% (19–20% in the amide form).

Soviet investigators confirmed that the final products are double compounds: calcium nitrate–urea and uronium phosphate[94,95]. It was noted that uronium nitrate is

† TVA = Tennessee Valley Authority (Ed. of Translation).

formed as an intermediate. The following reactions take place:

(1) $Ca(NO_3)_2 \cdot 4H_2O + 2H_3PO_4 \cdot 5H_2O + 2CO(NH_2)_2 = 2CO(NH_2)_2 \cdot HNO_3 + Ca(H_2PO_4)_2 \cdot H_2O + aq$,

(2) $Ca(NO_3)_2 \cdot 4H_2O + 4CO(NH_2)_2 = Ca(NO_3)_2 - 4CO(NH_2)_2$,

(3) $2CO(NH_2)_2 \cdot HNO_3 + Ca(H_2PO_4)_2 \cdot H_2O + 4CO(NH_2)_2 = Ca(NO_3)_2 \cdot 4CO(NH_2)_2 + 2CO(NH_2)_2 \cdot H_3PO_4$.

Some authors propose to neutralise the nitric acid extract with CaO, $Ca(OH)_2$, $CaCO_3$, or ammonia before or after the introduction of urea [96-100]. Others add the urea without neutralisation [93,97,98].

It is recommended to add urea to the product of the decomposition of phosphatic raw materials with strong nitric acid (70%) — nitrosuperphosphate — which contains 6–8% free acid; this prevents the liberation of oxides of nitrogen from the product and facilitates the production of a fertiliser with good physicochemical properties [101,102].

Methods have also been proposed for the production of urea-containing complex fertilisers based on the treatment of phosphates with a mixture of sulphuric and nitric acids [97,103,104]. For example [104], a mixture of 100 g natural phosphate (31.1% $P_2O_5$), 68 g $K_2O$, and 50 g urea is treated with a mixture of 35 g $H_2SO_4$ (98%) and 17.23 g $HNO_3$ (50%). There is 16% excess of acid against the stoichiometric amount. The product is treated with 8 g $MgCO_3$. The fertiliser obtained contains: $P_2O_{5\,tot}$ 7.91, $P_2O_{5\,avail}$ 7.58, $P_2O_{5\,sol}$ 7.5, $N_{nitr}$ 5.43, $N_{urea}$ 5.06, $K_2O$ 8.52%.

A method for making complex fertilisers during urea synthesis has been proposed [105]. Phosphorus pentoxide is used to remove water from the sphere of reaction during the conversion of carbamate into urea and an excess of ammonia is introduced. The reactions are:

$$NH_4CO_2NH_2 = NH_2CONH_2 + H_2O;$$
$$3H_2O + P_2O_5 = H_3PO_4;$$
$$2NH_3 + H_3PO_4 = (NH_4)_2HPO_4;$$

and yield a mixture of urea and diammonium hydrogen phosphate. The introduction of phosphorus pentoxide lowers the temperature for the synthesis of urea, accelerates the process, and increases the yield of urea. It has been found that at 160° the conversion is 53% with respect to the $NH_3$, 48% with respect to the $CO_2$. The fertiliser contains N 31, $P_2O_5$ 33%.

A method for obtaining double concentrated fertilisers using urea and phosphorus pentoxide as raw materials has been patented in the USA. [106] In this method a solution of urea is mixed with $P_2O_5$, the mixture is cooled and ammonia is added, giving a melt containing urea and $NH_4H_2PO_4$; the slab is then granulated. The fertiliser contains N 24, $P_2O_5$ 31%.

A method has been proposed [107] for making highly concentrated fertilisers containing 60–81% nutrients by fusing urea with monocalcium phosphate and potassium metaphosphate. The melting point of the mixture is 122–129°. The fusion of urea, readily soluble $KH_2PO_4$, and $KPO_3$ (sparingly soluble in water) with the introduction into the melt of trace elements enables complex fertilisers to be produced with any combination of soluble and insoluble potassium phosphates and various ratios of nutrients. A disadvantage of the fusion process is the partial decomposition of the urea (2%). [107]

Shell Chemicals is commercially producing a fertiliser made by fusion sulphur with urea and granulating the product; it contains urea 40, sulphur 10%. [108]

In addition to the use of urea as a constituent of complex and complex mixed fertilisers, it (together with ammonia) is a principal source of nitrogen in the manufacture of liquid complex fertilisers. Unlike ammonium nitrate, urea weakly salts out ammonium phosphate, therefore liquid fertilisers based on it have a higher concentration of nutrients — 27%, instead of 15–17% for ammonium nitrate basis (liquid concentrated fertiliser does not crystallise at 0°).

Urea is known to form various polymeric compounds. The polymer with formaldehyde gives under certain conditions a fertiliser with a long-acting form of nitrogen. Such a fertiliser is especially effective on irrigated soils and under conditions of a moist climate. This increases the degree of utilisation of the nitrogen and decreases its loss.

The problems connected with the use of urea in liquid fertilisers and also the composition of the fertilisers which contain slow-acting forms of nitrogen will not be discussed in this article.

From this review it is evident that there have been many physicochemical investigations of systems which include urea and other fertilisers as components. Knowledge of the equilibrium systems allows optimal process conditions to be selected for obtaining urea-containing fertilisers of required composition, whether liquid or solid.

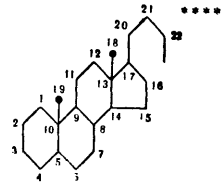
I. Methods of introducing fluorine into a steroid molecule 926
1. Opening of steroid oxides by fluorine-containing reagents 926
2. Preparation of fluorinated steroids from olefinic steroids 931
3. Replacement of other groups and other halogen atoms by fluorine 934
II. Physiological activity of fluorinated steroids 937

When studying methods for introducing an oxygen substituent at position 11 of a steroid molecule, Fried and Sabo[1] in 1954 observed unexpectedly that 9α-fluoro-11β,17α,21-trihydroxypregn-4-ene-3,20-dione has a several times greater hormonal and anti-arthritic activity than has cortisol. This discovery formed the beginning of a new field of research — the synthesis of modified steroidal compounds — in steroid chemistry. The number of papers and patents which have appeared during the past decade on the chemistry and pharmacology of these compounds has already reached thousands. The introduction of additional alkyl groups, heteroatoms, and double bonds into a steroid molecule produces a considerable increase in the hormonal activity of natural steroids. Special interest attaches to fluorinated steroids among modified steroids, since the introduction of fluorine into a steroid molecule produces a great change in the physiological activity of the hormone.

## I. METHODS OF INTRODUCING FLUORINE INTO A STEROID MOLECULE

The synthesis of 9α-fluoro-11β,17α,21-trihydroxypregn-4-ene-3,20-dione was first accomplished by Fried and Sabo[1], who opened the 9β,11β-oxide by means of hydrogen fluoride. Since then the cleavage of oxides has become one of the main methods for introducing fluorine into many positions in the steroid molecule. However, the exceptionally high physiological activity of fluorinated steroids has led investigators to seek new methods for the synthesis of fluorinated steroids. Thus methods have been worked out for introducing fluorine on the basis of the reaction of steroid olefins with an *N*-halogeno-amide and hydrogen fluoride[2] and with lead tetrafluoride[3], the reaction of steroid ketones with sulphur tetrafluoride[4], and of hydroxy-compounds with silver fluoride or hydrogen fluoride and other reagents; perchloryl fluoride has been studied and used for the synthesis of fluorinated steroids[5].

The above methods enable compounds to be prepared having isolated fluorine atoms, as well as *gem*- and *vic*-difluoro-derivatives. By combining several methods it is possible to introduce successively into the steroid molecule two, three, and four fluorine atoms, which produces a marked increase in the physiological activity of the steroids (see Section II).



The scope of the various methods of synthesising fluorinated steroids is summarised in Table 1, from which it is seen that each method has its own specific field of application, seldom overlapping with those of other methods. Therefore the suitability of different processes for introducing fluorine at a given position in the steroid molecule can be compared only in a few cases. Thus the synthesis of 6-fluoro-steroids, for example, can be effected by three methods, based on the addition of fluorine-containing reagents to the 5–6 double bond. When the steroid contains one double bond, synthesis through the 5α,6α-oxides is mostly used. With polyunsaturated steroids the corresponding oxides are obtained unselectively and in very low yields, and it therefore becomes more convenient to apply the addition of mixed halogens. The addition of lead tetrafluoride has the advantage over both these methods that it enables fluoro-derivatives having the 6α configuration to be obtained directly.

### 1. Opening of Steroid Oxides by Fluorine-Containing Reagents

The introduction of a fluorine atom into a steroid molecule by opening an epoxide with hydrogen fluoride, which takes place by an $S_N2$ mechanism and leads to a *trans*-diaxial cleavage of the oxide ring, has become one of the principal methods for introducing a fluorine atom not only into position 9 but also into positions 2, 6, 12, 15, 17, and 20 in the steroid molecule, since the corresponding epoxides are quite accessible and the techniques are simple.

Fluorinating agents which have been used in these cases are, besides hydrogen fluoride, 48% hydrofluoric acid, potassium hydrogen fluoride, and the boron trifluoride–ether

TABLE 1. Preparative possibilities of various methods for the fluorination of steroids.

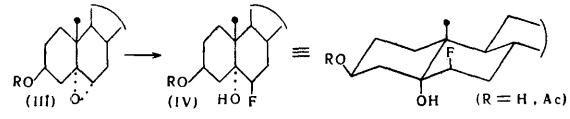
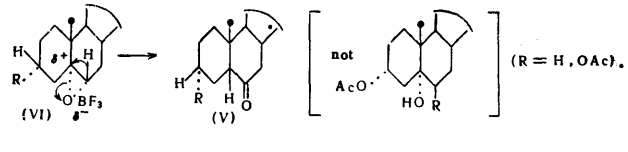
complex. The effect of the solvent, the temperature, and the duration of the reaction, and also of neighbouring substituents, on the course of the reaction has been studied.

Relatively little work has been done on the action of fluorine-containing reagents on oxide groups in the A ring of a steroid molecule. Thus cleavage of the 1β,2β-oxide (I) with hydrogen fluoride is accompanied by dehydration and yields the 2-fluoride (II) containing a fluorine atom adjacent to a double bond[6]:



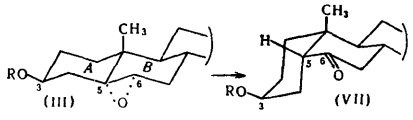
Fission of the 2α,3α-oxide under the same conditions gives the 2β-fluoro-3α-hydroxy-compound[7,8]. 4,5-Epoxides have been cleaved mainly with hydrochloric and hydrobromic acids, with the formation of 4-chloro- and 4-bromo-steroids[9,10].



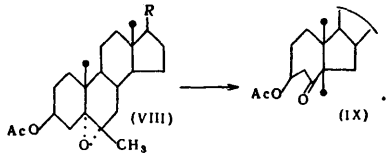
On the other hand, the cleavage of 5,6-epoxides has been subjected to quite detailed study on numerous examples and with various fluorinating reagents. The boron trifluoride–ether complex has been most widely used as such an agent, the reaction usually being conducted in benzene or in a mixture of benzene and ether at room temperature[11].

The opening of steroid 5α,6α-epoxides with the boron trifluoride–ether complex, first studied by Henbest and Wrigley[11,12], gives different products depending on the nature and the stereochemistry of the substituent attached to $C_{(3)}$. An epoxide which is unsubstituted at $C_{(3)}$ or else has a 3α-acetoxy-group (VI) gives as main product the corresponding $C_{(6)}$ ketone with rings A and B linked in the *cis*-configuration (V).

On the other hand, the 3β-hydroxy-epoxide — or its acetate (III) — undergoes cleavage by a quite different mechanism, the main product then being a fluorohydrin (IV).

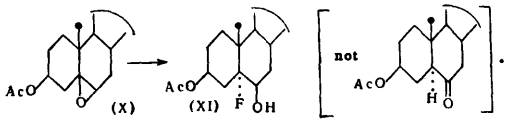


This course of the reaction was explained by considering the electronic and configurational factors. In unsubstituted epoxides (VI: R = H), boron trifluoride produces partial ionisation of the bond linking the epoxy-oxygen to the more alkylated $C_{(5)}$, promoting a simultaneous 1,2-hydride shift with the formation of a $C_{(6)}$ ketone (V).

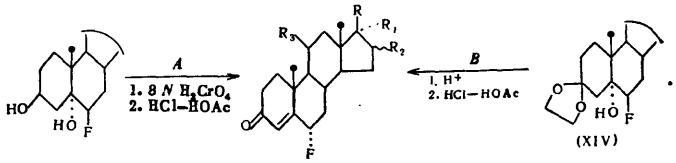


In the case of the 3β-alcohol (III) or its ester, however, two factors tend to prevent formation of the $C_{(6)}$ ketone. The first of these, the electronic factor, diminishes the partial ionisation of the bond linking the epoxy-oxygen to $C_{(5)}$ (this factor is necessary for formation of the $C_{(6)}$

ketone) owing to the increased inductive ($-I$) effect of the boron trifluoride–ether complex coordinated with the 3$\beta$--alcohol or ester. In this case the steric factor acts in the same direction, since formation of the $C_{(6)}$ ketone (VII) from (III) would have appreciably increased non-bonding 1,3-interactions in ring A, and the 3$\beta$-hydroxyl would have passed from the equatorial to the axial position.



Thus in this case the second reaction, resulting in formation of the fluorohydrin (IV), should predominate. When position 6 is substituted (e.g. by a methyl group) the reaction of the 5$\alpha$,6$\alpha$-oxide (VIII) with boron trifluoride is anomalous, being accompanied by rearrangement to an *A*-homo--*B*-nor-compound (IX).[13]



In the case of the 3$\alpha$-acetate of the 5$\alpha$,6$\alpha$-epoxide (VI: R = OAc), the above electronic and conformational factors act in opposite directions, but the predominance of the latter results in a very high yield of $C_{(6)}$ ketones (V).

5$\beta$,6$\beta$-Epoxides with no 3-substituent yield the $C_{(6)}$ ketone, whereas the 3$\beta$-acetoxy-compound (X) gives 5$\alpha$--fluoro-6$\beta$-hydroxy-derivatives (XI).

Bowers et al.[14], in an attempt to assess the role of electronic factors, studied the cleavage of 3-keto-5$\alpha$,6$\alpha$--epoxides with boron trifluoride. The above conformational factors, which play an important part in the fission of 3$\alpha$- and 3$\beta$-acetoxy-epoxides, are absent from this system, and therefore the composition of the reaction products is determined by competition between the increase in ionisation of the epoxy-oxygen under the influence of the boron trifluoride and its decrease due to the $-I$ effect of the keto-group. The latter obviously predominates, since treatment of 5$\alpha$,6$\alpha$-epoxypregnane-3,20-dione with the boron trifluoride–ether complex gives a 44% yield of the corresponding fluorohydrin.

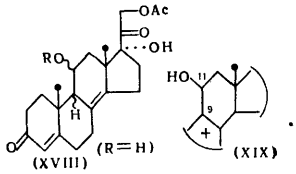
It was concluded from this that 3,3-ethylenedioxy--5$\alpha$,6$\alpha$-epoxides are suitable compounds for conversion into fluorohydrins, as was confirmed experimentally[14]. Thus the precursors of 6$\beta$-fluoro-5$\alpha$-hydroxy-compounds may be either 5$\alpha$,6$\alpha$-epoxy-3$\beta$-hydroxy-steroids and their acetates[11] or 5$\alpha$,6$\alpha$-epoxy-3,3-ethylenedioxy-steroids[14]. The last stage in the synthesis was the transition from 6$\beta$-fluoro-5$\alpha$-hydroxy-derivatives (XII) and (XIX) to the physiologically active 6$\alpha$-fluoro-4-en-3-ones (XIII), which was accomplished in two ways, *A* and *B*.[5-17] It was established that, when the 6$\beta$-fluoro-5$\alpha$-hydroxy-3-ones undergo isomerisation under the influence of hydrogen chloride in acetic acid, 6$\beta$-fluoro-analogues of 4-en-3-ones are formed, and these on further treatment are converted into 6$\alpha$-fluoro-4-en-3-ones. The scheme *A* has been used to synthesise the 6$\alpha$-fluoro-analogues of testosterone (XIII*a*), progesterone (XIII*b*),[15] 17$\alpha$-acetoxyprogesterone† (XIII*c*),[18] 17$\alpha$-bromoprogesterone (XIII*d*),[19,20] 16$\alpha$-methylcortisol (XIII*e*),[21,22] 16$\beta$-chloro-17$\alpha$-hydroxyprogesterone (XIII*f*),[23] 17$\alpha$-vinyltestosterone (XIII*g*),[24] and other derivatives[25-27]. Route *B* has provided syntheses of 6$\alpha$-fluoro-analogues of testosterone (XIII*a*), progesterone (XIII*b*), cortexone 17--acetate (XIII*h*), cortexone (XIII*i*), cortisone (XIII*j*),[14,17,28] and 16$\alpha$-methylcortisol (XIII*e*);[29] here, owing to the well--known instability of 17$\alpha$-hydroxy-20-ones to some types of Lewis acids, in the presence of which they undergo *D*-homo-rearrangement, the 17$\alpha$-hydroxy-group of the precursors was protected by acetylation ($R_1$ = OAc).

A modification of the above method is the synthesis of 6$\alpha$-fluorinated analogues of steroid hormones with the use of potassium hydrogen fluoride[30], hydrogen fluoride[31-39], or 48% hydrofluoric acid[40] to open the 5$\alpha$,6$\alpha$-oxides. In the last case 17$\alpha$-alkyl-6$\alpha$-fluorotestosterones[40], 6$\alpha$--fluorocortisone[41], 6$\alpha$-fluoro-16$\alpha$-methylcortisol[42], and other 6$\alpha$-fluorinated analogues[43-49] have been obtained.

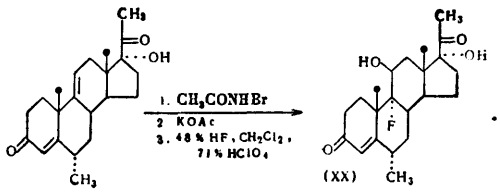
6-Fluoro-steroids can also be prepared from 6,7-epoxides (XV) and hydrogen fluoride. Dehydration of the resulting 6$\beta$-fluoro-7$\alpha$-hydroxy-derivative (XVI) yields a steroid 6-fluoro-4,6-dien-3-one (XVII).[50-55]



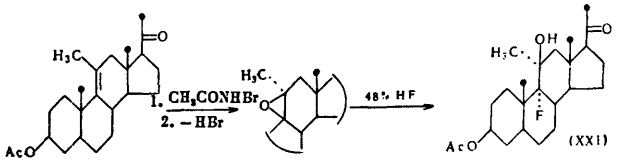
† The Russian text has been largely followed in the use of trivial names (Ed. of Translation).

‡ Monoperphthalic acid.

This procedure has been used to obtain 6-dehydro-6--fluoro-derivatives of 17α-ethynyltestosterone, progesterone, 17α-acetoxyprogesterone, cortexone, prednisone, etc.[50]

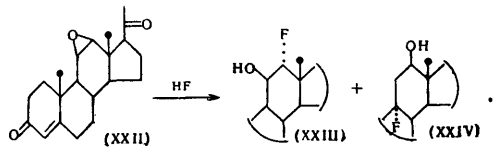


After Fried and Sabo's discovery of 9α-fluorocortisol[1,56], the cleavage of 9β,11β-epoxides of steroid hormones with hydrogen fluoride became the main method for introducing a fluorine atom into position 9 of a steroid molecule. Hirschmann et al.[57], and later Fried and Sabo[58], having carefully studied the reaction conditions, the kinetics, and the role of solvents, showed that, when the reaction is conducted in absolute chloroform, formation of 9α-fluoro--derivatives (obtained in 50% yield) is accompanied by that of a product (XVIII) containing no fluorine, the quantity of this compound depending on the reaction conditions. When the reaction is conducted in liquid hydrogen fluoride at -70°, (XVIII) becomes the main product.

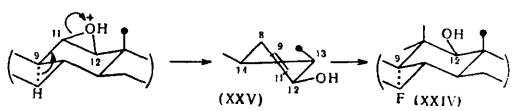


Formation of (XVIII) is probably due to inadequate concentration of the fluoride ion, resulting from the feeble dissociation of HF into $H^+$ and $F^-$ ions. Addition of a Lewis base (such as tetrahydrofuran) to the reaction medium raised the concentration of $F^-$ and diminished the quantity of (XVIII) with an increased yield of the fluorohydrin. Since, however, interaction of hydrogen fluoride with bases (in particular with tetrahydrofuran) lowers the acidity of the reaction medium, it is very important to select their optimum ratio. A kinetic study showed that, with a molar ratio of hydrogen fluoride to tetrahydrofuran of ~1.65 or above, the epoxide reacts at a sufficient rate at -30°. With a ratio of 1.94 the yield of the fluorohydrin reaches ~65%. The order in which the reagents are added is also important in this reaction: it is best to add a solution of the oxide in chloroform to a mixture of tetrahydrofuran and hydrogen fluoride cooled below -30°, which raises the yields to 75%. This reaction is kinetically of the first order with respect to the epoxide[57].

Fried and Sabo's method has been used to synthesise 9α-fluorinated derivatives of the pregnane[59-63] and androstane series[64-66]. Since 9α-fluorocortisol has found only limited application in medical practice owing to its broad spectrum of action[67], the same method has been used to prepare 9α-fluoro-analogues of corticosteroids containing also 2-alkyl,[68-72] 4-chloro,[73,74] 6-methyl,[75-79] 16-alkyl,[80-86] and 16-hydroxy-groups[75,76,87-94]. These substituents produce a considerable narrowing of the spectrum of biological action, at the same time intensifying the various types of activity (see Section II). For this purpose syntheses were made of compounds containing more than one fluorine atom, e.g. in the positions 6,9, 6,9,21, etc. A 9α-fluorine atom was introduced by Fried and Sabo's method into compounds already containing fluorine in position 6 or 21. In this way 6α,9α-difluoropregnanes[17,40,95-110] and 9α,21-difluoropregnanes[77,79,110,111] have been obtained.

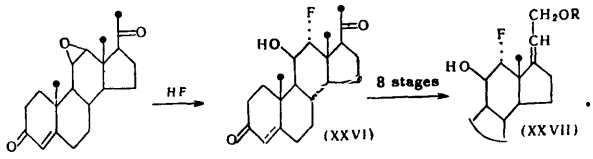


A somewhat modified method, involving the use of 48% hydrofluoric acid to cleave the 9β,11β-oxides, has been used to synthesise[112] 9α-fluoro-11β,17α-dihydroxy-6α--methylprogesterone (XX) and its 1-ene analogue:

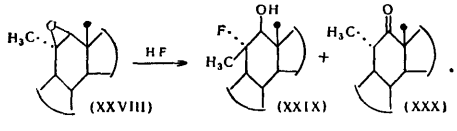


Introduction of a 9α-fluorine atom has been effected under the same conditions in the presence of an 11-methyl group[113,114]:

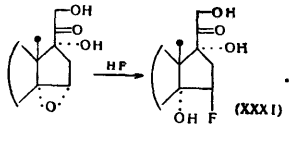
9α-Fluoro-analogues can be obtained also (together with 12-fluoro-derivatives) from 11β,12β-epoxides and hydrogen fluoride under the conditions employed by Fried and Sabo for the cleavage of 9β,11β-oxides. Thus in 1956 a paper appeared[115] on the synthesis of 12α-fluoro--11β-hydroxy- and -11-keto-progesterones. 11-Dehydroprogesterone gave with *N*-bromoacetamide a 45% yield of a bromohydrin, which formed in quantitative yield the 11β,12β-epoxide (XXII), from which the 11,12-fluorohydrin (XXIII) was obtained by the action of hydrogen fluoride in chloroform. In addition to a 70% yield of (XXIII), the hydrofluorination gives a 15% yield of the 9α-fluoro-12β-ol (XXIV). Application of the same reaction to an 11β,12β-epoxide in which ring A is saturated, and rings A and B are linked in the *cis* configuration, gives (XXIV) as the main product, whereas the 12α-fluoro-11β-hydroxy-derivative of type (XXIII) is formed only in small amounts[116]. This occurs also in the cleavage of 11β,12β-oxides of the spirostan series[117-119]:



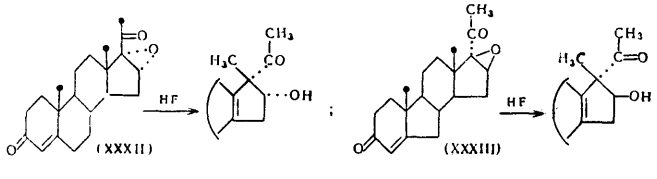
Formation of 9α-fluoro-12β-hydroxy-compounds of type (XXIV) from 11β,12β-oxides can be regarded as a simultaneous reaction involving the intermediate formation of the 9(11)-en-12β-ol (XXV) as an intermediate stage, followed by addition of HF to the resulting 9–11 double bond:



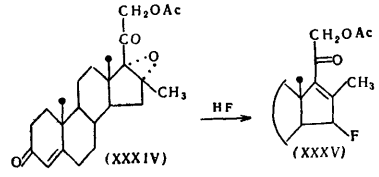
11β,12β-Epoxides have been used as starting materials for the synthesis of 12α-fluoro-analogues of androstane[120-123], progesterone[115,124,125], corticosterone[126-128], cortisone and prednisolone[129], 16α-hydroxyprednisolone[130],



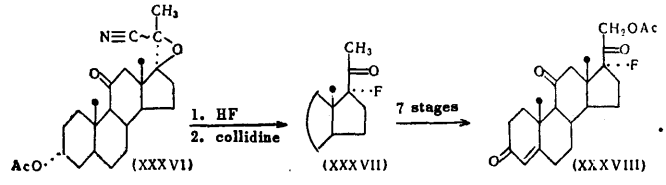
and other pregnanes[131-134]. For the synthesis of 12α--fluorocortisol, Fried et al.[135] tried to use 12α-fluoroprogesterone (XXVI) as intermediate, with subsequent introduction of the 17α- and 21-hydroxy-groups:



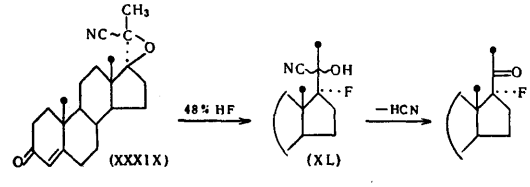
But it was found that, owing to steric and electronic factors, a 12α-fluorine atom prevents osmium tetroxide from approaching the 17–20 double bond, and the latter could not be oxidised in the compound (XXVII). This apparently explains the difficulty of cyclising the fluorohydrin (XXVI) to the oxide[135]. In order to avoid the effect of a 12α-fluoro--substituent, 11β,12β-epoxycortisone acetate was first synthesised, and smoothly converted in the usual way into the 12β-fluoro-analogue of cortisol. It is interesting that with 11α-methylated 11β,12β-epoxides (XXVIII) hydrogen fluoride reacts in two ways: under the influence of the electron-donor 11-methyl group, the oxide opens up with the formation of the 11α-fluoro-12β-hydroxy-11β-methyl derivative (XXIX), and this is accompanied by the acid--catalysed isomerisation of the epoxide to the 11α-methyl--12-one (XXX), the 12α-fluoro-derivative not being detected[136]:



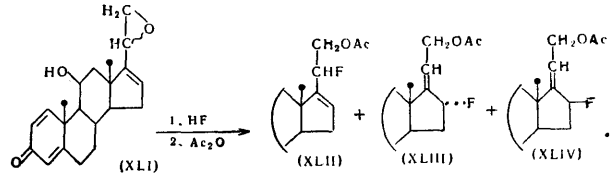
The 14α,15α-epoxide, in contrast to other steroid oxides, was extraordinarily stable towards such reagents as boiling acetic acid, trichloroacetic acid, etc.[137] Nevertheless, hydrogen fluoride[138,139] gives the normal *trans*-diaxial cleavage of the epoxide to form the corresponding 15β-fluoro-14α-hydroxy-derivative (XXXI):



Attempts to cleave the 16α,17α-epoxide and obtain 16-fluoro-compounds, by using hydrogen fluoride under the conditions described for the cleavage of 5α,6α- and 9β,11β-oxides, were unsuccessful[140-144]. It was shown[145] that, when hydrogen fluoride acts on 16,17-epoxides, in particular 16α,17α- and 16β,17β-epoxyprogesterones (XXXII) and (XXXIII), the latter undergo the Wagner–Meerwein rearrangement, no fluorine-containing products being detected:

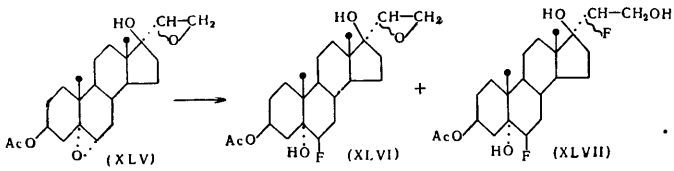


Fission of a 16α,17α-epoxide containing a 16β-methyl group (XXXIV) yielded the 15β-fluoro-16-methyl-16-ene (XXXV):[146]



Attempts to introduce fluorine into position 17 by the cleavage of 16,17-epoxypregnanes with hydrogen fluoride were likewise unsuccessful. A similar reaction with 20ξ-cyano--17,20-epoxy-17α-pregnanes (XXXVI) was investigated for the introduction of fluorine at position 17.[147-149] In this case the 17,20-oxide ring is opened under the influence of hydrogen fluoride with the formation of a 17α-fluoro-20--hydroxy-derivative; subsequent elimination of hydrocyanic acid yields the 17α-fluoro-20-ketone (XXXVII). This route has been used for the synthesis of 11-dehydro--17α-fluorocorticosterone acetate (XXXVIII):[147]

It is interesting that in the case of progesterone derivatives the cyano-epoxide (XXXIX) does not react with anhydrous hydrogen fluoride, giving the fluorohydrin (XL) only with 48% hydrofluoric acid[148]:

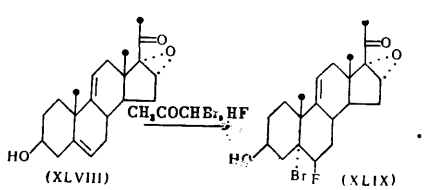


20ξ,21-Oxides have been least studied in relation to the action of fluorine-containing reagents. Until recently only the reaction of the 20ξ,21-epoxy-16-ene derivative (XLI) with hydrogen fluoride in the presence of acetic acid had been investigated[142,150]. The course of the reaction was ambiguous, the 16α (XLIII), 16β (XLIV), and 20ξ (XLII) fluorides being formed:

In the reaction of 5α,6α: 20ξ,21-dioxides, which are epimeric at $C_{(20)}$, with fluorine-containing reagents, it has been shown[24,151] that with one isomer (XLV) both oxide rings are cleaved with the formation of the 6β-fluoride (XLVI) and the 6β,20ξ-difluoride (XLVII). The entry of

fluorine at position 20 in the difluoride (XLVII) was established by nuclear magnetic resonance (with $^{19}F$).

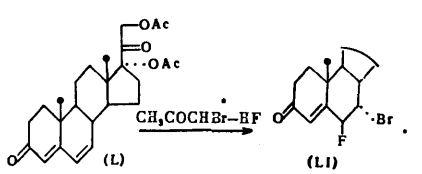
(XLV) (XLVI) (XLVII)



## 2. Preparation of Fluorinated Steroids From Olefinic Steroids

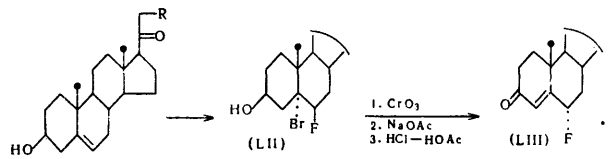
Direct addition of fluorine to carbon–carbon multiple bonds has not yet found application because of the extremely vigorous and uncontrollable reaction of fluorine both with C=C and with C–H bonds, even at low temperatures and with the halogen diluted with nitrogen.

Controlled addition of fluorine to olefins can be achieved only by replacing the gaseous halogen by various fluorine-containing reagents, among which have been used lead tetrafluoride, fluorine perchlorate, hydrogen fluoride, iodobenzene difluoride, trifluoroiodomethane, and difluorocarbene, as well as *N*-halogeno-amides together with hydrogen fluoride.



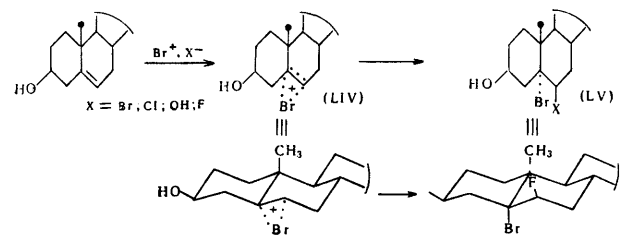
Addition of mixed halides. Fluorine can be introduced into a steroid molecule together with another halogen by the reaction of steroid olefins with *N*-halogeno-amides and hydrogen fluoride.

The halogeno-amides usually employed are *N*-bromo- and *N*-chloro-acetamide and *N*-chloro- and *N*-iodo-succinimide. The reaction is conducted at -80° in the presence of a proton-acceptor, must often pyridine or tetrahydrofuran, to increase the degree of ionisation of the hydrogen fluoride, which is present in large excess. This method of preparation enables fluorine to be introduced into positions 6, 11, and 16 of the steroid molecule, and is preferable to the cleavage of oxides, especially with polyunsaturated steroids, since the oxides of such compounds are obtained in very low yields. The present method is highly selective: in the case of 16$\alpha$,17$\alpha$-epoxy-3$\beta$-hydroxy-pregna-5,9(11)-dien-20-one (XLVIII), for example, reaction occurs primarily at the 5–6 double bond[152] with formation of the 5$\alpha$-bromo-6$\beta$-fluoro-derivatives (XLIX):



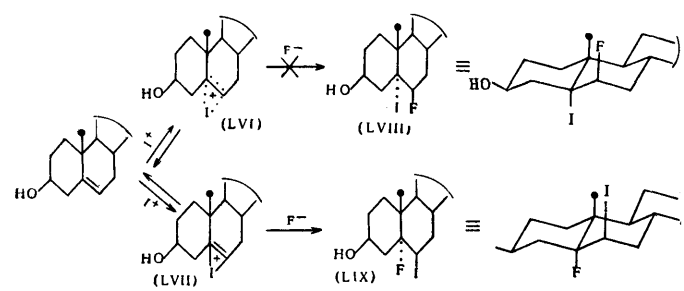
(XLVIII) (XLIX)

In the case of the 4,6-diene (L), however, the 7$\alpha$-bromo-6$\beta$-fluoro-derivative (LI) is formed[152,153]:



(L) (LI)

When the steroid molecule contains both 4–5 and 9–11 double bonds, the same pair of reagents add on at the latter bond[152,153]. This method of fluorination provides one of the best approaches to the biologically important 6$\alpha$-fluorinated steroid hormones[152,154–156]. Conversion of 6$\beta$-fluorinated (LII) to 6$\alpha$-fluorinated (LIII) compounds is accomplished by successive oxidation of the 3-hydroxy-group, dehydrohalogenation, and isomerisation in acetic acid:

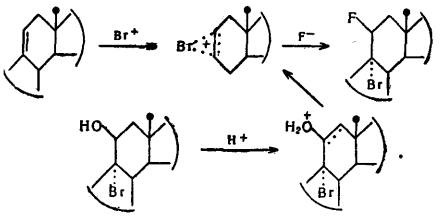


(LII) (LIII)

The halogenation of steroids with mixed halides, which is conducted in a polar medium, takes place by a mechanism of ionic addition. In the first stage an intermediate $\alpha$-bromonium cation (LIV) is formed. Approach of the bromine ion from the $\alpha$ region of the molecule is controlled by stereochemical factors[157]. Then the cation (LIV), on nucleophilic attack by the fluoride ion, forms the *trans*-diaxial cleavage product (LV).[158,159] Thus *trans*-diaxial addition of two halogens occurs in each case:

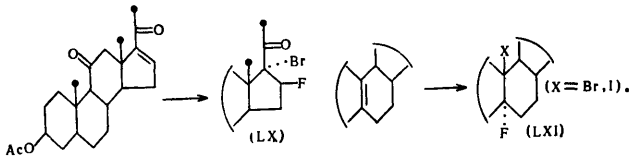
(LIV) (LV)

Reaction of steroids with *N*-iodosuccinimide and hydrogen fluoride shows an anomalous order of addition of the halogens, with the formation of a 5$\alpha$-fluoro-6$\beta$-iodo-derivative (LIX)[157] instead of the 6$\beta$-fluoro-5$\alpha$-iodo-compound (LVIII). This course of the reaction is explained by the existence of two possibilities — formation of an $\alpha$- or a $\beta$-iodonium cation (LVI) or (LVII) — in the first stage of the reaction:



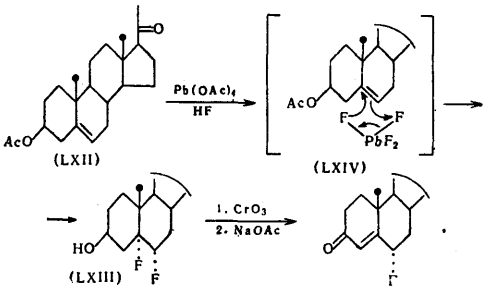
(LVI) (LVIII) (LVII) (LIX)

Two products (LVIII) and (LIX) can be formed on further attack by the fluoride anion. If formation of an iodonium ion is regarded as a reversible process, in which an equilibrium is present between the olefin and the two possible ions (LVI) and (LVII), the former (LVI) is kinetically preferred, as indicated above for the bromonium ion, in view of the preferred approach to the 5–6 double bond from the $\alpha$-region

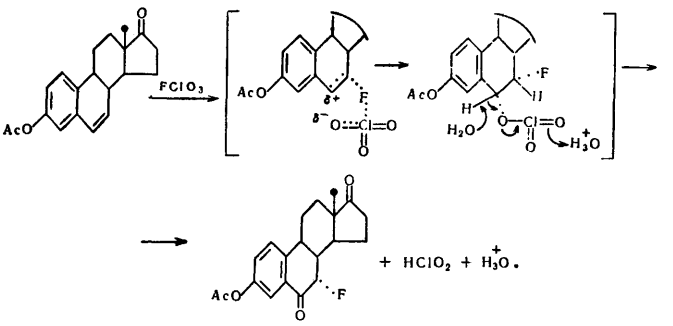


of the molecule. However, reaction of (LVI) with the fluoride anion yields the thermodynamically less stable (LVIII) of the two possible products (LVIII) and (LIX). From an examination of the non-bonding interaction of the iodine atom in these products, and also in view of the greater stability of secondary compared with tertiary iodides, it follows that (LIX) is more stable than (LVIII). Thus reaction involving the kinetically less preferred ion (LVII), but resulting in the thermodynamically more stable final product (LIX), is the dominant mode of addition of $I^+F^-$.

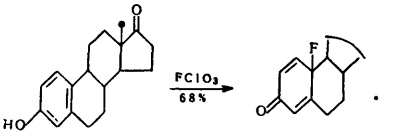
A particularly detailed study has been made of the addition of mixed halogens to the 9–11 double bond, which enables 9α-bromo(chloro, iodo)-11β-fluoro-derivatives to be obtained[153,160–167]. It was found that these products can be prepared from 9α-bromo-11-hydroxy-compounds by reaction with hydrogen fluoride in pyridine[160]. In both cases the reaction involves the 9,11-bromonium ion as intermediate stage, which is converted into the final product on nucleophilic attack by the fluoride ion:



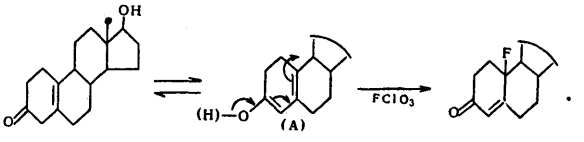
It is interesting that 9α,11β-difluoro-derivatives could not be obtained from 9α-fluoro-11β-hydroxy-steroids. It is probable that fluorine is too electronegative to form an onium ion[153,160].



Addition of BrF to the 16–17 double bond enables 17α--bromo-16β-fluoro-derivatives (LX) to be obtained[152,153], while reaction of hydrogen fluoride and *N*-bromoacetamide or *N*-iodosuccinimide with 5–10 olefinic steroids yields 10β-bromo(or iodo)-5α-fluoro-derivatives of the type (LXI).[168]

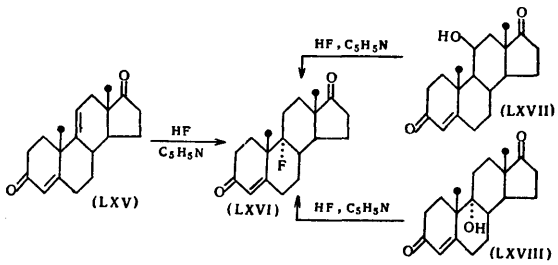


Addition of lead tetrafluoride to double bonds. Only one example of this reaction — with acetoxypregnenone (LXII) — is known at the present time. Lead tetrafluoride attacks this steroid at the instant of formation from lead tetraacetate and anhydrous hydrogen fluoride, the reaction being conducted in dichloromethane at -75°. The reaction product — the vicinal 5α,6α-difluoride (LXIII) — is formed in 27% yield based on the acetate (LXII) introduced into the reaction. The *cis*-addition of fluorine can be explained by the occurrence of reaction via a cyclic transition state (LXIV), in an analogous manner to the *cis* hydroxylation of steroids by osmium tetroxide. Oxidation of the 3β-hydroxyl with chromic acid and elimination of the 5α-fluorine by means of sodium acetate yield 6α-fluoroprogesterone; thus this reaction can serve also for the synthesis of 6α-fluorinated steroids[2,3,169]:

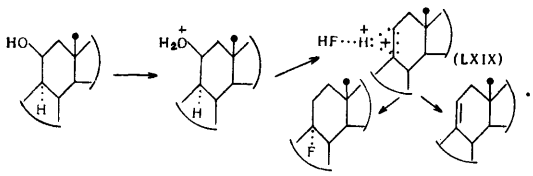


Addition of $FClO_3$. The action of perchloryl fluoride on steroids containing a double bond conjugated with an aromatic ring involves oxofluorination of the double bond, a reaction in which an oxo-group and a 7α--fluorine atom are simultaneously introduced into the steroid molecule. The suggested reaction mechanism is illustrated by the scheme[170]:

Reaction of steroids containing an aromatic ring A with perchloryl fluoride yields 10β-fluoro-19-norsteroids[171–174], the reaction being conducted in dimethylformamide at room temperature.

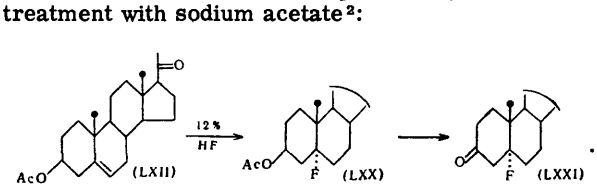


Compounds of the same type are formed from 3-oxo--5(10)-ene steroids[173], the enol (A) or the corresponding enolate ion probably being formed as an intermediate stage:

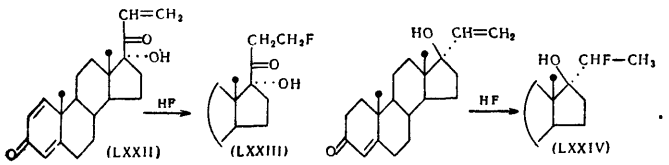


Addition of hydrogen fluoride (HF). The reaction of solutions of anhydrous hydrogen fluoride in pyridine with unsaturated steroids or the corresponding

hydroxy-compounds involves addition of HF to the double bond. An example of this reaction is provided by formation of the 9α-fluoroandrostenedione (LXVI) from the compound containing a 9–11 double bond (LXV), the 9α-hydroxy--derivative (LXVIII), and the 11β-hydroxy-derivative (LXVII). The 9α-configuration assumed for the fluorine atom is based on nuclear magnetic resonance spectra[175].

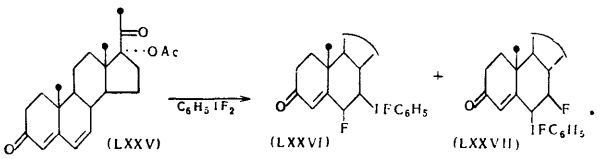


This reaction permits a 9α-fluorine atom to be introduced into derivatives of androstane and pregnane[176–179] without the simultaneous introduction of a hydroxy-group, as occurs in the cleavage of α-oxides. The most reasonable hypothesis is that hydrogen fluoride adds on, in accordance with the Markovnikov rule, to a double bond which is already present or is formed in the reaction. Actually, however, the matter is more complicated. Thus the yield of the 9α-fluoride (LXVI) is far higher from the 11β-ol (LXVII) than from the 9,11-dehydro-derivative (LXV); furthermore, paper chromatography of the reaction products shows that the fluoride (LXVI) is formed more rapidly from the 11β-ol (LXVII) than from the olefin (LXV). This suggests that 9α-fluoro-steroids may be formed directly from 11β-hydroxy-compounds. A probable mechanism of such a change involves protonation of the 11β-hydroxyl followed by elimination of the elements of water with formation of a solvated cation (LXIX), which can then be converted both into 9α-fluoro- and into 9,11-dehydro-compounds[175]:

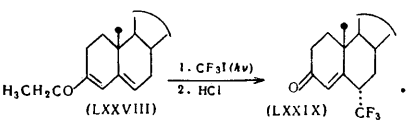


It is quite possible that the formation of 9α-fluoro-12β--hydroxy-steroids by the opening of 11β,12β-epoxides with hydrogen fluoride also occurs according to this scheme, and not by addition of hydrogen fluoride to an intermediate 9(11)-en-12β-ol, as has been assumed previously[117].

Addition of hydrogen fluoride to a 5–6 double bond is accomplished by a somewhat different method. Acetoxy-pregnenone (LXII) reacts with hydrogen fluoride only in the presence of a proton-acceptor (tetrahydrofuran), forming a 5α-fluoro-derivative (LXX); hydrolysis and oxidation of the latter under mild conditions give 5α-fluoropregnane-3,20-dione (LXXI), which splits off hydrogen fluoride on treatment with sodium acetate[2]:

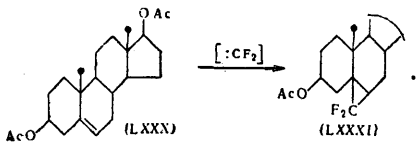


With the non-acetylated hydroxypregnenone under the same conditions, the action of hydrogen fluoride results in replacement of the 3β-hydroxy-group by the fluorine atom instead of addition to the 5–6 double bond.

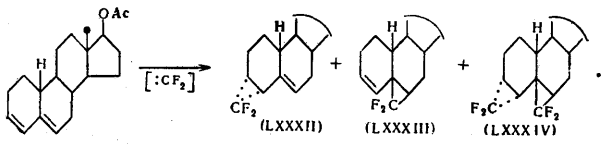


An example is also known of the addition of hydrogen fluoride to the 21–22 double bond§ in the compound (LXXII) with formation of the 22-fluoro-derivative (LXXIII),[180] and also to the 20–21 double bond of 17α-vinyltestoesterone to form the 20-fluoro-compound (LXXIV).[181] In these cases the reaction is also conducted in tetrahydrofuran with antimony trifluoride as catalyst.

Addition of iodobenzene difluoride $C_6H_5IF_2$. This reagent is formed *in situ* in chloroform solution from iodobenzene, hydrogen fluoride, and potassium hydrogen fluoride. Its reaction with the 4,6-diene (LXXV) gives a mixture of the compounds (LXXVI) and (LXXVII), containing fluorine in positions 6β and 7β, the adduced structures being assigned to them on the basis of nuclear magnetic resonance spectra[182].



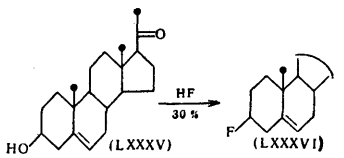
Addition of trifluoroiodomethane. Under the influence of ultraviolet radiation this reagent adds on to the 5–6 double bond of 3-enolic ethers of steroid 4-en--3-ones of the androstane and pregnane series (LXXVIII). Subsequent hydrolysis of the reaction products with hydrochloric acid yields 6α-trifluoromethylated steroids (LXXIX):[183–185]



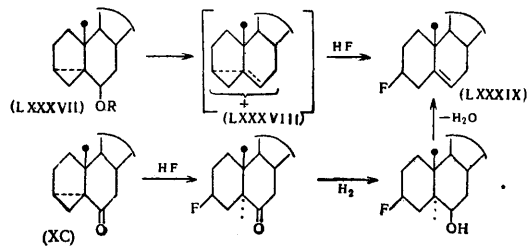
Addition of difluorocarbene. A peculiar method of introducing fluorine into unsaturated steroids is their reaction with difluorocarbene $CF_2$, which is formed when sodium chlorodifluoroacetate $CF_2ClCOONa$ is heated in high-boiling organic solvents[186]. Thus addition of difluorocarbene to the 5–6 bond of (LXXX) yields the 5β,6β--difluoromethano-derivative (LXXXI). The β configuration was assigned to the cyclopropane ring in (LXXXI) on the basis of steric hindrance to approach of the reagent from the α region, and is supported by the infrared and nuclear magnetic resonance spectra. It is interesting

§ Numbering as in formula in Table 1.

that the more bulky dichlorocarbene does not in general react with the 5–6 double bond in 10β-methylated steroids.

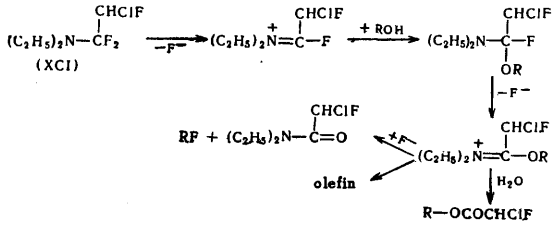


Addition of difluorocarbene to a 2–3 double bond gives two products, in which the three-membered ring has the 2α,3α and 2β,3β configuration respectively. Reaction with 3,5-dienes is more complicated, a mixture of the three products (LXXXII)–(LXXXIV) being formed.

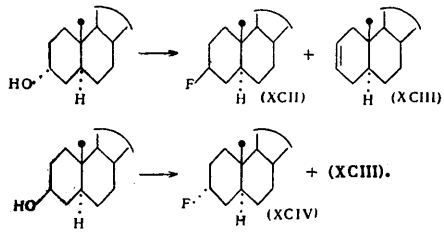


3. Replacement of Other Groups and Other Halogen Atoms by Fluorine

The last group of methods for synthesising fluorinated steroids comprises reactions in which other groups and also other halogens are replaced by fluorine. These include primarily the hydroxy-group and its toluene-*p*-sulphonyl or methanesulphonyl derivatives, which are replaced by fluorine on reaction with hydrofluoric acid or its salts. The substitution of fluorine for other halogens — bromine, chlorine, iodine — occurs in a similar manner. The present Section includes the reactions of perchloryl fluoride with compounds containing active hydrogen, and reactions of sulphur tetrafluoride with steroid ketones.

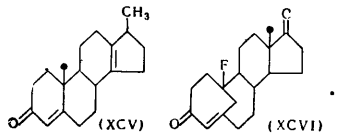


Replacement of hydroxyls by fluorine. This replacement occurs when certain steroid alcohols are treated with anhydrous hydrogen fluoride in tetrahydrofuran medium. Thus the hydroxypregnenone (LXXXV)[2] and its 16-dehydro-derivative[186–188] form 3β-fluoro-compounds (LXXXVI). The hydroxyl of 2-hydroxymethylated steroids is exchanged for fluorine under the same conditions[189].



Analogous products are formed when 3,5-cyclosteroids of the androstane and pregnane series of the type (LXXXVII), where R = H or $CH_3$, react with hydrogen fluoride in benzene[190–192]. Reaction occurs via the homoallylic cation (LXXXVIII) and gives a 40–50% yield of the 3β-fluorinated derivatives (LXXXIX). Cleavage of the 3,5-ring occurs also when the 6-ketone (XC) is treated under the same conditions[190].

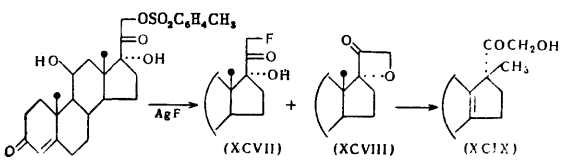
Replacement of hydroxyl by fluorine can be accomplished also by the action of *N*-(2-chloro-1,1,2-trifluoroethyl)diethylamine (XCI), which is formed when chlorotrifluoroethylene is passed through cooled diethylamine[193]. Products in which the hydroxyl has been split off and in which it has been esterified to form a chlorofluoroacetate are formed as side-products of this reaction and therefore the yields of the desired products do not usually exceed 20–50%. The reaction occurs according to the scheme[194,195] (in which R represents the residue of a steroid alcohol)



3α-Hydroxy-5α-androstan-17-one on treatment with the reagent (XCI) gives the 3β-fluoro-derivative (XCII), whereas its 3β-epimer yields the 3α-fluoro-derivative (XCIV), the reaction thus involving complete inversion of the configuration. In both cases the olefin — 5α-androst-2-en-17-one (XCIII) — is formed as a byproduct[194].

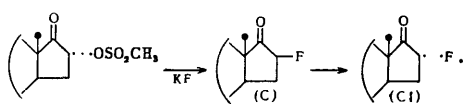
11α-Hydroxyprogesterone under these conditions forms a mixture of the 9α- and 11β-fluoro-derivatives, together with a small amount of the 9–11-olefinic derivative. The latter is the main product when the reagent (XCI) acts on 11β-hydroxyprogesterone[194]. Complete inversion of the configuration occurs when this reagent is used to substitute fluorine for a hydroxyl in the positions 6β,[194] 15β,[194,196,197] 17α,[198] and 17β.[194,195,198] Substitution of fluorine for hydroxy-groups in 2-, 16β-, and 19-hydroxymethylated steroids has also been reported[194,198–200].

The reactions of steroids with the reagent (XCI) can be complicated by various rearrangements. For example, testosterone yields, besides the normal reaction product, the Wagner–Meerwein rearrangement product (XCV), and



19-hydroxyandrostenediol gives the compound (XCVI), containing the bicyclo[4,4,1]undecane system[198].

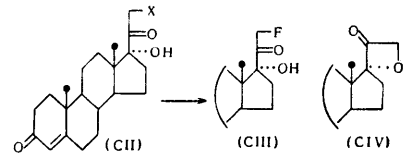
(XCV) (XCVI)



Replacement of toluene-*p*-sulphonate and methanesulphonate groups by fluorine. Since the direct replacement of hydroxyls by fluorine by the action of hydrofluoric acid may result in various rearrangements, and cannot be applied to polyols, methods have been worked out for accomplishing this substitution under milder conditions. One such method consists in converting the hydroxy-group into a toluene-*p*-sulphonate or a methanesulphonate, reaction of which with salts of hydrochloric acid enables the corresponding fluoro-derivatives to be obtained. The use of toluene-*p*-sulphonates is preferable, since they are formed more readily and give higher yields of the fluoro-derivatives (up to 75–90%)[201,202]. The reaction is conducted with potassium fluoride or silver fluoride in diethylene glycol, dimethylformamide, dimethyl sulphoxide, or acetonitrile[203–213].

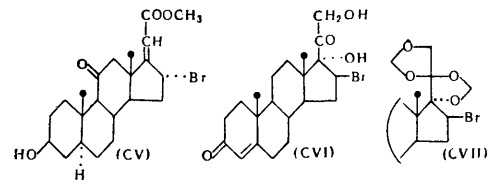
The main field of application of this reaction comprises the conversion of 21-hydroxy-steroids into the corresponding 21-fluoro-compounds (XCVII). As a result of the considerable basic strength of the fluoride ion, the oxide (XCVIII) is often formed as a byproduct, and under the influence of acids rearranges to the compound (XCIX)[207,214,215].

(XCVII) (XCVIII) (XCIX)



The action of potassium fluoride on methanesulphonates of 16$\alpha$-hydroxy-17-keto-steroids gives 16$\beta$-fluoro-compounds (C), which in the course of the reaction rearrange to the 16$\alpha$-fluoro-derivatives (CI).[216,217]

(C) (CI)

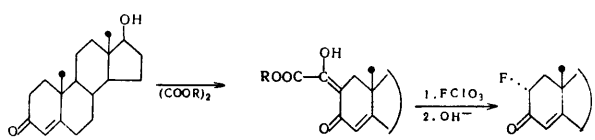


This reaction is employed also to substitute fluorine for hydroxy-groups in 6$\alpha$- and 16$\alpha$-hydroxymethyl-steroids[218–221]. Tetrabutylammonium fluoride $(C_4H_9)_4NF$ in acetone solution can be used instead of salts of hydrofluoric acid as source of fluoride ions in this reaction; under these conditions, structural rearrangements accompanying nucleophilic substitutions are diminished. The reaction involves a complete inversion of configuration: 3$\beta$-toluene-*p*-sulphonates give 3$\alpha$-fluoro-derivatives, whereas their 3$\alpha$-epimers yield the 3$\beta$-fluoro-compounds; testosterone toluene-*p*-sulphonate forms the 17$\alpha$-fluoro-derivative[222].

Replacement of other halogens by fluorine. This reaction is analogous to the replacement of alkane- and arene-sulphonates by fluorine. It occurs when potassium and silver fluorides act on halogenated steroids dissolved in acetonitrile or various alcohols. Ease of replacement by fluorine diminishes in the sequence iodine > bromine > chlorine. Thus when X = I, the main product of the action of salts of hydrofluoric acid on the compound (CII) is the fluoro-derivative (CIII) slightly contaminated with the 17,21-oxide (CIV); but when X = Cl, this oxide becomes the main product of the reaction[223,224]

(CII) (CIII) (CIV)

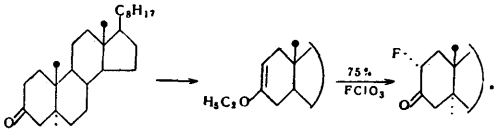
Interest attaches to the replacement of halogens in position 16 by fluorine. Whereas 16$\alpha$-iodooestrone[225] and the 16$\alpha$-bromo-steroid (CV)[226] form 16$\beta$-fluoro-derivatives, the reaction thus entailing an inversion of configuration, with 16$\beta$-bromocortexone (CVI) or its bismethylenedioxy-derivative (CVII) the configuration is preserved during the reaction, and 16$\beta$-fluoro-derivatives are produced[227–230]. The reasons for this difference in the stereochemical course of the reaction have not yet been elucidated.



(CV) (CVI) (CVII)

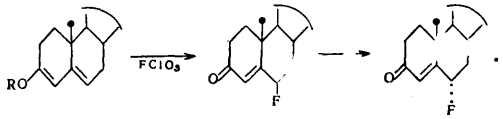
Replacement of halogens by fluorine has been used also to prepare 3$\beta$-fluorinated[231], 6$\alpha$-fluorinated[232], 6$\alpha$-fluoromethylated[233], and 16$\beta$-fluoromethylated[234] steroids. Being one of the principal methods for introducing fluorine into position 21 (because of activation of the 21-halogen by the adjacent $C_{(20)}$ carbonyl group[235–245]), this route serves also for the preparation of polyfluorinated steroids[246–250].

Replacement of hydrogen by fluorine. In contrast to bromination or chlorination, the direct fluorination of steroid ketones in the $\alpha$-position is impossible. Indirect routes are therefore necessary for this purpose, by the action of fluorine-containing reagents, e.g. perchloryl fluoride $FClO_3$, on those derivatives of keto-steroids in which the activity of the $\alpha$-hydrogen has been substantially increased.



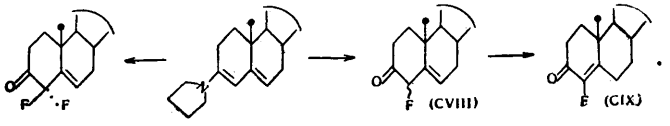
The first scheme for introducing fluorine into keto-steroids comprises three stages — preparation of an alkoxalyl or hydroxymethylene derivative of the steroid, followed by treatment with sodium ethoxide and perchloryl fluoride, and finally alkaline hydrolysis of the product to remove the alkoxalyl group — an example being the synthesis of 2$\alpha$-fluorotestosterone[251]:

A fluorine atom can be introduced into steroids by this method not only at the 2$\alpha$ position[5,170,251–262] but also at

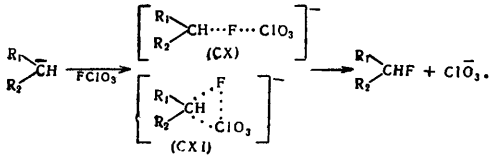


the 16$\alpha$, 16$\beta$,[263-268] and 21 [251,256,268] positions. In the two latter cases not only monofluoro-derivatives (16$\alpha$ or 21) can be obtained but also difluoro-compounds[270-272].

In the second scheme for the fluorination of keto--steroids, solutions of derivatives of the enolic form of these steroids in organic solvents are treated with perchloryl fluoride. Thus 2$\alpha$-fluorocholestan-3-one is formed from cholestanone via 3-ethoxycholest-2-ene:[269]

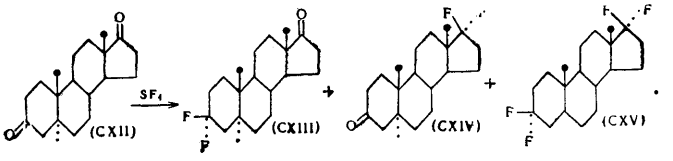


Enamines of 3-keto-5$\alpha$-steroids[273] react similarly, as also acetates of the enolic form of 17-keto-steroids[274]. In the latter case the yield of 16$\alpha$-fluoro-17-keto-steroids can be considerably increased by replacing the acetates by the acetamide derivatives of the enolic form[274-277].



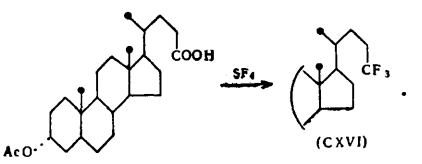
The reactions of perchloryl fluoride with derivatives of the steroid 4-en-3-ones are rather more complicated, the composition of the reaction products depending on the conditions and the type of enolic derivatives. Thus acetates[48,277] and ethyl ethers[269,278-280] of the enolic form of these steroid derivatives yield 6$\beta$-fluoro-compounds, which can be isomerised under the reaction conditions to the 6$\alpha$-fluoro-derivatives:

In contrast to this, the fluorination of pyrrolidine enamines of steroid 4-en-3-ones yields 4-fluorinated products. When the reaction is conducted in methanol[281-285], 4$\xi$--fluoro-5-ene derivatives (CVIII) are obtained, which in the presence of acids isomerise to 4-fluoro-4-enes (CIX); when the reaction was conducted in ether[284,286], only 4,4--difluoro-5-ene derivatives were isolated.



Since perchloryl fluoride has no dipole moment[287], it is difficult to predict *a priori* the type of ionisation and the mechanism of fluorination with this compound. It is possible that perchloryl fluoride will dissociate in different ways depending on the conditions[288,289]. It is assumed in most cases that the fluorine is electrophilic in character in this reaction, i.e. that fluorination consists in attack by an $F^+$ ion on a carbanion or a carbon atom of a double bond having a greater electron density. This view is supported by the formation of axial $\alpha$-halogeno--ketones both on fluorination with perchloryl fluoride and in the reaction of ketones with $Br^+$.[48,172,269] It is probable that in this case fluorination is a single-stage process, involving transition states of the type (CX) or (CXI):[290,291]

Conversion of carbonyl group into a *gem*--difluoro-derivative. Treatment of steroid aldehydes or ketones with sulphur tetrafluoride ($SF_4$) enables two fluorine atoms to be introduced simultaneously into the steroid molecule. This reaction is conducted at room temperature with hydrogen fluoride, boron trifluoride, or other fluorides ($AsF_3$, $TiF_4$, $PF_5$), as catalyst[292]. Although hydrogen fluoride is a less active catalyst than boron trifluoride its use is to be preferred, since fewer byproducts of the reaction are then formed[293]. Hydrogen fluoride can be generated directly during the reaction by adding to the mixture a quantity of ethanol, which forms hydrogen fluoride on reaction with sulphur tetrafluoride[4].

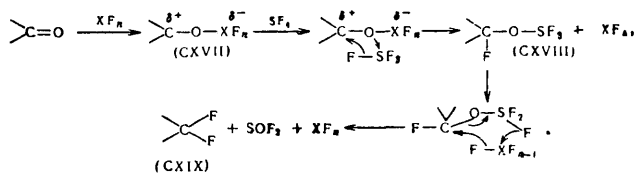


Comparatively mild reaction conditions ensure that esters, acetals, and bismethylenedioxy-derivatives shall be stable, and permit considerable expansion of the field of application of the reaction among such multifunctional compounds as steroids. Reaction with sulphur tetrafluoride has been used to introduce two fluorine atoms into positions 3, 11, 17, and 20 of the steroid molecule[4,293-297], and also to obtain 2- and 6-difluoromethylated steroids from the corresponding hydroxymethylene derivatives[293,298-300].

Compounds containing more than one carbonyl group in the molecule can react either at one or at all the reaction centres. Thus 5$\alpha$-androstane-3,17-dione (CXII) forms a mixture of di- and tetra-fluorinated derivatives (CXIII)--(CXV), with fluorination at $C_{(3)}$ predominating in the ratio 3:1.[4]

The reactivity of carbonyl groups in different positions in the steroid molecule towards sulphur tetrafluoride was found to decrease in the sequence 3-one $\simeq$ 6-formyl > 17--one > 20-one > conjugated 3-one > 11-one.[293]

Steroid acids on reaction with sulphur tetrafluoride form trifluoromethylated derivatives. Thus acetoxy--lithocholic acid yields the 24-trifluoro-derivative (CXVI):[293]



The reaction probably involves the intermediate formation of the acid fluoride, the hydrogen fluoride which is thus

evolved catalysing the further changes, so that in this case separate addition of a catalyst is not necessary[293]:

$$R{-}CO_2H + SF_4 \rightarrow R{-}COF + HF + SOF_2,$$
$$R{-}COF + SF_4 \rightarrow R{-}CF_3 + SOF_2.$$

Several schemes have been suggested for the mechanism of the reaction of ketones with sulphur tetrafluoride, the most probable of them being[293,294]

According to this scheme, the ability of $XF_n$ to catalyse the reaction is associated with its ability to polarise the carbonyl group as a Lewis acid. The first stage in the reaction consists in formation of the complex (CXVII) between the carbonyl group and the catalyst. Attack by a sulphur tetrafluoride molecule on this complex yields the adduct (CXVIII), cleavage of which by means of the catalyst forms the difluoride (CXIX).

## II. PHYSIOLOGICAL ACTIVITY OF FLUORINATED STEROIDS

The introduction of fluorine atoms into steroid compounds results in fundamental and varied changes in their physiological activity. The changes of greatest interest and practical importance are found in the corticosteroid series. The introduction of fluorine affects primarily the hormonal activity of these compounds — their control of the metabolism of carbohydrates (glucocorticoid activity) and salts (mineralcorticoid activity). The discovery of the anti-arthritic, antiallergic, and anti-inflammatory properties of modified corticosteroids extended the therapeutic effects of these compounds beyond the range of natural hormonal activity, and enabled their clinical application to be greatly expanded. At the present time fluorinated steroids are employed for the treatment of various types of arthritis, Addison's disease, dermatoses, etc. Since fairly detailed reviews are available in this field[67,301,302], only a brief account with the most recent results need be given here.

Introduction of fluorine at the 2$\alpha$ position in ring A of a steroid molecule lowers all forms of hormonal activity[253]; nevertheless, anti-tumour activity has been observed in 2$\alpha$-fluorotestosterone[254]. The only compound containing a 3$\beta$-fluorine atom which has been studied is 17$\alpha$-acetoxy-3$\beta$-fluoropregn-5-en-20-one, and this on oral application has three times the gestagenic activity of 17$\alpha$-acetoxyprogesterone[192]. Replacement of the 4-hydrogen atom by fluorine lowers the androgenic, gestagenic, and corticoid activities[284,303].

Compounds containing a 6$\alpha$-fluorine atom have, in comparison with the corresponding unsubstituted compounds, far greater glucocorticoid, anti-inflammatory, and thymolytic activities and at the same time diminished mineralcorticoid activity[17,28,40,304]. Increased anti-arthritic activity in 6$\alpha$-fluorocorticoid steroids has also been reported, although the increase is not quite so large as with the 9$\alpha$-fluoro-analogues[305]. The gestagenic and anabolic activities of the 6$\alpha$-fluoro-derivatives of progesterone and testosterone are also considerably enhanced[18,40,306]. On the other hand, the 6$\beta$-fluoro-epimers have a lower gestagenic activity than the unsubstituted compounds[306]. 6$\alpha$-Fluoromethylated steroids, like the 6$\beta$-fluoro-compounds, possess increased glucocorticoid and diminished mineralcorticoid activities[218].

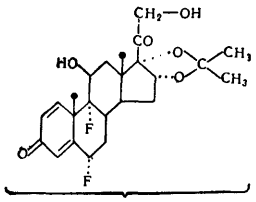
The therapeutic effects produced by the introduction of a 9$\alpha$-fluorine atom have been studied the most widely. It has been reported that the glucocorticoid activities of the 9$\alpha$-fluoro-analogues of cortisol and corticosterone exceed those of the unsubstituted compounds by factors of 8 and 3.5 respectively[80,115]. The mineralcorticoid, thymolytic, anti-inflammatory, and anti-arthritic activities are correspondingly increased too[76,80,304,305,307-309]. 9$\alpha$-Fluoroprogesterone has a greater gestagenic activity than has unsubstituted progesterone[63,175]; nevertheless, the 9$\alpha$-fluoro-11$\beta$-hydroxy-analogue has a lower progestative activity than the unsubstituted compound[310-312]. Analogous effects are found in the androstane series. The introduction of 9$\alpha$-fluorine into testosterone propionate increases the androgenic and anabolic activities of the steroid roughly fivefold[175], whereas 9$\alpha$-fluoroandrostan-11$\beta$-ols have an appreciably diminished androgenic activity[66]. Enhanced aldosterone-blocking activity is also noted when 9$\alpha$-fluorine is introduced into 17-spirolactones of the androstane series[313]. 9$\alpha$-Fluoro-11$\beta$,17$\alpha$-dihydroxy-6$\alpha$-methylpregna-1,4-diene-3,20-dione is an effective anti-tumour agent, arresting the growth of mouse adenocarcinoma and rat fibroadenoma[314].

An 11$\beta$-fluorine atom is introduced only together with another halogen — bromine, chlorine, or iodine — in the 9$\alpha$ position. In comparison with the corresponding unsubstituted compounds, such dihalogenated derivatives of progesterone have lower gestagenic activity[160,162], those of testosterone lower anabolic and androgenic activities[166], and those of cortexolone lower glucocorticoid activity[315].

12$\alpha$-Fluorinated analogues of corticosterone and 11$\beta$-hydroxyprogesterone have enhanced glucocorticoid activity, which is approximately equivalent to that of the corresponding 9$\alpha$-fluoro-derivatives[311,312]. Nevertheless, 12$\alpha$-fluorocortisone possesses neither glucocorticoid nor mineralcorticoid activity[135]. There are also data indicating enhanced gestagenic and anti-oestrogenic activity in 12$\alpha$-fluoro-11$\beta$-hydroxyprogesterone compared with progesterone itself[311,312].

Introduction of a fluorine atom into the 16$\alpha$ position increases the glucocorticoid and anti-inflammatory activity and sharply diminishes the mineralcorticoid activity[142,150]. Analogous effects are produced by introducing a 16$\alpha$-fluoromethyl group into a steroid[219]. Yet 16$\beta$-fluorinated steroids have diminished glucocorticoid and anti-inflammatory activity in comparison with the unsubsituted compounds[142,316]. The 17$\alpha$-fluoro-analogue of progesterone is a rather less active gestagen than is progesterone[148].

Compounds containing a fluorine atom in position 21 have glucocorticoid and mineralcorticoid activity intermediate between those of the relatively inactive 21-deoxy-compounds and the highly active 21-hydroxy-analogues[214,301]. 21-Fluoroprogesterone is a more active gestagen than is progesterone by a factor of 2–4.[223,224]



Data on the effect of fluorine atoms on the main forms of physiological activity of steroids are summarised in Table 2.

TABLE 2. Physiological activity of fluorinated steroids (+ = enhancement of activity; - = diminution in activity).

| Position of F | Activity compared with unsubstituted compound | | | | Position of F | Activity compared with unsubstituted compound | | | |
|---|---|---|---|---|---|---|---|---|---|
| | gestagenic | glucocorticoid | mineralocorticoid | anti-inflammatory | | gestagenic | glucocorticoid | mineralocorticoid | anti-inflammatory |
| 2α | − | − | − | | 12α | + | + | − | |
| 3β | + | | | | 16α | | + | − | + |
| 4 | − | − | − | | 16β | | − | | |
| 6α | + | + | − | + | 17α | − | | | |
| 6β | − | | | | 21 | + | + | + | + |
| 9α | + | + | + | + | | | | | |

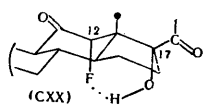
The clinical application of corticosteroids is impeded by the fact that many of them show mineralcorticoid activity, which on prolonged treatment produces oedema and a rise in blood pressure[317]. In order to obtain compounds suitable for practical application, therefore, it was necessary to suppress the mineralcorticoid activity, which in this case was a secondary effect. This was achieved by introducing appropriate substituents into the molecule, in particular fluorine atoms in positions 6α and 16α. The same effect can be obtained by introducing into the molecule a 1–2 ethylenic bond[60,62,305,312], methyl groups in positions 2α,[304,305,312] 6α,[301,304,305] and 16α and 16β,[80,83,96,304,305,318-320] or a 16α-hydroxy-group[87,301,305]. There occurs not only a sharp drop in mineralcorticoid activity but also a substantial increase in glucocorticoid and anti-inflammatory activity.

Results obtained for the modification of the cortisol molecule (Table 3) show that, when the molecule contains more than one modifying substituent, their effects on the activity are additive. This has enabled compounds to be prepared which have an extremely high level of physiological activity, exceeding that of natural corticosteroids several hundredfold. It must also be noted that 16α,17α-acetals of 16α-hydroxycorticosteroids, which are not included in Table 3, have 3–4 times the anti-inflammatory activity of the unsubstituted compounds[95,321,322].

Dexamethasone (9α-fluoro-11β,17α,21-trihydroxy-16α--methylpregna-1,4-diene-3,20-dione) and triamcinolone (16α,21-diacetoxy-9α-fluoro-11β,17α-dihydroxypregna-1,4--diene-3,20-dione) have been used in medical practice as antiarthritic and anti-inflammatory remedies[305]. Synalar (6α,9α-difluoro-11β,21-dihydroxy-16α,17α-isopropylidenedioxypregna-1,4-diene-3,20-dione) is used in the treatment of psoriasis and skin diseases[326].

The problem of the particular mechanism by which the introduction of fluorine affects physiological activity has not yet been solved. Fried[115,311] suggested that this effect was associated with the inductive (-*I*) effect of the fluorine atom on the neighbouring oxygen-containing group in position 11. This hypothesis was based on the parallelism observed between the effect of various 9α-substituents on the

TABLE 3. Physiological activity of analogues of cortisol.



| Substituents in cortisol molecule | | | | Physiological activity | | | Refs. |
|---|---|---|---|---|---|---|---|

TABLE 4. Glucocorticoid activity of 9α-substituted cortisols and acid dissociation constants of the substituted acetic acids[312].

| Substituent | Glucocorticoid activity | Acid dissociation constant $10^5 K_a$ |
|---|---|---|
| Fluorine | 10.7 | 217.00 |
| Chlorine | 4.7 | 155.00 |
| Bromine | 0.3 | 138.00 |
| Iodine | 0.1 | 75.00 |
| Hydroxyl | 0.2 | 16.00 |
| Methoxyl | <0.2 | 33.00 |
| Hydrogen | 1.00 | 1.82 |

activity of a steroid hormone and their inductive effects assessed from the strengths of the corresponding substituted acetic acids (Table 4).

This hypothesis was regarded as supported also by the presence in 12α-fluoro-steroids (12α-fluorocorticosterone[115] and 12α-fluoro-11β-hydroxyprogesterone[311]) of enhanced glucocorticoid activity of the same order as in the 9α-fluoro-analogues, which are symmetrically substituted about $C_{(11)}$. The difficulty presented by the absence of glucocorticoid or mineralcorticoid activity in 12α-fluorocortisone[135] could be bypassed on the assumption that in this case such absence resulted from the formation of a hydrogen bond between the axial 12α-fluoro- and 17α--hydroxy-groups (CXX).

(CXX)

However, recently discovered facts have considerably diminished the value of this hypothesis. The acetate of 9α-fluorocortexone, *containing no oxygen in position 11*, shows twelve times the mineralcorticoid activity of cortexone acetate[177]. This indicates that the increase in hormonal activity accompanying introduction of 9α-fluorine is not due to an inductive effect on a neighbouring oxygen function. It is evidently more probable that modified hormones are less rapidly metabolised by the organism, and

thus remain for a longer period in an active state in the latter[323]. In particular, the presence of fluorine atoms may prevent one of the normal metabolic processes, hydroxylation. It is interesting in this connection that the most active fluorinated steroids have the fluorine atoms in the positions 6, 9, 16, and 21, i.e. in those positions in which enzymic hydroxylation of steroid hormones occurs in the animal organism[324].

The enhanced activity of fluorinated steroids has been explained also by a diminution in their bonding by blood plasma[325]. Real progress in explaining the phenomena observed in this field can be made only when a deeper understanding has been obtained of the molecular mechanism of the action of steroids, about which almost nothing is known at the present time[324].

3. Phosphitylation by esters 946
4. Phosphitylation by nitrogen-containing derivatives 947

## I. INTRODUCTION

Although a large number of monographs and reviews have been published on the chemical modification of cellulose, questions associated with the phosphorylation of this important polysaccharide are treated superficially and incidentally in them, or even omitted altogether, as has been done in the latest treatise on the chemistry of cellulose [1].

The task of the present paper is to fill the gap: it represents the first attempt to collect together all the information on methods of preparation as well as the properties and practical application of phosphorus-containing derivatives of cellulose. The paper summarises investigations on the phosphorylation of cellulose, made mainly during the past thirty years, recent progress being reported in the greatest detail. A special place is given to describing the achievements made in the practical application of phosphorus-containing cellulosic materials.

The large amount of experimental work on the preparation of phosphorus-containing cellulose derivatives can be divided into two groups, according as phosphorylation is effected with derivatives of acids containing quinquevalent or tervalent phosphorus. The first group is in turn divided into two subgroups, the first of which comprises

papers on procedures for the direct phosphorylation of the polysaccharide, i.e. the replacement of the hydrogen atoms of hydroxy-groups by phosphorus-containing acid radicals; the second subgroup contains other methods for the chemical bonding of phosphorus to the macromolecular chain (indirect phosphorylation). A large number of papers and especially patents are devoted to the problem of conferring particular properties on cellulosic materials by impregnating them with compositions which include phosphorus compounds. In the latter case the formation of chemical bonds between cellulose and the phosphorus component has not in general been established, and therefore this question is not discussed in the review†.

The large number of publications on the preparation of phosphorylated celluloses is due to the growing technical interest in them. An important application of these products is the production of non-flammable textiles. The introduction of phosphorus into cellulose confers on articles made from it the ability to withstand the action of a flame‡. Cloth made from phosphorus-containing cellulose and clothes manufactured from it can be employed in firefighting, in furnace work, in the army, etc. [2-16]. Phosphorus-containing celluloses are used in several cases in the production of shrink-resistant [17] and crease-resistant [18,19] fabrics, which are resistant to water [8,20,21] and possess antiseptic [20,22] and rotproof [21,23,24] properties.

Phosphorylated celluloses are novel, as yet little studied, but promising ion exchangers. Their desirable properties are their hydrophilic character, in some cases high selectivity of ion-exchange action, and characteristic physical properties. In contrast to most other known adsorbents, these substances may be in the form of powders, wadding, or sheets, and are therefore employed in different ways in the ion-exchange process. They are used not only in the form of columns but also in other ways: thus a very promising procedure at the present time is continuous ion exchange by means of an endless belt of phosphorylated cotton [25]. The use of phosphorylated celluloses has been recommended for the isolation of $Th^{4+}$, $Ti^{4+}$, $U^{4+}$, $Ce^{4+}$, $Fe^{2+}$, $ZrO^{2+}$, $UO^{2+}$, $Hf^{2+}$, $Cu^{2+}$, and other ions from synthetic and technical solutions [22,25-46].

In some cases these esters are employed in radiometric instruments for the control of waters containing small concentrations of radioactive elements [47]. References have also appeared to the use of cellulose phosphates for the purification and separation of proteins, vitamins, and other important natural products [48-55].

Phosphorylated celluloses are fairly efficient cation exchangers: the ion-exchange properties of these compounds and other ion exchangers of similar type are compared in the accompanying Table [37].

Ion-exchange processes have been studied mainly with cellulose specimens containing acid phosphate groups, which, as is well known [56-58], are not always the most suitable for bonding a particular ion. Phosphonates, phosphoramidates, and phosphonamidates of cellulose have not yet been assessed from this point of view, which reveals certain prospects for the preparation of novel polymeric complexing agents. The usefulness of such researches is supported by the appearance of papers on the application to ion exchange of celluloses which have been impregnated with certain phosphorus-containing extractants for metals [59-61].

TABLE.

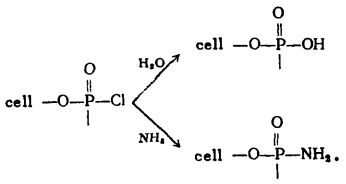
| Ion exchanger | Exchange capacity, mg-equiv. $g^{-1}$ | pH at half capacity |
|---|---|---|
| Cellulose phosphate, 1st H atom | 1.3 | 1.5 |
| Cellulose phosphate, 2nd H atom | 2.6 | 7.5 |
| Sulphoethylated cellulose | 0.5 | 0.5 |
| Carboxymethylated cellulose | 0.3 | 3.7 |
| Diethylaminoethylated cellulose | 0.3 | 7.7 |

Phosphates and phosphonates of cellulose are of interest to several investigators concerned to establish a relationship between the physicochemical characteristics of substances and their structure [62,63].

## II. PHOSPHORYLATION OF CELLULOSE BY DERIVATIVES OF ACIDS OF QUINQUEVALENT PHOSPHORUS

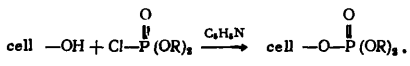
### 1. Phosphorylation by Acid Chlorides

The most widely used method for preparing esters of phosphorus acids is the reaction of alcohols or their alkoxides with the corresponding acid chlorides [64,65]. Several variants of this process have been used for the phosphorylation of cellulose. Work was published in 1932 on the reaction of cellulose with phosphorus oxychloride in the presence of phosphoric acid with and without a solvent present, a highly degraded, water-soluble product being obtained [66]. A less degraded material is obtained by employing cellulose which has first been treated with alkali [26,49,67-70], a water-insoluble phosphate being formed when the reaction is conducted in absolute benzene [26].



Much attention has been paid to the phosphorylation of cellulose with phosphorus oxychloride in the presence of ammonia [71] or pyridine [25,27,35,72,73], when a polysaccharide containing rather more than 9% of phosphorus could be obtained (the phosphorus content was somewhat higher when hydrocellulose was used [27]). Under the conditions of esterification, partial replacement of the hydroxy-groups of the polysaccharide by chlorine is observed [25]. Phosphorylation in the presence of pyridine is also accompanied by considerable degradation of the product. Thus the preparation of a cellulose phosphate containing 3.5% of phosphorus involved a loss of strength of 50%, and the loss increases with rise in the phosphorus content [27]. There are indications that, in the presence of pyridine, phosphorus oxychloride will phosphorylate derivatives of cellulose, e.g. ethyl- and hydroxyethyl-cellulose and cellulose acetate [27,73].

Treatment of cellulose with phosphorus oxychloride yields mainly phosphorochloridates, apparently consisting mainly of Cell–O–$POCl_2$ residues [27]. The lability of the chlorine atoms in these compounds corresponds to that in ordinary alkyl (or aryl) phosphorochloridates [64,65]. They are exchanged for hydroxyl on treatment with water, and



† Detailed accounts of the modification of the properties of cellulose by impregnation with phosphorus-containing compositions will be found in several monographs [2-4].

‡ Several theories have been put forward to explain from various points of view the non-combustibility of phosphorylated celluloses [2,4,5].

for an amino-group with ammonia, cellulose phosphates and phosphoramidates respectively being formed[70]:

Cellulose is phosphorylated also by alkyl (and aryl) phosphorochloridates in the presence of tertiary amines [10,74-79], when mixed phosphoric esters are formed, e.g.

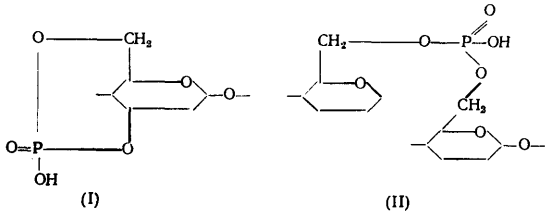
Derivatives of cellulose undergo similar reactions[73,80].

References have recently appeared to the possibility of the phosphorylation of cellulose with phosphoramidochloridates[81] and with phosphonochloridates[76,77,81-83], the products containing fragments in which phosphorus–carbon and phosphorus–nitrogen bonds are present. Phosphoramidochloridates obviously phosphorylate cellulose partly also by a mechanism involving alcoholysis of phosphoramidates[81].

The interaction of cellulose with polyphosphonitrilic chlorides in the presence of pyridine has been described[19,84], but there is no rigorous evidence of the formation of macromolecular glycosylphosphonitriles.

## 2. Phosphorylation by Acids

At ordinary temperatures cellulose hardly reacts at all with phosphoric acid, but only swells and partly dissolves in it[85,86]. Nor are cellulose phosphates obtained on heating, owing to degradation of the polysaccharide[87,88]. Unsatisfactory results have been obtained also for phosphorylation with phosphoric acid in the presence of sulphuric acid[89] or of phosphorus pentoxide[90], only water-soluble oligomers being obtained in these cases. An only slightly degraded product containing a few per cent of phosphorus was obtained by Ermolenko and Kaputskii, who acylated cellulose with phosphoric acid (0–10°), the reaction being activated with oxides of nitrogen[91,92]. These workers consider that macroradicals are produced by the action of nitrogen dioxide on cellulose, and it is these which are responsible for phosphorylation.

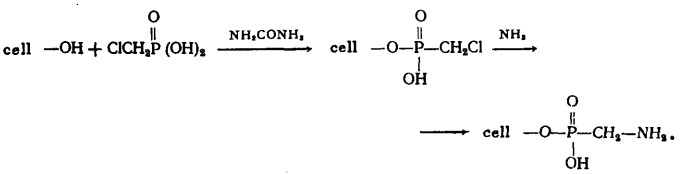


Considerably better results were obtained for the phosphorylation of cellulose with phosphoric acid in the presence of ammonia and other compounds containing nitrogen. The reaction is often conducted under relatively mild conditions, and in several cases it is possible to obtain cellulose phosphates with little degradation. The addition of nitrogenous bases is necessary to neutralise the phosphoric acid, and consequently to diminish its dehydrating effect. It is possible that urea increases the reactivity of cellulose, since the latter is known to be able to change its supermolecular structure under the influence of nitrogeneous bases[93].

The esterification of cellulose with phosphoric acid in the presence of urea was first accomplished towards the end of the 1930s[6,94]. A large (mainly patent) literature then appeared on new variants of the phosphorylation of cellulose with phosphoric acid in the presence of amines, urea, dicyanodiamide, melamine, guanidine, formamide, and other compounds containing nitrogen[6,8,16,18,20,31-34,37,39,95-120]. It has recently been proposed to conduct the process also in the presence of 2-alkoxyethanols and sulphonates[108]. The technique of this reaction is simple and convenient, and it has therefore been applied in industry. The phosphorylation of cellulose is usually accomplished by heating the reaction mixture at 130–200° for from 15 min to several hours. In order to obtain a more homogeneous product and increase the reactivity of the cellulose, it has been proposed to subject the initial compound to preliminary scouring, desizing, and mercerisation[6].

In spite of the extensive literature on this method of phosphorylation, the effectiveness of the reaction has been obscure until quite recently. Many authors do not indicate the phosphorus content of their products, and sometimes publish extremely contradictory results. Thus the synthesis of a cellulose phosphate containing 11–13% of phosphorus has been reported[33], whereas similar work[101,103] has given specimens containing only 4–6% of phosphorus. The most careful investigation[102] has shown that a phosphorus content of 9% can be obtained only by repeating the phosphorylation procedure three times.

The structure of the cellulose phosphates obtained has not yet been finally elucidated. Most authors suggest that phosphorylation involves mainly the primary hydroxyls of the glucose units[3,120], but this has not been proved. Some research workers[6,26,31,120] regard the products obtained as primary and secondary phosphoric esters, pointing out that monoalkyl phosphates are formed on heating to 150°, and dialkyl phosphates above 150°.

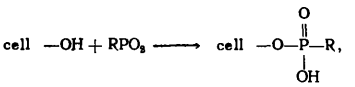


The secondary esters can be of two types — cyclic (I), in which the phosphorus atom is linked by the two bonds with only one glucose unit, and cross-linked (II).

(I) (II)

Several authors associate the formation of structures (I) or (II) with the appearance of definite properties in the resulting compounds, e.g. the cross-linking of the macromolecules through phosphorus with the acquirement of rotproof properties[98].

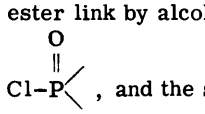
Alkyl phosphates[124,125] and *NNN'N'*-tetramethylphosphorodiamidic[81], chloromethylphosphonic, and hydroxymethylphosphonic[123] acids[42,43], besides phosphoric acid, can react with cellulose in the presence of nitrogen bases. Above 130° this reaction is accompanied by secondary ammonolysis of the chloromethylphosphonate, with formation of the cellulose aminomethylphosphonate[43]:



Phosphorylated celluloses obtained by the above method often possess poor mechanical properties, and are therefore unsatisfactory to the consumer. Recently, in order

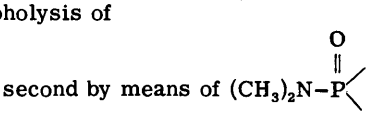
to obtain less degraded products, phosphorylation has frequently been achieved with poly(vinyl phosphate)[28,30,40,103,124,125]. The loss in mechanical strength of the specimens thus obtained corresponds to the loss for cellulose phosphates containing one-third to one-quarter of the phosphorus content[103]. The mechanism of the reaction has not yet been elucidated; it is suggested that, depending on the conditions, either trans-esterification of poly(vinyl phosphate) by the cellulose or condensation with formation of a mixed phosphate of the two macromolecular compounds can occur[28].

Towards the end of the 1940s reports had appeared in the literature of the phosphorylation of cellulose with pentaerythritolphosphoric acids[126-133]. Reaction is usually complete at 130–180° in 15 min. The phosphorus content of the resulting phosphates does not exceed 3%. No comparison has yet been made of the characteristics of phosphorylated celluloses obtained in this way and by other methods. Nor are data available on the mechanism of this reaction.

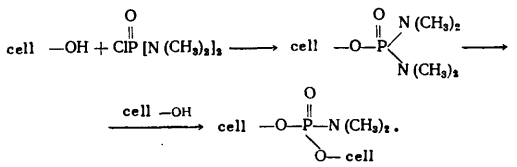


### 3. Phosphorylation by Other Reagents

Anhydrides of phosphoric acids are interesting phosphorylating agents for cellulose. The use of phosphorus pentoxide for this purpose has been patented[134,135]. Derivatives of meta-, pyro-, and poly-phosphoric acids have also found application[104,108,109,114,118,119,136]. It has recently been proposed to obtain acid phosphonates of cellulose by phosphorylating the latter with phosphonic anhydrides[137]:



where R = $CH_3$, $C_2H_5$.



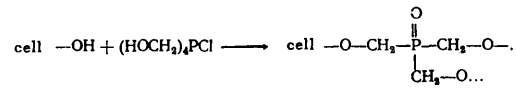
The phosphorylation of cellulose with amides and hydrazides of phosphorus is of definite value, e.g. with the corresponding polyphosphonitrilic derivatives[81,138,139]. In spite of the relatively high temperature (~ 140°) the reaction involves hardly any degradation of the polysaccharide, since no deleterious substances are evolved in the process. A reaction which develops by a mixed mechanism must also be mentioned. Thus tetramethylphosphorodiamidic chloride, on interaction with cellulose, forms its first ester link by alcoholysis of

, and the second by means of

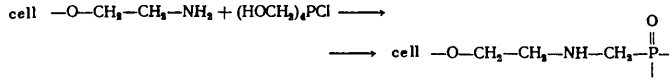
:[81]

### 4. Indirect Phosphorylation

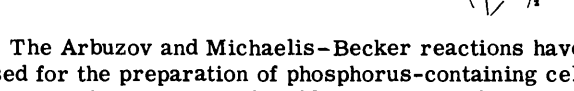
It appears that derivatives of cellulose containing phosphorus have been prepared in which hydrogen atoms of hydroxy-groups of the cellulose have not been replaced by acid radicals containing phosphorus. Treatment of cellulose with 2-chloroethyl phosphates in alkaline medium yields 2-phosphatoethylcellulose containing 1.3% of phosphorus[140]:



The phosphonomethylation of cellulose by the action of salts[22,25,40,45,141,142] or esters[45] of chloromethylphosphonic acid has been comparatively well studied:

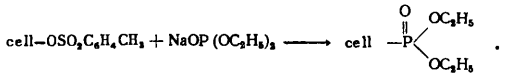


The phosphorus content of the resulting samples usually varies between 0.7% and 2%. The mechanical qualities of phosphonomethylcellulose are not very high, and it is therefore recommended that the initial material should first be treated with 1,3-dichloropropane for the partial cross-linking of the macromolecules[142].



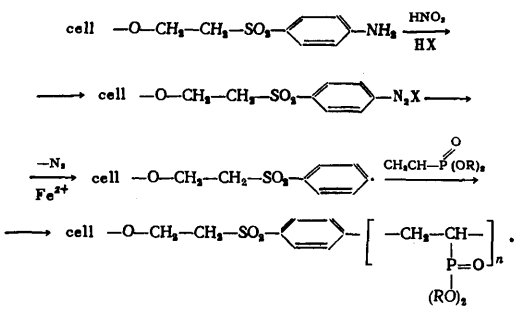
A phosphinylmethylated cellulose is formed when the polysaccharide is treated with tetrakishydroxymethylphosphonium chloride[23,24,143]:

It appears that aminoethylcellulose can be used in this reaction[144]:



2-Phosphinylaminoethylcellulose has been obtained by the use of azirides of phosphoric or phosphorothioic acids as modifying reagents[145-147]:

The Arbuzov and Michaelis–Becker reactions have been used for the preparation of phosphorus-containing celluloses. Thus reaction of a chloroacetate with triethyl phosphite yields a product which was regarded as a phosphonoacetate[148]. In view of the results of a more detailed study of the Arbuzov reaction using $\alpha$-halogeno-carbonyl compounds[149], such a structure cannot be entirely justified for the product obtained. Quite recently a study has been made of the reaction of chlorodeoxycellulose with triethyl phosphite[77]:



The product contains 5% of phosphorus. An analogous material is obtained by the interaction of cellulose toluene-*p*-sulphonate with sodium diethyl phosphite[13]:

Recently an original method has been developed in the Soviet Union for preparing phosphorus-containing cellulose derivatives by grafting vinylphosphonic esters to the cellulose. The principle of the method consists in introducing a small quantity of aromatic amino-groups into the macromolecule. After diazotisation of the amino-derivative in

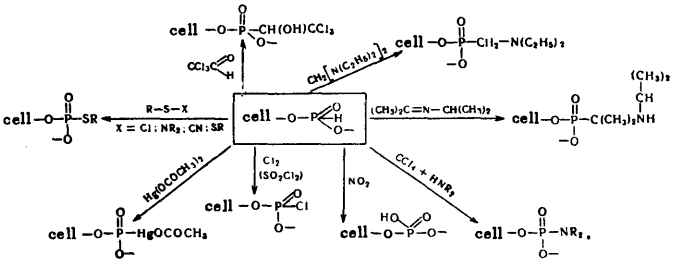
the presence of a reducing agent, e.g. a ferrous salt, nitrogen is evolved and macroradicals are formed, which initiate the formation of graft chains on the cellulose. The 2-sulphanilylethyl ether has been used as cellulose derivative containing an aromatic amino-group [150]:

The phosphorus content of the product does not usually exceed 4–4.2%.

## III. PHOSPHITYLATION OF CELLULOSE BY DERIVATIVES OF ACIDS OF TERVALENT PHOSPHORUS

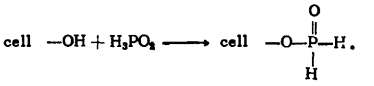
During recent years interest has grown in macromolecular compounds containing acid radicals of tervalent phosphorus. There are obviously three main reasons for this: firstly phosphitylation with acid derivatives of tervalent phosphorus is usually more efficient and occurs under milder conditions than with derivatives of quinquevalent phosphorus [64]; secondly, macromolecular phosphites and phosphonites can be readily converted by reactions of polymeric type into various derivatives of acids of quinquevalent phosphorus which it is difficult or even impossible to obtain by direct phosphorylation [151]; and thirdly, macromolecular derivatives of tervalent phosphorus acids possess specific properties which make them promising for industrial exploitation, e.g. as antioxidants and stabilisers for polymers [152,153], additives in oils [154], etc.

All this obviously applies to modified celluloses containing acid radicals of tervalent phosphorus. Since 1960, therefore, patents and scientific publications have started to appear systematically on the preparation and properties of these compounds.



### 1. Phosphitylation by Acid Chlorides

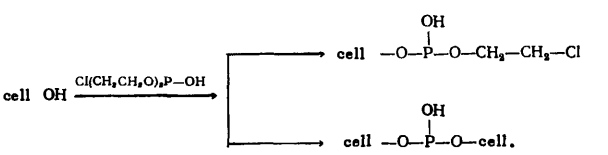
Only one report has appeared on this topic, acetates, butyrates, and other esters of cellulose being phosphitylated with alkyl(or aryl)phosphonous dichlorides and dialkyl(or diaryl)phosphinous chlorides in the presence of tertiary amines [73]. In view of the complexity of the phosphitylation of cellulose with chlorophosphines and similar compounds, as well as the publication of a large number of papers on new methods for the mild phosphitylation of hydroxy-compounds with other reagents, little development on these lines is to be expected in the future.



### 2. Phosphitylation by Acids

Phosphorous acid is known to be an effective phosphitylating agent [155], and its reaction with cellulose has therefore been studied. The reaction can be accomplished in several ways — by phosphitylation in an organic solvent, in molten phosphorous acid, or in an inert gas [156] — the second method enabling cellulose phosphites to be obtained containing up to 17% of phosphorus, though the product is strongly degraded. It is most convenient to modify cellulose by the third method [156], the optimum temperature being 120–130°, the duration being 3–15 h, and the phosphorus content reaching 14%.

The products obtained, which are acid phosphites, are reactive compounds which can be converted by reactions of polymeric type into cellulose derivatives containing fragments of various acids of quinquevalent phosphorus [157]:

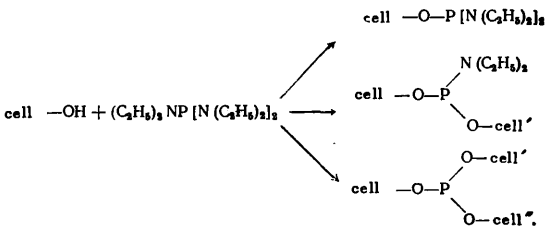


Quite recently cellulose has been phosphinylated by heating it with hypo-phosphorous (phosphinous) acid [158]:

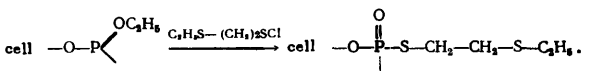
In view of the high coordination and saturation of phosphorus in the compounds obtained, they show great promise for various chemical transformations.

### 3. Phosphitylation by Esters

As efficient phosphitylating agents, esters of tervalent acids of phosphorus are employed also for the phosphitylation of cellulose. A comparatively detailed study of this reaction has been made on mono- [157,159], di- [160–162], and tri-alkyl (or -aryl) phosphites [162,163] of various types and on acid phosphonites [160,164]. Transesterification of acid phosphonites with the reaction products gives cellulose phosphonites cell–O–P($CH_3$)–OH in which $\gamma$ = 150. The transesterification of di- and tri-alkyl (or -aryl) phosphites is a more complex process, products being formed in which one, two, or three alkoxyls (or aroxyls) have been replaced by a polysaccharide residue. The reaction can be followed by introducing a phosphite in which the alkyl radical contains a halogen atom. In the transesterification of bis-2-chloroethyl phosphite, for example, the content of phosphorus and of chlorine in the reaction product is used to establish under what conditions polyesters containing mainly alkyl glycosyl phosphite or mainly diglycosyl phosphite fragments are formed [162]:

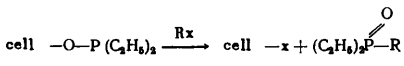


Acid phosphites of the cellulose series, especially those obtained with industrial dimethyl phosphite [161], are of



interest for the preparation of various phosphorylated celluloses. They have been converted into compounds containing fragments capable of complex formation, pesticidal activity, etc.[161]

4. Phosphitylation by Nitrogen-Containing Derivatives



One of the most effective and convenient methods of phosphitylation is the alcoholysis of amides of tervalent acids of phosphorus[165]. This reaction has been applied also to cellulose[166]. Tetraethylphosphinous amide, ethyl tetraethylphosphorodiamidite, and phosphorus hexaethyltriamide have been studied as phosphorylating agents. In the first case a cellulose diethylphosphinite is formed (under optimum conditions the degree of phosphorylation is close to 20%); in the second and third cases, amido-esters or cross-linked esters of cellulose are obtained, e.g.

The normal phosphites and the phosphinites of cellulose which have been prepared are reactive compounds, being oxidised to the corresponding quinquevalent derivatives merely by the action of oxygen[166]. With sulphur they give phosphorothionates and phosphinothionates not hitherto described in the literature. With sulphenyl chlorides, cellulose phosphates are converted into phosphorothiolates. In this way it has been possible to prepare a phosphorylated cellulose containing residues of the well-known insecticide Isosystox[166]:

Dialkylphosphinites of cellulose, like simple esters of tervalent phosphorus, undergo the Arbuzov reaction, forming a deoxyhalogenocellulose:

A paper has appeared very recently on the phosphitylation of cellulose with hydrazides of phosphorous acid. Thus 1-methyltrimethylene dimethylphosphorohydrazidite acylates cellulose under milder conditions than in the corresponding preparation with amides[167].

---o0o---

A large amount of research has been done on the phosphorylation of cellulose, but a certain uniformity of chemical approach to phosphorylation can be seen in most of the work. In recent years success has been achieved in developing new ways of phosphorylating cellulose by methods which have not yet become "classical". These investigations may be expected to yield new phosphorus-containing materials of interest for the national economy.

Fresh progress in the phosphorylation of cellulose will depend to a considerable extent on the attention paid to physicochemical laws in conducting these transformations of polymeric type.

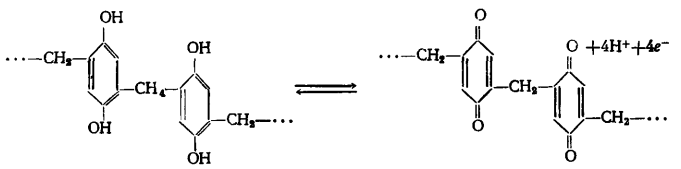
7. Applications of redox polymers 960

## 1. INTRODUCTION†

Great interest has arisen in recent years in macromolecular compounds of a new type, oxidation–reduction polymers or, as they are still called, electron exchangers. The latter term has been coined by analogy with ion exchangers, but its choice is unfortunate, since the oxidation or reduction of a polymer does not involve the



† Fresh results have been published since this paper was submitted for publication, and are collected together in the supplementary references [205–275].

exchange of electrons, as occurs with ions in the case of ion exchangers, but their absorption or donation. Nevertheless, the term has become widely used both in the Soviet and in the foreign literature. Several authors prefer the term "redox resins" or "redoxites".

The synthesis of ion-exchange resins was accomplished in 1936. It was established that the acidic or basic groups of the original monomers retain their properties in the polymeric compounds. The question naturally arose of the possibility of obtaining similar systems containing other functional groups. Much attention was paid to the synthesis of macromolecular compounds containing groups capable of reversible oxidation and reduction. Tsvet discussed the role of such a system as early as 1906 [1] in papers on the chromatographic method of investigation. Many workers have shown that redox groups maintain their oxidation–reduction functions in polymeric compounds. Numerous papers have been published on the synthesis and application of redox polymers, but they have usually been concerned with particular questions, and do not show the present-day position or the prospects for this class of compounds. The few papers and reviews [2-25,205-207] of general character do not give an all-round account of the subject. No systematic classification of redox polymers or rational nomenclature for them has yet appeared.

Redox polymers are macromolecular compounds showing limited swelling, of three-dimensional structure (sometimes linear), which differ in composition but contain groups capable of undergoing reversible oxidation–reduction reactions with substances which can undergo these reactions and are present in contact with the polymers. Their behaviour is similar to that of soluble redox systems, the main difference being that redox polymers are obtained in the form of insoluble granules, can therefore be readily separated from the solution with which they are in contact, and do not contaminate the reaction products.

The reaction resembles the redox process between quinol and quinone. The oxidation–reduction process of a redox polymer can be represented by the equation

Redox polymers are not in the nature of ion exchangers, since they do not contain fixed ions, and therefore undergo oxidation and reduction, not ion exchange, although the phenolic hydroxyls of some redox polymers behave in strongly alkaline medium as fixed ionogenic groups. Individual redox polymers obtained in recent years contain, in addition to the redox groups, fixed strongly acid groups (they are sometimes termed redox ion exchangers [25]).

Work on the synthesis of redox polymers began only comparatively recently. Prokhorov and Yankovskii [26] first obtained redox ion exchangers in the early 1940s by treating sulphonated coal with an iron(II) salt. Later Mills and Dickinson [27] prepared redox ion exchangers by treating anion exchangers with solutions of copper (or silver) salts. According to Sansoni [15] patent claims appeared in 1944 for the preparation of redox polymers by polycondensation methods.

At the end of the 1940s Cassidy and his coworkers [28,29] made extensive investigations on the synthesis and application of polymeric electron exchangers based on vinylquinol. Somewhat later Sansoni [30] published work on the preparation of redox ion exchangers based on monomeric redox systems sorbed on ion exchangers.

Manecke [31] synthesised polycondensation polymers based on benzenepolyols, and Soloway and Schwartz [32] those based on naphthaquinones. The work of Gregor and his coworkers [33,208], Overberger and Lebovits [34], Trostyanskaya [2], Berlin et al. [35-37], Davankov [38,39], Dalibor [40], etc. is also widely known.

## 2. SYNTHESIS OF REDOX POLYMERS BY POLYCONDENSATION

Attempts have been made to obtain redox polymers by the polycondensation of polyhydric phenols, aminophenols, and phenylenepolyamines with formaldehyde [15].

Redox polymers have been synthesised by the polycondensation of quinol or resorcinol with formaldehyde, and of quinol, pyrogallol, and catechol with phenol and formaldehyde [41,42]; and the synthesis and properties of monomolecular quinol–phenol–formaldehyde compounds have been described [43].

A method has been patented [44] for preparing a series of redox condensation polymers on the basis of pyrogallic acid, catechol, and resorcinol.

In order to improve the chemical stability, redox polymers have been synthesised [45,46] on the basis of polycyclic aromatic derivatives of juglone, 2-hydroxyanthraquinone, alizarin, anthrarufin, quinalizarin, chrysazin, and purpurin.

Redox polymers have been obtained also from quinol and formaldehyde, or quinol, phenol, and formaldehyde [19,47-49], or resorcinol, Methylene Blue, and formaldehyde [50], or resorcinol, various dyes, and formaldehyde [40].

Conditions for the production of resorcinol–quinol–formaldehyde polymers have been more closely specified [51].

Berlin and his coworkers [35-37,52,53] have synthesised a new class of macromolecular compounds, the polyaminoquinones, which are capable of oxidation–reduction, and have high thermal stability. These polymers have been obtained by the reaction of chloranil with benzidine (or hexamethylenediamine), quinone with diamines, and of *p*-benzoquinone with bisdiazotised *p*-phenylenediamine, benzidine, and benzidine-3,3′-dicarboxylic acid. Their enhanced thermal stability and their improved magnetic, electrical, and ion-exchange properties make them of great interest [54-56].

Polycondensation of the original monomer with formaldehyde has been used to obtain [57] redox polymers from *p*-nitrosophenol, *p*-nitrosoaniline, hydrazobenzene, arsenobenzene, indamines, indophenols, benzenepolyols, anthracenepolyols, naphthalenediols, phenanthrenepolyols, etc. [209]

A polymer possessing high redox capacity has been synthesised [32] from naphthazarin (5,8-dihydroxy-1,4-naphthaquinone) and formaldehyde.

A linear redox polymer has been obtained [58] by converting *N*-methoxymethyl-polyamides into the *N*-mercaptomethyl form, which in turn can probably be reversibly oxidised and reduced.

The polycondensation[59] of equimolecular quantities of *p*-dimethoxybenzene and 1,4-bischloromethyl-2,5-dimethoxybenzene gives poly-(2,5-dimethoxy-1,4-phenylenemethylene), which after demethylation and oxidation gives a polyquinone. Polymeric quinones are also obtained by oxidising the product of the polycondensation of quinol, phenol, and formaldehyde in the molecular proportions 1:1:3, etc.[210,211]

Polycondensation redox polymers have unsatisfactory kinetic properties[25]. This is one of the principal reasons for their limited use. The poor kinetic properties are to a considerable extent due to the low swellability of the polymers. The ability to diffuse[19,25,60,61], which in these cases determined the reaction velocity, was inadequate. The hydrocarbon skeleton of ion exchangers is hydrophobic, and only the introduction of polar groups into the skeleton confers hydrophilic properties — and hence the power of limited swelling — on the polymer. Although polar (phenolic) groups are present in the macromolecule of polycondensation redox polymers, they are little dissociated in aqueous solution, and therefore the swelling power of the polymer is low. On the other hand, redox reactions, unlike ion-exchange processes, are not ionic, and therefore occur slowly.

Redox processes in solution can be catalysed by certain substances[62,63]. The oxidation $Fe^{2+} \rightarrow Fe^{3+}$, for example, occurs more rapidly in the presence of chloride ions. It has been established[64], in an investigation of electron-exchangers, that chloride ions accelerate the reaction of cerium ions with the polymer. Manecke and his co-workers[46] did not observe this effect of chloride ions on their redox polymers, but they showed that, when monomeric quinones are added to the solution, the reaction between oxidant and polymer is more rapid and the potential of the polymer is established within a shorter time on titration (Fig. 1). The monomeric quinone is here acting as a catalyst. The quinone probably reacts with the quinol form of the polymer to form a semiquinone, the latter form of the polymer being oxidised more rapidly[46]. It is generally known[65,66] that under certain conditions a monomeric quinol can react with a monomeric quinone, and that intermediate products can be formed in the oxidation of quinol. Thus there are no grounds for completely excluding the possibility of such processes in polymeric compounds.

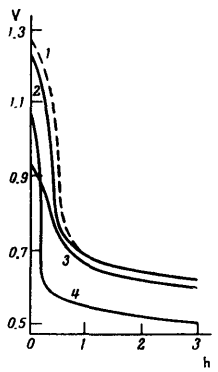


Fig. 1. Fall in potential with time during the reduction of a sulphuric-acid solution of $Ce^{4+}$ on various redox polymers[46]: 1) redox polymer from quinol, phenol, and formaldehyde; 2) redox polymer from quinol, hydroxybenzenesulphonic acid, and formaldehyde; 3) as (2) in 1 *N* KCl solution; 4) as (2) with additions of a catalyst (dimethylbenzoquinone).

It has been proposed to introduce other polar groups, mainly sulpho-groups[46,212] (Fig. 1), to improve the hydrophilic and kinetic properties of redox polymers. However, they are found to diminish the stability of the polymer, and above all do not produce sufficient effect.

The addition of oxidation and reduction catalysts does not solve the kinetic problem. The decisive factor in the reaction velocity is the diffusion of reactants into the interior of the polymer. The low swelling power of the polymer does not provide sufficiently large intramolecular pores, commensurate with the radius of the reactant ions or molecules. Therefore reaction takes place only on the surface of the polymer grains, or else inside the grain but at an extremely low rate. There is no great value in accelerating the process on the surface of the grains, since the redox capacity is insignificant in such cases. The rate-determining factor is not the reaction itself but the diffusion process.

The authors consider that it is possible to accelerate redox processes by producing a polymer of definite structure, e.g. macroporous, which would ensure ready access of the reactants to all functional groups.

An extensive literature exists on the effect of structure on ion-exchange processes[213] and on the use of ion-exchange sieves[67-96]. The use of strongly swelling polymers, possessing great intramolecular porosity, is of decisive importance for the ion exchange of substances of high molecular weight[97,98]. The synthesis has recently been developed, and the industrial manufacture organised, of macroporous ion exchangers of low swelling power. Such resins have considerable advantages over the usual strongly swelling ion-exchange resins, being characterised by improved physicochemical properties[99,214-232].

A method has been proposed[100] for the synthesis of macroporous redox polymers which permits a considerable increase and control of their moisture content, and hence of the reaction velocity. It yields polymers of high and controllable porosity, this being achieved by adding to the reaction mass sufficient of an inert diluent, which is subsequently washed out of the final product. Compounds containing hydroxyl, carboxyl, or carbonyl groups, several inorganic salts, carbohydrates, and other substances can be mixed with the initial monomers for this purpose. Isopentyl alcohol and oleic acid are the most effective; pyridine, sodium chloride, glucose, etc. are less effective. The resulting redox polymers are characterised by increased moisture-absorption and redox capacity and improved kinetic properties (Fig. 2). The amount of additive used is of great significance here.

Methods for the synthesis of phenol–formaldehyde polymers have been worked out in some detail. However, the first attempts at preparing quinol–phenol–formaldehyde redox polymers showed little success. The polymers were obtained as a powdery mass, which was hydrophobic and of low redox capacity. It was later proposed[42] that ethanol and other organic substances should be used as solvents, and this permitted considerable improvement in the properties of the resulting electron exchangers.

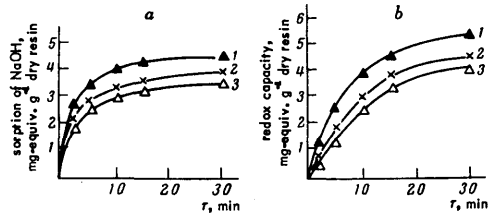

Fig. 2. Kinetic curves for macroporous redox polymers [100]: *a*) sorption of NaOH; *b*) the reduction $Fe^{3+} \rightarrow Fe^{2+}$; with the pores formed by different concentrations of isopentyl alcohol: 1) 0.55 M; 2) 0.92 M; 3) 0.

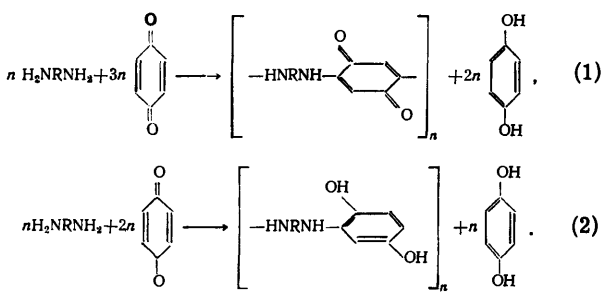
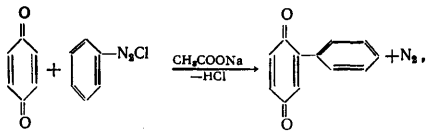
Phenol has also been used as third component in the synthesis of benzenepolyol–formaldehyde redox polymers, with the aim of (1) obtaining insoluble cross-linked polymers, and (2) avoiding the formation of semiquinones.



Little difference is found among methods suggested for the synthesis of this type of redox polymers. The preparation of quinol–formaldehyde polymers can be cited as a characteristic example [19,42,100]. A mixture of quinol and phenol was dissolved in ethanol, concentrated hydrochloric acid was added, and then a solution of formaldehyde was gradually introduced. The reaction mass was heated to about 60°, and maintained at this temperature first with stirring in the reaction vessel and then in a thermostat. The resulting polymer was ground up, and unchanged monomers were rinsed out and extracted with alcohol and water.

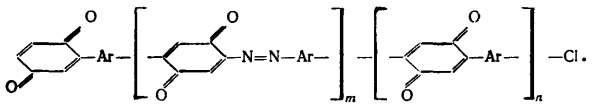
In order to obtain redox polymers based on mixtures of benzenepolyols, a solution of formaldehyde and quinol in methanol was added to the reaction vessel. After some time resorcinol and an acid catalyst were added at an elevated temperature, and an exothermic reaction began. The polymer was freed from unchanged impurities by steam-distilling off the latter [51].

Redox polymers were obtained based on resorcinol and Methylene Blue [50] and on resorcinol and various dyes [32,40].



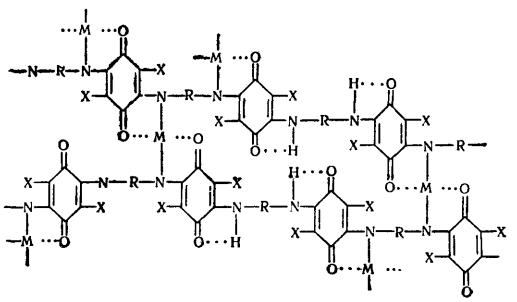
Polymers based on juglone, 2-hydroxyanthraquinone, alizarin, anthrarufin, chrysazin, quinalizarin, and purpurin have been obtained in the same way as quinol–phenol–formaldehyde polymers, in alcoholic medium but under more severe conditions, with precondensation at 100°, hardening, and aging of the gel at 100–150° for several hours. The more severe processing conditions have a deleterious effect on the redox properties of the resulting polymers [45,46].

Polyaminoquinones have been obtained by the interaction of various diamines with chloranil and *p*-benzoquinone in alcohol at elevated temperature [35,52]. The reaction of quinones with diamines can be represented by the scheme [52]



Increasing the quantity of diamine had no effect on the yield of polyaminoquinone.

The process of arylating quinones by the action of diazonium salts [101,102]



and the application of this method to the preparation of arylated quinones [103], as well as the synthesis of a diquinonylbenzene by the reaction of *p*-phenylenebisdiazonium salts with *p*-benzoquinone, have been described previously [104].

The interaction of bisdiazotised *p*-phenylenediamine, benzidine, and benzidine-3,3′-dicarboxylic acid with quinone has been used [53] to obtain hitherto undescribed polymeric azophenylenequinones of general formula

The polymers possess electron-exchange properties and appreciable electronic conductivity, are fairly thermostable, and gave narrow electron spin resonance signals having an integral intensity of the order of $10^{18}$–$10^{20}$ paramagnetic particles per gramme [53]. Polymeric aminoquinones are also able to form with metal salts insoluble and infusible complexes having roughly the structure [35]

The electron-exchange properties, reaction velocity, chemical stability, redox potential, and several other properties have been examined with many types of redox polymers. In the investigation of oxidation–reduction processes, oxidised polymers can be reduced with various reducing agents — ammoniacal sodium dithionite (10% solution in 1 *N* ammonia), a sulphuric-acid solution of titanous chloride (10% solution in 1 *N* sulphuric acid) — rate of oxidation usually being expressed by the change in potential of the polymer with time. The potentiometric titration curves obtained show that condensation products of quinol react more slowly than polymers of pyrogallol and catechol, a gradual slowing down in the redox process being observed with all specimens [31].

Polymers based on pyrogallol with a high phenol content reacted more rapidly (Fig. 3) and had lower chemical stability [31] (Table 2). The rate of oxidation of naphthaquinone (juglone) polymers was higher than that of polymers of the anthraquinone (quinalizarin) series, but lower than that of quinol polymers [45,46] (Fig. 4).

The redox capacity was most frequently determined from the number of milliequivalents of tervalent iron which could be reduced by one gramme of polymer (based on the

dry material) under equilibrium conditions[233]. Values representing the redox capacity of several polymers are given in Tables 1 and 2.

Chemical stability has usually been determined by repeating oxidation–reduction cycles, the redox capacity being determined after each cycle and the stability of the polymer being assessed from the change therein. Polymer samples obtained from dihydric phenols showed inadequate stability: their capacity fell somewhat after many alternations of oxidation–reduction cycles (Table 2)[19,31]. The stability fell also under the action of solutions of oxidising agents and of alkalis. Polymers obtained by treating sulphonated phenol-formaldehyde resins with potassium hydrogen fluoride or with diazotised sulphanilic acid and then reducing with sodium dithionite solution were also unstable[47].

The fall in redox capacity might be a consequence of — (1) gradual elution of components of low molecular weight containing active groups, (2) irreversible oxidation of hydroxybenzenes in the polymer to quinone methides[31,105], and (3) degradative processes.

Polymers based on chloranil and benzidine were black in colour, did not melt, and did not dissolve in the usual organic solvents, being soluble only in concentrated sulphuric acid and partly in formic acid and dimethylformamide; whereas polymers of chloranil and hexamethylenediamine were infusible pinkish grey powders, insoluble in the usual organic solvents but soluble in concentrated sulphuric acid[35,37]. Their disadvantage is the difficulty of quantitative reduction of active groups. Polyaminoquinones are more difficult to reduce[52] than polyvinylquinols[28,29], being similar in this respect to aromatic polyquinones[106] containing systems of conjugated bonds.

The ability of polyquinones in oxidised and reduced states to swell has been examined[107,234]. The infrared spectra have shown that, after a few oxidation and reduction cycles, polyquinones acquire a very small number of carboxy-groups.

The physical and mechanical properties, the chemical stability, and the static and dynamic redox capacity of resorcinol–quinol–formaldehyde polymers have been examined[51] as functions of the hydrogen-ion concentration, the rate of filtration, and the concentration of reducible iron ion; the reproducibility of the static redox capacity has also been determined. After seven oxidation–reduction cycles, the capacity has fallen from 4.4. to 3.6 mg-equiv. × × $g^{-1}$, the mean decrease per cycle being 2.6% (Fig. 5). The apparent redox potential was determined by potentiometric titration, and a technique worked out for regenerating the oxidised polymer. Tin(II) chloride, sodium sulphite, sodium dithionite, hydroxylamine, and other substances were used as reductants, the most successful reducing agent for this polymer being sodium dithionite. The physical and mechanical properties and the chemical stability of the resulting polymers are listed in Table 3.

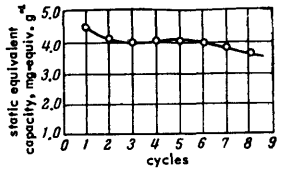

Fig. 5. Reproducibility of static redox capacity of resorcinol–quinol–formaldehyde polymer with respect to the iron ion [51].

TABLE 3. Physical and mechanical properties and chemical stability of quinol–resorcinol–formaldehyde polymers [51] (determined by methods described in monograph [108]).

| Conditions | Solvent | Loss in wt., % |
|---|---|---|
| Thermal stability 150° | Methanol | 20.45 |
| Comminution 93.2% | Ethanol | 17.4 |
| Grinding 102.7% | Acetone | 19.7 |
| Bulk density of air-dry polymer 0.686 t $m^{-3}$ | Benzene | 2.5 |
| Bulk density of moist polymer 0.588 t $m^{-3}$ | Hydrogenated kerosene | 2.0 |
| Swellability, 11.66% | 3.5 *N* nitric acid | 4.2 |
| | 3.5 *N* hydrochloric acid | 0.2 |
| | 6.0 *N* sulphuric acid | 1.5 |
| | 2.5 *N* caustic soda | 6.1 |

It was concluded from an analysis of the potentiometric titration curves that a semiquinone is formed during the redox titration of a polymer based on quinol, resorcinol, and formaldehyde, or on quinol, phenol, and formaldehyde [41,109]. An equation suggested earlier [110] was used to calculate the equilibrium constant for oxidised and reduced forms of the condensation products, which in the second case (molecular proportions 1 : 1 : 2) was 43. [41]

The standard redox potential $E_0$ of these polymers has been determined. For the first group of polymers $E_0$ = = 0.68 V, [51] whereas the values for the second group are 0.605 V at pH 1.67, [41] and 0.70 V at pH 0.2. [31]

Measurement of the redox potential of an electron--exchange polymer by potentiometric titration consists in mixing the insoluble polymer with a soluble compound possessing a redox function, in which it is easy to measure the redox potential [23,41,111]. When equilibrium is established, the redox potential of the polymer $E_{pol}$ is equal to the potential of the solution $E_{soln}$. By means of the auxiliary system in solution, therefore, the equilibrium potential of the solid redox polymer can be measured at the same time.

If the concentration of oxidised substances is represented [23] by [Ox], and that of reduced substances by [Red], we obtain for the solution

$$E_{soln} = E_{0\,soln} + \frac{RT}{nF} \ln \frac{[Ox]_{soln}}{[Red]_{soln}}, \quad (1)$$

and for the polymer

$$E_{pol} = E_{0\,pol} + \frac{RT}{nF} \ln \frac{[Ox]_{pol}}{[Red]_{pol}}, \quad (2)$$

where $E_0$ is the standard redox potential (in V), $n$ the number of electrons involved in the reaction, $F$ Faraday's constant (96 500 C), $R$ the gas constant (8.31 J $deg^{-1}$ $mole^{-1}$), and $T$ the absolute temperature (°K). When equilibrium is established, we have

$$E_{0\,soln} + \frac{RT}{nF} \ln \frac{[Ox]_{soln}}{[Red]_{soln}} = E_{0\,pol} + \frac{RT}{nF} \ln \frac{[Ox]_{pol}}{[Red]_{pol}}, \quad (3)$$

which can be written

$$E_{0\,pol} = E_{0\,soln} + \frac{RT}{nF} \ln \frac{[Ox]_{soln}}{[Red]_{soln}} - \frac{RT}{nF} \ln \frac{[Ox]_{pol}}{[Red]_{pol}}. \quad (4)$$

Substitution for the difference in potential from Eqn. (1) in Eqn. (4) yields for the redox potential of the polymer finally

$$E_{0\,pol} = E_{soln} - \frac{RT}{nF} \ln \frac{[Ox]_{pol}}{[Red]_{pol}}. \quad (5)$$

If $[Ox]_{pol}/[Red]_{pol}$ is known, $E_{0\,pol}$ can be calculated. When 50% of the reactive groups in the polymer have been oxidised, we obtain

$$\frac{[Ox]_{pol}}{[Red]_{pol}} = 1 \quad \text{and} \quad \frac{RT}{nF} \ln \frac{[Ox]_{pol}}{[Red]_{pol}} = 0, \quad (6)$$

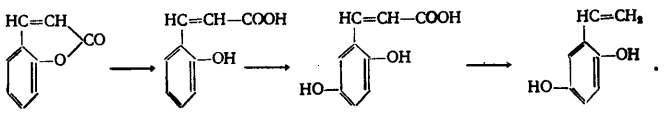
i.e.

$$E_{0\,pol} = E_{soln}. \quad (7)$$

The equilibrium constant can be calculated in the way described by Manecke [112]. Reaction of the redox polymer in the reduced form $H_2R$ with oxygen, for example, can be represented schematically by the equation

$$2H_2R + O_2 \rightleftarrows 2R + 2H_2O.$$

The equilibrium constant $k$ for this reaction is computed from the difference between the potential of oxygen $E_{0\,O_2}$ and that of the polymer $E_{0\,pol}$:



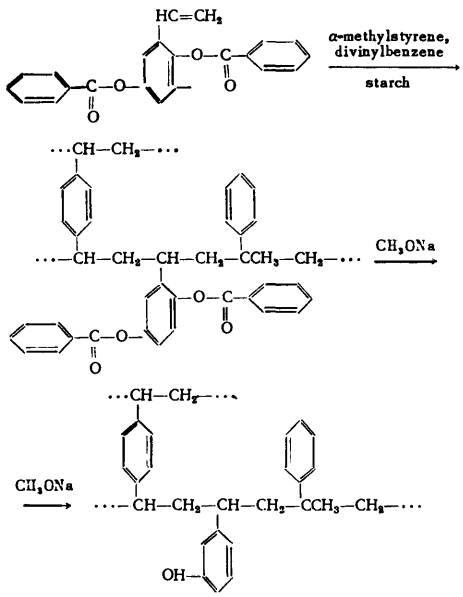
$$E_{0\,O_2} - E_{0\,pol} = \frac{RT}{4F} \ln \frac{a_R^2 \, a_{H_2O}^2}{a_{H_2R}^2 \, P_{O_2}} = \frac{RT}{4F} \ln k, \quad (8)$$

$$\ln k = \frac{4R}{RT} (E_{0O_2} - E_{0\,pol}). \quad (9)$$

Putting $E_{0\,O_2}$ = 1.23 V and $E_{0\,pol}$ = 0.7 V, [31,41,42] we obtain $k = 3 \times 10^{36}$.

## 3. SYNTHESIS OF REDOX POLYMERS BY POLYMERISATION

In 1949 macromolecular compounds capable of oxidation and reduction were obtained by the polymerisation of vinylquinol [28,29]. The vinylquinol starting material was prepared by the scheme [28,29,113,114]



It can also be prepared by another method [115,116], which consists of several stages and its very laborious. The final yield of vinylquinol is low as in the previous case.

The polymerisation of vinylquinol was conducted, without a catalyst, in sealed tubes at 125°. After cooling, the polymer was extracted with hot benzene to remove unchanged monomer. The polymer was a brittle solid mass, pale amber in colour, soluble in polar organic solvents but insoluble in benzene. In the presence of water the polymer became soft and tacky. It was not a success: although all the active groups were reduced, the polymer gradually lost its activity with repeated oxidation–reduction cycles [28,29].

It was established later[117,118] that these polymers consisted predominantly of dimers and trimers of vinylquinol. It is difficult to obtain macromolecular compounds because quinol itself inhibits polymerisation[119].

When the hydroxy-groups in vinylquinol were protected by conversion into dibenzoates or diacetates, polymers could be obtained of molecular weight of the order of 70 000.[117,121] The dibenzoate or the diacetate was copolymerised also with styrene, α-methylstyrene, vinylpyridine, methyl methacrylate, methyl acrylate, or divinylbenzene in the presence of an initiator (benzoyl peroxide, azoisobutyronitrile) and a protective colloid (starch) at an elevated temperature (58–90°) in sealed tubes which had first been evacuated and then filled with nitrogen. The polymerisation was conducted in toluene (styrene and α-methylstyrene), chloroform (4-vinylpyridine), or benzene (methyl methacrylate and methyl acrylate). The duration of polymerisation was 30 minutes, and the degree of conversion <10%.[121-125]

The linear polymers were precipitated with hexane[124]. Linear benzoylated polymers dissolved better in toluene than in acetic acid; whereas the solubility of acetylated polymers was greater in acetic acid.

Polymers of different composition were obtained[126] by copolymerising vinylquinol with acrylic or maleic acid.

In order to improve the kinetic properties[64,122-123,127], cross-linked polymers and copolymers of the above dibenzoates or diacetates were sulphonated, and the ion-exchange and electron-exchange properties investigated. Oxidation and reduction of the sulphonated polymers were extremely slow, but completely reversible over the range $8.5 > pH > 4.7$. Outside these pH limits, partial decomposition of the polymers and irreversible oxidation were observed, and under certain conditions the cation-exchange capacity decreased. The stability of the polymers could be increased by replacing vinylquinol by its methylated derivatives, and divinylbenzene by other cross-linking agents. The polymerisation of 2,5-dimethoxy-3,4,6-trimethylstyrene and 2,5-dimethoxy-3,6-dimethylstyrene gave[128] new methylated vinylquinol polymers — polyvinyl-3,4,6-trimethylquinol and polyvinyl-3,6-dimethylquinol — possessing redox properties. Polymerisation was conducted in the presence of the boron trifluoride–ether complex at a low temperature (-20°) for 36 h. The resulting polymer was treated with hydrobromic acid in glacial acetic acid. The former dissolved in organic solvents, whereas the latter was an insoluble rubberlike substance.

The chemical shifts in the nuclear magnetic resonance signals of several methylated quinols and their derivatives have been measured[129], and the behaviour of dimethyl ethers of quinol and that of methylated quinols on oxidation, etc. have been studied[120,130,235,236].

It has been proposed[127] to obtain redox polymers also by the copolymerisation of vinylquinol with monomers of general formula $CH_2 : CAlkAr$, where the alkyl group contains 1–8 C atoms, and Ar represents phenyl, biphenylyl, naphthyl, or their derivatives. Sometimes other components have been added to the initial reaction mixture.

Reaction with carbonyl chloride of a suspension of 2,5-diacetoxyphenylalanine hydrochloride[131] in dioxan gave 4-(2,5-diacetoxybenzyl)-2,5-dioxooxazolidine, polymerisation of which in dioxan in the presence of alcoholic alkali yielded poly-β-(2,5-diacetoxyphenyl)-DL-alanine of molecular weight 11 000, which could be hydrolysed by alkali and by concentrated hydrochloric acid to poly-β-(2,5-dihydroxyphenyl)-DL-alanine. These methods can be used to obtain new redox polymers of polypeptide character.

A general method has been worked out[132] for obtaining hydroxylated polystyrenes possessing electron-exchange properties and high redox potentials, and methods have been improved for the synthesis of polyvinylquinol. Poly-3-vinylcatechol and poly-3-vinylbiphenyl-4,4′-diol have been prepared from the bismethoxymethyl ethers of the 3-vinyl derivatives of respectively quinol, catechol, and biphenyl-4,4′-diol. The structure of the ethers was established by hydrolysis and reduction to ethyl derivatives of phenols, and also by infrared and ultraviolet spectroscopy. Polymerisation of the resulting monomers was conducted in toluene in the presence of benzoyl peroxide.

Sulphonated derivatives of dicyclopentadienyliron (ferrocene) have also been obtained[133], but were unstable to oxidants. They deposited iron. Potentiometric titration of ferrocene and several of its derivatives has been undertaken. Titration of the diammonium disulphonate gave no positive results, since the reversible transition of iron from the ferrous to the ferric form was accompanied by side-reactions.

Redox potentials have been determined[64,134], ultraviolet spectra of polymers and copolymers of vinylquinol have been recorded, and the effects of pH, salt concentration, and sulphonation on the absorption spectra have been studied. The apparent standard redox potential has been found to depend on the degree of reduction and to be independent of molecular weight when the latter is large. The polymers proved to have higher potentials than the monomers. The potential of a polymer is established slowly on titration at a platinum electrode.

Methods have been described[135] for obtaining 2-vinylanthraquinone from 2-methylanthraquinone. Macromolecular compounds having electron-exchange properties have been prepared by the polymerisation of 2-vinylanthraquinone or by its copolymerisation with styrene, α-methylstyrene, or maleic anhydride in the presence of azoisobutyronitrile, benzoyl peroxide, titanous chloride, or metallic sodium.

Anthraquinone redox polymers have been obtained[136] by the polymerisation of 2-vinylanthraquinone, the reaction of anthraquinone-2-aldehyde and anthraquinon-2--ylmethyl toluene-*p*-sulphonate with poly(vinyl aclohol), and also the polycondensation of ethyl anthraquinon-2--ylmethylenemalonate with ethylene glycol, butane-1,4--diol, diethylene glycol, glycerol, etc.[237].

2,3,5-Trimethyl-6-vinylbenzene-1,4-diol[137], 2-methyl--3-vinyl-1,4-naphthaquinone[138], 1(and 2)-vinylanthraquinone[139], 2,3-dimethyl-5-vinyl-1,4-phenylene diacetate, and 2,3,5-trimethyl-6-vinyl-1,4-phenylene diacetate[140] have been synthesised, among other monomers[238-248], for the preparation of redox polymers.

Soluble and cross-linked poly-*m*-aminostyrene has formed the basis[141,142] for the synthesis of poly-6-vinylisatin, poly-6-vinylindirubin, and poly-6-vinylindol-3-benzothien-2′-ylindigo, and the redox capacity, apparent standard redox potential, and other properties have been examined. Porous indigoid resins have been obtained from porous poly-*m*-aminostyrene.

2-Methyl-3-vinyl-1,4-naphthaquinone and 2-vinylanthraquinone have been used to obtain redox polymers of more ordered structure[143,144,249] and improve chemical properties. Naphthaquinone derivatives did not polymerise, and their diacetates polymerised with great difficulty. Therefore only copolymers of 2-vinylanthraquinone with styrene and with divinylbenzene possessing redox properties were obtained. The copolymerisation was conducted in dimethyl sulphoxide at 140°. Replacement of part of the latter by n-butyl acetate and lowering the temperature of copolymerisation to 100° yielded redox polymers of spongy structure. The copolymer was sulphonated to improve its kinetic properties. The rate of the redox reaction was sufficiently high if not more than 70–80% of the total redox capacity was used. Other parameters are given in Table 4.

2,5-Bistetrahydropyran-2′-yloxyphenyl *p*-vinylphenyl sulphone, 2-tetrahydropyranyl *p*-vinylphenyl sulphide, and 4-methyl-2,5-bistetrahydropyran-2′-yloxyphenyl *p*-vinylphenyl sulphone have been synthesised[145,146,250], and converted into redox polymers. Continuous titration and a method of periodic titration with bromine in 80% acetic acid gave the standard redox potentials $E_0$ of the linear redox polymers as 0.753 ± 0.005 V for poly-*p*-vinylphenylsulphonylquinol, 0.718–0.721 V for poly-2-methyl-5-*p*--vinylphenylsulphonylquinol, and also other values for intermediate and model compounds. It was established that substituents in an unoxidised benzenoid ring have no significant influence of $E_0$, whereas the value of the latter is appreciably affected by the nature of a substituent in a quinonoid ring. Addition of an $RC_6H_4SO_2$ group to quinones increased $E_0$ by 44–66 mV in the case of quinol derivatives, and by 77–88 mV in the case of methylquinol.

Macromolecular redox systems can be obtained which are based on compounds of the polyvinylformal type[147].

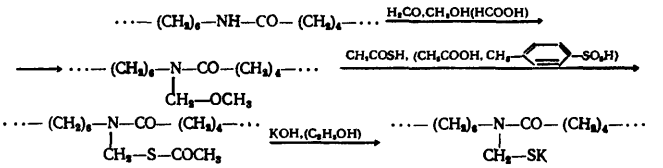


TABLE 4. Composition, ion-exchange capacity, and redox capacity of sulphonated 2-vinylanthraquinone polymers[144].

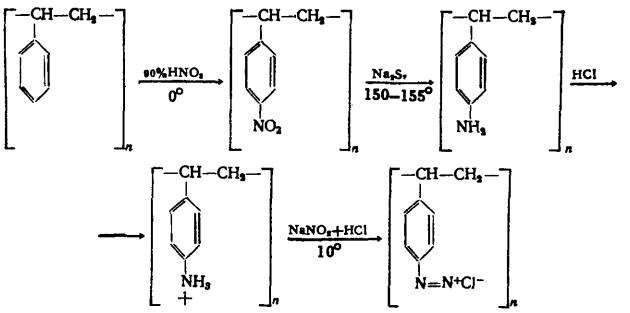
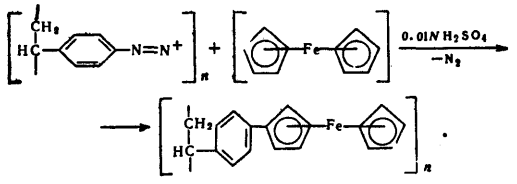
| Specimen | Molar ratio of 2-vinylanthraquinone to sum of comonomers | Divinylbenzene in polymer, mole % | Ion-exchange capacity, mg-equiv. $g^{-1}$ | Redox capacity, mg-equiv. $g^{-1}$ |
|---|---|---|---|---|
| 1 | 1:10 spongy | 12.5 | 4.375 | 1.26 |
| 2 | 1:10 | 12.5 | 4.491 | 1.01 |
| 3 | 1:3 | 6.0 | 3.563 | 2.60 |
| 4 | 1:2 | 6.0 | 3.080 | 3.24 |
| 5 | 1:1 | 8.0 | 2.021 | 4.76 |
| 6 | 1:1 | 6.0 | 2.042 | 4.61 |
| 7 | 1:1 | 4.0 | 2.084 | 4.46 |



## 4. SYNTHESIS OF REDOX POLYMERS BY THE INTRODUCTION OF REACTIVE GROUPS INTO AN INERT POLYMER

Inert macromolecular compounds, containing no redox groups, have been used to obtain redox polymers.

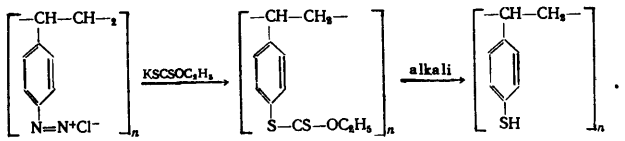
The introduction of mercapto-groups into polyamides (nylon) yields electron-exchange polymers[25]:



Sansoni[15] nitrated[148] cross-linked polystyrene, reduced the resulting poly-*p*-nitrostyrene to poly-*p*-aminostyrene, and diazotised the product:

He obtained[15,21] the redox polymers KVPAS, MVPAS, PFPAS, WBPAS, MBPAS, and CHPAS by coupling the diazotised poly-*p*-aminostyrene with Crystal Violet, Methyl Violet, Parafuchsine, tetramethyl-*p*-phenylenediamine, Methylene Blue, and *p*-benzoquinone respectively. These polymers showed different colours in oxidised and reduced forms. The most successful product was obtained by coupling with Methylene Blue.

The coupling of diazotised poly-*p*-aminostyrene[251] with *p*-benzoquinone, 1,4-naphthaquinone, naphthaquinone oxide, anthraquinone, and 1-chloroanthraquinone gives polymers having electron-exchange properties[23]. When quinol is used, polymers of the polyphenylbenzoquinone type are obtained[149].

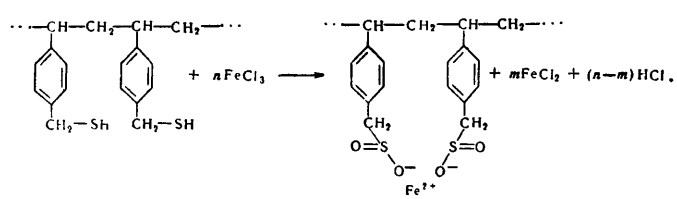


Polyferrocenestyrene redox resins have been obtained from diazotised poly-*p*-aminostyrene and ferrocene[150,207]:

Their apparent redox potentials (415 ± 10 mV) and their redox capacity with respect to the $Fe^{3+}$ ion (5.4 mg-equiv.$g^{-1}$) were determined. After twelve oxidation–reduction cycles the redox capacity had fallen from 5.4 to 2.4 mg-equiv. $g^{-1}$.

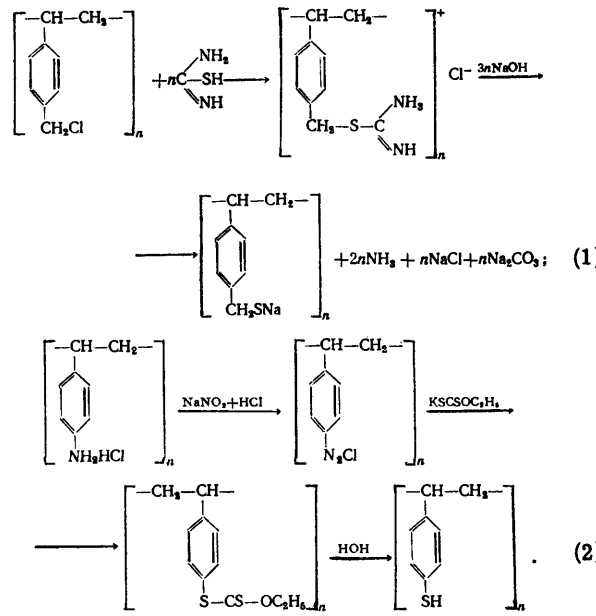
A similar method for obtaining redox polymers has been described by other authors[151,152,252].

Redox polymers of benzenethiol type have been obtained in a similar way[33,153]. Diazotised polyaminostyrene was converted by the action of potassium xanthate into poly-(vinylphenyl xanthate), which was hydrolysed to the corresponding thiol:



The redox capacity of the resulting polymer was 6.6 mg-equiv. $g^{-1}$. The same polymer has been synthesised from *p*-aminoacetophenone[34].

It has been proposed[154] to obtain redox polymers by introducing mercapto-groups and others[253,254] into copolymers of styrene and divinylbenzene.



Trostyanskaya and Tevlina[155] tested methods for preparing styrene–divinylbenzene copolymers containing mercapto-groups, and found the optimum conditions for the synthesis. Copolymers of styrene with divinylbenzene or diallyl maleate, obtained by copolymerisation in suspension, were chloromethylated by the action of paraformaldehyde and hydrogen chloride in the presence of zinc chloride[156]. The chlorine atoms in the copolymers were replaced by mercapto-groups by the action of sodium sulphide or thiourea followed by hydrolysis.

The thio-copolymers showed high redox power, which remained unchanged during 8–10 cycles. The exchange capacity for the sodium ion was 2.9 mg-equiv. $g^{-1}$ at pH > 10, and 1.9 mg-equiv. $g^{-1}$ at pH 7, while the electron-exchange capacity with respect to the $Fe^{3+}$ ion was 0.4 mg-equiv. $g^{-1}$. It was pointed out that most of the mercapto-groups could be oxidised to the sulphinic acid, and take part in ion-exchange with reduced iron cations:

Mercapto-copolymers of styrene and divinylbenzene have been used for the reduction of bivalent copper ions from $CuCl_2$ solution to univalent copper, and of silver ions to metallic silver.

The synthesis[38] and properties have been described of polymers of two types containing thiol groups, a chloromethylated styrene-divinylbenzene copolymer being treated with a solution of thiourea (scheme 1) or an aminated copolymer being diazotised, xanthated, and hydrolysed (scheme 2):

The polymers possessed both electron-exchange and ion-exchange properties. The dynamic exchange capacity with respect to the $Ag^+$ ion from 0.1 *N* silver nitrate solution was 2.7–2.8 and 2.13 mg-equiv. $g^{-1}$ for (1) and (2) respectively.

A simplified method has been developed[157–159] for obtaining electron-exchange polymers of thiol type based on styrene–divinylbenzene copolymers, by treating the swollen copolymer with a solution of elementary sulphur in carbon tetrachloride in the presence of aluminium chloride with heating. The duration of the reaction at 75–78° was 8–9 h. The redox capacity of such a polymer is lower than 1.6 mg-equiv. $g^{-1}$.

Conditions have been studied[160,161] for the interaction of sulphur and polystyrene in dichloroethane and nitrobenzene in the presence of Friedel–Crafts catalysts. The products possessed little redox ability.

Redox polymers have been prepared by the reaction of anthraquinone-2-aldehyde with poly(vinyl acetate) and poly-(vinyl alcohol)[162,255], the reduction of sulphonyl chlorides of styrene-divinylbenzene copolymer with polysulphides[163], and the treatment of polymers of 2-vinylpyridine with chloromethane or bromomethane[164] or of polymers and copolymers of vinyl monochloroacetate with alkali or alkaline-earth metal hydrosulphides[165], etc.[166] Treatment of poly(vinyl chloride) with hydrogen sulphide under pressure gives polychloroethylenethiol[167]. Poly(methyl α-mercaptoacrylate) has been obtained by the reaction of poly-(methyl α-bromoacrylate) with potassium hydrosulphide.

Reaction of a solution of poly(vinyl alcohol) with thiourea in the presence of hydrogen bromide gives a thiouronium salt[168–179], which is hydrolysed by alkali to polyethylenethiol.

Macromolecular compounds possessing redox properties have been obtained by the reaction[171] of styrene–maleic anhydride copolymers with 1-aminoanthraquinone,

7-amino-3-oxophenothiazine, and *p*-amino-*p'p"*-bisdimethylaminotriphenylmethane.

It has been claimed[172] that thermostable polymers having electron-exchange properties can be obtained by adding an alcoholic solution of a diamine and/or a polyamine rapidly with stirring to a hot alcoholic solution of *p*-benzoquinone. The mixture is boiled for about 40 minutes, and the polymer separated after a few hours.

Redox polymers have been obtained by using the reaction of a polymeric primary or secondary amine with the lactone of β-2,5-dihydroxyphenylpropionic acid[173].

Electron-exchange polymers have been obtained by treating polychlorotrifluoroethylene (Kel-F) powder with a solution of tetrachloroquinol in ether[174]. The redox capacity was 1.6 mg-equiv. $g^{-1}$ based on the dry polymer. These redox polymers were unstable: after a few oxidation-reduction cycles, a fall was observed in the already low redox capacity (perhaps owing to the elution of active components of low molecular weight).

## 5. REDOX ION EXCHANGERS

Ion-exchange materials, which form the framework, can be used as starting materials for the preparation of redox ion exchangers. Additional functional groups are attached to them by subsequent treatment with monomeric compounds possessing redox properties. These monomers either react with the resin or are adsorbed on it.

Prokhorov and Yankovskii[26] suggested a method for removing dissolved oxygen from water by passing the latter through a layer of sulphonated coal previously treated with a solution of a ferrous salt. This for the first time opened up a path to the preparation of redox ion exchangers.

Redox ion-exchange resins have been obtained also by treating anion exchangers with solutions of copper or silver salts[27], which formed complex compounds with the amino-groups of the anion-exchange resin:

$$4R{-}NH_2 + CuSO_4 \longrightarrow [Cu\,(R{-}NH_2)_4]SO_4.$$

Reducing properties were conferred on them by subsequent treatment with alkaline sodium dithionite solution. This reduced the copper (or silver) to a finely divided metallic state, in which the corresponding oxidation readily occurred, and the reaction products could again be reduced. The cycle could be repeated many times. On passage of water through a layer of such an ion exchanger, however, small amounts of copper (or silver) ions passed into the filtrate as a result of dissociation of the complex compounds on the surface of the anion-exchange resin. In order to retain the ions, it was proposed to use a cation-exchange resin in the sodium form, or an anion-exchange resin in the hydroxide form.

Redox ion exchangers have been obtained[15,30,175] by treating the water-swollen cation-exchange resins Wofatit F, Amberlite IR 120, and Dowex 50 with solutions of salts of iron, tin, cerium, titanium, Fuchsine, Methyl Violet, Crystal Violet, Tolusafranine, Rosinduline, Capri Blue, or Methylene Blue; and the anion-exchange resins Wofatit M and Amberlite IRA 400 with solutions of quinol, anthraquinol, tetrachloroquinol, and dihydroindigodisulphonic acid.

In the same way[175-178] strongly basic anion-exchange resins have been used as the basis for the preparation of redox ion-exchangers with inorganic anions — $H_3PO_2^-$, $S_2O_3^{2-}$, $SO_3^{2-}$, $S_2O_4^{2-}$, $NH_2NHCSO_2^-$, and $BH_4^-$ — their redox capacities and redox potentials being given in Table 5.

Redox ion-exchange resins (Table 6) have been obtained also by treating the strongly basic anion-exchange resin Dowex 2 with solutions of Alizarin, thymolphthalein, indigotetrasulphonate, indigodisulphonate, or Thymol Blue; the weakly basic anion-exchange resin Dowex 3 with a solution of thymolphthalein; or the cation-exchange resins Dowex 50 and Amberlite IRC 50 with solutions of Methylene Blue or Crystal Violet[180] (see also Ref. 256).

Redox ion-exchangers have been prepared in an analogous manner using Fuchsine and other active substances[19,257,258].

Dalibor[40,259] prepared redox ion exchangers by treating the strongly acidic KPS and the weakly acidic CP cation-exchange resins with solutions of dyes (Capri Blue, Thionine, Methylene Blue, Nile Blue, Neutral Red, etc.) and inorganic salts ($TiCl_3$, $CrCl_2$, $CuCl_2$, $Na_2S_2O_4$), and also by saturating the anion-exchange resin L 150 with solutions of mercaptoacetic or α-mercaptopropionic acid. This resulted in ionogenic bonding of the dye or inorganic salt with the resin. The interaction of Methylene Blue and of titanous chloride with the cation-exchange resin can be represented by the schemes

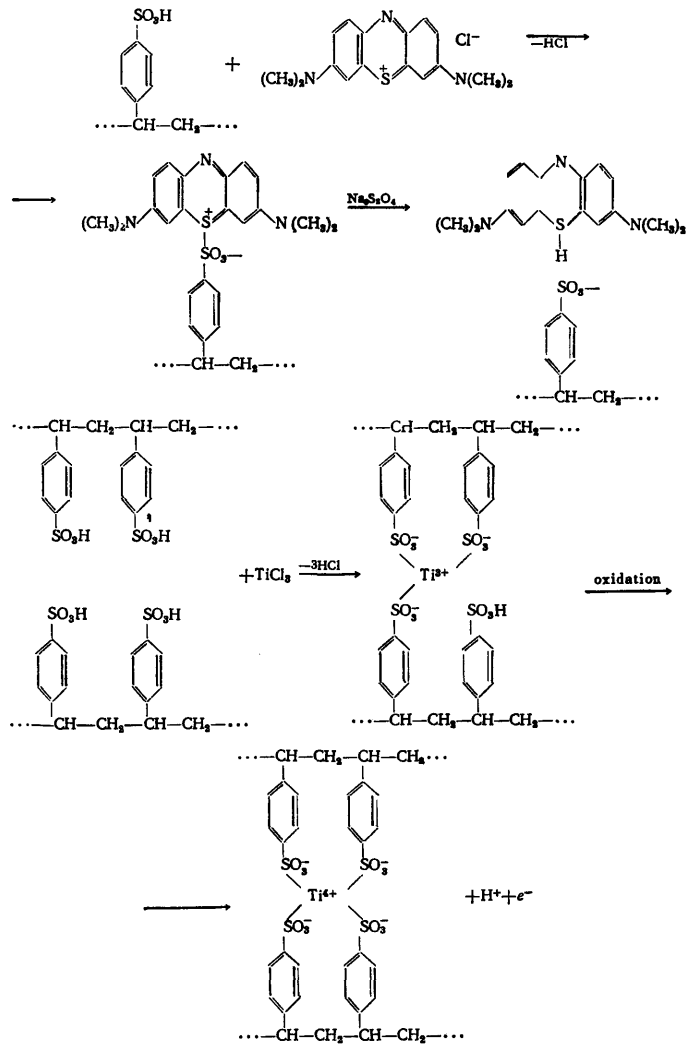


TABLE 5. Properties of some redox ion exchangers [176].

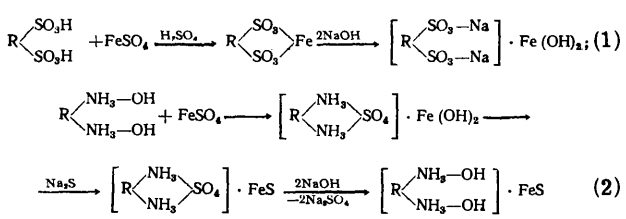

| Bound anion | Redox capacity, mg-equiv. $g^{-1}$ | time, min, to reach 50% | time, min, to reach 100% | Standard redox potential of free anion (Ref. 179) |
|---|---|---|---|---|
| $SO_3^{2-}$ | 0.83 | 5.0 | 20 | −0.17 |
| $S_2O_3^{2-}$ | 2.14 | 8.7 | 35 | −0.08 |
| $H_3PO_2^-$ | 0.37 | 8.3 | 30 | +0.50 |
| $S_2O_4^{2-}$ | 1.99 | 3.3 | 25 | +1.12 |
| $NH_2NHCSO_2^-$ | 2.13 | 5.4 | 60 | |
| $BH_4^-$ | 8.4 | — | — | |

TABLE 6. Quantities of dyes adsorbed in various ion exchangers [180].

| Dye | Ion-exchanger | Bound dye, mg/2 g ion-exchanger |
|---|---|---|
| Thymol Blue | Dowex 2 (strongly basic) | 58.0 |
| Indigodisulphonate | ditto | 100.0 |
| Indigotetrasulphonate | » | 100.0 |
| Thymolphthalein | » | 40.0 |
| Alizarin | » | 99.8 |
| Thymol Blue | Dowex 3 (weakly basic) | 8.0 |
| Thymolphthalein | ditto | 10.0 |
| Methylene Blue | Dowex 50 (strongly acidic) | 98.2 |
| Crystal Violet | ditto | 99.2 |
| Crystal Violet | Amberlite IRC 50 (weakly acidic) | 99.4 |

The quantity of dye which is bonded, but not of titanium, depends on the degree of cross-linking and the porosity of the ion-exchanger (Table 7). This can be explained by the fact that the pores in the cation-exchange resin are smaller than the radius of the dye molecule but comparable with the radius of the titanium ion.

Vol'f and his coworkers [181-184] obtained redox ion exchangers by successively treating (1) cation exchangers and (2) anion exchangers with solutions of iron(II) sulphate, alkali, and sodium sulphide (see also Refs. 260 and 261):

Redox ion-exchange resins have been obtained also by saturating a weakly basic anion-exchange resin with $CuSO_4$ solution and then reducing with alkaline sodium dithionite solution, a strongly basic anion-exchange resin with sodium sulphite solution, and a polystyrene cation-exchange resin with iron(II) sulphate solution [49].

According to available information, the Chemical Process Co. of California has placed on the market in the U.S.A. the redox ion exchanger Dualite S-10, obtained by treating the anion-exchange resin Dualite A-3 with a solution of a copper salt [16,19,22,185].

A redox anion exchanger has been obtained by saturating [186] an anion-exchange resin containing strongly and feebly basic functional groups (in the proportions 1 : 1) with an ammoniacal solution of sodium dithionite, and has been used to remove dissolved oxygen from desalinated water.

TABLE 7. Quantities of dye or titanium bound on cation exchanger [40].

| Dye or titanium | Cation-exchanger and its degree of cross-linking, % | | Bound dye or Ti, mg |
|---|---|---|---|

| » | » | 8 | 48.0 |

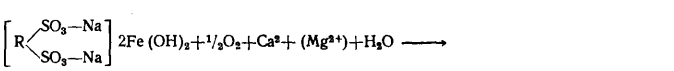
The anion-exchange resin used was a product of the condensation of phenoxyethyl chloride with tetraethylenepentamine.

The method of preparing redox ion exchangers is fairly simple. The water-swollen cation-exchange resin in the hydrogen form, or the anion-exchange resin in the hydroxide form, is stirred for a definite time in a solution of the appropriate dye or inorganic salt, and then carefully washed with water and alcohol to remove unchanged dye or salt. The compounds mentioned above are used as reducing agents.

Redox ion exchangers have not yet found wide practical application. As already mentioned, this is due mainly to their instability, low redox capacity and gradual decrease therein, and sometimes to unsatisfactory kinetic properties. Redox ion exchangers are therefore less promising than redox polymers.

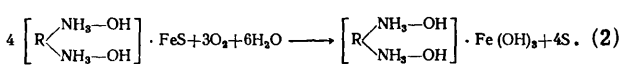
Another class of compounds containing metals of variable valency must be mentioned, in particular derivatives of chlorophyll and haemin, which possess redox functions [187]. They are of no practical value owing to their insignificant redox capacity, but they are of some interest as models of enzymes [187-193]. Natural compounds of this type play an important part in biological processes [187].

## 6. INORGANIC ELECTRON EXCHANGERS



Several inorganic redox electron exchangers are known. The redox capacity of the mineral nontronite is 0.16 mg-equiv. $g^{-1}$, which corresponds to one-third of the total iron content [194]. The exchange capacity of the reduced form is aproximately 0.005 and 0.085 mg-equiv. $g^{-1}$ with respect to the $Cl^-$ and the $^{60}Co^{2+}$ ion respectively. Other inorganic electron exchangers — sodium polyvanadate, hydroxyphenyl silicate, etc. — also exist. The advantages of inorganic electron exchangers over redox polymers are absence of irreversible oxidation, relatively high rate of oxidation, and great stability to high temperatures and radiation; their disadvantages are very low capacity and instability in strongly acid and strongly alkaline media.

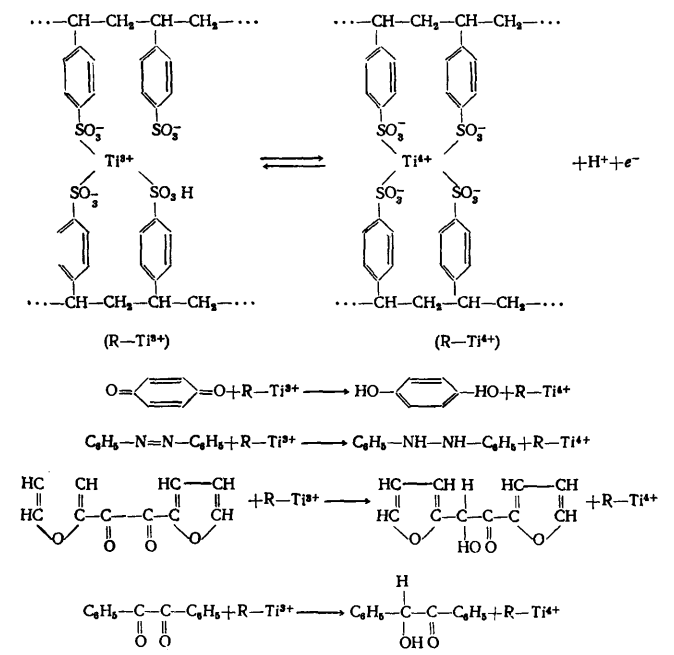
## 7. APPLICATIONS OF REDOX POLYMERS

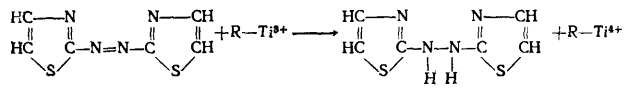


Redox polymers can be used to reduce the ions $Fe^{3+}$, $Cr^{6+}$, $V^{5+}$, $Ce^{4+}$, $Ti^{4+}$, $Ag^{+}$, $Pu^{2+}$, etc.[2,48,100,174,175,195]; to separate cations by selective reduction[15]; for the selective reduction of aldehydes to alcohols[164]; for the oxidation of copper, tin, chromium, bromide, and iodide ions[100,155]; for the oxidation of aldehydes to acids[164]; for the dehydrogenation of hydrazobenzene, cysteine, ascorbic acid, tetrahydronaphthalene, etc.[112,196]; and also for the preparation of hydrogen peroxide[17,19,100,197,198]. They can be employed to remove peroxides or readily reducible substances from lubricating and transformer oils, to remove sulphur from refined petroleum fractions[164], and to free acetylene from oxygen[19] (see also Refs. 261-265).

By means of redox polymers it is also possible to remove dissolved oxygen from water, which is very important in the struggle against corrosion[17,19,42,186,199,261,266-269].

Redox ion exchangers can be employed for the simultaneous deoxygenation and softening of water[183,184]:





(1)

(2)

Redox ion exchangers based on Methylene Blue, Thionine, Capri Blue, Nile Blue, Neutral Red, and some other compounds have been used for the reduction of indigotetrasulphonate, indigodisulphonate, and Rosinduline GG. Redox ion exchangers prepared with $Ti^{3+}$ and $Cr^{2+}$ are employed for the reduction of *p*-benzoquinone, 1,4-naphthaquinone, benzil, furil, azobenzene, 2,2'-azothiazole, ammonium metavanadate, etc.[40]:

Redox ion-exchangers prepared by treating the anion-exchange resin L 150 with sodium dithionite solution have been used for the reduction of triphenyltetrazolium chloride and some other substances. The reduction of sodium tellurite and 2,2'-*p*-(di-*o*-methoxy)diphenylene-3,3',5,5'-tetraphenylditetrazole bromide by the anion-exchanger L 150 on which mercaptoacetic or $\alpha$-mercaptopropionic acid has been adsorbed was accelerated by light[40].

Paper impregnated with a solution — or coated with an insoluble powder — of a redox polymer can be used in radial chromatography[121] and as an indicator for the detection of small traces of oxygen, chlorine, and other oxidising agents[50,201].

Redox polymers can be employed as electrodes for the measurement of solution pH[202] and as catalysts for oxidation or reduction[17,19,100,164] and other reactions[203].

The application of redox polymers in medicine for therapeutic purposes[163], mainly for protection from radiation[204], will evidently acquire great importance[270-275].

Redox polymers have not hitherto become widespread in industry. The reasons are the unsatisfactory kinetic properties, the instability of the capacity values, and the high cost of the initial components.

The immediate task is to develop methods for the synthesis of redox polymers which will ensure a high reaction velocity and chemical stability of the polymers.

The kinetics of redox processes can be improved by producing redox polymers of macroporous structure. The chemical stability can probably be increased by using very pure vinyl monomers and producing polymers of more regular structure.

The development of effective methods, involving few stages, of the synthesis of the initial monomers may appreciably lower the cost of redox polymers.
