4. Copolymerisation of the anhydrides of *N*-carboxy-α-amino-acids 357
5. Preparation of graft and block copolymers 360

## I. INTRODUCTION

Among polyamides there is a large group of polymers which differ from other polyamides in their properties and methods of preparation. This group, called polypeptides or poly-α-amino-acids, is very close in its composition and structure to one of the most important classes of polymeric substances — proteins. In contrast to proteins in which there is a strictly defined alternation of amino-acids, synthetic polypeptides usually contain only one amino-acid or several amino-acids with a random distribution along the chain of the macromolecule.

By polycondensation of various low-molecular-weight derivatives of peptides, it proved possible to prepare block-polypeptides with a random distribution of the blocks but with a known alternation of the amino-acids within each block, and also polypeptides with a defined alternation of amino-acids, whose number however was small.

$$[-HNCHR_1COHNCHR_2CO-]_x[-HNCHR_3COHNCHR_4CO-]_y \text{ and}$$
$$[-HNCHR_1COHNCHR_2COHNCHR_3CO-]_n.$$

Starting with the work of Fischer [1], Bergmann [2], and Leuchs [3], studies of the synthesis and properties of peptides and polypeptides have proceeded on a wide front. The results of the investigations published up to 1957 were described in detail previously [4,5]. The further increase in the number of papers published, including reviews, on the individual problems of the chemistry of polypeptides [6-13] indicates the growing importance of synthetic polypeptides.

One of the main aims of protein chemistry in the last decade has been the elucidation of the correspondence between biological functions and the chemical structure of proteins [14]. Synthesis of polypeptides as model compounds is one of the possible ways of determining the effect of various amino-acids, their sequence, and steric configuration on biological properties.

Synthetic polypeptides are also of considerable interest for polymer chemistry, since the methods of their preparation permit nowadays the synthesis of polymers with various amino-acid compositions and different structures, and with molecular weights ranging from several hundred to a million and above, and also they provide a means of modelling natural peptides, and modifying their composition, structure, and properties. This makes it possible to obtain polymers whose properties vary within very wide limits, and thereby solve important problems in the chemistry of macromolecular compounds.

In view of the abundance of data available, we are obliged to restrict ourselves to a description of the principal results of studies of the synthesis of polypeptides, published between 1957 and 1963, including certain important sections such as the chemical reactions and conformational analysis of polypeptides and also the methods of investigating their structures. Furthermore, the review does not deal with the important field of stepwise syntheses of peptides and their application, which is of independent interest. The review considers in detail the synthetic methods which have been most extensively developed in the last six years.

## II. SYNTHESIS OF POLYPEPTIDES FROM α-AMINO--ACIDS, PEPTIDES, AND 2,5-DIOXOPIPERAZINE DERIVATIVES

### 1. Thermal Polycondensation of α-Amino-Acids and Peptides

It has been found that the usual method of polycondensation of amino-acids containing an amino-group at some distance from the carboxy-group [$H_2N(CH_2)_nCOOH$, $n \geq 5$] cannot be successfully used with α-amino-acids and peptides. At elevated temperatures the amino-acids and peptides undergo various side reactions (decarboxylation, deamination, cyclodehydration, etc.) resulting in the formation of low--molecular-weight products. Furthermore, the closeness of the amino- and carboxy-groups in α-amino-acids favours the formation at high temperatures of 2,5-dioxopiperazines, dimeric cyclic derivatives with high stability [15]. 2,5-Dioxopiperazines are also formed as a result of the degradation of polypeptides [16-18] on prolonged exposure to high temperatures. All these facts make it extremely difficult to obtain linear polypeptides directly from α-amino-acids. However, attempts to simplify to the greatest possible extent the synthesis of polypeptides are continued and to this day attract the attention of many investigators.

Among the various amino-acids studied, glycine undergoes polycondensation most readily. Meggy [19] suggested that, since glycine can be dehydrated at 140–180° in glycerol or ethylene glycol with the formation of 2,5-dioxopiperazine and the latter is thermodynamically less stable over a wide temperature range (60°–180°) than polyglycine, direct condensation of glycine to polyglycine is quite possible. Indeed, when glycine is heated with a small amount of hydrochloric acid in sealed tubes at temperatures in excess of 140°, it is converted into polyglycine, the yield of the polymer varying with the glycine : hydrochloric acid ratio.

Polyglycine is not obtained below 130° and when tubes which had been heated to 140° are kept a further 24 h at 130° the yield of the polymer falls appreciably. It appears that this reaction requires a temperature above 140° and the presence of a solid phase. Apart from hydrochloric acid, the reaction is catalysed by phosphoric acid, ammonium chloride, and sodium hydroxide. It can also be carried out in the presence of water alone, but hydrochloric acid ensures the highest yield and the best quality of the polymer.

Meggy believes that the polymerisation of glycine may be regarded as a heterogeneous stepwise reaction between glycine in solution and the solid polyglycine:

$$\text{glycine} + \text{X-mer} = (\text{X} + \text{I})\text{-mer} + H_2O. \qquad (1)$$

It would appear that this process could result in prolonged growth of the polymeric chain and hence in a prolonged increase of the average degree of polymerisation $n$. However, it is probably accompanied by internal hydrolysis of the peptide bonds (X + Y)-mer + $H_2O$ = X-mer + Y-mer, as a result of which equilibrium is established under the given conditions and $n$ remains constant. Having measured the partial pressure of water in the system, Meggy calculated that for this reaction $\Delta H$ = 3.3 kcal mole$^{-1}$ and $\Delta S$ = = 5.9 kcal mole$^{-1}$ deg$^{-1}$.

Attempts at polycondensation of other amino-acids were unsuccessful. α-Aminoisobutyric acid does not change on heating with a small amount of hydrochloric acid at 140° for 24 h. At 220–240° traces of a sublimate were observed, which Meggy believes to be 3,3,6,6-tetramethyl-2,5-dioxopiperazine. Prolonged heating at this temperature resulted in appreciable pyrolysis of the initial amino-acid. Under similar conditions DL-phenylalanine decomposes partially with the formation of resinous products; L- and DL-alanine is converted into dark viscous products which are completely soluble in water. Thus the majority of α-amino-acids do not form homopolypeptides on heating. The ease with which glycine undergoes polycondensation is probably due to the absence of a side-chain capable of causing steric hindrance.

Fox and Middlebrook [20-22] suggested that the conditions of the thermal polycondensation of amino-acids are very similar to the conditions obtaining in the formation of protein species on earth and showed that amino-acids which fail to yield peptides when heated in a pure form are partially converted into linear polypeptides when they are heat-treated in a mixture with other amino-acids. Further study led to a number of interesting findings and the observation of a number of interesting phenomena. Thus when equimolar mixtures of the DL-forms of aspartic acid, leucine, valine, and phenylalanine are heated at 200° for 0.5–3 h, in addition to appreciable quantities of acetone-soluble tarry products, polymers were obtained whose hydrolysate contained the initial amino-acids [23,24]. On the basis of the results obtained for the polycondensation of various pairs of amino--acid in different combinations, Fox and Harada concluded that copolymeric peptides are obtained by the thermal method only when the reaction mixture contains either glutamic or aspartic acid [25]. Table 1 presents the results of biuret tests of the products of the joint thermal condensation of glutamic acid with other α-amino-acids. Usually [25] L- or DL-glutamic acid was heated for 0.5–2 h with various amino-acids in equimolar proportions at 160–190°. The

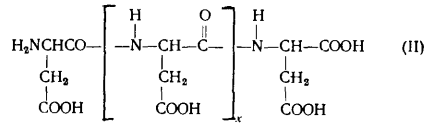
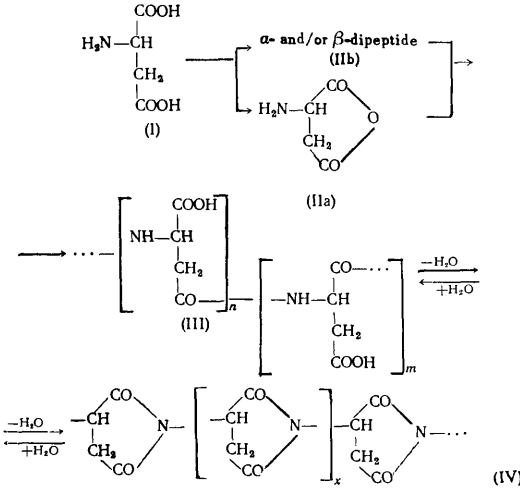
molecular weight of the copolymers with glycine reached 10 000–20 000.



During thermal copolycondensation glutamic acid is converted into pyroglutamic acid[26] which melts in the presence of other substances at 170° and probably behaves as a solvent for the reaction mixture thus favouring a more rapid and complete reaction. Furthermore, a relative estimate of the yields of the products showed that pyroglutamic acid is more reactive than glutamic acid. It is also extremely probable that glutamic and pyroglutamic acids can behave as "acid" catalysts for amino-acid copolycondensation, since it is known that the formation of the amide bond is catalysed by protons, in particular in the presence of traces of water. However, the above workers did not present any evidence for this hypothesis.

Heating of aspartic acid does not result in the formation of any liquid products at temperatures below 200° but the acid is also capable of forming copolymers, which in contrast to the copolymers with glutamic acid, contain a smaller proportion of neutral and basic acids. A striking property of aspartic acid is that it is capable of homopolymerisation on heating above 100°. This interesting property attracted attention long ago and has been the subject of numerous studies.

It has been shown[27,28] that polyaspartic acid is a polyimide (I), which firmly retains water (approximately one molecule of water per imide bond); the latter can only be removed by thorough drying at 200° in a vacuum. The polyimide polyhydrate is converted into polyaspartic acid with the structure of a true polypeptide (II) on brief heating in dilute sodium hydroxide solution. The mean molecular weight of polyaspartic acid, which is approximately 110 000, was determined by end-group analysis and from the rate of sedimentation in the ultracentrifuge.



(I)

(II)

Earlier, Kovacs, Könyves, and coworkers[29-34], who studied the mechanism of the thermal polycondensation of aspartic acid and the structure of the resulting polymeric products, arrived at a similar conclusion. The polycondensation of aspartic acid was carried out either by heating in a vacuum (0.1 mmHg) at 200° or by boiling a suspension of aspartic acid in tetralin which made it possible to remove the water, evolved during the condensation, by azeotropic distillation. The authors found that thermal polycondensation of aspartic acid (I) yields the so-called "anhydropolyaspartic acid" (IV):

(IV)

Using the Hofmann degradation, the authors determined the ratio of the $\alpha$- and $\beta$-links in the intermediate $\alpha\beta$-polyaspartic acid (III), which proved to be 1 : 1.3. The molecular weights of different specimens of substance (III) calculated by Van Slyke's method were in the range 6000–12 000.

Anhydropolyaspartic acid, prepared by different methods, had identical properties: it did not dissolve in water or a dilute solution of sodium bicarbonate, and on partial hydrolysis (0.1 *N* NaOH) it was converted into $\alpha\beta$-polyaspartic acid. In addition, study of the mechanism of the initial stage of the condensation showed that heating of acetylaspartic acid (145–200°) also yields anhydropolyaspartic acid (IV) instead of the expected monomeric anhydride.

When mixtures of aspartic and glutamic acids in various proportions were heated at 170–180°, polymers of fairly high molecular weight, with a polyimide structure according to infrared spectroscopic data, were obtained[35]. As in the case of the homopolymer of aspartic acid, the imide form of the copolymer is converted into the polypeptide on treatment with a hot solution of sodium hydroxide or boiling water. If the polypeptide thus isolated is heated, it is reconverted into the imide form, identical with the initial polymer. The authors propose the following mechanism for the mutual interconversions of the various forms of polyaspartic acid and the products of the thermal copolycondensation of glutamic and aspartic acids.

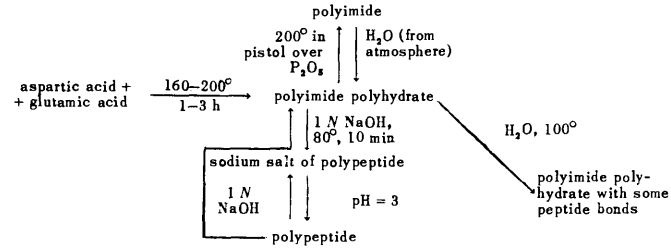


Table 2 presents data on the effect of temperature on the copolycondensation of L-aspartic and L-glutamic acids [35]. It is evident that the mean molecular weight and the yield appreciably increase with temperature. The dependence of the yield of the polymer on the proportions of the initial acid is given in Fig. 1, which shows that the optimum yield of the polypeptides is achieved when the aspartic : glutamic acid ratio is (3–4) : 1.

It was found that the glutamic acid content of the copolymer in the *N*-terminal position is 2–2.5 times greater than its total content in the polypeptide (Table 3).

On the basis of these data, Fox and Harada put forward the hypothesis [35-39] that on copolycondensation amino-acids "spontaneously" take up a specified ordered arrangement in the polymeric chain.

The results of the polycondensation of glutamic and aspartic acids with one another and with other α-amino-acids show that all 18 amino-acids which are present in natural proteins can take part in polycondensation simultaneously. As a result of such synthesis, Fox and Harada obtained a number of protein-like substances which they called "proteinoids"; the qualitative composition of their hydrolysates was the same as that of most natural proteins [36-38]. "Proteinoids" are fairly readily obtained only in the presence of a large excess of aspartic and glutamic acids. When they are present in equimolar proportions with other amino-acids, side-products are formed (for example 2,5-dioxopiperazines) in addition to peptides, and the isolation of the peptides becomes difficult.

The proteinoids were prepared by heating (2 h at 170–180°) two parts of glutamic acid, two parts of aspartic acid, and one part of an equimolar mixture of the remaining amino-acids. Apart from an excess of the acid amino-acids, the success of the reaction requires the removal of water from the reaction vessel, which is achieved by heating the reactants above 100°. Glutamic acid may be replaced by glutamine. The reaction is accelerated by orthophosphoric acid, whose effect on the copolycondensation of α-amino-acids was studied using as an example the copolycondensation of aspartic acid with glutamic acid and of aspartic acid with glycine, which takes place readily [39]. Phosphoric acid increases the yield but has almost no effect on the molecular weight of the polypeptides. On more prolonged heating, the amount of product which does not dialyse through the cellophane membrane increases, which is probably due to an increase in the yield of the high-molecular-weight fraction of the polymer. The formation of non-dialysable polymer after heating for 1 h begins at a temperature as low as 150°. In the absence of phosphoric acid comparable results are obtained only at 170°. Table 4 presents data on the effect of temperature on the copolycondensation.

In the presence of phosphoric acid the *N*-terminal composition of the copolymer changes little and the aspartic acid content of the copolymer rapidly increases with increase of the aspartic acid : glutamic acid ratio in the initial mixture. The difference between the aspartic acid : glutamic acid ratios calculated from the total and *N*-terminal compositions is in this case even greater. It follows from this that phosphoric acid favours the self-regulation of the disposition of the amino-acid residues in the polypeptide chain. The relative content of phosphoric acid in the initial reaction mixture has an appreciable effect on the rate of condensation (Fig. 2). The authors believe that phosphoric acid can behave in this reaction both as a solvent and as an acid catalyst and can also facilitate the removal of water from the reaction sphere and the formation of intermediate active compounds [40].

All the proteinoid fractions gave positive biuret, xanthoproteic, and other qualitative tests for protein. In the cold proteinoids do not react with ninhydrin. However, in hot solutions they give the colour characteristic of this test (clearly as a result of the partial removal of amino-acids)

but at a slower rate than natural proteins. The mean molecular weight of proteinoids is smaller than that of the copolymers of aspartic and glutamic acids obtained under the same conditions, amounting to about 4000–8000.

Infrared spectra show that proteinoids have a typical polypeptide structure. In addition, the spectra show absorption bands characteristic of imide bonds but the peaks characteristic of 2,5-dioxopiperazines are completely absent.

The solubility of proteinoids depends on the method of preparation. Copolymers synthesised in the usual way were nine-tenths insoluble in water but were soluble in salt solutions, for example in 0.1 *N* phosphate buffer at pH 7.9 or in 3.5% solution of sodium chloride. Like natural proteins, synthetic proteinoids can be salted out by the addition of a saturated solution of ammonium sulphate to the salt solution.

Proteinoids can replace the peptone in the broth culture of *Lactobacillus arabinosus*; although the growth rate of the bacteria in the broth based on the proteinoid is somewhat lower, the very fact of the growth of the microorganisms indicates that the links in the proteinoid are susceptible to attack by bacterial proteases.

Thus in many of their properties the products of the thermal copolycondensation of the mixture of 18 amino-acids closely resembles natural proteins. However, heating at 170–180° inevitably results in partial racemisation of the asymmetric centres in the amino-acids and, in contrast to the protein chain, the peptide chain of protenoids is built up of amino-acid residues of different configuration. As a result of this, it is impossible to obtain by this method polypeptides with the steric structure of protein molecules.

The available data are insufficient for a complete answer to the problem of the arrangement of the amino-acid residues in proteinoids — whether the arrangement is completely random or whether it is ordered in some specified way. The authors of the investigation believe that, since the *N*-terminal ratios of glutamic acid, aspartic acid, and neutral amino-acids appreciably differ from the ratios in the total composition and from the ratios of the components in the initial mixture (Tables 5 and 6) and since the *N*-terminal amino-acid composition varies with the temperature of the synthesis while the total composition remains constant, the thermal reaction of the mixture of amino-acids cannot be regarded as a completely disordered process.

Krampitz[41-43] obtained several proteinoids by heating a mixture of amino-acids in sealed tubes in an atmosphere of nitrogen (3 h at 170°). Proteinoid (I) was synthesised from two parts of aspartic acid, two parts of glutamic acid, and one part of an equimolar mixture of other amino-acids, namely: DL-alanine, DL-isoleucine, DL-thereonine, DL-valine, DL-methionine, DL-phenylalanine, DL-serine, DL-tryptophan, L-arginine, L-histidine, L-proline, L-leucine, L-tyrosine, glycine, and lysine monohydrochloride. Proteinoid (II) contained four parts of aspartic acid, four parts of glutamic acid, and one part of the above equimolar mixture of amino-acids. After purification the copolymers give the following positive reactions: biuret, xanthoproteic, Hopkins–Cole–Adamkewicz, Salkowski, and the reaction with Azocarmine B. The *N*-terminal positions in both proteinoids contain mainly aspartic and glutamic acid residues, the contents of neutral and basic acids being only slight. It was found that the hydrolysis of copolymers (I) and (II) by a number of proteolytic enzymes, such as pepsin, trypsin, erepsin, and papain proceeds to different extents. Similar results were obtained by Fox and Harada, who studied the effect of chymotrypsin and pepsin on two proteinoid specimens[37]. Fig. 3 presents the results of the proteolysis of the synthetic products and casein. It is evident that casein is hydrolysed more

1) proteolysis of 2 : 2 : 1-proteinoid with chymotrypsin; 2) proteolysis of casein with chymotrypsin; 3) proteolysis of 1 : 1 : 1-proteinoid with pepsin; 4) proteolysis of casein with pepsin.

completely by the enzymes than the proteinoid, because proteases act only upon the links between L-amino-acid residues. Pepsin is particularly active in the presence of acid amino-acid residues and for this reason proteinoids are more susceptible to "attack" by pepsin than by other enzymes.

Like dicarboxylic amino-acids, free DL-lysine is converted at 150–170° into the liquid lactam and at 180–230° it undergoes homopolymerisation[44]. Lysine also readily condenses with glycine, alanine, and other neutral amino--acids, glutamic and aspartic acids, caprolactam, and succinic, terephthalic, and other acids. The infrared spectra of the lysine homopolymer and the copolymers of lysine with neutral amino-acids and with glutamic acid show that these are typical polypeptides. Lysine monohydrochloride is incapable of homopolycondensation but it readily undergoes copolycondensation with glutamic acid and other amino-acids in the presence of orthophosphoric acid.

The lysine homopolymer is soluble in water but does not dialyse through a cellophane membrane. The copolymers of lysine with glutamic acid and with glycine are gel-like substances while its copolymer with aspartic acid is a spongy solid mass. The amorphous copolymers of lysine with glutamic and with aspartic acids swell in alkalis and acids but do not dissolve in them. This is probably because the copolymers are highly branched and probably possess to some extent also a three-dimensional structure.

In 1961 Fox et al.[45] reported the thermal copolymerisation of all 18 α-amino-acids in the presence in the reaction mixture of acid or basic components. One of the copolymers was obtained on heating the mixture of amino-acids with an excess of aspartic acid and another, under similar conditions, with an excess of lysine. In many of their properties both copolymers closely resemble proteins. The first proteinoid readily dissolved in water, dilute sodium bicarbonate solution, and phosphate buffer, had a molecular weight of the order of 3000–9000, and an isoelectric point close to 2.8. The infrared spectrum shows that the copolymer contains a considerable number of imide links which disappear when the proteinoid is treated with alkali, its spectrum then becoming typical of a polypeptide structure. Copolymer (II) was an elastic rubberlike substance soluble in mineral acids and only partially soluble in water (10%). Its molecular weight exceeded 25 000, its isoelectric point was of the order of 8.4, and it had the additional interesting feature that it could form films.

Soon after the start of the investigation of the thermal synthesis of peptides, Fox et al.[23] observed by chromatography that the hydrolysis mixtures contain a greater number of amino-acids than were taken initially in the reaction. This is probably because under the conditions of the thermal polycondensation the initial reactants undergo various chemical changes with the formation of new amino-acids and other products. It was shown, for example, that aspartic acid is converted into α- and β-alanine, and on heating with urea into ureidosuccinic acid, an intermediate in the synthesis of many pyrimidine bases. It is also interesting that spots characteristic of alanine and aspartic acid were found on chromatograms of the hydrolysis products from polymers obtained on heating ammonium fumarate and maleate.

Meggy[46] described the synthesis of polymers on heating glycine in water at 140–180° in an autoclave. The yield of products varied with temperature and the reactant ratio. The reaction is catalysed by hydrochloric acid, nitric acid, sulphuric acid, phosphoric acid, ammonium hydroxide, sodium hydroxide, and potassium hydroxide.

Bahadur[47–49] studied the photosynthesis of α-amino-acids and peptides in aqueous media. The reaction of electric light on a sterilised mixture of paraformaldehyde, water, and colloidal molybdenum oxide resulted in the formation of alanine and glycine together with a small amount of valine, histidine, glutamic acid, and ornithine, the nitrogen required for the synthesis being "fixed" from the atmosphere. Illumination of aqueous solutions of glycine in the presence of sucrose leads to the formation of oligomeric peptides, in particular glycylalanine, glycylnorleucine, and glycylglycine. When sterilised solutions of glycine and aspartic acid were illuminated with a 1000 W electric lamp for 400 h in the presence of benzoyl peroxide as the photocatalyst and sucrose as an additional energy source, new amino-acids and peptides were formed. A control experiment in the dark gave a negative result.

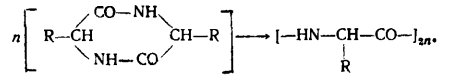
Ellenbogen[50] published an interesting paper on the synthesis of polypeptides on illumination with a mercury or a hydrogen lamp of aqueous solutions of ammonium salts through which a mixture of hydrocarbons (from methane to pentane) was passed continuously. The catalysts were certain salts of sodium, potassium, calcium, and a number of heavy metal oxides. The amino-acid composition of the resulting polypeptides varied with the composition of the reaction mixture and the conditions of synthesis.

Apart from early work[51–54] in which it was shown that thermal polycondensation of glycylglycine and glycylalanine usually yields 2,5-dioxopiperazines, there is no information in the literature on the polycondensation of di- and tri--peptides, probably because no significant results were obtained in such attempts.

## 2. Synthesis of Polypeptides Using Condensing Agents

Synthetic polypeptides frequently have a relatively low molecular weight; it may be increased by means of condensing agents which are widely used in experiments on stepwise synthesis of peptides with a known amino-acid sequence. Such condensing agents are *NN'*-dicyclohexylcarbodiimide[55], tetraethyl pyrophosphite[56], phosphorus pentoxide[57], etc. Furuyama et al.[58] used the relatively readily available bis-*o*-phenylene pyrophosphite as a condensing agent. After polycondensation of L-leucylglycylglycine in dry pyridine (for 6 h at 100°), two polypeptide

TABLE 7.



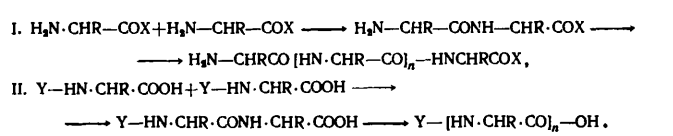
| Initial peptide | M | Final polypeptide | |
|---|---|---|---|
| | | solvent | M |
| Poly(γ-benzyl L-glutamate) | 200 000 | dioxan | 950 000 |
| Poly(γ-benzyl L-glutamate) | 225 000 | chloroform | 1 000 000 |
| Poly-ε-benzyloxycarbonyl-L-lysine | 350 000 | chloroform | 840 000 |
| Poly-L-proline | 10 000 | water | 32 000 |
| Poly(γ-benzyl L-glutamate) + poly-ε-benzyloxycarbonyl-L-lysine(1 : 1) | 200 000<br>300 000 | chloroform | 6 000 000 |

fractions with molecular weights ($M$) of 3220 and 1730 were isolated. The polypeptides dissolved in 80% aqueous phenol and 85% formic acid.

When $NN'$-dicyclohexylcarbodiimide is used for the polycondensation of oligomeric peptides with free carboxy- and amino-groups, polymers with high molecular weight are obtained (Table 7)[59]. The polycondensation was carried out at room temperature in different organic solvents. The authors of these studies believe that the condensation involves three terminal $NH_2$ and COOH groups. In those cases where the polypeptide has terminal amino- and carbamoyl groups, no increase in molecular weight is observed. The method can also be used to prepare high-molecular-weight polypeptides, including water-soluble peptides, whose synthesis by other methods presents considerable difficulties. In the presence of free carboxy- and amino-groups at the end of the peptide chain, this method can yield block copolymers and branched-chain polypeptides.

### 3. Polymerisation of 2,5-Dioxopiperazine Derivatives

It has been shown in a number of investigations[60-63] that 2,5-dioxopiperazine is thermodynamically less stable than polyglycine and is relatively readily converted into the polypeptide under various conditions. By analogy with glycolide and lactide, which polymerise into linear polyesters, it might have been expected that substituted 2,5-dioxopiperazine would also polymerise into polypeptides by the following reaction:



However, there have been only a few studies on the polymerisation of 3,6-substituted 2,5-dioxopiperazines. Goto[64] achieved the copolymerisation of 3,6-diisobutyl-2,5-dioxopiperazine with 2-oxopyrrolidine-5-carboxylic acid by heating an equimolar mixture of the starting materials (200°, 36 h) in glycerol. The copolymer thus isolated (yield 70%) gave a positive biuret reaction. The author believes that the product is the polypeptide, which he called a "protein analogue". Fox and Harada[25] mentioned the possibility of the copolymerisation of glutamic acid with 2,5-dioxopiperazine. However, they established that, when 2,5-dioxopiperazine and 2-oxopyrrolidine-5-carboxylic acid are heated together under anhydrous conditions, no polypeptide is formed and only after the addition of a certain amount of water to the mixture does the copolymer give a positive biuret test.

Attempts to prepare polypeptides by hydrolytic polymerisation of 1-ethyl-1,4-diphenyl- and 3,6-dimethyl-2,5-dioxopiperazines were unsuccessful. Hall[65] failed to obtain positive results in the anionic polymerisation of 1,4-dimethyl-2,5-dioxopiperazine in the presence of metallic sodium, sodium hydride, and acetylcaprolactam.

## III. SYNTHESIS OF POLYPEPTIDES FROM α-AMINO-ACID DERIVATIVES WITH MODIFIED AMINO- OR CARBOXY-GROUPS

The low tendency of free α-amino-acids and dipeptides towards polycondensation and their marked tendency to undergo cyclisation precludes their use for the synthesis of high-molecular-weight peptides under conditions excluding the possibility of racemisation of asymmetric centres. To facilitate the formation of the peptide bond, it is necessary to activate the carboxy- or the amino-group of the acid. An enhanced reactivity of amino-acids is usually achieved[4,5] by converting them into various $O$- or $N$-derivatives in which the link between the substituent and the amino-acid residue is readily susceptible to aminolysis in the case of $O$-derivatives or to acylation in the case of $N$-derivatives.

Usually such derivatives are esters and thioesters of amino-acids and peptides, amides, acid chlorides, azides, and also $N$-benzyloxycarbonyl-, $N$-phenylthiocarbonyl-, $N$-nitrophenoxycarbonyl-, and other derivatives of amino-acids.

### 1. Polycondensation of α-Amino-Acid Amides and Nitriles

Kovacs and Nagy[66] described the separation of polyaspartic acid by boiling a 5–10% aqueous solution of L-asparagine. Part of the asparagine hydrolyses to aspartic acid but most of it is converted into an amorphous mixture of oligo- and poly-peptides, among which, in particular, L-asparagylaspartic acid was identified. The mean molecular weight of the polymeric products isolated was about 500, the yield being 63%. If the reaction is carried out at 70–75°, the yield falls to 18%. Polymers of high molecular weight were obtained by dialysis. The mean molecular weight of various preparations after dialysis varied from 1700 to 3000. Like αβ-polyaspartic acid, these polypeptides readily dissolve in water and give a positive biuret reaction; their infrared spectra are identical with those of polyaspartic acid.

Guidry[67,68] studied the polycondensation of glycine amide in aqueous ammonia solution. The reaction was carried out by heating glycine amide (or its hydrochloride) with half its weight of ammonium hydroxide solution at 100° for several hours. The product was purified by dialysis and then lyophilised. Table 8 presents data on the yield and mean degree of polymerisation.

The authors quote preliminary kinetic data on the polycondensation of glycine amide, which are presented in Fig. 4. The graph shows that the initial rate of reaction is fairly high, so that polycondensation can successfully compete with hydrolytic and aminolytic side-reactions. The polycondensation products were white or slightly coloured powders, insoluble in water but soluble in concentrated lithium bromide solutions; they gave the biuret reaction

TABLE 8.

| Composition of reaction mixture | Mean degree of polymerisation | Molar yield of polyglycine, % |
|---|---|---|
| 2 g of glycine amide hydrochloride + + 1 ml 2 *N* $NH_4OH$ | 40 | 16.5 |
| 2 g glycine amide hydrochloride + + 1 ml 8 *N* $NH_4OH$ | 29 | 74.8 |
| Glycine amide (not recrystallised) | 33 | 27.4 |
| Glycine amide (recrystallised) | 34 | 75.0 |

Note. The specimens were heated in closed tubes at 100° for 20 h and more. The degree of polymerisation of the first two substances was determined by formol titration by the Sorensen method in lithium bromide solution, and that of the other two by the Van Slyke method.

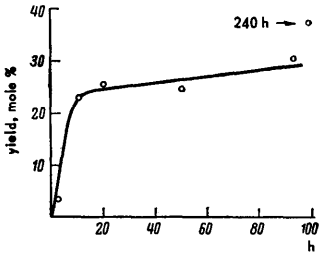


Fig. 4. The rate of formation of polyglycine from glycine amide on heating the latter in ammonium hydroxide solution at 100°.

and were completely hydrolysed to glycine in boiling acid. The infrared spectra of the polymers showed two broad absorption bands characteristic of the NH and CO bending vibrations (1534–1562 and 1634–1648 $cm^{-1}$ respectively), which means that the polymers contain predominantly bonds corresponding to the $\alpha$- and $\beta$-forms of polyglycine. This is also indicated by the presence of absorption bands in the region of 1015 $cm^{-1}$ ($\alpha$) and 1028 $cm^{-1}$ ($\beta$). At a lower reaction temperature (60°) the polyglycine was obtained in 20% yield.

Copolycondensation of glycine amide with the amides of other amino-acids does not give appreciable yields of polymeric products, but the residues of most of the amino-acids whose amides were used as starting materials were detected in the copolymers.

On heating aminoacetonitrile[67] in aqueous ammonia, a black polymer was obtained, which however could not be characterised. Heat treatment of methyleneaminoacetonitrile in the presence of ammonium sulphate leads to the formation of a non-dialysable product consisting mainly of glycine and probably cysteine residues. All the peptides were characterised by the usual analytical methods and had relatively low molecular weights of the order of 570–930.

Mach put forward the hypothesis[69] that the primary synthesis of amino-acids and proteins took place in three stages. Initially aminoacetonitrile was formed from the simple compounds HCN, HCOOH, and $NH_3$ and this then underwent polycondensation into polyglycine. The reaction of the polyglycine with aldehydes and unsaturated compounds in the third stage resulted in the synthesis of polypeptides. To confirm this hypothesis, the author heated one part of aminoacetonitrile with kaolin (20 parts) at 130° for 5 h. Chromatographic analysis revealed the presence in the reaction products of glycylglycine, diglycylglycine, and polyglycine. After treatment of the polyglycine with formaldehyde in the presence of basic catalysts, serine was detected in the hydrolysis mixture.

Losse and Anders[70] studied the polymerisation of $\alpha$-aminopropionitrile on mineral carriers. They regarded this reaction as one of the possible ways in which protein is synthesised in nature. One part of $\alpha$-aminopropionitrile was heated with two parts of a mineral adsorbent (Fuller's earth) for 50 h at 80° and 5 h at 130°. The initial nitrile was then converted to the extent of 60% into polyamidine, the hydrolysis of which yielded polyalanine with a number-average molecular weight of the order of 20 000.

$$n\,H_2N{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}C{\equiv}N \longrightarrow (-HN{-}CH(CH_3){-}\underset{\displaystyle NH}{\underset{\|}{C}}{-})_n \xrightarrow[-n NH_3]{+n H_2O} (-HN{-}CH(CH_3)\,CO{-})_n.$$

The polypeptide was isolated, characterised by the usual analytical methods, and compared with the polymer obtained by the synthesis from *N*-carboxyalanine anhydride. The properties of both polypeptides proved to be identical. It is interesting that, when $\alpha$-aminopropionitrile is heated in the absence of a mineral carrier, there is virtually no polymerisation, $\alpha\alpha'$-iminodipropionitrile $HN[CH(CH_3)CN]_2$ being formed.

## 2. Polycondensation of $\alpha$-Amino-Acid Esters

The alkoxy-group in amino-esters is fairly active and readily undergoes aminolysis, particularly in the presence of acid catalysts[71]:

$$H_2NCHRCOOR' + H_2NCHRCOOR' \xrightarrow{H^+} H_2NCHRCOHNCHRCOOR'.$$

Thus polycondensation of amino-acid esters would appear to be a convenient way of synthesising linear polypeptides; however, the main reaction in the polycondensation is frequently the cyclisation of the ester of the dipeptide formed into 3,6-disubstituted 2,5-dioxopiperazines[72,73]. Thus the methyl esters of glycine and DL-alanine gave 53 and 96% respectively of 2,5-dioxopiperazines on their polycondensation in the presence of 2% $CO_2$ [74] and $SiO_2$.[75]

The characteristic features of the polycondensation of glycine and DL-alanine esters in the presence of carbon dioxide and ester carbamates have been investigated[76,77]. According to the authors, the first stage in the reaction is rapid formation of the carbamate of the amino-acid ester:

$$CO_2 + 2H_2NCHRCOOR' \longrightarrow R'OOCCHR\overset{+}{N}H_3\cdot\overset{-}{O}OCNHCHRCOOR'.$$

The reaction is strongly exothermic and in the case of the ethyl ester of glycine terminates after 2–3 s with absorption of one mole of carbon dioxide for two moles of the ester[78]. The resulting carbamate is fairly stable, decomposing into the initial compound at about 60°.

In the symmetric carbamate one ester group is in the activated state and readily undergoes aminolysis. Thus in the polycondensation of amino-esters the growth of peptide chains proceeds as a result of the reaction of the symmetric carbamate with the amino-groups of the peptides or (in the

case of the initiation of a new chain) with the amino-group of the amino-acid ester with the formation of an asymmetric carbamate[77,79]:

$$R'OOCCHR\overset{+}{N}H_3\cdot\overset{-}{O}OCNHCHRCOOR'+H-[HNCHRCO]_x-OR'\xrightarrow{-R'OH}$$

$$\longrightarrow R'OOCCHR\overset{+}{N}H_3-\overset{-}{O}OCNHCHRCO-[HNCHRCO]_x-OR'\longrightarrow$$

$$\longrightarrow R'OOCCHRNH_2+CO_2+H-[HNCHRCO]_{x+1}-OR'.$$

Because of its instability[80], the asymmetric carbamate breaks down with the regeneration of carbon dioxide and the formation of a peptide containing one amino-acid residue more than the initial peptide or, what is more probable, the carbamate reacts with a new molecule of the monomer with the formation of the symmetric carbamate and the free peptide[81]:

$$R'OOCCHR\overset{+}{N}H_3\cdot\overset{-}{O}OCHNCHRCO[HNCHRCO]_xOR'+H_2NCHRCOOR'\longrightarrow$$

$$\longrightarrow R'OOCCHR\overset{+}{N}H_3\,\overset{-}{O}OCHNCHRCOOR'+H[HNCHRCO]_{x+1}OR'.$$

The increase of the reactivity of the ester group in the symmetric carbamate of the amino-acid ester, as a result of the influence of the carbamate group, was confirmed by the study of the polycondensation of the ethyl ester of glycylglycine. In this case the increased distance between the carbamate and ester groups results in a sharp decrease of their mutual influence, which is reflected in an almost complete absence of the catalytic effect of carbon dioxide on the polycondensation of the glycylglycine ester[82].

The polycondensation process probably proceeds in steps, its rate increasing with the concentration of the initiator (Fig. 5).

The slowest stage in the polycondensation of ethyl glycinate is the formation of the ester of the dipeptide, which is relatively rapidly converted into the tripeptide and 2,5-dioxopiperazine. Figs. 6 and 7 show the variation of the products of the polycondensation of ethyl glycinate with the duration of the reaction. At the beginning of the process almost half the solid products consist of 2,5-dioxopiperazine, whose relative amount diminishes as the process approaches completion. The amount of tripeptide reaches a maximum and then gradually falls as a result of its rapid conversion into the polymer. The process is autocatalytic and, as the peptides accumulate and their length increases, there is an increase of the relative rate of consumption of the monomer by virtue of the polypeptide chain growth.

Determination of the rate of aminolysis of *p*-nitrophenyl esters of benzyloxycarbonyl derivatives of glycine and its

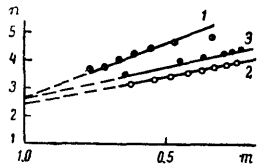

Fig. 5. Variation of the mean degree of polymerisation $n$ of the initial fraction with the consumption of the monomer $m$ for different initial molar ratios $\xi_0$ of carbon dioxide and the monomer:
1) $\xi_0 = 0.02$; 2) $\xi_0 = 0.04$; 3) $\xi_0 = 0.08$.

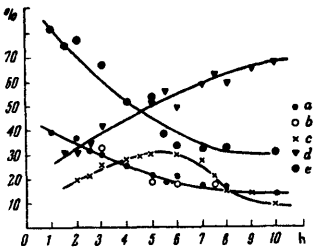

Fig. 6. Composition of the polycondensation products of ethyl glycinate (%):

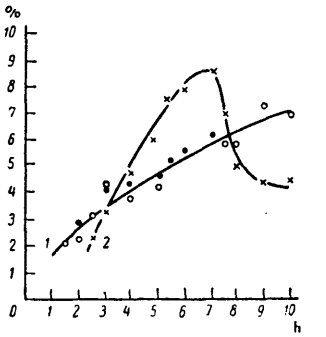

Fig. 7. The content of 2,5-dioxopiperazine and the ethyl ester of diglycylglycine (as a percentage of the initial monomer sample):
1) 2,5-dioxopiperazine; 2) ethyl ester of diglycylglycine.

di- and tri-peptides by ethyl glycinate and also the esters of the di- and tri-peptides indicates an increase in the rate of reaction of the amino- and ester groups with increase in chain length, particularly on going from the monomer to the dipeptides, which is consistent with the idea that polycondensation of amino-acid esters is autocatalytic[86].

In the absence of carbon dioxide the polycondensation of ethyl glycinate is very slow and takes place in two stages. The rate of the first stage is very low, but subsequently it increases (Fig. 8). In the second stage the monomer is used up much more rapidly. Addition of the polycondensation mixture accelerates the reaction, which still takes place in two stages, but the first stage is much shorter. An even greater shortening of the first stage occurs on addition of 20 mole % of the methyl ester of alanylglycylglycine, the rate of the second stage remaining almost unchanged, as in the case where the polycondensation mixture was added[87]. It was found that the addition of ethanol has a similar accelerating effect[88] on the polycondensation, which the authors explained by the catalytic action of the alcohol on the aminolysis reaction.

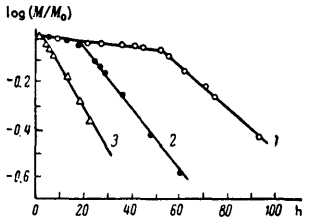

Fig. 8. Polycondensation of ethyl glycinate: 1) without additives; 2) in the presence of the polycondensate; 3) in the presence of the tripeptide ester.

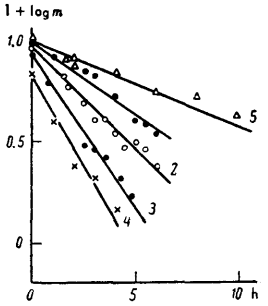

Fig. 9. Kinetics of the monomer consumption ($m$) in the polycondensation of ethyl glycinate; initial concentration of the initiator ($\xi_0$): 1) 0.02; 2) 0.04; 3) 0.08; 4) 0.16; 5) 0.01; the values of $m_0 - 1 - 2\xi_0$ are plotted along the ordinate.

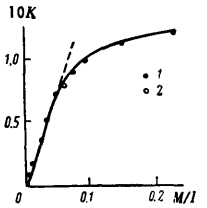
Extrapolation of the data obtained in the polycondensation of ethyl glycinate with carbon dioxide (Fig. 9) shows that the true relative concentration of the monomer $(M_2 - \Delta M_0)/M_0 = m$, where $\Delta M_0$ is the amount of monomer combined with carbon dioxide, is less than unity at zero time and decreases with increase in the concentration of the initiator. This confirms that, at the beginning of the reaction, part of the monomer $(1 - m_0)$ is rapidly combined and only then does the second stage of the reaction, characterised by first-order consumption of the monomer, begin.

Study of the kinetics of the polycondensation of ethyl glycinate in the presence of its carbamate [89,90] and carbon dioxide [87] showed that the nature of the process does not change when the method of initiation of the polycondensation is modified and confirmed that the carbamate of the amino-acid ester indeed catalyses the polycondensation. At all the catalyst concentrations investigated, the monomer is consumed by a first-order reaction. Comparison of the rate constants for the consumption of the monomer when the polycondensation of ethyl glycinate is initiated with the carbamate and carbon dioxide shows that the reaction kinetics in the two cases are the same (Fig. 10).

The nature of the polycondensation of the amino-esters does not change in the presence of the anhydrides of the $N$-carboxy-derivatives of the acids [91-93]. As in the polycondensation initiated with carbon dioxide, the reaction proceeds in two stages. In the polycondensation of ethyl



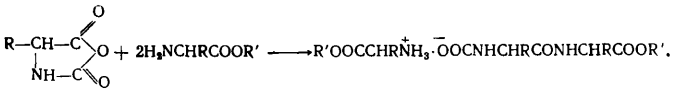


Fig. 10. Dependence of the rate constant for the consumption of the monomer ($K$, $s^{-1}$ $mole^{-1}$) on the initial concentration of the initiator (weight fraction): 1) initiation with carbon dioxide; 2) initiation with carbamate.

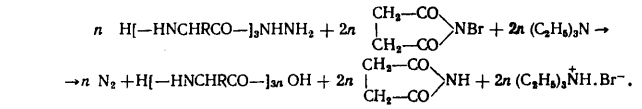
glycinate and the anhydride of $N$-carboxyglycine it was found that in the first stage the ester is consumed very rapidly, which in the authors' view is due to the formation of the asymmetric carbamate:

The second stage, which is slower, proceeds by the carbamate mechanism with the formation of similar polycondensation products as in the case where the process is initiated with carbon dioxide or the carbamate of the amino-acid ester [93,94].

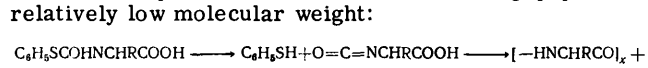


Metallic sodium and triphenylmethylsodium have also been described as catalysts for the polycondensation of amino-acid and peptide esters. Brenner and Rickenbacher [95] carried out the polycondensation of the methyl esters of DL-lysine and L-leucine (3–4 h at 5°) with a suspension of sodium (without additional solvent) and obtained in 60–70% yield polypeptides with a mean degree of polymerisation of 7 and 10 respectively. Polycondensation under these conditions of a mixture of the esters of L-leucine, DL-lysine, and DL-aspartic acid gave only a mixed polypeptide with a molecular weight of about 4000, which is difficultly soluble in water. The authors indicate that in the polycondensation of the methyl ester of L-leucine almost complete racemisation takes place. The authors explain the decrease of the yield of 2,5-dioxopiperazines when esters are subjected to polycondensation with metallic sodium by the adsorption of the amino-acid esters and the formation of polypeptides on the surface of the catalyst, while 2,5-dioxopiperazines form mainly in solution. In the polycondensation of esters in the presence of triphenylmethylsodium in ethereal solution the mean degree of polymerisation reaches 10–13. [96]

The polycondensation of the esters of oligopeptides has been considered in a relatively small number of studies. Thus Poroshin et al. state that when the methyl ester of L-prolyl-glycyl-L-proline is heated (15 h at 110° and $3 \times 10^{-3}$ mmHg), a complex mixture of polypeptides is formed, which the authors did not analyse in detail [97]. De-Tar et al. [98] treated the hydrobromide of the $p$-nitrophenyl ester of $\beta$-methoxy-L-asparagylglycylglycine with the exact calculated amount of triethylamine in dimethylformamide or dimethylsulphoxide at room temperature and obtained a polypeptide with a molecular weight of about 12 000. It was shown that whether a linear polypeptide or cyclic compounds are formed is to a large extent determined by the concentration of the initial tripeptide ester. Thus treatment of a 15% solution of the

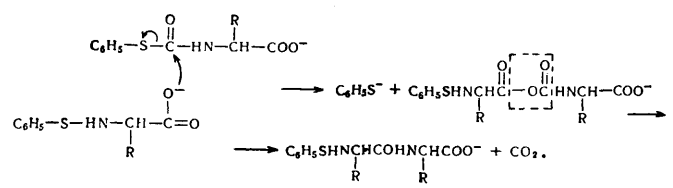
tripeptide ester resulted in a very small yield of polypeptides because of the formation of a cyclic hexapeptide. The authors used this method to prepare a number of polypeptides containing aspartic acid, phenylalanine, and glycine, or histidine and glycine, or phenylalanine and glycine. The synthesis of the last polypeptide from the hydrobromide of the *p*-nitrophenyl ester of phenylalanylglycine is particularly interesting, because it shows that linear polypeptides and not cyclic compounds are formed from the nitrophenyl esters of dipeptides.

Polypeptides of high molecular weight were prepared by the polycondensation of the thiophenyl $\alpha\gamma$-dimethyl ester of $\gamma$-L-glutamyl-L-glutamic acid, the mixture being slightly heated[99]. After purification the resulting polypeptide gave positive biuret and ninhydrin reactions. The authors demonstrated by paper chromatography that the polypeptide is polydisperse and contains high-molecular-weight fractions which remain at the starting point of the paper chromatogram after a 36 h run.



Among other work on the synthesis of polypeptides from tripeptide derivatives, that of Wolman et al.[100] is interesting. They oxidised the hydrazide of prolylglycylglycine with bromosuccinimide in dimethylformamide in the presence of triethylamine and obtained a polypeptide with a molecular weight of 1400. They suggested the following mechanism for the reaction:

The method is fairly simple and may be used when the initial tripeptide does not contain side-groups susceptible to oxidation by *N*-bromosuccinimide.



### 3. Polycondensation of *N*-Phenylthiocarbonyl Derivatives of $\alpha$-Amino-Acids and Oligopeptides

Noguchi[101,102] showed that on heating *N*-phenylthiocarbonyl amino-acids to 150–160° thiophenol and carbon dioxide are split off with the formation of oligopeptides of relatively low molecular weight:

Apart from the polypeptides, the reaction products include 2,5-dioxopiperazine and other side-products. When the polycondensation is carried out in solution (frequently in the presence of pyridine), high-molecular-weight polypeptides with molecular weights up to more than 100 000 are formed.

Thermal polycondensation of *N*-phenylthiocarbonyl amino-acids can yield both homogeneous and mixed polypeptides of almost all nautral and basic amino-acids. The authors assumed the possibility that thiophenol may be split off as a result of the intermolecular reaction with subsequent removal of carbon dioxide from the anhydride and formation of the polypeptide chain:

Tables 9 and 10 list the polypeptides prepared by this method and some properties of the initial *N*-phenylthiocarbonyl amino-acids and polypeptides. The data in Tables 8 and 9 indicate the possibility of wide application of the method involving the polycondensation of *N*-phenylthiocarbonyl derivatives of amino-acids for the preparation of DL-polypeptides. When derivatives of dipeptides are used, the formation of polypeptides with a known sequence of amino-acid residues may be expected.

However, Weymouth[122] showed that this method has a number of disadvantages. When polyglycine is synthesised under the above conditions, considerable amounts of 2,5-dioxopiperazines (in excess of 20% of the total weight of products) are deposited on the walls of the vessel. Usually about 50% of the residue is soluble in water, and comparison of the viscosity of the solutions of these polymers with the viscosity of similar specimens of polyglycine, for which the end-groups have been determined, yields the molecular weight in the range 1000–2500. Noguchi and coworkers[104] found the molecular weight of polyglycine of similar viscosity to be 135 000.

Having checked Noguchi's data using the polycondensation of phenylthiocarbonylalanine and sarcosine, the author concludes that the polycondensation of *N*-phenylthiocarbonyl amino-acids involves the formation of polypeptides of relatively low molecular weight. Furthermore there is no proof that these polymers are purely linear polypeptides.

The polycondensation of other *N*-substituted amino-acids has been described, i.e. the polycondensation of *N*-benzyloxycarbonyl[123] and phenoxycarbonyl[124] derivatives, including those with different substituents in the phenyl ring. Ishizuka and Saito[125] established that the most suitable medium for the polycondensation of phenoxycarbonyl amino-acid derivatives is nitrobenzene. In this case the time of polycondensation is greatly reduced and the polypeptide has a higher molecular weight (Table 11).

Ishizuka[126–128] carried out the polycondensation of *N*-*o*-nitrophenoxycarbonyl derivatives of amino-acids and dipeptides by this method and obtained polyleucine ($M$ = 14 000), poly-DL-phenylalanine ($M$ = 12 000), polyglycine ($M$ = 14 000), polyalanylglycine ($M$ = 28 500), polyglycylalanine [a previous line is repeated at this point in the Russian text instead of the conclusion of the sentence (Ed. of Translation)].

The polycondensation of *N*-*p*-methylphenoxycarbonyl amino-acids, in solution in a mixture of benzene and toluene, in a sealed tube at 60° for 1200 h yielded polyglycine ($M$ = 10 500), poly-DL-phenylalanine ($M$ = 17 600), poly-L-leucine ($M$ = 11 000), and poly-$\alpha$-aminobutyric acid ($M$ = 18 300). The molecular weights were determined osmometrically in dichloroacetic acid[129]. Polyleucine with an intrinsic viscosity of 0.28 was prepared by the polycondensation of *N*-phenoxycarbonyl-L-leucine in nitrobenzene at 125° for 20 h.[130]

Bruckner et al.[99] prepared a high-molecular-weight polypeptide from the $\alpha\gamma$-dimethyl ester of benzyloxycarbonyl-$\gamma$-L-glutamyl-L-glutamic acid. The initial dipeptide was treated with ethyl chloroformate in the presence of triethylamine. After the hydrogenolysis of the benzyloxycarbonyl group over a palladium catalyst, the catalyst was filtered off and the solution of the mixed anhydride of the dipeptide was divided into two parts. The first part was allowed to stand for 24 h at room temperature, after which the solvent was distilled off in a vacuum and the residue was further heated for 1 h also in a vacuum. The

* The viscosity of 0.2% solution in 80% dichloroacetic acid was determined.

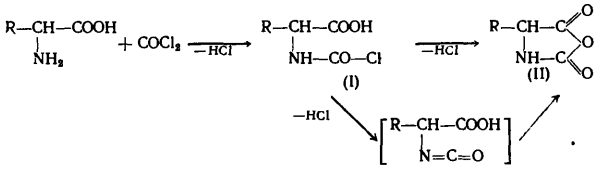
second half of the solution was treated similarly after the addition of triethylamine. In order to isolate the free polymeric acid, the polypeptides were treated in the cold with alkali and purified via the copper salt with subsequent dialysis. The molecular weight of the polypeptide obtained without triethylamine was 12 180 and that obtained with triethylamine was 20 000.

The polypeptides very tenaciously retain water and after drying in a vacuum over phosphorus pentoxide at room temperature contain one molecule of water per glutamic acid residue. Both products were colourless powders, readily soluble in water and gave positive biuret reactions and a weak ninhydrin reaction.

The amino-group can also be activated by treating amino--acids with isocyanates. The resulting amide of the alkanecarbamic acid, with the general formula

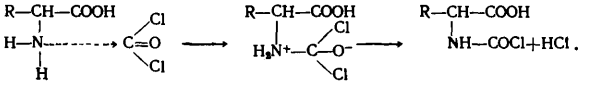
RNHCONHCRHCOOH,

where R = t-alkyl, breaks down at a temperature above 175° with the formation of a polypeptide in more than 80% yield. The degree of polycondensation of polypeptides prepared in this way reaches 100.[131] An interesting synthesis of polypeptides is by the polycondensation of the isothiocyanates of aliphatic carboxylic acids, prepared by treating α-amino-acids with carbon disulphide and then decomposing the dithiocarbamic derivatives with mercuric chloride[132]. However, in this case it is assumed that heating of the isothiocyanate leads to the formation of the anhydride of the *N*-thiocarboxy-acid and its polymerisation and not the removal of the substituent from the nitrogen atom:



## IV. SYNTHESIS OF POLYPEPTIDES BY THE POLYMERISATION OF THE ANHYDRIDES OF *N*-CARBOXY--α-AMINO-ACIDS

### 1. Synthesis of the Anhydrides of *N*-Carboxy-α-amino--Acids

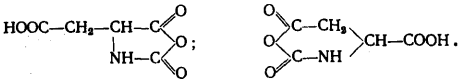


The most usual synthesis of polypeptides is by the polymerisation of the anhydrides of *N*-carboxy-α-amino-acids, which permit the preparation of polymers with a specified molecular weight, capable of being varied over a very wide range, with complete elimination of the racemisation of the amino-acids.

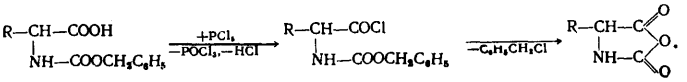
The most widely used procedure for the preparation of the cyclic anhydrides of *N*-carboxy-α-amino-acids is that proposed by Fuchs[133], Farthing[134], and Levy[135]. Finely ground amino-acids, their chlorides, or sodium salts, suspended in an inert solvent (dioxan, ethyl acetate) are treated with phosgene at 30–50°. The reaction may be carried out with simultaneous addition of equivalent amounts of a solution of phosgene in dioxan and a suspension of the amino-acid in dioxan to an excess of the solvent[136]. The anhydrides of the *N*-carboxy-acids and their thio-analogues are also obtained on heating the chlorides of amino-acids with $COCl_2$ or $CSCl_2$ in nitrobenzene[137].

The reaction of α-amino-acids with phosgene proceeds as follows:

The first stage, the formation of the carbamoyl chloride (I) begins with the nucleophilic attack by the amino-nitrogen on the carbonyl carbon in phosgene:



The rate of this process should increase with increase in the electron-donor effect of the R group in the amino-acid, which enhances the basicity of the amino-group. This hypothesis agrees satisfactorily with the observed increase in the rate of reaction with phosgene in the series glycine < alanine < < α-aminobutyric acid ≃ phenylalanine < norleucine < < leucine < isoleucine < pseudoleucine (*C*-t-butylglycine), where the substituent R varies from H to $(CH_3)_3C-$.[138,139]



Preliminary saturation of dioxan with sulphur dioxide[140] and also the addition of small amounts of acetic anhydride increase the rate of reaction with phosgene, while impurities may retard it to a large extent[138].

The stage of the cyclisation of the carbamoyl chloride (I) to the anhydride (II) of the *N*-carboxy-α-amino-acid occurs spontaneously and only in the case of proline and its derivatives, where the closure of the second ring involves considerable stresses in the molecule, is additional treatment of the carbamoyl chloride with triethylamine[141] or silver oxide[142,143] necessary.

In the synthesis of the anhydrides of trifunctional *N*-carboxy-α-amino-acids it is necessary to protect the functional groups capable of reacting with phosgene[144]. In the absence of protection aspartic acid gives a mixture of five- and six-membered anhydrides of the *N*-carboxy--acid[145]:

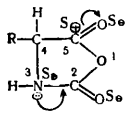
The anhydrides of *N*-carboxy-α-amino-acid are also obtained by treatment of *N*-alkoxycarbonyl- and particularly *N*-benzyloxycarbonyl-α-amino-acids with thionyl chloride, phosphorus pentachloride, or phosphorus tribromide:

This method[3] is usually employed for β-amino-acids, the *N*-carboxy-derivatives of which yield six-membered anhydrides capable of polymerising[148].

An interesting method of preparation of the anhydrides of the *N*-carboxy-derivatives of various amino-acids[149,150] involves the reaction of thionyl chloride or phosgene with the disodium salt of the *N*-carboxy-amino-acid which is readily obtained from sodium carbonate and the amino-acid or by the simultaneous treatment of the amino-acid with sodium methoxide and carbon dioxide[134,147,148].

The synthesis of the anhydrides of *N*-carboxy-α-amino--acids from the malonic ester[151,152] is suitable only for the preparation of racemic products and has not been used in recent years.

High-molecular-weight polypeptides can be synthesised only from thoroughly purified anhydrides of *N*-carboxy-α--amino-acids which in their synthesis by the reaction of phosgene with α-amino-acids are usually contaminated with the dichloride (III) of the *N*-carboxy-α-amino-acid and the isocyanate (IV) formed from it:



(III);

(IV).

However, the impurities are readily removed on recrystallisation[153] or sublimation in a high vacuum. The removal of chlorine-containing impurities by treating a solution of the anhydride of the *N*-carboxy-α-amino-acid in ethyl acetate with the copolymer of ethyl β-(formyl-*N*-methylamino)-acrylate and divinylbenzene has been described[154]. The anhydrides of *N*-carboxy-α-amino-acids are kept at a temperature not exceeding -30°. The anhydrides of *N*-carboxy--α-amino-acids whose synthesis has been described in recent years are listed in Table 12.

The anhydrides of *N*-carboxy-α-amino-acids are determined quantitatively by titration in a non-aqueous medium with sodium methoxide[155,156] or by the determination of the carbon dioxide evolved on their acid hydrolysis[157,158]; the carbon dioxide is absorbed by an ethanol–dioxan solution of benzylamine to form the benzylammonium salt of toluene--ω-carbamic acid, and then titrated with a solution of sodium methoxide using Thymol Blue as the indicator.

## 2. Chemical Properties of the Anhydrides of *N*-Carboxy--α-amino-Acids

The anhydrides of *N*-carboxy-α-amino-acids are extremely reactive. They have the structure of 2,5-dioxo-oxazolidine substituted in position 4.

The electronegativity of the oxygen atom gives rise to partial positive charges on carbon atom 5 and the nitrogen atom which results in a weakening of the N–H bond and great enhancement of the reactivity of the carbonyl carbon atom 5 towards nucleophilic reagents compared with carbon atom 2. Indeed, nucleophilic addition to the carbonyl carbon atom 5 and reactions involving the participation of the N–H group are the most characteristic reactions of the anhydrides of *N*-carboxy-α-amino-acids.

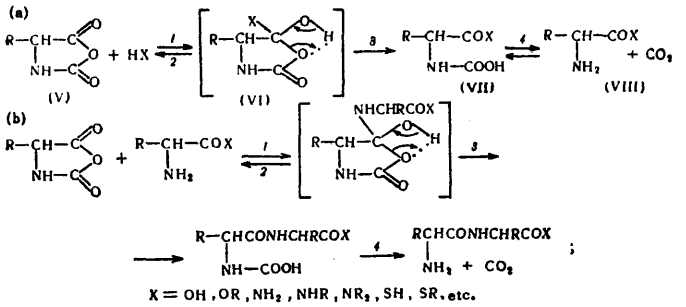


TABLE 12. Synthesis of the anhydrides of *N*-carboxy-α-amino--acids not included in the monograph of Bamford et al.[4] and the review of Katchalski and Sela[5].

The reaction with nucleophilic reagents HX usually proceeds as follows:

X = OH, OR, $NH_2$, NHR, $NR_2$, SH, SR, etc.

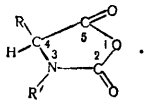
Compound (VIII) has a free amino-group and may react with another molecule of the anhydride like any nucleophilic reagent. Therefore in the presence of a large excess of the anhydride of the *N*-carboxy-α-amino-acid this reaction results in the formation of a polypeptide. In the presence of an excess of HX only compounds of the type of (VIII) are formed.

In the reaction with water, in which many anhydrides of *N*-carboxy-α-amino-acids are quite soluble, the following equilibrium is established at low temperatures [3,159-162]:

It has been shown that the decomposition of the anhydrides of *N*-carboxy-α-amino-acid is catalysed by bases and acids [163].

Hydrogen sulphide, alcohols, phenols, and mercaptans react in the presence of triethylamine [164,165] similarly to water with the formation of α-amino-thioacids, esters, and thioesters.

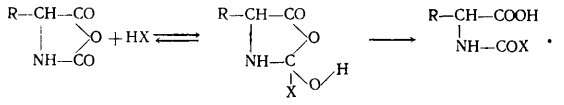
Anhydrous hydrogen chloride in an inert medium reacts with the anhydrides of *N*-carboxy-α-amino-acids to yield the hydrochlorides of the amino-acid chlorides [166,167] while in alcoholic medium it accelerates alcoholysis, a fact which has been used for the preparation of the esters of various α-amino-acids [168-172]. Alcoholysis is also accelerated by alkoxides, a finding on which the titration of the anhydrides of *N*-carboxy-α-amino-acids with sodium methoxide is based [155]:



Since primary and secondary amines are nucleophilic agents, they react with the anhydrides of *N*-carboxy-α--amino-acids according to mechanism (a) given above with the formation of peptides and amino-acid amides [133,173-177]. The thio-analogues of the anhydrides of *N*-carboxy-α--amino-acids are capable of the formation of a number of other products [178].

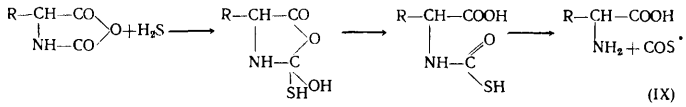
The rate of reaction with nucleophilic reagents decreases with decreasing basicity in the following order: $CH_3O^-$, $OH^-$, $RNH_2$, $ArNH_2$, ROH, $H_2O$. In the reaction with the last three members of the series the free amino-group formed after their addition is more nucleophilic and readily reacts with the free molecules of the anhydrides of *N*-carboxy-α--amino-acids according to mechanism (b) with the formation of oligomers and polymers even in the presence of an excess of the above reagents [175].

The rate of reaction depends also on the nature of the *N*-carboxy-α-amino-acid anhydride and is greater the greater the partial positive charge on the carbonyl carbon atom 5 and the lower the steric hindrance for the attacking nucleophilic agent. For this reason, the reactivity and the rate of polymerisation of the anhydride diminish with increase in the electron-donor effect and particularly with increase in the size of the substituent R, in the following series: glycine, alanine, α-aminobutyric acid, phenylalanine, norleucine, leucine, isoleucine, pseudoleucine, and α-methylalanine [138,139,179].



The considerable influence of steric factors on the rate of reaction of the anhydrides of *N*-carboxy-α-amino-acids with primary and secondary amines has been demonstrated by Ballard and Bamford [179]. The usual five-membered ring of the *N*-carboxy-α-amino-acid anhydride, which incorporates nitrogen, oxygen, and two trigonal carbon atoms, is planar and unstrained, the substituent R lying to one side or another of the molecule depending on the asymmetry of carbon atom 4. In the case of *N*- substituted

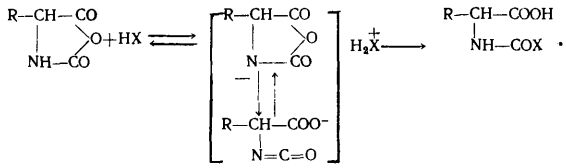
anhydrides the substituent R′ at the nitrogen is located in the *trans*-position relative to R.



The attacking reagent approaches the carbon atom 5 from the side opposite to that of the carbonyl oxygen along the line passing at a small angle to the plane of the ring in the immediate vicinity of the nitrogen atom. The presence of the substituents R and R′ gives rise to considerable steric hindrance to attack from both sides of the ring, particularly in the case of bulky nucleophilic agents such as secondary amines, and sharply reduces the rate of reaction. In the anhydrides of *N*-carboxyproline and its derivatives both substituents lie on one side of the plane of the ring, which is responsible for the enhanced rate of their reaction with secondary amines.

Similarly, the second carbonyl group can also react with nucleophilic agents: with the formation of urethanes, thiourethanes, and urea derivatives in the case of alcohols, mercaptans, and amines respectively.

However, by virtue of the smaller positive charge of carbon atom 2 the activation energy for this reaction is much higher and it becomes important only at high temperatures and concentration, and when the reactivity of the nucleophilic reagent is high; steric factors can also have an appreciable effect.



The addition to the carbonyl carbon atom 2 is usually referred to as "erroneous", leading to the disappearance of the amino-group at the end of the growing chain and termination of the polymerisation. The possibility of this reaction was confirmed by Berger et al.[155], who observed the formation of urethane in the reaction of the anhydride of *N*-carboxyphenylalanine with a solution of sodium methoxide. Wieland and Euler[165] allowed the anhydrides of *N*-carboxy-α-amino-acids to react with dry hydrogen sulphide in the presence of triethylamine and obtained α-aminothio-acids, which were always contaminated with α-amino-acids, whose formation can be explained by the decomposition of the corresponding thiocarbamic acids (IX):

(IX)

In the presence of a large excess of amines the addition to carbon atom 2 can occur to a considerable extent[180,181] but the amount of the product of the normal addition rapidly increases when the concentration and basicity of the amine are reduced[180].

However, the anhydride of *N*-carboxysarcosine combines even with nucleophilic agents as powerful as methoxide ions only at carbonyl carbon atom 5.[181] Possibly, the formation of compounds of the type RCH(COOH)NHCOX requires a hydrogen atom linked to the nitrogen atom. In this case nucleophilic attack can occur not only at the carbonyl carbon atom 2 but also at the hydrogen atom, with formation of carbamic acid derivatives via the isocyanate stage[165,181]:

The increase of the affinity of the base HX for a proton should favour this reaction, which agrees with experimental findings[181,182].

The active role of the NH group is particularly evident in the reaction of the anhydrides of *N*-carboxy-α-amino--acids with Grignard reagents[183]. In the *N*-substituted *N*-carboxy-α-amino-acid anhydrides the carbonyl group in position 2 does not react with RMgX and the anhydride of *N*-carboxy-*N*-phenylglycine gives only the following compounds:

$$C_6H_5NHCH_2—COOR,\quad C_6H_5NHCH_2—C(OH)R_2\ (R=CH_3,\ C_2H_5,\ C_6H_5).$$

At the same time the anhydride of *N*-carboxyphenylalanine forms under the same conditions *N*-acylated amino-ketones and amino-alcohols:

$$C_6H_5CH_2CH(COR)NHCOR\quad C_6H_5CH_2CH(NHCOR)C(OH)R_2.\ (R=C_2H_5,\ C_6H_5)$$

Among other reactions of the anhydrides of *N*-carboxy--α-amino-acids unrelated to their polymerisation, their reduction with lithium aluminium hydride[184] and their application in the Friedel–Crafts synthesis have been described[185,186].

## 3. Polymerisation of the Anhydrides of *N*-Carboxy-α--amino-Acids†

The anhydrides of *N*-carboxy-α-amino-acids readily polymerise both in the solid and in solution. The molecular weight and the polydispersity of the polypeptides formed are determined by the nature of the initiator and the polymerisation conditions. Solid polymerisation is usually carried out at elevated temperatures and low-molecular--weight products are obtained. Inert solvents are used for polymerisation in solution, which is carried out at low temperatures, the initiators being amines, alkoxides, alkalis, or water. The initiators and inhibitors of radical type polymerisation do not have any influence on the polymerisation of the anhydrides of *N*-carboxy-α-amino-acids[187,188]. Primary and secondary amines yield polymers with the degree of polymerisation up to 200, depending on the amount of amine.

Using excess amounts of amino-acid esters in the reaction with the anhydrides of *N*-carboxy-α-amino-acids, it is possible to obtain dipeptides[175,189,190]. However, in this case it is difficult to avoid the formation of higher

† It should be noted that the polymerisation of the anhydrides of *N*-carboxy-α-amino-acids differs considerably from the classical example of polymerisation and polycondensation. A better name for it would be polyaddition with subsequent removal of some of the molecules.

oligopeptides [191] and urea derivatives [192]. At low temperatures (-40°) in the presence of triethylamine, which stabilises by salt formation the carbamic acid (VII) formed in the first addition reaction, it proved possible to synthesise di- and tri-peptides in good yields [193-198]. The use of the thio-analogues of the anhydrides of *N*-carboxy-α-amino-acids is also promising for stepwise polypeptide synthesis of this kind [178].

Polypeptides of the highest molecular weight are obtained in the polymerisation of the anhydrides of *N*-carboxy-α-amino-acids in the presence of tertiary amines, alkoxides, and alkali metal hydroxides. However, the reproducibility of the results and the molecular weight of the polypeptides depend also on the purity of the initial compounds and solvents. Impurities, for example chloride ions at concentrations of about 0.01%, can completely vitiate the results of the experiment [199].

Because it is impossible to determine the impurities at such concentrations by the usual methods, it is recommended that the purity of the anhydrides of *N*-carboxy-α-amino-acids be checked by their polymerisation under standard conditions. Thus Idelson and Blout [200] regarded the anhydride of γ-benzyl *N*-carboxy-L-glutamate to be pure if at room temperature in 4% dioxan solution it gave a polymer with a molecular weight not less than 360 000, using sodium methoxide as the initiator with $[I_0]/[M_0] = 1:200$ (see below).

The polymerisation of the anhydrides of *N*-carboxy-α-amino-acids is inhibited by a large number of compounds: boric and dichloroacetic acids [201], hydrogen chloride [202], aldehydes [203,204], phenyl isocyanate, acetic anhydride, etc. Acids inhibit the reaction [205], even if it is initiated by inorganic salts [206,207]. Acetyl chloride, thionyl chloride, aluminium chloride, etc. fully inhibit the polymerisation of the anhydride of *N*-carboxyglycine when present in concentrations up to 0.2 mole %. [208]

The polypeptides obtained under different conditions by the polymerisation of the anhydrides of *N*-carboxy-α-amino-acids, and some of their properties, are listed in Table 13.

A. Polymerisation in the solid form. The anhydrides of *N*-carboxy-α-amino-acids are stable only at temperatures below -30°. At room temperature under the influence of atmospheric moisture the anhydrides of the *N*-carboxy-derivatives of glycine [3,174,210], L-alanine [211], L-leucine [209,211], *C*-phenylglycine, and phenylalanine [209] are converted into polymers. The rate of polymerisation is

TABLE 13. Preparation of polypeptides by the polymerisation of the anhydrides of the *N*-carboxy-derivatives of α-amino-acids (examples not included in the monograph of Bamford et al. [4] and the review of Katchalski and Sela [5]).

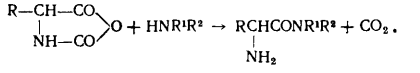
determined by the structure and the temperature. The mechanism of the polymerisation of crystalline anhydrides of *N*-carboxy-α-amino-acids initiated by atmospheric moisture is as yet unknown. The shape of the crystals remains unchanged during polymerisation and only X-ray diffraction analysis can detect the alterations in the crystal lattice [212]. Wessely and Siegmund [213] isolated from the polymerisation products of the anhydride of *N*-carboxysarcosine 4% of 1,4-dimethyl-2,5-dioxopiperazine in addition to 7% of polysarcosine.

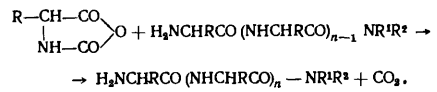
In the molten state all the anhydrides of *N*-carboxy-α-amino-acids rapidly split off carbon dioxide and are converted into polymers with a relatively low degree of polymerisation [171,214–217].

The mechanism of thermal polymerisation is obscure. Possibly the α-isocyanatocarboxylic acid, capable of polymerising with subsequent removal of carbon dioxide, is an intermediate [218].



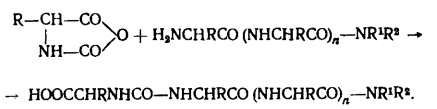
$$OCN—CHRCOOH + OCN—CHRCOOH \longrightarrow OCN—CHR—CO—O—CO—$$
$$—NHCHRCOOH \longrightarrow OCN—CHRCO—NHCHRCOOH + CO_2 .$$

The termination of the growing chain can occur as a result of the deactivation of the isocyanato-end-group.



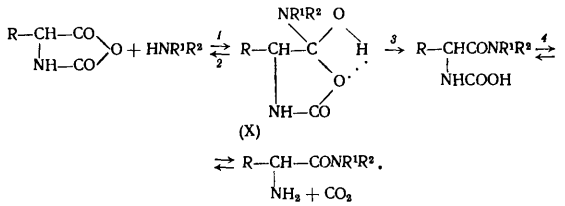
Heyns and Brockmann [219] showed that in the thermal polymerisation of [$^{13}$C]-*N*-carboxyglycine anhydride the carbon dioxide split off contains exclusively the second carbon atom of the ring. However, this is insufficient to settle the problem whether the polymer forms as a result of normal chain growth at the amine end or via the intermediate isocyanatocarboxylic acid, which is probably present in equilibrium with the anhydride of the *N*-carboxy-α-amino-acid [165,181]. The detection of considerable amounts of 2,5-dioxopiperazines in the polymerisation of the anhydrides of *N*-carboxyglycine and *N*-carboxyalanine at 100–165° [220] also prevents final conclusions concerning the mechanism of the reaction.

B. Polymerisation in solution. Initiation with primary and secondary amines. All the known anhydrides of *N*-carboxy-α-amino-acids, except for the anhydride of *N*-carboxy-α-methylalanine [179,247] readily polymerise in the presence of amines in inert solvents (dioxan, benzene, nitrobenzene, chloroform, acetophenone, dimethylformamide, etc.) at relatively low temperatures. The polymerisation can be divided into three main stages.



Initiation:

Chain growth:



Chain termination:

The initiation and chain growth correspond to "normal" addition of nucleophilic agents to the carbonyl group in position 5, and chain termination to "erroneous" addition. The average degree of polymerisation $\overline{P}_n$ of the polypeptides formed (10–200) is usually equal to the ratio of the initial concentrations of the monomer $[M_0]$ and initiator $[I_0]$, variation of which permits the preparation of polypeptides of the required molecular weight.

*Initiation* proceeds according to the usual mechanism involving the addition of nucleophilic agents to the anhydrides of *N*-carboxy-α-amino-acids:

The rate of initiation depends on the rate of the individual reactions *1*, *2*, and *3*. If among the three stages reaction *3* is the slowest, equilibrium is established between the anhydride of the *N*-carboxy-α-amino-acid and compound (X). On the other hand, if the rate of reaction *1* is slow, i.e. because of its low basicity or because of steric hindrance, the initiator $HNR^1R^2$ adds with difficulty to the carbonyl group in position 5 and is readily split off again, stage *1* determining the rate of the overall initiation process. On the basis of measurements of the isotopic effect (see below) Heyns and Schultze [150] concluded that the anhydrides of the *N*-carboxy-derivatives of phenylalanine and sarcosine react in this way with aniline. The ratios of the rate constants of reactions *1*, *2*, and *3* are 0.08 : 75 : 15 in the case of phenylalanine and 0.07 : 86 : 10 in the case of sarcosine.

The rate of initiation may be measured in the reaction with a large excess of the amine, when the polymerisation does not have a significant effect on the rate of consumption of the anhydride. It was found that in this case the reaction is of second order.

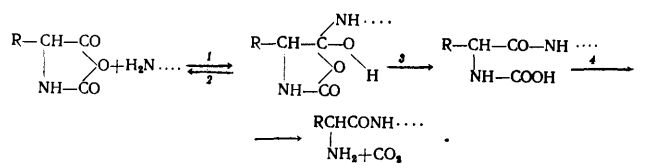
Ballard and Bamford [221] measured the rate constants $K_1$ for the reactions of various anhydrides of *N*-carboxy-α-amino-acids with amines of the type $RHNCH_2CON(CH_3)_2$. The results, which are presented in Table 14, indicate a considerable effect of steric hindrance, due to substituents at the nitrogen and carbon atom 4, on the rate of reaction with secondary amines.

Direct determination of the rate of initiation in polymerisation is very difficult. It can be only approximately estimated from the overall rate of initiation and polymerisation during early stages of the process. It was thus

TABLE 14. Rate constants $K_1$ (litre $mole^{-1}$ $s^{-1}$) for the initiation of the polymerisation of the anhydrides of *N*-carboxy-α-amino-acids with amines of the type $RNHCH_2CON.(CH_3)_2$ in nitrobenzene at 15°.

| Anhydride of *N*-carboxy-derivative of / R | Alanine | Sarcosine | *N*-methyl-alanine | Phenyl-alanine | *N*-isopropyl-glycine | α-Methyl-alanine | L-Proline |
|---|---|---|---|---|---|---|---|
| R= H | 1.13 | 0.82 | 0.45 | 1.0 | 0.83 | 0.29 | 2.68 |
| R= $CH_3$ | 0.48 | 0.57 | 0.16 | 0.40 | 0.48 | $8.4\cdot10^{-4}$ | 2.00 |
| R=$CH(CH_3)_2$ | 0.10 | 7.4 | $2\cdot10^{-5}$ | 0.30 | $<10^{-7}$ | $1\cdot10^{-6}$ | 0.12 |

shown that initiation with n-hexylamine is approximately ten times faster than the polymerisation of the anhydride of γ-benzyl *N*-carboxy-L-glutamate in dioxan [200]. The rate constant for initiation is in this case $K_1 = 0.2 \pm 0.1$ litre × × $mole^{-1}$ $s^{-1}$. [199] The rate of initiation with *p*-chloroaniline of the polymerisation of the anhydride *N*-carboxy-DL-phenylalanine is smaller by a factor of 6000 than the rate of polymerisation itself, while in the case of initiation with *N*-ethylglycine diethylamide in benzene and nitrobenzene the two rates are approximately equal [222]. Relatively rapid initiation has been observed in the systems comprising the anhydride of α-*N*-carboxy-ε-*N*-benzyloxycarbonyl-L-lysine and ammonia and dioxan [223] and the anhydride of *N*-carboxy-DL-phenylalanine or *N*-carboxy-DL-leucine and the sodium salt of DL-phenylalanine [224].



Ballard and Bamford [225] studied the effect of the peptide chain length on the rate of initiation of the polymerisation of the anhydrides of *N*-carboxy-DL-leucine and *N*-carboxy-DL-phenylalanine in nitrobenzene. They found that the dimethylamide of leucine is 3–4 times more active than the dipeptide, tripeptide, and higher peptides, the chain growth having begun proceeds at a constant rate since the reactivity of the amine of the amino-group at the chain end remains virtually constant, starting with the dimer.

It is evident from the mechanism of the initiation reaction that the initiator remains at the end of the polypeptide chain. This enabled Ritschard [226] to follow directly by means of paper chromatography the rate of consumption of the initiator in the polymerisation of γ-benzyl L-glutamate. He employed a coloured initiator — 2,4-dinitrophenylethylenediamine. From photometric measurements on such coloured polymers, their molecular weights were calculated [228]; this can also be done by determining, for example, the halogen content of polypeptides obtained in the presence of halogen-containing initiators [227].

Using as initiators polypeptides with free amino-groups or amines of large molecular weight [229], it is possible to obtain various block copolymers. The rate of initiation and chain growth are usually equal and independent of the degree of polymerisation ($\overline{P}_n$) of the initiator [225]. However, in the case of the polymerisation of the anhydride of *N*-carboxy-DL-phenylalanine initiated with polysarcosine Ballard and Bamford [230,231] observed a direct relation between the rate of polymerisation and initiator chain length up to $\overline{P}_n = 20$, polysarcosine being a hundred times more effective than the monomeric sarcosine dimethylamide. Further increase of $\overline{P}_n$ did not raise the rate of polymerisation. According to the authors, polysarcosine, which does not have intramolecular hydrogen bonds, forms hydrogen bonds with the NH groups of the anhydrides of *N*-carboxy-α-amino-acids, and this increases their concentration on the surface of polysarcosine and as a result increases the rate of polymerisation. This hypothesis has

not as yet been adequately confirmed, since the behaviour of polyproline and polyhydroxyproline, which also do not have NH groups, has not been investigated.

*Chain growth.* The mechanism of chain growth is similar to that of initiation:

Using radioactive carbon, it was shown that, as was to be expected, the carbon dioxide evolved during polymerisation contains carbon originating exclusively from the carbonyl in position 2 of the *N*-carboxy-$\alpha$-amino-acid anhydride ring [149]. From a study of the time variation of the isotopic composition of the carbon dioxide evolved, Heyns and Schultze [150] established that the removal of carbon dioxide (stage *4*) in the polymerisation of the anhydrides of the *N*-carboxy--derivatives of glycine, sarcosine, phenylalanine, and *p*-nitrophenylglycine is relatively rapid. The slowest stage in the polymerisation of the anhydrides of the *N*-carboxy--derivatives of phenylalanine, phenylglycine, and *p*-nitrophenylglycine is reaction *1*, while in the case of glycine the stage involving ring opening (reaction *3*) is slower, and in the case of sarcosine the rates of both reactions are approximately the same. Thus the rate of polymerisation is determined by stage *1* or *3*, depending on the nature of the anhydride of the *N*-carboxy-$\alpha$-amino-acid.

This conclusion agrees with earlier observations. The polymerisation of *N*-carboxy-$\alpha$-amino-acid anhydrides usually is accelerated by increase of temperature [225]. In the polymerisation of sarcosine in nitrobenzene and in acetophenone initiated by sarcosine dimethylamide or poly-(sarcosine dimethylamide) a negative temperature effect was observed [232,233]. According to Heyns' findings [150], the rate of polymerisation in this case is determined not by only one individual reaction but by all the reactions at once.

The removal of carbon dioxide from the growing chain (stage *4*) is reversible. An increase in carbon dioxide pressure slows down the breakdown of the terminal carbamic acid group; this group can be further stabilised by the formation of carbamates with free terminal amino--groups, which reduces their concentration and the rate of polymerisation. For this reason, measurements of the rate of reaction from the carbon dioxide evolved using constant pressure [225] and constant volume [232] apparatus usually differ from one another.

In a homogeneous medium at constant carbon dioxide pressure the rate of polymerisation should also be constant, since the reactivity of the terminal amino-group does not vary with chain growth. Indeed, after the termination of the initiation stage, the polymerisation is a first-order reaction with respect to the anhydride. This was confirmed by Ballard and Bamford for the polymerisation of the anhydrides of the *N*-carboxy-derivatives of DL-leucine, DL-phenylalanine [225], and sarcosine [234], by Breitenbach and Allinger [222] for the polymerisation of the anhydride of *N*-carboxyl-DL-phenylalanine in nitrobenzene, and by Lundberg and Doty [199] for the polymerisation of the anhydride of $\gamma$-benzyl *N*-carboxy--L-glutamate in dimethylformamide.

Short chains [235-237] of poly($\gamma$-benzyl L-glutamate) have the random $\beta$-conformation in inert solvents, while in the case of long chains the $\alpha$-spiral conformation is more stable. It might have been expected that during polymerisation the polypeptide chains undergo changes in conformation on attainment of a certain length and that these changes will be reflected in the polymerisation process. Indeed [199,238], the rate of polymerisation of the anhydride of $\gamma$-benzyl *N*-carboxy L-glutamate in dioxan, nitrobenzene, dichloroethane, chloroform, and benzene in the presence of n-hexylamine increases approximately fivefold when the growing chains reach a length equivalent to eight structural units (Fig. 11). In the presence of a larger amount of hexylamine ($[M_0]/[I_0] = 4$) the appearance of the second, more rapid stage is not observed, since in this case only short chains are formed, while in the initiation with a polypeptide having $\bar{P}_n = 10$ there is only the rapid stage of chain growth.

It has been demonstrated by infrared spectroscopy that the formation of the poly($\gamma$-benzyl L-glutamate) $\alpha$-spiral begins on attaining a chain length equivalent to 7–13 units [200], and certainly not less than 5 units [239]. For this reason, Lundberg and Doty attribute the sharp increase in the rate of polymerisation to changes in the conformation of the growing polypeptide chain.

The formation of a new polypeptide fraction in the second stage of the reaction has been convincingly demonstrated by paper chromatography [226] and the measurements of the electric double refraction (Kerr effect) [240]. Additional confirmation that the polymerisation proceeds in two stages was obtained in a study of the polydispersity of poly-($\gamma$-benzyl L-glutamate) [199,203,241]. In dimethylformamide, where only one stage is observed, the polymer exhibits a very narrow molecular weight distribution. In dioxan and chloroform, where the reaction takes place in two stages, the various polymeric chains grow at different rates, depending on their conformation, and give rise to a polypeptide with a very wide molecular weight distribution. The average degree of polymerisation is much higher than the theoretical value, calculated from the relation $\bar{P}_n = [M_0]/[I_0]$, and is in no way related to it.

From a study of the dispersion of optical rotation [242,244], it has been shown that poly($\gamma$-benzyl L-glutamate) has the configuration of a right-hand spiral, while its antipode should have the configuration of a left-hand spiral. If the configuration is important, the rate of polymerisation should depend also on the relative concentrations of the

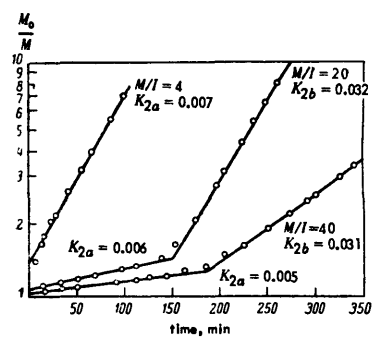


Fig. 11. The rate of polymerisation of the anhydride of $\gamma$-benzyl *N*-carboxy-L-glutamate in dioxan at 25°; initial concentration of the monomer $[M_0] = 4\%$; the units of $K_2$ are litre mole$^{-1}$ s$^{-1}$.

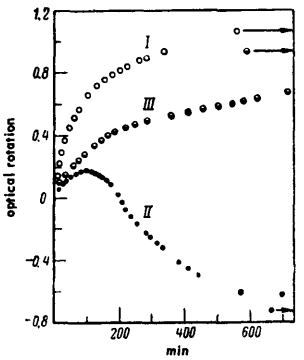
optical antipodes in the initial mixture. Indeed, the pure optical isomers polymerise twice as fast as the racemic mixture of the D- and L-antipodes. The second stage begins in the latter case much later, which is due to the much later formation of the stable racemic $\alpha$-spiral[199,245].

When poly($\gamma$-benzyl L-glutamate) is used as the initiator, the polymerisation of the anhydride of the *N*-carboxy--L-derivative proceeds at a high rate and the optical rotation of the system steadily increases with the growth of the $\alpha$-spirals. In the case of the racemic anhydride the polymerisation proceeds at a rate smaller by a factor of two, but the form of the spirals does not change when D-units are incorporated in it. In the L-polymer (initiator)–D-anhydride system a different relation obtains (Fig. 12). Initially D-units enter into the composition of the right--hand spiral of the L-polymer without changing its form, but as the D-units accumulate inversion of the optical rotation of the system takes place with simultaneous increase of the rate of polymerisation, which is probably due to the transformation of the right-hand $\alpha$-spiral of the L-polymer into the left-hand $\alpha$-spiral characteristic of the D-polymer. Comparison of the relative rates of addition of the D- and L-antipodes to the right-hand $\alpha$-spiral of the L-polymer shows that the L-anhydride is almost five times more reactive than the D-anhydride.

Two stages were also observed in the polymerisation, initiated by n-hexylamine, of the anhydrides of the *N*-carboxy--derivatives of L-leucine in nitrobenzene[199], *O*-benzyloxycarbonyl-L-tyrosine[246], glycine, $\epsilon$-*N*-benzyloxycarbonyl-L--lysine, $\gamma$-benzyl L-glutamate, DL-alanine, DL-$\alpha$-aminobutyric acid, DL-leucine, and DL-valine in dioxan[247]. However, in these cases the polymer is usually precipitated in the form of a gel, the reaction being accelerated simultaneously with the appearance of the new phase.

Ballard and Bamford[248] questioned the existence of two stages in homogeneous polymerisation of the anhydride of $\gamma$-benzyl *N*-carboxy-L-glutamate. According to their observations, the reaction is of first order with respect to the anhydride, and has a constant rate whether it is initiated by n-hexylamine or oligopeptides with $\overline{P}_n$ = 4.5 and 15. Doty and Lundberg[249] indicate that the second, rapid stage is observed only in experiments with thoroughly purified anhydrides. Impurities at low concentrations, for example 0.67 mole % of hexylammonium chloride, completely eliminate the second stage. Furthermore, an additive of this kind results in the formation of a polymer with a much lower molecular weight and a much narrower molecular weight distribution.



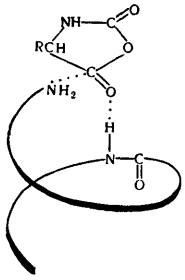


Fig. 12. Variation of the optical rotation of the system during the polymerisation of the anhydrides of $\gamma$-benzyl *N*-carboxy-glutamate [I) L-isomer; II) D-isomer; III) DL-isomer] initiated by the L-polymer; solvent — dioxan; temperature 25°; initial concentration 2%; optical pathlength of the cell $l$ = 20 cm.

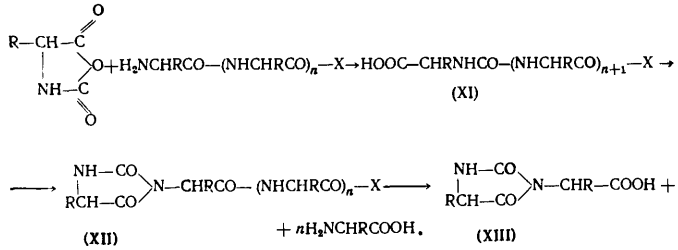
In the latest papers[234,250] Ballard and Bamford state that in most systems homogeneous conditions do not obtain, since polypeptides are poorly soluble and form a gel even at the trimer and tetramer stage, the rate of polymerisation increasing by a factor of 5–8 at the same time. Further coagulation of the gel into denser formations lowers the rate. Probably this is due to the adsorption of the polymerising anhydride on the polymeric gel. The polymerisation of the anhydride of $\gamma$-benzyl *N*-carboxy-L-glutamate, whose polymer does not form true solutions in dioxan according to the above authors, has been assigned to reactions of the same class.

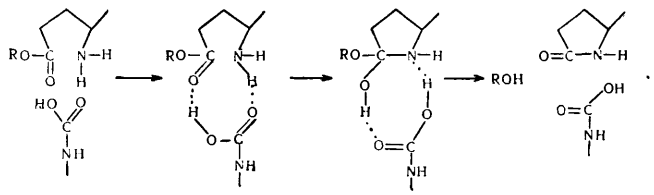
Adsorption can occur also in true solutions as a result of the formation of hydrogen bonds between monomer molecules and the polymeric chain, which probably in fact explains the "chain effect" in polysarcosine[231], poly-*N*-ethylglycine, and poly-*N*-benzylglycine[250], their reactivity increasing with increase in $\overline{P}_n$ in the initiation of the polymerisation of the anhydrides of *N*-carboxy-derivatives with free NH groups. The polymerisation of the anhydride of *N*-carboxysarcosine itself is not autocatalytic in a homogeneous medium, since polysarcosine does not form hydrogen bonds with the monomer[250].

However, the single-stage polymerisation of $\gamma$-benzyl *N*-carboxy-L-glutamate in dimethylformamide, in which the polymer is readily soluble and forms $\alpha$-spirals, contradicts both the hypothesis of Lundberg and Doty that the conformation of the growing chain influences the rate of polymerisation and the hypothesis of Ballard and Bamford that adsorption on polymeric chains takes place.



The two hypotheses have been in a way combined in the mechanism proposed by Weingarten[247], according to which activating adsorption of anhydride molecules is possible only at the ends of the growing chains when these have the spiral conformation:

Thus the molecule of the anhydride of the *N*-carboxy--derivative being added assumes a definite orientation even before its reaction with the terminal amino-group. Below yet another attempt will be made to explain the occurrence of the two stages in the polymerisation of the anhydride of $\gamma$-benzyl *N*-carboxy-L-glutamate.



*Chain termination.* The disappearance of the free amino-group at the end of the polypeptide chain, for any reason, results in the cessation of its growth. The cessation of chain growth occurs as a result of the "erroneous"

addition of the terminal amino-group to the carbonyl group in position 2 of the anhydride ring [192,251,252] with formation of the urea derivative (XI), which is capable of cyclising into the hydantoin derivative (XII). In the acid hydrolysis of polypeptides this derivative may be isolated in the form of the substituted hydantoin-3-acetic acid (XIII).

Possibly the cyclisation takes place only during hydrolysis, which is indicated by the presence of free carboxy--groups in polypeptides [241,251,253].

Chain termination can also occur in the intramolecular interaction of the terminal amino-group with any reactive group in the polymeric chain. Thus in the preparation of poly($\gamma$-benzyl L-glutamate) great importance attaches to the intramolecular cyclisation due to the reaction of the terminal amino-group with the ester group of the same structural unit, benzyl alcohol being eliminated [199,241,254]. Recently it has been shown that the cyclisation is catalysed by weak acids, including carbamic acid, and has the following mechanism [164]:

Intramolecular chain termination as a result of the migration of the acetyl group from the oxygen to the nitrogen was noted in the polymerisation of the anhydride of the *N*-carboxy-derivatives of *O*-acetoxyproline [255] and *O*-acetylserine [257,258].

*Polymerisation kinetics.* The polymerisation of the anhydrides of *N*-carboxy-derivatives is very convenient for the investigation of the kinetics of the process, the rate of which may be determined both by the titration of the monomer which failed to react [158,247] and from the amount of carbon dioxide evolved during polymerisation. In the latter case more reliable results are obtained at constant carbon dioxide pressure [206,225]. Closed systems of constant volume [187,232,233,259] are less suitable for kinetic studies. A convenient method is one in which the carbon dioxide evolved is swept by dry nitrogen into an absorption vessel where the change in the concentration of sodium hydroxide [222], barium hydroxide [199], or benzylamine [158] is determined conductimetrically [199,222] or by titration [158]. Idelson and Blout [200] studied the kinetics of the polymerisation of the anhydride of $\gamma$-benzyl *N*-carboxy-L-glutamate by infrared spectroscopy, which makes it possible to follow the disappearance of the monomer, the formation of the polymer, and the changes in the conformation of the polymeric chain.

In most cases of homogeneous polymerisation with fairly high basicity of the initiator and low rate of chain termination there is direct proportionality between the rate of reaction and the initial concentration of the monomer $[M_0]$ and initiator $[I_0]$. The kinetics of this process were examined theoretically by a group of English workers [225,232] and in a general form by Katchalski and coworkers [260,261]. Three stages of the process are distinguished: initiation ($K_1$), chain growth ($K_2$), and chain termination ($K_3$); the process can take place in one of the following possible ways.

If the rate of initiation is equal to the rate of chain growth ($K_1 = K_2$) and chain termination may be neglected ($K_3 = 0$), the rate of polymerisation is given by

$$-\frac{d[M]}{dt} = \frac{d[CO_2]}{dt} = K_2[I_0][M].$$

These conditions are satisfied by the homogeneous polymerisation of the anhydrides initiated by the amides or esters of amino-acids, peptides, or polypeptides, in solvents where the process takes place in one stage only and at low temperatures when chain termination does not play a significant role. The number-average degree of polymerisation of the polymer formed is defined by the relation $\bar{P}_n = ([M_0] - [M])/[I_0]$, or $\bar{P}_n = [M_0]/[I_0]$ on completion of polymerisation when $[M] = 0$. The molecular weight distribution should be of the Poisson type, i.e. the polydispersity is low with $\bar{P}_w/\bar{P}_n \simeq 1$.

The actual molecular weight distribution has been determined in only a few cases. It proved to be fairly narrow for polysarcosine [262], poly($\gamma$-benzyl L-glutamate) [199,263], and poly-$\epsilon$-*N*-benzyloxycarbonyl-L-lysine [246], obtained in dimethylformamide.

If the rates of initiation and chain growth differ from one another ($K_1 \neq K_2$), then when the rate of chain termination is low ($K_3 = 0$) the rate of polymerisation is given by the expression

$$-\frac{d[M]}{dt} = \frac{d[CO_2]}{dt} = K_1[I][M] + K_2\sum_{i=1}^{\infty} N_i^*[M],$$

where $[I]$ represents the concentration of the initiator at any instant, and $N_i^*$ the concentration of growing polymer chains containing at a given instant the following number of $i$-units: $[I] + \sum_{i=1}^{\infty} N_i^* = [I_0]$. At the early stages of the process when $[I_0] \simeq [I] \gg \sum_{i=1}^{\infty} N_i^*$, the overall rate of reaction is determined mainly by the first term of the equation, and on completion of polymerisation, when $[I] \ll \sum_{i=1}^{\infty} N_i^* \simeq [I_0]$, by the second term. Thus in this case polymerisation is of first order with respect to the anhydride and the rate of evolution of carbon dioxide is determined by the constants $K_1$ at the beginning and $K_2$ at the end of polymerisation. If $K_1 > K_2$, which occurs when the initiators are strong bases, the initiation process terminates rapidly and the rate of chain growth remains constant throughout the process. The molecular weight distribution of the polymer is very narrow and $\bar{P}_n = [M_0]/[I_0]$. When weak initiators are used, with $K_1 < K_2$, the initiation process is protracted and the overall rate of the reaction increases with increase in the number of new chains, and the polymer formed is polydisperse. $\bar{P}_n = [M_0]/[I_0]$ obtains only in the case where the entire initiator is able to react before the end of polymerisation.

If in the case of rapid initiation ($K_1 > K_2$, $K_3 \simeq 0$) two stages are observed in the chain propagation process ($K_{2a}$ and $K_{2b}$), the transition from $K_{2a}$ to $K_{2b}$ being completed

after the attainment of a chain length equivalent to $s$-units, the rate of the process is given by the expression

$$-\frac{d[M]}{dt}=\frac{d[CO_2]}{dt}=K_1[I][M]+K_{2a}\sum_{i=1}^{i=s}N_i^*[M]+K_{2b}\sum_{i=s}^{\infty}N_i^*[M].$$

This case was examined by Katchalski[246] on the basis of the kinetic data obtained by Lundberg and Doty[199] for two-stage polymerisation of the anhydride of $\gamma$-benzyl $N$-carboxy-L-glutamate in dioxan. Similarly to the preceding case, the polymerisation is again of first order with respect to the anhydride, its rate being determined mainly by the constant $K_{2a}$ at the beginning and $K_{2b}$ at the end: $-d[M]/dt = K_2[I_0]/[M]$. The polymer fractions with a degree of polymerisation less than $s$ exhibit the Poisson distribution. The fractions with $\overline{P}_n > s$ are more polydisperse the greater the difference between $K_{2a}$ and $K_{2b}$. On the basis of mathematical analysis, the authors believe that the number of $\beta$-chains diminishes during the polymerisation at a slower rate the greater the value of $s$, and the weight fraction of the $\beta$-polymer falls after reaching a maximum proportional to $s$. It is reasonable that the time of transition from $K_{2a}$ to $K_{2b}$ depends only on $[M_0]$ and not on $[I_0]$, since the rate of formation of the polymer with $\overline{P}_n = s$ depends on the concentration of the monomer $[M_0]$ and not on the number of chains $[I_0]$.

However, the relation observed by Doty and Blout[199,200] between $[M_0]$ and the time of transition from $K_{2a}$ to $K_{2b}$ is the opposite of that which would be expected on the basis of Katchalski's conclusions (Fig. 11). Furthermore, in one of his latest papers Katchalski[256] notes that the polydispersity found by Doty ($\overline{P}_w/\overline{P}_n = 8.5$) is much greater than the theoretical value. Thus the conclusions derived from an analysis of the polymerisation kinetics on the basis of the hypothesis of Doty and Lundberg, that chain conformation influences the rate of chain growth, is in poor agreement with experiment. On the other hand, no conclusion can be reached about the hypothesis of Ballard and Bamford that the adsorption of the monomer on polymer chains affects the rate of polymerisation, since the example examined by Katchalski assumes that $K_{2a}$ and $K_{2b}$ are constant, a possibility which is excluded in Ballard's hypothesis.

If in the case of a high rate of initiation and a single-stage process ($K_1 > K_2$) some of the polymerising chains are terminated ($K_3 \neq 0$) as a result of a bimolecular reaction with the anhydride, the amount of carbon dioxide evolved is less than that of the anhydride which has reacted ($[M_0] - [M]$). The difference $[M_0] - [M] - [CO_2]$ corresponds to the amount of terminal carboxy-groups. Katchalski[260,261] showed that in this case the molecular weight distribution of the growing chains remains of the Poisson type, but the polymer fraction with terminal carboxy-groups is polydisperse with $\overline{P}_w/\overline{P}_n \simeq 2$. The maximum attainable degree of polymerisation of the polymer as a whole is then $\overline{P}_n = K_2/K_3$.

This case is close to real polymerisation conditions. The chain termination reaction, which is rare at low temperatures (one reaction for 300 addition reactions)[199,241] plays a considerable role at elevated temperatures, since the activation energy for chain termination is somewhat higher than that for chain propagation, which in the case of $\gamma$-benzyl L-glutamate is only 6.6 kcal mole$^{-1}$.[199,200]

The kinetics of the polymerisation of the anhydrides of the $N$-carboxy-derivatives of trifunctional acids, for which intramolecular chain termination is possible, have not been examined theoretically.

Table 15 lists the latest data on the rates of polymerisation of the anhydrides of $N$-carboxy-derivatives, from which it follows that the rate of polymerisation is a maximum in the case of glycine and proline. Racemates polymerise more slowly than enantiomers. Non-polar solvents, which cannot form hydrogen bonds, accelerate the reaction[199].

The determinations of the rates of polymerisation are not very accurate because of the difficulty of purifying the anhydrides of $N$-carboxy-derivatives and the solvents, and because of failure to achieve the conditions of a homogeneous reaction[247]; the fact that the reaction is homogeneous is established with difficulty by a visual procedure (cf. Refs. 199 and 250). Furthermore, because the reaction of the anhydrides of $N$-carboxy-derivatives with strong amines proceeds in different ways, the true concentration of growing chains is only approximately equal to the initial concentration of the initiator. When the process takes place in two stages, the constant $K_{2b}$ is much too low, since not all the growing chains attain a length necessary for the acceleration of the reaction. Finally, polymerisation initiated by primary and secondary amines must proceed in several ways simultaneously. Otherwise it would have to be of first order with respect to the initiator and the rate of chain propagation would be independent of the nature of the initiator.

In fact $K_2$ does depend on the initiator. Thus diethylamine leads as a rule to polymerisation twice as fast as that given by hexylamine[247]. Furthermore, the order of the reaction with respect to the initiator is sometimes other than unity. In the polymerisation of the anhydrides of the $N$-carboxy-derivatives of DL-valine, DL-leucine, $\epsilon$-$N$-benzyloxycarbonyl-DL-lysine, and DL-$\alpha$-aminobutyric acid in dioxan a fractional reaction order was found[247]. In the polymerisation of the anhydride of $N$-carboxysarcosine Heyns and Schultze[150] found the reaction to be of second order with respect to the initiator, and later it was shown that the rate is proportional to the expression

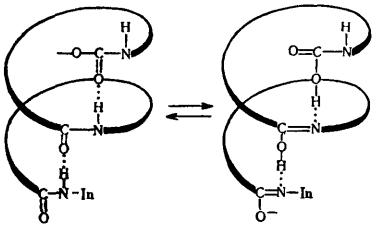
$$a[I_0]+b[I_0]^2 \quad ,$$

where $a$ and $b$ are constants[232,247].

In an investigation of the two-stage polymerisation of the anhydride of $\gamma$-benzyl $N$-carboxyl-L-glutamate the slow stage was found to be of first order with respect to the

anhydride and its rate proved to be independent of the initiator. On the other hand, the second, rapid stage was of fractional order (3/2) with respect to the anhydride and its rate did depend on the initiator [228].

The authors propose the following mechanism for chain propagation which explains the peculiarities of this process:



$$P_n\text{—}NH_2 + M \xrightarrow{K_{2a}} P_n\text{—}NHCOCHRNHCOOH, \quad (c)$$

$$P_n\text{—}NHCOCHRNHCOOH \xrightarrow{K_4} P_n\text{—}NHCOCHRNH_2 + CO_2, \quad (d)$$

$$P_n\text{—}NH_2 + P_m\text{—}NHCOOH \xrightarrow{K} P_n\overset{+}{N}H_3 + P_mNHCOO^-, \quad (e)$$

$$P_mNHCOO^- + M \xrightarrow{K_{2b}} P_mNHCOCHRNHCOO^- + CO_2. \quad (f)$$

Chain propagation can proceed according to the generally accepted mechanisms (c)–(d) with a rate constant $K_{2a}$ or by reaction (f) with a higher rate constant $K_{2b}$. Usually the contribution of reaction (f) is small because of the instability of carbamic acid and the resulting low concentration of the carbamate anion. However, on formation of the $\alpha$-spiral the stability of the anion may be significantly increased because of the distribution of the charge throughout the spiral:

As a result, the initiator can influence the stability of the carbamate anion and hence the rate of polymerisation. The rate of reaction (f) is defined by the equation

$$\frac{d[M]}{dt} = K_{2b}\left(\frac{K_{2a}}{K_4}\right)^{\frac{1}{2}} K^{\frac{1}{2}} [I_0]\,[M]^{\frac{3}{2}},$$

i.e. the reaction is of order 3/2 with respect to the anhydride, which agrees with experiment.

The mechanism proposed constitutes a very interesting attempt to account for the effect of spiral conformation and the initiator on the rate of polymerisation. However, we feel bound to point out that according to this mechanism secondary amines should not affect the reactivity of the terminal amino-group of the growing chain, since they are incapable of participating in the suggested system of hydrogen bonds.

Bamford and Block [264] proposed another mechanism for the effect of the initiator on the rate of polymerisation, which will be examined below.

C. Initiation with water. Polymerisation in the presence of water proceeds similarly as the polymerisation initiated by amines [265]. However, the initiation stage is slower because of the lower basicity of water, and the ionisation of free carboxy- and amino-groups in the system greatly slows down chain growth, particularly in the first polymerisation stage [224,266–270]. The use of water as the initiator is of interest for the preparation of polypeptides with terminal carboxy- and amino-groups capable of further condensation, for example by the carbodiimide method [271].

In the case of initiation by water side-reactions are possible. The polyglycine obtained in this way contains up to 2% of 2,5-dioxopiperazine [253]. Polymerisation in polar solvents, for example dimethylformamide, probably takes place by a different mechanism and leads to considerable amounts of hydantoin derivatives [207,272].

In many cases water can be used not only as the initiator but also as the polymerisation medium [174]. In recent years the dependence of the rate of polymerisation of various anhydrides of *N*-carboxy-derivatives on the pH of the medium has been studied in detail [163,269,273–275].

D. Initiation with strong bases. Sodium hydroxide [276], sodium methoxide, sodium borohydride [203], and triphenylmethylsodium [277], which have been proposed by Blout and coworkers as the initiators of the polymerisation of the anhydrides of *N*-carboxy-derivatives, yield exclusively high-molecular-weight polypeptides [poly($\gamma$-benzyl L-glutamate, $M$ = 600 000; poly-$\epsilon$-*N*-benzyloxycarbonyl--L-lysine, $M$ = 2 000 000], which are of low dispersity and are free of 2,5-dioxopiperazine and other cyclic compounds [278,279]. A detailed study of this process [203,277,280,281] has shown that polypeptides with the maximum molecular weights are formed in solvents such as dioxan, chloroform, and benzene at temperatures below 30° and monomer concentrations below 4%. In nitrobenzene the rate of polymerisation is smaller by a factor of almost 30 and the polymer has a much lower molecular weight. There is no proportionality between the degree of polymerisation and the ratio $[M_0]/[I_0]$, the molecular weight of the polymer being always higher than the calculated value [203,281].

The rate of polymerisation and the molecular weight of polymers increase in the series lithium, sodium, potassium, and caesium methoxides [280]. The polymerisation of the anhydride of $\gamma$-benzyl *N*-carboxy-L-glutamate in dioxan at 34° proceeds after a brief autocatalytic period as a first--order reaction with respect to the monomer at a rate one hundred times greater ($K_2$ = 4.3–6.3 litre mole$^{-1}$ s$^{-1}$) than in the case of initiation by primary or secondary amines [280]. Addition to the reaction system of fresh portions of the anhydride of the *N*-carboxy-derivative does not increase the

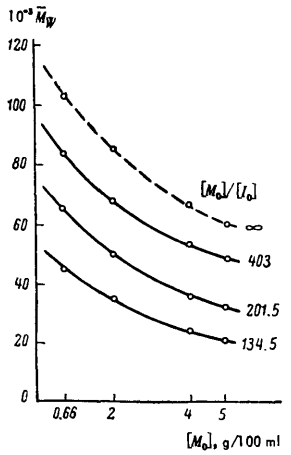


Fig. 13. Dependence of the molecular weight $\bar{M}_w$ of poly-DL-phenylalanine on the initial monomer concentration $[M_0]$ for various values of $[M_0]/[I_0]$.

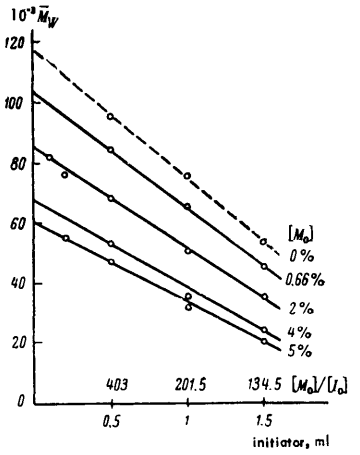

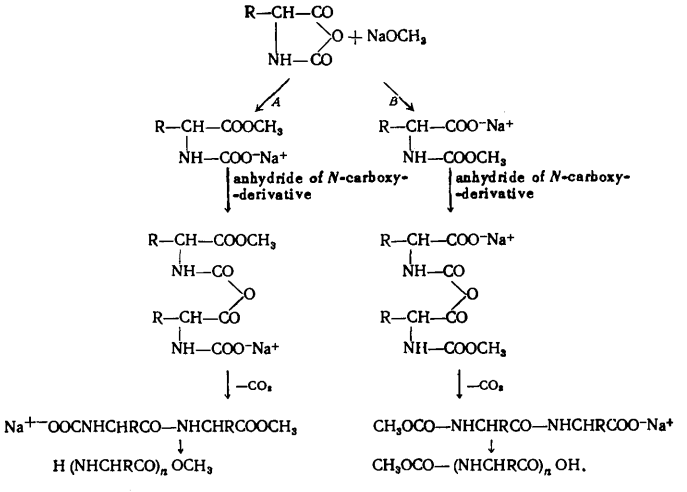

Fig. 14. Dependence of the molecular weight $\bar{M}_W$ of poly-DL-phenylalanine on the ratio $[M_0]/[I_0]$ for various initial monomer concentrations $[M_0]$.

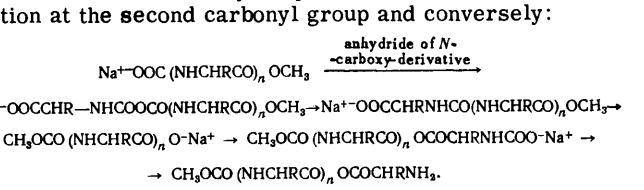
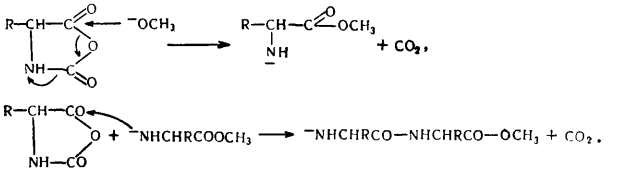


molecular weight of the polymer. The replacement of the L-anhydride by the racemate lowers the rate of polymerisation by a factor of seventeen and the molecular weight of the polymer by a factor of about five.

The above features of the process have also been found for the neutral amino-acid DL-phenylalanine[279]. Figs. 13 and 14 show the experimental dependence of the molecular weight $\bar{M}_W$ of the polypeptide on the concentration of the anhydride $[M_0]$ and the ratio $[M_0]/[I_0]$. The polymerisation was carried out at 40° in chloroform in the presence of sodium methoxide. The dashed lines, corresponding to $[M_0] = 0$ and $[M_0]/[I_0] = \infty$ (0 ml of initiator) were obtained by extrapolation. The molecular weights were found from the light scattering.

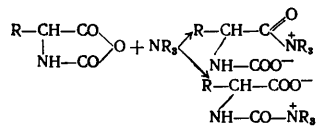
These results led Blout and Idelson[280] to the hypothesis that the polymerisation in this case has an ionic mechanism:



The growth of the polymeric chain proceeds by successive addition of the polymeric anions to the anhydride of the *N*-carboxy-derivative either at the carbonyl in position 5 (pathway *A*) or at the carbonyl in position 2 (pathway *B*) with formation of mixed anhydrides which readily eliminate carbon dioxide. Chain termination occurs when the addition at the carbonyl in position 5 is followed by the addition at the second carbonyl group and conversely:

In the first case the polymer should contain urea and in the second anhydride and urethane groups.

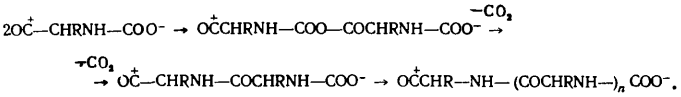
A more probable mechanism[282] for chain propagation[280], also proposed by the same workers, is one in which the participation of an amine anion is assumed, and the elimination of carbon dioxide is attributed to simple electron pair transfers:



E. Initiation with tertiary amines. Tertiary amines (pyridine[174,182,224,283-285], α-picoline, 2,6-lutidine[182], triethylamine[103,259,286,287], tri-n-butylamine[259,285,288], and trimethylamine[289]) are effective initiators for the polymerisation of the anhydrides of *N*-carboxy-derivatives with a free NH group. However, the resulting polypeptides contain some substituted hydantoin-3-acetic acid[207,283].

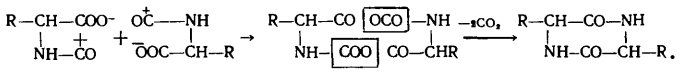
As regards the anhydrides of *N*-substituted *N*-carboxy--derivatives, there is no single view concerning their ability to polymerise under the action of tertiary amines. In contrast to the anhydride of *N*-carboxy-*N*-cyclohexylglycine[284], the anhydride of *N*-carboxy-*N*-phenylglycine does not polymerise in pyridine even at an elevated temperature[174,175]. The anhydride of *N*-carboxysarcosine polymerises at room temperature in pyridine[175,283] even when it is most thoroughly purified by means of phenylmagnesium bromide[284]. The anhydrides of the *N*-carboxy--derivatives of L-proline[141,290], L-hydroxyproline, and *O*-(*p*-toluenesulphonyl)-L-hydroxyproline[290] also polymerise readily in pyridine. Nevertheless, Ballard and Bamford[182,206,259,285] believe that the polymerisation of sarcosine and proline and their derivatives is due to impurities and that after thorough purification it is possible to reduce to a minimum the initial rate of polymerisation[259].

Tertiary amines give rise to rapid polymerisation of the anhydrides of *N*-carboxy-derivatives in organic solvents even in the case of high $[M_0]/[I_0]$ ratios, yielding high--molecular-weight polypeptides, the degree of polymerisation of which is independent of the $[M_0]/[I_0]$ ratio[203]. These features resemble in many ways the polymerisation initiated by strong bases.

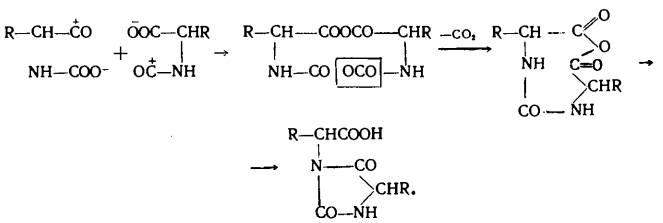


The polypeptides obtained in an anhydrous medium with tertiary amines as the initiators cannot have terminal amino- and carboxy-groups, i.e. they must have a cyclic structure. Thorough analysis of polysarcosine ($M$ = 22 000) and poly-*N*-cyclohexylglycine, prepared in dry pyridine, showed that these polymers have virtually no end-groups[284]. Cyclic dipeptides, substituted 2,5-dioxopiperazines, have been isolated, the yield reaching 35% in the case of poly--*N*-cyclohexylglycine. According to Wieland[291], in this

case the anhydride ring is opened by the tertiary amine with formation of a zwitter-ion:

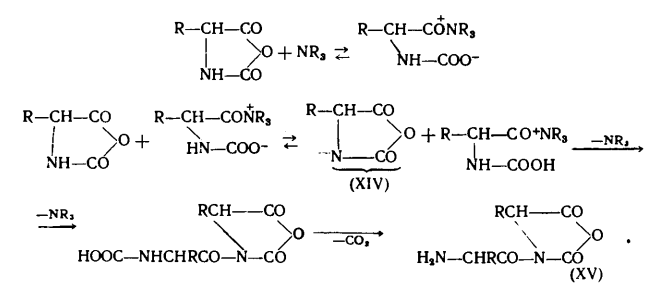


The formation of polypeptides, 2,5-dioxopiperazines and substituted hydantoin-3-acetic acid can be explained by different possibilities of combining the zwitter-ions.

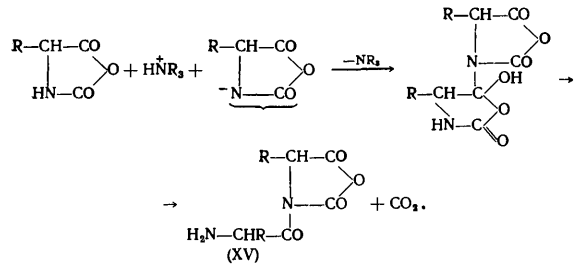


Formation of polypeptide:

Formation of 2,5-dioxopiperazine:

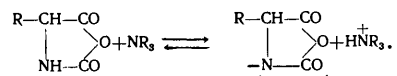


Formation of substituted hydantoin-3-acetic acid:

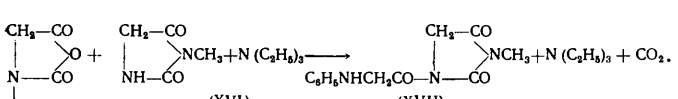


The rapid polymerisation of the anhydrides of *N*-carboxy-derivatives in organic solvents in the presence of catalytic amounts of tertiary amines [203] shows, however, that the growth of the polypeptide chain proceeds mainly not as a result of the interaction of two zwitter-ions but as a result of their reaction with the anhydrides of *N*-carboxy--derivatives.

The mechanism proposed by Ballard and Bamford [182,259,285] for the reaction between the anhydrides of *N*-carboxy--derivatives and tertiary amines excludes the possibility of the polymerisation of the anhydrides of *N*-substituted *N*-carboxy-derivatives, since the primary products of the reaction are believed to be the anhydride anion (XIV) and 3-(α-aminoacyl)-2,5-dioxooxazolidine (XV):



Subsequently the anion (XIV) can also react with a molecule of the anhydride by the mechanism



Compound (XV) initiates chain growth both at the amine end and at the *N*-carboxy-derivative anhydride end.

However, measurements of the rate of polymerisation of the anhydrides of the *N*-carboxy-derivatives of γ-ethyl L-glutamate in dimethylformamide and of DL-phenylalanine in nitrobenzene in the presence of pyridine, α-picoline, and 2,6-lutidine as the initiators [182] showed that the anion (XIV) does not form as a result of the nucleophilic attack by the tertiary amine on the carbonyl group in position 5 but as a result of direct attack by the amide hydrogen (cf. Ref. 181):

Otherwise the rate of reaction of the tertiary amines with the anhydrides of the *N*-carboxy-derivatives should decrease in the series pyridine, α-picoline, 2,6-lutidine due to increasing steric hindrance, while experiment showed that the rate actually increases in this series because of the increasing basicity of the amines.

Chain termination occurs also as a result of intramolecular cyclisation of the bifunctional polymeric chain or as a result of deactivation of the terminal amino-group. The formation of substituted hydantoin-3-acetic acid is explained by a rearrangement of compound (XV). In the authors' view [259] the mechanism proposed is proved by the fact that the rapid polymerisation of the anhydride of *N*-carboxy-sarcosine proceeds only in the presence of 3-methylhydantoin (XVI), an analogue of the anhydride of the *N*-carboxy--derivative not substituted at the nitrogen atom, and also by the fact that it proved possible to isolate 3-methyl-1--(*N*-phenylglycyl)hydantoin (XVII) from the products of the reaction of the anhydride of *N*-carboxy-*N*-phenylglycine, triethylamine, and 3-methylhydantoin:

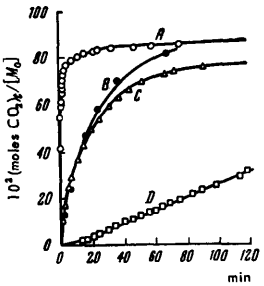
As already pointed out, the suggested mechanism excludes the possibility of the polymerisation of *N*-substituted anhydrides, which cannot be regarded as completely proved. Furthermore, it entirely fails to account for the extremely rapid rate of polymerisation, which is comparable with the rate of ionic polymerisation. The chain growth of the anhydride end cannot increase significantly the rate of polymerisation, since it involves interaction either with

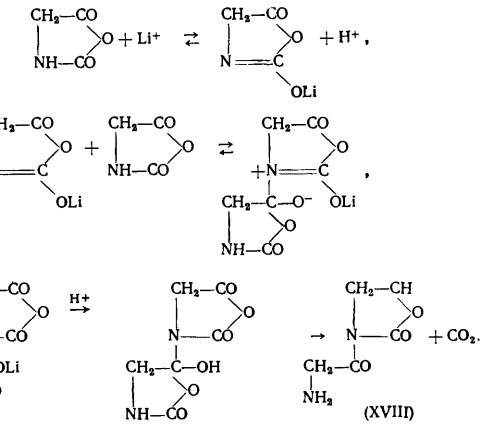
activated molecules of the anhydride of the *N*-carboxy--derivative, the concentration of which is extremely low, or with terminal amino-groups, which would reduce the concentration of the active centres for chain propagation.

It has been shown[264] that the polymerisation in the presence of secondary and primary amines also frequently proceeds by the mechanism characteristic of the initiation by tertiary amines. Blout[203] observed a considerable similarity between the polymerisations of the anhydride of $\gamma$-benzyl *N*-carboxy-L-glutamate initiated by diethylamine and triethylamine. In both cases the polymerisation was rapid and the molecular weight of the polymer was independent of the $[M_0]/[I_0]$ ratio.

Bamford found (Fig. 15) that the polymerisation of the anhydrides of the *N*-carboxy-derivatives of sarcosine and $\gamma$-ethyl L-glutamate in the presence of n-hexylamine and diisopropylamine takes a normal course only when initiated by n-hexylamine (curves *B* and *C*). Because of the considerable steric hindrance caused by the isopropyl groups, the initiation of the polymerisation of sarcosine by diisopropylamine is slow and the reaction becomes accelerated only as active terminal amino-groups appear in the growing chain (curve *D*). It would appear that this should also hold for other anhydrides. However, in the case of the anhydride of the *N*-carboxy-derivative not substituted at the nitrogen atom (curve *A*) the sterically hindered diisopropylamine gives rise to much more rapid polymerisation than does hexylamine, which can be explained only by the preferential occurrence of the process involving the mechanism characteristic of tertiary amines. This conclusion is also confirmed by the analysis of the molecular weights of the polymers. Whereas poly($\gamma$-ethyl L-glutamate) obtained in the presence of hexylamine has $\overline{P}_n = 60$, in the initiation with diisopropylamine $\overline{P}_n$ reaches 150 under the same polymerisation conditions with $[M_0]/[I_0] = 15$. It is interesting that in the latter case the amount of carbon dioxide evolved is much smaller than the theoretical value.

F. Initiation with salts. Inorganic salts were proposed by Ballard as the initiators of the polymerisation of the anhydrides of *N*-carboxy-derivatives as early as 1954 [206,207] but did not find wide application, since the resulting polypeptides contained up to 30–40% of hydantoin derivatives. However, this type of initiation is very interesting from the chemical point of view, because it is believed that there is considerable similarity in the mechanisms of the reaction of the anhydrides of *N*-carboxy--derivatives with salts and tertiary amines[207,259].





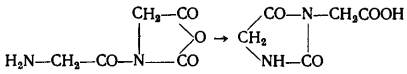


Fig. 15. Rate of evolution of carbon dioxide in different systems in diethylformamide solution at 25°:
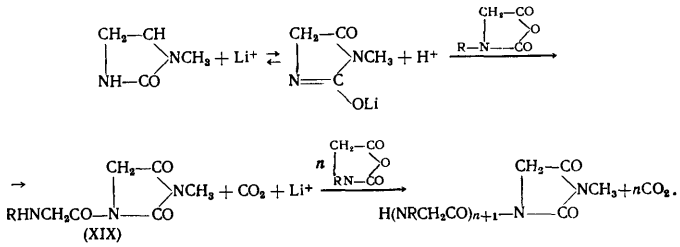
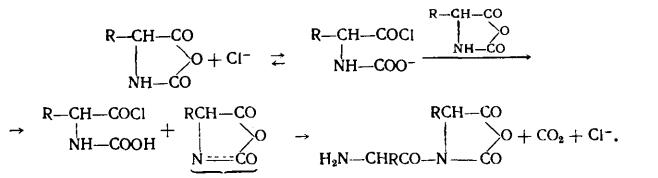
*A*) anhydride of $\gamma$-ethyl *N*-carboxy-L-glutamate–diisopropylamine; *B*) anhydride of *N*-carboxysarcosine–n-hexylamine; *C*) anhydride of $\gamma$-ethyl *N*-carboxy-L-glutamate–n-hexylamine; *D*) anhydride of *N*-carboxysarcosine–diisopropylamine; $[M_0] = 0.224$ M; $[I_0] = 0.015$ M.

The following mechanism has been proposed for the initiation of polymerisation:

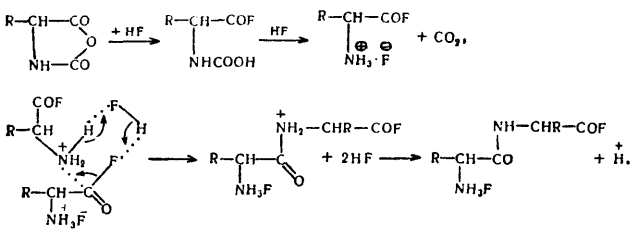


An intermediate compound, 3-aminoacetyl-2,5-dioxooxazolidine (XVIII), is formed and initiates chain growth or is converted into hydantoin-3-acetic acid:



The polypeptide chains have reactive end-groups and can react with one another or form macro-rings.

The anhydrides of *N*-substituted *N*-carboxy-derivatives do not react with salts, but they readily polymerise in the presence of 3-methylhydantoin:



The first chain unit, 3-methyl-1-(*N*-phenylglycyl)hydantoin (XIX) was isolated from the products of the reaction of the anhydride of *N*-carboxy-*N*-phenylglycine, 3-methylhydantoin, and lithium chloride[259]. Later it was found that lithium perchlorate does not initiate the polymerisation of the anhydrides[250], which means that the active component of lithium chloride is not the cation $Li^+$ but the anion $Cl^-$.[259]

G. Initiation with acids. Acids usually inhibit the polymerisation of the anhydrides of *N*-carboxy-derivatives. However, the anhydride of γ-methyl *N*-carboxy-L--glutamate rapidly polymerises in chloroform in the presence of acetic acid[292]. With $[M_0]/[I_0] = 2$ the reaction is initially slow ($K_{2a} = 0.0035$), but after 30 min the rate increases sharply ($K_{2b} = 0.029$) and the polymerisation terminates in 2 h with formation of a polypeptide having $\overline{P}_n = 500-600$. The increase in rate corresponds to $\overline{P}_n = 50-60$, which the authors of this investigation attribute to the gel effect.

It is interesting that in dioxan polymerisation does not take place, the addition of 10% of dioxan to chloroform causing the appearance of an induction period (70 min). In the pure acid tripeptides are formed slowly. Acylated products and 2,5-dioxopiperazines have not been detected in the reaction products. The polymerisation of the anhydrides of *N*-carboxy-derivatives in chloroform is also induced by a number of other acids[201].

H. Polymerisation in anhydrous hydrogen fluoride. Anhydrous hydrogen fluoride readily dissolves the anhydrides of *N*-carboxy-α-amino-acids and polypeptides[293]. An attempt was made to use it as a polymerisation medium[294]; the polymerisation then proceeds without additional initiators but involves the racemisation of the amino-acids and the formation of considerable amounts of 2,5-dioxopiperazines. The degree of polymerisation reaches 25–30. The following mechanism has been suggested for this reaction:

I. Initiation with organometallic compounds. The polymerisation of the anhydride of *N*-carboxy-DL-alanine in tetrahydrofuran in the presence of a number of organometallic compounds was investigated recently[295]. Diethylcadmium and triethylaluminium proved to be the most effective compounds. Diethylzinc, phenylmagnesium bromide, and butyllithium were less effective, and tributylboron did not initiate the polymerisation at all. In contrast to other polymers, the polyalanine obtained in the presence of triethylaluminium was insoluble in water. Since poly-D-alanine and poly-L-alanine are also insoluble in water, the authors of this investigation suggested that triethylaluminium causes stereospecific polymerisation of the anhydride of the *N*-carboxy-derivative.

A similar property is shown by aluminium isopropoxide and by catalytic systems consisting of triethylaluminium and methanol or borneol, although in this case the insoluble fraction forms only part of the product. On the other hand, mixtures of diethylzinc with methanol and water and of diethylcadmium with methanol give only the water-soluble poly-DL-alanine.

When the optically active (+)-borneol and (-)-menthol were used as initiators, polyalanine exhibiting optical activity in solution was obtained, but the polymerisation of the monomer was incomplete.

4. Copolymerisation of the Anhydrides of *N*-Carboxy-α--amino-Acids

The available methods for the synthesis of the copolymers of α-amino-acids starting with the anhydrides of the *N*-carboxy-derivatives do not permit the preparation of copolypeptides with a specified sequence of the amino-acid residues. Usually the synthesis of copolypeptides reduces to the polymerisation in the solid state or in solution of a mixture of the anhydrides of the *N*-carboxy-derivatives using as the initiators the same compounds as in homopolymerisation, i.e. primary, secondary, and tertiary amines, sodium methoxide, amino-acid amides, polypeptides with free amino-groups, water, etc.

It is quite reasonable that copolymerisation should be a more complex process than the polymerisation of a pure *N*-carboxy-α-amino-acid anhydride and that it should have a number of specific features. Most of the published studies on copolymerisation were undertaken in order to elucidate the effect of the polypeptide composition on the conformation of macromolecules in solution; less attention was given to problems of the kinetics and mechanism of the reaction. For this reason, a considerable part of these investigations will be examined very briefly in this Section.

Katchalski and Sela[5] considered the copolymerisation of two anhydrides of *N*-carboxy-α-amino-acids as a system of the following reactions:

$$\cdots A + A \xrightarrow{K_1} \cdots A,$$
$$\cdots A + B \xrightarrow{K_2} \cdots B,$$
$$\cdots B + A \xrightarrow{K_3} \cdots A,$$
$$\cdots B + B \xrightarrow{K_4} \cdots B,$$

where A and B are monomers, ....A and ....B the growing peptide chains containing the terminal amino-group of the amino-acids A or B and $K_1$, $K_2$, $K_3$, and $K_4$ are the rate constants. The anhydrides of *N*-carboxy-derivatives of various amino-acids greatly differ in their reactivity and therefore the above reactions can proceed at different rates. However, Shalitin and Katchalski[319] found that the rates of copolymerisation are determined by the nature of the monomer and not of the terminal amino-acid residue of the growing chain, and therefore $K_1 = K_3$ and $K_2 = K_4$. It has been found that the rates of copolymerisation with diethylamine as the initiator, of the anhydrides of the *N*-carboxy-derivatives of γ-benzyl L-glutamate and ε-*N*-benzyloxycarbonyl-L-lysine in dimethylformamide, which is a good solvent both for homopolymers and copolymers at 25°, are equal to the sum of the rates of polymerisation of the individual monomers (Figs. 16 and 17).

On the basis of the data obtained, the rate of copolymerisation $-d[G + L]/dt$ can be represented thus:

$$-\frac{d[G+L]}{dt} = K_G[I_0][G] + K_L[I_0][L], \quad (1)$$

or

$$-\frac{d[G+L]}{dt} = K_{cop}[I_0][G+L],$$

where

$$K_{cop} = \frac{K_G[G] + K_L[L]}{[G] + [L]}. \quad (2)$$

Since $K_G$ is greater than $K_L$, the anhydrides of γ-benzyl *N*-carboxy-L-glutamate ($G$) will be consumed more rapidly

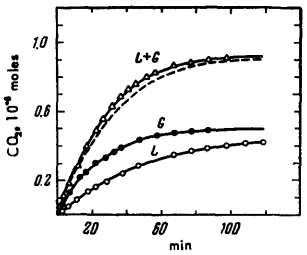


Fig. 16. Polymerisation of the anhydrides of the *N*-carboxy-derivatives of ϵ-*N*-benzyloxycarbonyl-L-lysine (*L*) and γ-benzyl L-glutamate (*G*) and their mixture (*G* + *L*) in dimethylformamide at 25° with diethylamine as the initiator; the dashed curve represents the sum of curves *L* and *G*.

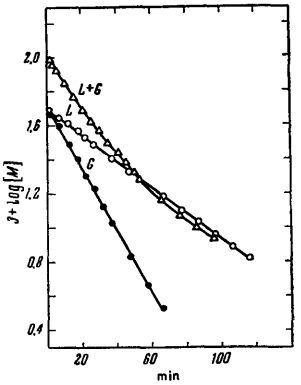

Fig. 17. Consumption of the monomers *L* and *G* as a function of time; [*M*] is the molar concentration of the monomer which has not reacted.

during copolymerisation than the anhydride of ϵ-*N*-benzyloxycarbonyl-α-*N*-carboxy-L-lysine (*L*). For this reason, the reaction mixture at the end of the process will contain only traces of the first anhydride and relatively large amounts of the second, and $K_{cop}$ will be virtually equal to $K_L$. The time variation of the composition of the copolymer formed is clearly shown in the electrophoretic pattern obtained in phosphate buffer at pH 7.8 for glutamic acid, lysine, and the copolymers of glutamic acid and lysine in the initial and final stages of copolymerisation (Fig. 18).

It is seen that the copolymers isolated at the beginning of the reaction were negatively charged and migrated towards the anode, like glutamic acid, while those isolated at the end of the reaction were positively charged and migrated towards the cathode, like lysine. The copolymers isolated after 25, 50, and 93% of conversion of the monomers contained glutamic acid and lysine residues in molar ratios of 3.0, 1.3, and 0.22 respectively.

The hypothesis concerning the mechanism of copolymerisation made it possible to derive an equation for the composition of the resulting copolymer as a function of

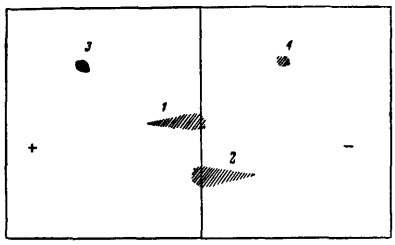

Fig. 18. Electrophoretic pattern of the copolymer of lysine and glutamic acid:
1) copolymer after 20% conversion; 2) copolymer after completion of reaction; 3) glutamic acid; 4) lysine.

time *t* and the initial composition of the reaction mixture $[G_0]/[L_0]$:

$$\frac{[G]_x}{[L]_x} = \frac{[G_0]}{[L_0]} \frac{1-\exp(K_G[I_0])t}{1-\exp(K_L[I])t}, \qquad (3)$$

where $[G]_x/[L]_x$ is the ratio of the glutamic acid and lysine residues in the copolymer.

Investigation of the copolymerisation of other anhydrides of *N*-carboxy-α-amino-acids (L-phenylalanine and ϵ-*N*-benzyloxycarbonyl-L-lysine, L-phenylalanine and γ-benzyl L-glutamate, glycine and ϵ-*N*-benzyloxycarbonyl-L-lysine, ϵ-*N*-benzyloxycarbonyl-L-lysine and DL-alanine, and γ-benzyl L-glutamate and DL-alanine) in dimethylformamide with diethylamine as the initiator established that the copolymerisation of these monomeric pairs proceeds similarly to the copolymerisation of the anhydrides of the *N*-carboxy-derivatives of γ-benzyl L-glutamate and ϵ-*N*-benzyloxycarbonyl-L-lysine, i.e. the rates of copolymerisation are equal to the sum of the rates of polymerisation of the corresponding individual monomers. The resulting copolypeptides had a molecular weight distribution close to the molecular weight distribution of the corresponding homopolymers.

A number of copolypeptides with different contents of L-glutamic acid, L-lysine, L-tyrosine, and L-phenylalanine have been synthesised[320] from the anhydrides of the corresponding N-carboxy-derivatives in absolute benzene at 25° using sodium methoxide as the initiator ($[M_0]/[I_0]$ = = 400). The molecular weights of the resulting copolymers were in the range 50 000–100 000. On the basic of kinetic data, the authors concluded that up to 90% conversion the copolymerisation is of first order, the reaction order departing from unity subsequently. Table 16 presents data on the composition of the initial reaction mixture and the copolypeptides.

A number of copolymers with *M* = 30 000–550 000 containing different amounts of L-glutamic acid, L-lysine, L-tyrosine, L-phenylalanine, and L-alanine were prepared later[321,322]. Blout and Idelson[323] obtained four high-molecular-weight copolypeptides of L-lysine and L-glutamic acid with a disordered structure and different molar ratios of the components (7 : 3, 6 : 4, 5 : 5, and 4 : 6) from the anhydrides of the *N*-carboxy-derivatives of γ-benzyl L-glutamate and ϵ-*N*-benzyloxycarbonyl-L-lysine in 1% solution of absolute benzene at room temperature using sodium methoxide as the initiator ($[M_0]/[I_0]$ = 200); the benzyl and benzyloxycarbonyl groups were subsequently removed with dry hydrogen bromide. The resulting copolypeptides had an average molecular weight ranging from 36 000 to 110 000,

TABLE 16. Dependence of the composition of copolypeptides on the composition of the initial mixture.

| Molar composition of initial mixture, % | | | | Molar composition of copolypeptides, % | | | |
|---|---|---|---|---|---|---|---|
| L-glutamic acid | L-lysine | L-phenyl-alanine | L-tyrosine | L-glutamic acid | L-lysine | L-phenyl-alanine | L-tyrosine |
| 50.0 | 33.3 | — | 16.7 | 49.8 | 34.3 | — | 15.9 |
| 47.6 | 38.4 | — | 4.0 | 56.4 | 37.8 | — | 5.8 |
| 58.0 | 42.0 | — | — | 59.0 | 41.0 | — | — |
| 58.0 | 41.0 | — | 1.0 | 56.1 | 42.6 | — | 1.3 |
| 58.0 | 38.0 | 4.0 | — | 61.6 | 33.4 | 5.0 | — |

| 100 | — | — | — | 100 | — | — | — |

and were readily soluble in water both at low and high pH, the solubility being a minimum in the region of neutral pH and depending on the composition and charge of the polypeptide, i.e. as regards their solubility they resembled polyamphoteric compounds and certain proteins.

In order to elucidate the dependence of the conformation of macromolecules on the composition of copolymers, the copolypeptides of *S*-methyl-L-cysteine and L-methionine with molar ratios of 1 : 9, 2 : 8, 3 : 7, and 5 : 5 and the copolymers of L-valine and L-methionine with the same molar ratios were synthesised[324] from the anhydrides of the corresponding *N*-carboxy-derivatives in nitrobenzene solution (4%) using sodium methoxide as the initiator ($[M_0]/[I_0]$ = = 200). For the same purpose, Karlson et al.[144] synthesised poly-$\beta$-benzyl esters of L- and D-aspartic acid, the poly-$\gamma$-benzyl ester of glutamic acid, and also a series of their copolymers by the polymerisation of a mixture of the anhydrides of the *N*-carboxy-derivatives in methylene chloride solution using sodium methoxide as the initiator ($[M_0]/[I_0]$ = 200) with different monomer ratios (1 : 9, 2 : 8, 3 : 7, 5 : 5, 7 : 3, 9 : 1). It was established that poly($\beta$-benzyl L-aspartate) and poly($\gamma$-benzyl L-glutamate) have an $\alpha$-spiral conformation but with the opposite direction of turns.

To study the effect of the ester group on the conformation and properties of poly-$\beta$-aryl esters of L-aspartic acid, a number of copolymers with different molar ratios of ester residues were prepared[302] by the copolymerisation of the anhydrides of $\beta$-*p*-nitrobenzyl and $\beta$-benzyl esters of *N*-carboxy-L-aspartic acid in dimethylformamide using diethylamine as the initiator. It was found that the copolymers have a spiral conformation, the introduction of more than 35–40% *p*-nitrobenzyl residues into poly($\beta$-benzyl L-aspartate) reversing the direction of the turns of the spiral.

By the copolymerisation of the anhydride of $\gamma$-benzyl *N*-carboxy-L-glutamate with the anhydrides of the *N*-carboxy-derivatives of L-alanine, L-leucine, and L-methionine at different ratios, Kulkarni and Blout obtained copolypeptides of interesting structure[325]. The $\gamma$-ester groups in the copolymers were replaced by 2-morpholinoethylamine residues. Such copolypeptides were readily soluble in water and showed a high content of the spiral conformation in solution. Addition to the solution of denaturing agents (urea) and salts caused their transition to a randomly coiled conformation.

To elucidate the influence of the steric configuration of the monomers and their ratio on the molecular weight and properties of the resulting copolypeptides[326], a number of polypeptides were synthesised by the copolymerisation of a 3% solution of a mixture of the anhydrides of the *N*-carboxy-derivatives in benzene saturated with water (70°, 24 h). The anhydrides of the *N*-carboxy-derivatives of the strongly basic D- or L-lysine and the acidic L-tyrosine were taken in 1 : 1 and 3 : 1 ratios. For the 3 : 1 monomer ratio, the resulting copolymers had a mean molecular weight of about 18 000 regardless of the configuration of the lysine. When the monomer ratio was 1 : 1, copolymers with the molecular weight $\overline{M}_W$ = 18 000 and $\overline{M}_W$ = 40 000 were obtained in the case of DL-lysine and D-lysine respectively as well as two polymers with different molecular weights in the case of L-lysine. The product with the higher molecular weight ($\overline{M}_W$ = 600 000) had a much higher content of L-tyrosine than the copolymer with the lower molecular weight ($\overline{M}_W$ = = 13 000).

To synthesise polypeptides having a structure similar to that of proteins, polypeptides were prepared[327] by the copolymerisation (using 0.5 mole % of sodium methoxide) of an equimolar mixture of the anhydrides of the *N*-carboxy-derivatives (4% solution in dimethylformamide) of L-lysine and L-glutamic acid, whose homopolymers have the $\alpha$-spiral conformation at pH above 10.5 and below 4.5 respectively. It was expected that such copolymers would have the $\alpha$-spiral conformation at a neutral pH. The resulting copolymers had a molecular weight of about 40 000 and were soluble in water. Up to 15% of the spiral conformation was detected in a neutral 0.15 M sodium chloride solution, the amount increasing to 50% at pH 4 and falling to zero at pH 12 or on removal of sodium chloride.

In an attempt to synthesise soluble amphoteric polypeptides, a study was made of the copolymerisation of the anhydrides of the *N*-carboxy-derivatives of L-glutamic acid, L-lysine, and L-phenylalanine in the ratios 1 : 1 : 3 and of L-glutamic acid, L-lysine, and L-leucine in the ratios 1 : 1 : 1.9.[328–330] The resulting polypeptides had typical amphoteric properties. They dissolved in dilute mineral acids and alkalis but not in water at pH between 4.0 and 10.8, which the authors of these studies explained by the aggregation of the copolypeptides on approach to the isoelectric point, which for the second polymer is 7.3.

Later Yuki[329] found that, in order to increase the solubility in the region of neutral pH, it is necessary to introduce serine residues, which together with threonine residues are responsible for the solubility of albumin. Copolypeptides containing L-glutamic acid and DL-serine in molar ratios of 4 : 1, 3 : 2, 2 : 3, and 1 : 4 were obtained. The last two copolymers were soluble even in water. The free copolymer containing L-glutamic acid, L-lysine, and DL-serine in the proportions 1 : 1 : 2 dissolved at any pH. The specific viscosity of this copolymer was found to be related to the pH (Fig. 19). The viscosity is a minimum at the isoelectric point (pH 7), which is characteristic of amphoteric polyelectrolytes.

Linear water-soluble copolypeptides of L-glutamic acid, L-lysine, and L-tyrosine in the proportions 2.8 : 2.6 : 1.0 have also been obtained[331], by the polymerisation of the anhydrides of the corresponding *N*-carboxy-derivatives in benzene solution using sodium methoxide as the initiator ($[M_0]/[I_0]$ = 400), with subsequent removal of the benzyloxycarbonyl group. The copolymer had $\overline{M}_W \simeq$ 49 000 and was soluble in water, but it dissolved in 0.15 M sodium chloride solution only at pH $>$ 10.

The following tyrosine-containing copolymers have been prepared[332] from the anhydrides of the corresponding *N*-carboxy-derivatives: glycine–L-tyrosine with molar ratios 1 : 1 ($\overline{M}_W$ = 7390) and 2 : 1 ($\overline{M}_W$ = 6520); L-phenylalanine–L-tyrosine with molar ratios 1 : 1 ($\overline{M}_W$ = 6370) and 2 : 1 ($\overline{M}_W$ = 8780); and glycine–DL-alanine–L-tyrosine with molar ratios 8 : 4 : 1 ($\overline{M}_W$ = 2360).

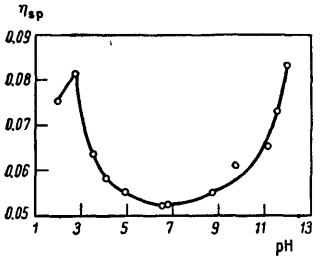

Fig. 19. Dependence of the intrinsic viscosity of the 1 : 1 : 2 glutamic acid–L-lysine–DL-serine copolymer on the pH of the medium.

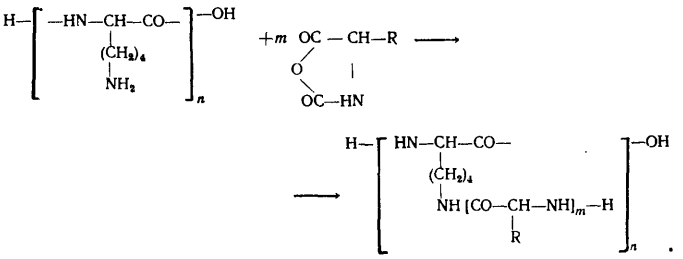

Since many physical and chemical properties of collagen and gelatine are determined by their large content of proline and hydroxyproline, model polypeptides containing the above amino-acid residues were synthesised [333]. Copolymers with the following monomer ratios were obtained by the copolymerisation at room temperature of a mixture of the anhydrides of the corresponding *N*-carboxy-derivatives in dioxan solution with diethylamine and triethylamine as the initiators or in pyridine without initiator: L-proline : glycine = 1 : 1, 1 : 2, and 1 : 3; L-proline : glycine : L-hydroxyproline = 1 : 2 : 1.

Copolypeptides containing L-arginine and L-leucine (2.3 : 1), which have a weak inhibiting effect on blood coagulation [334], and L-glutamic acid, 2,5-dihydroxyphenylalanine, and 3,4-dihydroxyphenylalanine, with weak catalytic properties [335], have been described.

Patents dealing with the method of preparation of copolypeptides and their application in various branches of industries have appeared in recent years. Thus a patent describes the preparation of copolypeptides by the treatment of solutions of the sodium salts of amino-acids (obtained from proteins, for example serum albumin) with the esters of chloro-acids, for example methyl chloroformate, and then with thionyl chloride, which yields a mixture of the anhydrides of the *N*-carboxy-derivatives; the latter is polymerised by the usual methods and converted into fibres and films [336]. Another patent [337] describes the method of preparation of copolypeptides from a mixture of the anhydrides of the *N*-carboxy-derivatives of L-leucine and phenylalanine. The molecular weight of the resulting copolypeptides exceeds 7000. These copolymers can be used for the preparation of fibres, sheets of various types, and moulds.

## 5. Preparation of Graft and Block Copolymers

Proteins react under mild conditions with the anhydrides of *N*-carboxy-derivatives of $\alpha$-amino-acids with the formation of polypeptidyl proteins. Like synthetic polypeptides with free amino-groups, proteins with free amino-groups function as polyinitiators in these reactions. Branched polyamino-acids have been prepared [338] by the polymerisation of the anhydrides of the *N*-carboxy-derivatives of DL-alanine, sarcosine, and L-lysine in the presence of poly-L-lysine, which functioned as the polymerisation initiator. Poly($\epsilon$-*N*-poly-DL-alanyl)-L-lysine with $n$ = 20 and $m$ = 20, water-soluble poly($\epsilon$-*N*-polysarcosyl)-L-lysine with $n$ = 20 and $m$ = 7, and branched poly($\epsilon$-*N*-poly-L-lysyl)-L-lysine with $n$ = 30 and $m$ = 15 have been obtained.

Similarly an aqueous solution of the hydrobromide of poly-L-lysine was used as a polyvalent initiator [339] for the polymerisation of the anhydride of $\gamma$-benzyl *N*-carboxyglutamate; the product was a branched polypeptide with $n$ = 280 and $m$ = 40, whose molecular weight was 1 500 000.

Poroshin [340] studied the reaction of the products of the primary degradation of casein (peptone hydrolysis mixture) with the anhydrides of the *N*-carboxy-derivatives of glycine, DL-alanine, and DL-proline in cooled dioxan solutions or in phosphate buffer. The reaction products were dialysed and then examined for their amino-acid content. It was established that in the case of polyglycylpeptone the degree of polymerisation ($m$) of glycine was 8–10 while for poly-DL-alanylpeptone $m$ was 18–20. The poly-DL-alanylpeptone was used for the polymerisation of the anhydride of *N*-carboxy-DL-proline, the products being poly-DL-alanyl--poly-DL-prolylpeptone which was readily soluble in water.

Konigsberg and Becker [341] grafted the anhydrides of the *N*-carboxy-derivatives of glycine and phenylalanine, with a [$^{13}$C]carboxyl carbon atom, on to a number of proteins (albumin, egg albumin, chymotrypsin, chymotrypsinogen, and lysosyme) in 0.067 M phosphate buffer at pH 6.2–7.8, in 0.1 M borate buffer at pH 8.2–9.1, and in sodium bicarbonate solution saturated with carbon dioxide, at pH 6.9–7.6. A gradual increase in the amount of grafted glycine was observed when the pH was altered from 6.2 to 9. Among the above solutions, the bicarbonate solution proved to be the most effective. For example, in phosphate buffer 41 moles of glycine residues were grafted on to one mole of protein, while under otherwise the same conditions in sodium bicarbonate solution 72 moles of glycine residues were grafted on to one mole of protein.

Kley et al. [342,343] treated bovine and rabbit blood albumin in bicarbonate solution or in phosphate buffer with the anhydrides of the *N*-carboxy-derivatives of glycine, leucine, phenylalanine, glutamic acid, and lysine. Microtitration showed an appreciable change in the amounts of carboxy-, imidazole, and $\alpha$- and $\epsilon$-amino-groups and established that grafting takes place partly (to the extent of 30%) at $\epsilon$-amino-groups.

A water soluble gliadine fraction was obtained by peptidylation [344]. For this purpose, DL-alanine and $N^4$-(3-hydroxypropyl)-L-asparagine were grafted on to gliadine. In the first case the reaction was carried out with the anhydride of *N*-carboxy-DL-alanine and gliadine in a mixture of dioxan and 0.05 M phosphate buffer (pH 6.8, 2°, 48 h), and water soluble poly-DL-alanylgliadine was isolated. The alanine content increased from 1.4% in gliadine to 23.6% in poly-DL-alanylgliadine, which corresponds to the grafting, on average, of 4.1 millimoles of alanine residues per gramme of gliadine. In the second case the reaction was

carried out with the anhydride of benzyl *N*-carboxyaspartate and gliadine in dimethylformamide (20°, 48 h). After its isolation, the polybenzyloxy-L-aspartylgliadine was kept for 30 min at 40° in propanolamine; the water-soluble *N*-(3-hydroxypropyl)-L-aspartylgliadine, enriched in aspartic acid residues up to 6.3 millimoles per gramme of gliadine, was then isolated by precipitation with 4 M acetic acid.

As pointed out by Katchalski and Sela[5], peptidylation does not interfere in most cases with the biological properties of proteins, but modifies a number of their other properties. Bearing in mind the stability of valine peptides towards acid hydrolysis, a study was made of the effect of grafting valine on to proteins on the biological and chemical properties of the latter[345]. Poly-DL-valylchymotrypsin, poly-DL-valyllysosyme, and poly-DL-valylinsulin were obtained by the reaction of the anhydride of *N*-carboxy-DL-valine with proteins at 4° in phosphate (pH 7.6) and borate (pH 8.5) buffers. The modified proteins are unusually stable towards acid hydrolysis. Hydrolysis is complete only after boiling with hydrochloric acid for 96 h. The enzymic activity of poly-DL-valylchymotrypsin is reduced only by 60% compared with the activity of the natural protein, while in the case of polyglycylchymotrypsin the activity is the same as that of the natural enzyme.

The effect of grafting L-tyrosine, L-tryptophan, L-phenylalanine, L-cysteine, L-proline, L-glutamic acid, L-lysine, L-alanine, L-serine, L-cyclohexylalanine, a mixture of L-glutamic acid and L-tyrosine, and of L-glutamic acid and L-cyclohexylalanine on the physiological activity of gelatine has been investigated[346]. It was found that when amino-acids with aromatic and cyclohexane rings in the side-chains are grafted on to gelatine, the physiological activity of the latter increases.

The problem of converting certain enzymes into water-insoluble products, with specific catalytic activity, is interesting because the "water-insoluble enzymes" can be readily removed from the reaction sphere. They can also be used for the preparation of columns with enzymic activity. For this purpose, Atara Bar-Eli and Katchalski[347] prepared polytyrosyltrypsin which was completely soluble and retained the enzymic activity of trypsin. When it was combined by diazotisation with the copolymer of *p*-aminophenylalanine and leucine, trypsin which was completely insoluble in water but nevertheless retained its enzymic activity was obtained. The latter could be used for the preparation of an active trypsin column for systematic amino-acid analysis.

Polytyrosyltrypsin containing 20–28 tyrosine residues grafted per mole of trypsin was prepared[348] by the polymerisation of the anhydride of *N*-carboxy-L-tyrosine in aqueous solution using trypsin as a polyvalent initiator. It was established that approximately half of the $\epsilon$-amino-groups of trypsin were acylated by the anhydride of *N*-carboxy-L-tyrosine, the average chain length of the grafted tyrosine being about 2.5. In contrast to trypsin, polytyrosyltrypsin is moderately soluble at pH 5–9. In its response to denaturing agents (urea, soya bean oil) and in its enzymic activity polytyrosyltrypsin is indistinguishable from trypsin.

A water-soluble block polypeptide consisting of a central poly-L-alanine block and two side poly-DL-glutamic acid blocks was synthesised[349]. The synthesis was carried out in benzene solution, the initial concentration of the anhydride of $\gamma$-benzyl *N*-carboxy-DL-glutamate being 2%. The initiator was n-hexylamine to which the anhydrides of *N*-carboxy-L-alanine and then of $\gamma$-benzyl *N*-carboxy-DL-glutamate were added in succession. The course of polymerisation was followed from the carbon dioxide evolved. According to the amino-acid analysis, the molar ratio of glutamic acid to alanine was 1.54. It was established that the molecule of the block polymer had a block consisting of 175 residues of L-alanine and two DL-glutamic acid blocks consisting of 325 residues altogether.

Any polymeric material containing free primary or secondary amino-groups can be used as a polyvalent initiator of the polymerisation of the anhydrides of *N*-carboxy-derivatives and not only natural proteins or synthetic poly-$\alpha$-amino-acids. Thus polymerisation of styrene in liquid ammonia with sodium as the initiator at -40°, with subsequent addition of ammonium chloride and removal of ammonium by distillation, yielded polystyrene containing 11% of nitrogen. The polymerisation of the anhydride of *N*-carboxyl-DL-valine in benzene solution of this polystyrene gave a product containing 24–29% of polystyrene and soluble only in *m*-cresol. The copolymers styrene–glycidyl methacrylate–DL-phenylalanine and styrene–glycidyl acrylate–DL-phenylalanine were prepared similarly[350]. These unusual polyamides are thermoplastic and exhibit exceptional stability towards solvents.

# COPOLYMERISATION OF HYDROCARBONS IN THE PRESENCE OF IONIC CATALYSTS

L. S. Bresler

CONTENTS

1. Introduction 366
2. Theoretical concepts 366
3. Copolymerisation by means of catalysts of cationic type 370
4. Copolymerisation by means of catalysts of anionic type 370
5. Copolymerisation by means of complex organometallic catalysts of the Ziegler–Natta type 373

## 1. INTRODUCTION

Comparison of the relative activities of monomers in copolymerisation has been successfully used to study the mechanism of chain growth in radical polymerisation. The copolymerisation constants yield quantitative estimates of the relative reactivities of monomers and of the corresponding active centres.

During recent years a great deal of attention has been paid to catalysts which bring about polymerisation by an ionic mechanism, in connection with the use of catalysts of ionic type for the synthesis of several polymers having valuable properties, especially stereoregular polymers. Data on copolymerisation provide a deeper insight into the mechanism of chain formation in cationic, anionic, and coordination–ionic polymerisation.

## 2. THEORETICAL CONCEPTS

A theoretical treatment of the problems involved in radical copolymerisation has been given, and we must therefore examine the possibility of applying to ionic polymerisation the relations obtained. Scheme (1), suggested by Alfrey and Goldfinger[1], considers four possible modes of chain growth in the copolymerisation of two monomers: i.e. the reactivity of the growing polymeric ion is assumed to depend on the nature of the terminal active unit in the chain, and the rate constant for chain growth to be determined by the reactivity both of the monomer and of the active centre. Here M* denotes a cation in the case of cationic polymerisation, and an anion in anionic polymerisation, while in the case of coordination-complex polymerisation it represents a catalytic complex bound to the active end of the growing chain.

$$\begin{aligned} &\sim M_1^* + M_1 \xrightarrow{k_{11}} \sim M_1^*, \\ &\sim M_1^* + M_2 \xrightarrow{k_{12}} \sim M_2^*, \\ &\sim M_2^* + M_2 \xrightarrow{k_{22}} \sim M_2^*, \\ &\sim M_2^* + M_1 \xrightarrow{k_{21}} \sim M_1^*. \end{aligned} \qquad (1)$$

When the concentration of growing chains is constant, we can apply the relationship that has been termed the fundamental equation of copolymerisation[1,2]

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1]}{[M_2]}\left(\frac{r_1[M_1]+[M_2]}{r_2[M_2]+[M_1]}\right), \qquad (2)$$

where $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$ are copolymerisation constants for the first and second monomers, representing the relative activities of the monomers towards addition to the active centres $\sim M_1^*$ ($r_1$) and $M_2^*$ ($r_2$). Eqn. (2) is applicable to ionic copolymerisation only if the concentration of active centres remains constant during such processes. The necessity for this condition had already been noted by Landler[3,4], who was the first to generalise data on ionic polymerisation.

The presence of a constant concentration of active centres in several cases of cationic[5,6] and anionic[7-9] polymerisation has now been established by direct measurement, from the ultraviolet absorption spectrum, of the concentration of growing polymeric cations and anions during polymerisation. In the presence of complex organometallic catalysts, too, the concentration of active centres is usually constant as a result of the catalytic character of the process[10]. Consequently the general equation of copolymerisation is applicable to most cases of ionic copolymerisation. The relative reactivity of monomers in the growth reaction can be measured by the copolymerisation constants calculated from experimental data by the usual procedures developed for radical copolymerisation — by the intersection method based on the integral or differential equation of Mayo and Lewis[2,11] by Alfrey's method of trial and error[1], or by the method of Fineman and Ross[12].

Constancy of the concentration of active centres has different causes in radical and in ionic polymerisation. In the former case it arises from the fact that, during a given period of time, equal quantities of radicals are formed by initiation and disappear by termination reactions which lead to the destruction of active centres. In ionic processes, active centres cannot be destroyed by interaction with one another, because the polymer chains bear charges of the same sign[13]. Therefore the constancy of the concentration of active centres is not due to a balance between processes of creation and destruction but to the fact that many ionic processes are unaccompanied by the destruction of active centres — by processes of chain termination[6,10,13,14] — and active centres, once formed, can cause chain growth until no monomer remains. If in such cases initiation is sufficiently rapid, and formation of all the active centres is complete within a time which is considerably shorter than the duration of the whole process of polymerisation, a constant concentration of active centres will be established during the process[5-10].

In cationic polymerisation, initiation is usually rapid, and all the active centres begin to take part in chain growth almost at the same time[6,15]. With anionic polymerisation cases are known in which initiation occurs throughout the process of polymerisation, and then the condition that the concentration of active centres should be constant is not satisfied. This is observed when polymerisation occurs under the influence of organolithium compounds in hydrocarbon solvents at a catalyst concentration exceeding 0.02 M.[9,16] The low rate of initiation in these cases is explained by the high degree of association of the organolithium compound[9]. When copolymerisation is carried out under such conditions, account must be taken, in deriving the equation for the composition of the copolymer, of the initiation stage[17] (i.e. of the rate of interaction with the catalyst of each of the two monomers)

$$A^- + M_1 \xrightarrow{k_1} AM_1^-, \qquad A^- + M_2 \xrightarrow{k_2} AM_2^-, \qquad (3)$$

and only after this are the usual four possible growth reactions (1) considered.

Even in this case, however, the Alfrey–Goldfinger equation (2) is incapable of giving the composition of the copolymer correctly only when the anions formed from the different monomers differ greatly in activity. If the initiator can react with both monomers, while the anion $AM_2^-$ is practically unable to add on the monomer $M_1$, the composition of the copolymer in the initial stages of polymerisation will be represented by the equation

$$\frac{d[M_1]}{d[M_2]} = (k_{11}/k_{12})(k_1/k_2)\left(\frac{[M_1]}{[M_2]}\right)^2, \qquad (4)$$

instead of by the fundamental equation of copolymerisation.

In the copolymerisation of styrene with methyl methacrylate, for example, the polystyrene anion initiates the polymerisation of both these monomers[18], whereas the poly(methyl methacrylate) anion does not bring about the polymerisation of styrene[19]. In this case — Eqn. (4) — the ratios of the mole fractions of styrene and methyl methacrylate in the copolymer and the monomer mixture are actually linked by a relation of the second degree[17].

The above can be summarised in the statement that equations obtained from an examination of radical processes of copolymerisation are general for all mechanisms of polymerisation, being inapplicable only in isolated special cases.

We at once adopted Alfrey and Goldfinger's scheme (1) to represent processes of ionic copolymerisation, i.e. we took into account the different reactivities both of the monomers and of the active centres formed from them. Differing activities of two polymeric anions is clearly exhibited in the above case of the copolymerisation of styrene and methyl methacrylate[18,19], in which the less active anion — the poly(methyl methacrylate) anion — does not initiate polymerisation of the less active monomer (styrene). Comparison based on quantum-mechanical calculations[20] of the reactivities of various monomers and of the ions obtainable from them has shown that, in cationic and anionic polymerisation, the more active monomer always yields the less active ion, just as in radical polymerisation the more active monomer gives the less active radical[21,22]. The correctness of this conclusion is confirmed by measurements of the absolute rate constants of all four stages of the growth reaction in copolymerisation. In the case of cationic polymerisation such data have been obtained[23] for the copolymerisation of isobutyl vinyl ether with chloroethyl vinyl ether under the influence of iodine in dichloroethane solution (Table 1). The less active monomer — 2-chloroethyl vinyl ether ($k_{12} < k_{11}$) — forms the more active cation ($k_{22} > k_{12}$).

TABLE 1. Absolute rate constants (in litre × × mole$^{-1}$ min$^{-1}$) for the growth reactions in the copolymerisation of isobutyl vinyl ether ($M_1$) and 2-chloroethyl vinyl ether ($M_2$) in the presence of iodine in dichloroethane solution at 30°.

In the case of anionic polymerisation under the influence of "live" polymers, monomers which are less active than styrene ($k_{12} < k_{11}$) give an anion to which styrene adds on more rapidly than to the anion of polystyrene ($k_{21} > k_{11}$) (Table 2)[24]. Thus with anionic polymerisation, too, the less active monomer forms the more active anion. The only exception is provided by the anion of the dimer of 1,1-diphenylethylene, but this is due to the greater steric hindrance to the addition of styrene caused by the two phenyl groups of the anion.

Until recently most investigators, when discussing experimental data on ionic copolymerisation, ignored differences in reactivity between polymeric ions differing in their

TABLE 2. Absolute rate constants (in litre mole$^{-1}$ s$^{-1}$) for the growth reactions in the copolymerisation of styrene ($M_1$) with other monomers in the presence of "living" polymers with Na as counter-ion in tetrahydrofuran solution. (Concentration of active centres 0.003 M at 25°.)

active terminal units ($\sim M_1^*$ and $\sim M_2^*$). It was usually accepted that the rate of addition of a monomer is independent of the nature of the end group in the polymeric ion[23-33]. Only two chain-growth reactions were then taken into account in copolymerisation[34]. Such a simplified view of ionic copolymerisation arose from an incorrect interpretation of the frequently observed cases of ideal copolymerisation in ionic processes[4,33]. In ideal copolymerisation $r_1 r_2 = 1$, i.e. $k_{11}/k_{12} = k_{21}/k_{22}$. Although it is sufficient, for this equation to be valid, that the rates of addition of monomer $M_1$ to the two polymeric ions should differ from the rates of addition of $M_2$ to these ions by the same factor ($k_{11} = Xk_{21}$ and $k_{12} = Xk_{22}$), Flory concluded that each monomer adds on to any ion at the same rate, i.e. $k_{11} = k_{21}$ and $k_{12} = k_{22}$, and thus the equation for the composition of the copolymer assumes the form of Wall's equation[34]

$$\frac{d[M_1]}{d[M_2]} = \frac{k_{11}[M_1]}{k_{22}[M_2]}. \qquad (5)$$

It follows from these concepts that the copolymerisation constant for monomer $M_1$ with monomer $M_2$, $r_1 = 1/r_2 = k_{11}/k_{22}$, should be equal to the ratio of the rate constants for chain growth in the homopolymerisation of these monomers. However, this conclusion is contradicted by the experimental results. In the copolymerisation of butadiene with isoprene[29] and of butadiene[26,27,32] or isoprene[25,30,31] with styrene under the influence of organolithium compounds, the more active monomer (according to copolymerisation data) possesses the lower rate of homopolymerisation. In order to explain the "reversal of activity" the concept is introduced[25-32,35-48] of a selective solvation of an active centre by one of the monomers, which thus proves more active in copolymerisation. Calculation[26] based on kinetic data for the copolymerisation of butadiene with styrene in the presence of butyllithium has shown that, in order to explain the experimental differences between the copolymerisation constant and the ratio of the rates of homopolymerisation, the ability of butadiene to solvate an active centre must exceed that of styrene by a factor of 80. It is difficult to explain such a large difference in solvating power by the structural differences between butadiene and styrene.

If differences in the activity of polymeric ions towards the same monomer are taken into account, the contradictions discussed above do not arise. The more active monomer yields the less active ion[20]; if the ions exhibit greater differences in activity than do the monomers, the rate of homopolymerisation of the more active monomer will be smaller than that of the less active monomer ("reversal" of activity). Direct measurement of all four rate constants for chain growth in the copolymerisation of butadiene with styrene in the presence of butyllithium[35] has shown that the rates of addition of the butadiene molecule to the anions of polystyrene and of polybutadiene differ by a factor of 75, while the rates of addition of the two different monomers (styrene and butadiene) to the same anion (polystyrene or polybutadiene) differ by factors of 15 and 3 respectively. Thus it is evident that in this case the "reversal of activity" of the monomers in homopolymerisation compared with copolymerisation[26,27] is actually due to the greater differences in activity between the polymeric anions than between the monomers, not to selective solvation of an active centre by one of the monomers. If the simultaneous occurrence of four different reactions of chain growth is taken into account, it is possible[36] by means of the usual kinetic equations to calculate a rate curve for the copolymerisation of butadiene with styrene which agrees with the experimental results. Consequently the results of a kinetic study of copolymerisation also show that, in ionic as in radical copolymerisation, ions with different end-groups, as well as the monomers, show differences in activity.

Copolymerisation constants can be used to compare the relative activities of a series of monomers only when they relate to copolymerisation of all these monomers with the same standard monomer. It is therefore desirable for ionic copolymerisation to generalise all known values of relative reactivity in the form of a scheme resembling the $Q-e$ scheme of Alfrey and Price[21]. With ionic, in contrast to radical, copolymerisation however, the copolymerisation constants are usually found to depend on the nature of the catalyst and of the polymerisation medium[25,26,28,31,32,37-44] (Table 3, pairs 3, 4, 7, 8, and 11; Table 5, pairs 1, 4–6, 10, and 12). As a consequence, it has not yet proved possible to set up a scheme which will take into account all the factors influencing the relative activity of monomers in ionic copolymerisation.

Hammett's rule[45,46] is widely used for the quantitative correlation of the reactivity of monomers in ionic copolymerisation with their structure. This rule links the rate constants for reactions of benzene derivatives with the electronic characteristics of their substituents in the formula

$$\log(K/K_0) = \rho\sigma, \qquad (6)$$

where $K$ and $K_0$ are rate constants (or equilibrium constants) for substituted and unsubstituted benzene derivatives in reactions of a given type, $\rho$ is a constant characteristic of a given reaction (the reaction constant), and $\sigma$ is a constant characterising a given constituent in all types of reactions. The actual value of the substituent constant $\sigma$ depends on the type of reaction taken as standard, and is a quantitative expression of the electron-acceptor or electron-donor character of this substituent. The standard is chosen in such a way that the $\sigma$ constant of electron-acceptor substituents is positive[45,46]. The influence of the polar effects of substituents on the rate constants is associated with a change in the activation energy during the reaction; if steric effects predominate, deviations from the Hammett rule are observed[45,46]. In comparing the activities of monomers undergoing polymerisation, the polar effect can be allowed for, not by means of the Hammett $\sigma$ constant, which is known only for substituents in the benzene ring, but from the magnitude of the polar factor in the $Q-e$ scheme, since the quantity $e$ also characterises the electron-donating or electron-accepting power of a substituent,

and is linearly related with $\sigma$, as has been shown for substituted styrenes[47,48].

Work on ionic copolymerisation is discussed in greater detail below. Results on copolymerisation in the presence of alkali metals and of the sodium–naphthalene complex are not included, since these processes involve the intermediate formation of ion-radicals[13,49,50], and may be complicated by simultaneous polymerisation by ionic and radical mechanisms[51-54].

## 3. COPOLYMERISATION BY MEANS OF CATALYSTS OF CATIONIC TYPE

In polymerisation by a cationic mechanism the growing chain is a carbonium ion[5,15,55]. Various Lewis acids are catalysts for cationic polymerisation. Results obtained for processes of copolymerisation occurring by a cationic mechanism are given in Table 3.[37-41,56-70]. Comparison of the copolymerisation constants shows that, when reacting with the same polymeric cation, the more active monomer is usually that in which the electron density on the double bond is the greater, in agreement with the view that growth of the polymer chain takes place with the latter in the form of a cation. The above rule is observed in the copolymerisation of styrene (Table 3, pairs 1–8), *p*-chlorostyrene (pairs 13–20), and $\alpha$-methylstyrene (pairs 22-24) with nuclear-substituted styrenes, of styrene with chloroprene (pair 11) and with methylpropene (pair 12), of *p*-chlorostyrene with methylpropene (pair 21), of $\alpha$-methylstyrene with isoprene (pair 25), of *p*-methylstyrene with *p*-methoxystyrene (pair 26), and of butadiene with isoprene and with 2,3-dimethylbutadiene (pairs 29 and 30). An exception is observed only in the copolymerisation of styrene with isoprene and with butadiene (pairs 9 and 10), when styrene is the more active monomer, although it has the lower value of $e$ in the $Q$–$e$ scheme (and hence a lower electron density on the double bond). Gantmakher and Medvedev[62] explain this exception by the participation of double bonds of the polymer in interaction with the active centres, as a result of which data on the composition of the copolymer do not reflect the true relation between the activities of the monomers in chain growth.

By means of the Hammett rule it is possible to obtain a quantitative estimate of the variation in copolymerisation constants with the electron-donor or electron-acceptor character of the substituent. The copolymerisation of *para*-substituted styrenes satisfies the relationship

$$\ln r_1 = \ln (k_{11}/k_{12}) = \ln k_{11} - \ln k_{12} = \rho_1(\sigma_1 - \sigma_2), \qquad (7)$$

where $\sigma_1$ and $\sigma_2$ are the constants of the substituents in the monomers $M_1$ and $M_2$. Table 4, taken from a paper by Tobolsky and Boudreau[37], gives values of $\rho_1$ for the copolymerisation of substituted styrenes in the presence of various catalysts (from data for the pairs 2–6 and 13–15 in Table 3). The negative value of the reaction constant $\rho_1$ also agrees with the concept of cationic chain growth in the presence of Lewis acids as catalysts. Furthermore, the linear dependence of $\ln r_1$ on $\sigma$ shows that differences in the relative activity of *para*-substituted styrenes are determined not by steric but by polar factors — by differences in electron density on the double bonds of the monomers.

TABLE 4. Reaction constants $\rho_1$ in the cationic copolymerisation of substituted styrenes.

| Catalyst | Medium | $\rho_1$ | Monomer $M_1$ |
|---|---|---|---|
| $TiCl_4$ | nitrobenzene | −1.5±0.4 | styrene |
| $TiCl_4$ | » | −2.2±0.4 | *p*-methoxystyrene |
| $TiCl_4$ | » | −1.1±0.5 | *p*-methylstyrene |
| $SnCl_4$ | $CCl_4$–nitrobenzene (1:1) | −4.0±0.5 | styrene |
| $SnCl_4$ | ditto | −3.3±1.0 | *p*-methylstyrene |
| $TiCl_4$ | $CCl_4$ | −4.2±0.8 | styrene |

Steric hindrance determines the relative activity of the monomers only when $\beta$-substituted styrenes are involved in copolymerisation (pairs 18–20). When reacting with a $\beta$-alkylstyrene end-group, the *p*-chlorostyrene molecule is more active than the $\beta$-alkylstyrene molecule ($r_2 < 1$), although the electron density on the double bond in *p*-chlorostyrene is smaller owing to the presence of an electron-acceptor substituent in the ring[59]. In copolymerisation with $\alpha$-methylstyrene the relative activity of the monomers is determined by the relative electron densities on their double bonds (pairs 8, 17, and 22–25). This difference in steric hindrance, produced by substituents in the $\alpha$- and $\beta$-positions of the vinyl group in styrene, is consistent with the view that attack by the polymeric carbonium cation is directed mainly on the $\beta$ carbon atom of styrene (since the phenyl-substituted cation should be thermodynamically the more stable[71]).

The influence of the gegenion and that of the solvent on the kinetics of cationic homopolymerisation are usually attributed[55] to changes in the concentration of active cations resulting from different degrees of dissociation in solvents differing in dielectric constant or in ion-pairs with different gegenions. However, variation in ionic concentration would probably affect equally all four rates of growth in copolymerisation, and then the copolymerisation constants would not depend on the nature of the solvent or on that of the gegenion. Nevertheless, the relative activities of the monomers depend in several cases (pairs 3, 4, 8, 11, and 21) both on the nature of the gegenion and on that of the medium in which polymerisation is carried out. In the presence of different catalysts in the same solvent, the copolymerisation constants depend to different extents on the polarity of the monomer (this corresponds to different values of the reaction constant $\rho_1$ in the copolymerisation of substituted styrenes, Table 4). Variation in the copolymerisation constants when the process is carried out in different solvents or in the presence of different catalysts shows that, at least in some solvents, chain growth involves not free ions but ion-pairs.

Thus study of copolymerisation in the presence of Lewis acids has shown that — (1) the relationship between the relative activities of the monomers and the electron densities on their double bonds corresponds to a cationic mechanism of chain growth; (2) steric hindrance produced by $\beta$-substituents in styrene is consistent with the view that the styrene molecule adds on to the growing chain by the $\beta$ carbon atom; and (3) since the use of different catalysts and solvents affects not only the kinetics of homopolymerisation but also the copolymerisation constants, the growing chain is usually not a free cation, chain growth probably occurring in ion-pairs.

## 4. COPOLYMERISATION BY MEANS OF CATALYSTS OF ANIONIC TYPE

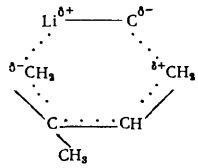
The polymerisation of hydrocarbon monomers by an anionic mechanism is initiated by various organometallic

compounds and their complexes. According to modern views, first put forward by Ziegler[72], growth of the polymer chain occurs by introduction of monomer at a polarised metal–carbon bond, when separation of the charges on the polarised bond may lead to the formation of an ion-pair in which the active end of the growing chain is the anion[33,72-75]. In a series of organometallic compounds of the alkali metals, the ionic character of the bond increases on passing from lithium to sodium, potassium, rubidium, and caesium[76], as is shown in the polymerisation of dienes by a change in the structure of the polymer. In the presence of organolithium compounds, the polymers formed consist of 1,4 monomeric units; the polymers formed under the influence of organopotassium compounds contain a considerable quantity of 1,2 units[72,73]. The structure of the polydiene chain changes in the same direction if polymerisation under the influence of organolithium compounds is carried out in the presence of substances capable of forming "onium" complexes (ethers, amines, sulphides[72-75,77,78]). Hence it can be concluded that the ionic character of the lithium–carbon bond is enhanced by the coordination with lithium of electron-donor compounds, and in such solvents as tetrahydrofuran the process of polymerisation under the influence of organolithium compounds approaches in character a typically anionic polymerisation (such as, for example, polymerisation under the influence of organopotassium compounds)[74,75,77]. The influence of the counterion on the kinetics of polymerisation and the structure of the polymer shows that, in anionic polymerisation, chain growth involves not the free anion but an ion-pair or the polarised metal–carbon bond. Data on copolymerisation by an anionic mechanism are given in Table 5.[24,25,32,35,37,43,44,69,70,73,79-86]

Study of the composition of isoprene–styrene (Table 5, pair 6 [25]) and butadiene–isoprene (pair 12 [77]) copolymers shows that practically the same composition is obtained in the presence of organopotassium or organosodium compounds as in the presence of complexes of organolithium compounds with electron-donor substances. These results support the view that, under the influence of complexes of organolithium compounds, polymerisation occurs by the same mechanism as in the presence of organopotassium and organosodium compounds, i.e. by a typical anionic mechanism. However, it must be stressed that, even in tetrahydrofuran solution, chain growth by an anionic mechanism occurs in an ion-pair, and does not involve a free anion, since the rate of polymerisation of styrene in tetrahydrofuran depends on the nature of the alkali-metal ion[24].

The dependence of the relative activity of monomers on the electron density at the double bonds in the case of copolymerisation in the presence of organopotassium and organosodium compounds and of complexes of organolithium compounds with tetrahydrofuran supports the view that the active end of the growing chain is anionic in character. Actually, determinations of copolymerisation constants or of the composition of the copolymers indicate that the reactivity of the monomers in the growth reaction of a polymeric anion diminishes in the sequence

*p*-chlorostyrene ($e=-0.33$) > styrene ($e=-0.80$) > butadiene ($e=-1.05$) > isoprene ($e=-1.22$) > 2,3-dimethylbutadiene ($e=-1.81$),



with increasing electron density on the double bonds in the monomer (with increase in $e$ in the $Q-e$ scheme). The rate constants for the addition of various derivatives of styrene to "live" polystyrene in tetrahydrofuran solution obey the Hammett rule, with $\rho = +0.5$ having a positive value in conformity with the assumption of an anionic mechanism for chain growth. In the copolymerisation of butadiene with isoprene and with 2,3-dimethylbutadiene in tetrahydrofuran[69,70,84] or in hexane[28,29] (pairs 11 and 12 in Table 5), and also of styrene with *p*-methylstyrene and with *p*-methoxystyrene (pairs 2 and 3), the Hammett rule is obeyed by quantities representing the reactivities of the monomers towards the same active terminal unit

$$\left(\frac{1}{r_1}=\frac{k_{12}}{k_{11}}\right).$$

Instead of the $\sigma$ constants, let us use the polar factor $e$ in the $Q-e$ scheme, in order to take into consideration results obtained in the copolymerisation of dienes:

$$\log\frac{1}{r_1}=\text{const}\,e. \qquad (8)$$

As noted above, 1,4 polymers of dienes are formed in the presence of organolithium compounds in hydrocarbon medium, in contrast to the 1,2 and 3,4 polymers obtained under the influence of other organometallic compounds of alkali metals[74]. In discussions of this phenomenon the lithium–carbon bond has been regarded as a polarised covalent bond instead of being ionic[76]. Stearns and Forman[87] suggested a mechanism of chain growth in which the first stage involved formation of an intermediate cyclic complex with a coordinate link between $Li^{\delta+}$ and the $\pi$ electrons of the double bond in the monomer, e.g. for isoprene

In the first stage the conformation of the monomeric molecule is fixed by formation of the cyclic complex, which ensures that the second stage — addition of monomer to the negatively polarised end of the chain — shall be stereospecific. In present-day terminology this mechanism of polymerisation is said to be coordinate-anionic[10,81]. With the addition of increasing quantities of an electron-donor complexing agent (or with increasing complexing power of the additive, e.g. on passing from diethyl ether to triethylamine and tetrahydrofuran), the ability of the lithium atom to form a complex with the monomer diminishes, and a transition occurs from coordinate-anionic to typically anionic polymerisation. This change in the mechanism of polymerisation produces a change in structure when isoprene is polymerised in different solvents. The relation between the activities of isoprene and styrene on copolymerisation under the influence of butyllithium changes to the same extent in the presence of different electron-donor additives[25].

Since the changes in the structure of polyisoprene and in the composition of its copolymer with styrene have the same causes, a linear correlation exists between these quantities (Fig. 2 [25]). The change in relative reactivity of the monomers on passing from copolymerisation by means of organolithium compounds in hydrocarbon medium to copolymerisation in the presence of complexes of organolithium compounds with electron-donor substances has been studied on the following pairs of monomers — styrene–butadiene (pair 5 [Table 5]), styrene–isoprene (pair 6), styrene–$\alpha$-methylstyrene (pair 4), and butadiene–isoprene

(pair 12). In all these cases the relative activity of the monomer having the lower electron density on the double bonds increases with the complexing power of the electron-donor additive or with its concentration (see e.g. the data on the copolymerisation of butadiene with styrene, pair 5).

In the copolymerisation of butadiene and of isoprene with styrene by means of butyllithium in hydrocarbon medium, the monomer having the higher electron density on the double bonds (isoprene with $e = -1.22$, and butadiene with $e = -1.05$) is even more active than styrene, in which

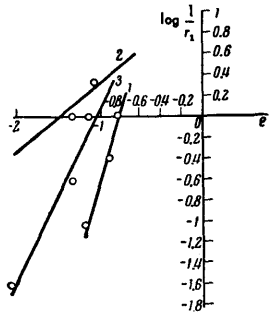

Fig. 1. Dependence, on electron density at double bonds, of reactivity of monomers in the presence of $C_4H_9Li$ towards: 1) styrene, copolymerised with *p*-methyl- and *p*-methoxy-styrenes in toluene[37]; 2) isoprene, copolymerised with butadiene[28] and 2,3-dimethylbutadiene[29] in hexane; 3) butadiene, copolymerised with isoprene and with 2,3-dimethylbutadiene in tetrahydrofuran[68,70,84].

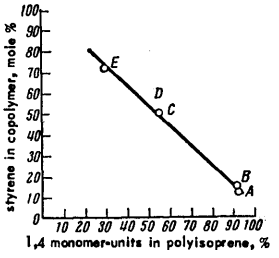

Fig. 2. Relation between structure of homopolymers of isoprene and composition of isoprene–styrene copolymers obtained from an equimolecular mixture by anionic polymerisation[25] in the presence of $C_4H_9Li$ in: *A*) benzene; *B*) monomer; *C*) triethylamine; *D*) ether; *E*) tetrahydrofuran.

the electron density on the double bond is lower ($e$ = -0.80), which would appear to contradict the view that a partial negative charge is present on the end of the growing chain. Actually, these results confirm the coordination nature of chain growth under the influence of organolithium compounds. The first stage — formation of a $\pi$ complex with the lithium atom — should tend to produce a higher electron density on the double bonds of the monomer; the second stage — addition of monomer to the negatively polarised end of the chain — occurs more readily with monomers of lower electron density on the double bonds.

In all the cases mentioned (pairs 4–6 and 12), in conformity with this mechanism, the relative activity of the monomer of greater electron density on the double bonds increases on passing from copolymerisation under the conditions of a typically anionic process (in the presence of organopotassium compounds or of LiR in tetrahydrofuran) to polymerisation of the same monomers in the presence of organolithium compounds without electron-donor additives. The reactivity of the monomers could be changed on reaction via a cyclic complex, in comparison with polymerisation in ion-pairs, for steric reasons; but then the activity of $\alpha$-methylstyrene could have been expected to decrease in comparison with styrene on passing to reaction in the ring, whereas the opposite is observed[77].

Use of the copolymerisation method to study the mechanism of polymerisation in the presence of organometallic compounds has in the first place provided evidence that the active unit in the growing chain is negatively charged, i.e. that polymerisation actually takes place by an anionic mechanism. Data on copolymerisation under the influence of organolithium compounds in various media have shown the coordinate–anionic mechanism of the action of this catalyst in a hydrocarbon solvent.

## 5. COPOLYMERISATION BY MEANS OF COMPLEX ORGANOMETALLIC CATALYSTS OF THE ZIEGLER–NATTA TYPE

Complex organometallic catalysts for the stereospecific polymerisation of alkenes and dienes are prepared from compounds of metals in the secondary subgroups of Groups IV–VI of the Periodic System and organometallic compounds of metals in Groups I–III.[10,88] The ionic and complex nature of these catalysts has now been proved; during growth the active unit in the chain is coordinated with the catalyst, and the act of addition of a new monomeric unit involves heterolytic cleavage of the bond between the catalyst and the terminal unit in the chain, with formation of a new polarised bond[10,75].

Study of copolymerisation enables several details of the mechanism of chain growth to be elucidated. Data on copolymerisation in the presence of Ziegler–Natta catalysts[69,70,89–128] are given in Tables 6 and 7. Investigation has been based mainly on styrene (Table 6, pairs 1–18), ethylene, propene (pair 24), and dienes (pairs 31–33).

The copolymerisation of styrene with nuclear-substituted styrenes is ideal in character, i.e. $r_1r_2 = 1$. Moreover, Wall's condition (5) is satisfied: the copolymerisation constant is equal to the ratio of the growth rate constants for the homopolymerisation of the monomers under the same conditions[129–132]: $r_2 = 1/r_1 = k_{22}/k_{11}$, so that the nature of the terminal unit in the chain does not affect the rate of addition of the monomer unit. The relative activities of *para*-substituted styrenes depend on the electron-donor power of the substituents: the copolymerisation constants obey the Hammett rule $\ln r_2 = \rho\sigma$, the reaction constant $\rho$ being negative. Consequently monomers of higher electron density on the double bond are more active, as in cationic polymerisation. On the other hand, the higher reactivity of ethylene compared with propene, which has a higher electron density on the double bond owing to the presence of an electron-donor substituent, has previously been regarded as an argument in support of the anionic nature of the growing chain[89,90].

In order to remove the contradiction, a mechanism of chain growth has been suggested[81,93] which takes into account the complex nature of stereospecific polymerisation. As in the mechanism quoted earlier for chain

growth in the presence of organolithium compounds in hydrocarbon medium, chain growth is regarded as a two-stage process, in which the first stage involves formation of a monomer–active centre complex, and the second stage consists in addition of monomer to the end of the growing chain bound to the catalyst. The electron density on the double bonds in the monomers has opposite effects in these stages, and the dependence of the relative activity of a monomer on the polar effect of the substituents is determined by which of the two stages in the growth reaction is the slower. Natta and his coworkers consider that, in the stereospecific polymerisation of styrenes, chain growth takes place by an anionic mechanism, but the overall kinetics of growth is determined by the stage of formation of a $\pi$ complex between the monomer and the transition metal of the active centre: this stage is favoured by a higher electron density on the double bond of the monomer.

Danusso[81] proposes that this mechanism of polymerisation should be termed "anionic polymerisation with counterion attack". As accepted previously, the term "anionic polymerisation" indicates the sign of the partial charge on the active unit in the growing polymer chain; the term "counterion attack" shows that the rate of growth is determined by interaction between the monomer and the counterion.

The proposed scheme makes it clear why the nature of the terminal unit in the chain does not affect the rate of growth in copolymerisation in contrast to cationic and anionic copolymerisation. When styrenes undergo copolymerisation and homopolymerisation in the presence of Ziegler–Natta catalysts, the rate of growth is determined solely by the stage involving formation of a complex between the monomer molecule and the transition metal, and this stage is unaffected by differences in reactivity between the terminal units formed from different monomers.

According to the mechanism of chain growth under consideration, the lower relative activity of propene and but-1-ene compared with ethylène (pairs 24 and 25 in Table 6) is due not to differences in electron density on the double bonds but to steric factors. When polar factors are decisive, differences in copolymerisation constants are due to differences in the activation energy of chain growth[20]. However, the activation energy of growth in the presence of the catalyst $(C_6H_{13})_3Al + VOCl_3$ or $VCl_4$ is the same for the homopolymerisation of ethylene and of propene as for their copolymerisation[105]. Consequently, the difference in activity is associated with steric factors — with the increase in steric hindrance to chain growth in the sequence ethylene–propene–but-1-ene.[10] The decisive role of steric factors in the copolymerisation of ethylene with propene (pair 24) and with but-1-ene (pair 25), as well as of but-1-ene with propene (pair 28), is indicated also by the absence of temperature variation in the copolymerisation constants of these monomers in the presence of any of the catalysts studied[90,91,101–111].

In copolymerisation of ethylene with propene[90,91,101–107,110], the atom of the transition metal present in the catalytic complex takes part in the stage of chain growth, which determines the rate of the overall process, since the copolymerisation constants vary with the nature of the compound of the transition metal. On the basis of the two-stage scheme of chain growth, however, it cannot be concluded from this variation, as is done by Carrick and his coworkers[110], that chain growth involves incorporation of monomer at the transition metal–carbon bond.

The view that in the growth reaction the position of the monomer is fixed in the reaction complex provides at the present time the most widely accepted explanation for the stereospecificity of the action of Ziegler–Natta catalysts[10]. This stereospecific action appears also in copolymerisation: in the presence of $VCl_4$ and $(C_6H_{13})_3Al$, ethylene forms crystalline copolymers with *cis*-but-2-ene and with cycloalkenes in which the monomer units alternate regularly, with the units of the second monomer forming a diisotactic structure[112–116,121] (Table 7). The steric selectivity of these catalysts is shown in the fact that mixtures of some monomers, in the presence of Ziegler–Natta catalysts, yield not copolymers but mixtures of homopolymers or of two copolymers differing in composition[95,96,98,100,120,122] (pairs 2, 12, 18, 19, 21–23, and 30 of Table 6).

Data on the copolymerisation of conjugated dienes (butadiene and isoprene, *cis*- and *trans*-penta-1,3-diene and 2,3-dimethylbutadiene — pairs 31–33 in Table 6) show especially clearly the difference between Ziegler–Natta coordination catalysts and ordinary cationic and anionic catalysts. Whereas when typical cationic and anionic catalysts are employed, the relative reactivity of a diene monomer is determined primarily by the electron density at its double bonds[28,29,69,70,84], in the presence of coordination catalysts the copolymerisation constants differ little among themselves, and are probably almost independent of the electron density on the double bonds in the monomer.

It has now been shown that complex catalysts based on titanium halides effect polymerisation by a coordinate-anionic mechanism[133,134], whereas those based on cobalt halides do so by a coordinate–cationic mechanism[134,135]. However, these distinctions do not lead to any substantial difference in the copolymerisation constants of the dienes in the presence of the two types of complex catalysts

TABLE 7. Copolymerisation of ethylene ($M_1$) with disubstituted ethylenes in the presence of Ziegler–Natta catalysts. | | | colloidal | 3 | 65.5 | 121 |
| 7 | *cis*-cyclooctene | soluble | 3 | 90 | 121 |
| | | colloidal | 3 | 92 | 121 |

(pairs 31 and 32 in Table 6). It may be supposed that the relative activity of diene monomers undergoing copolymerisation is determined primarily by steric factors. This is supported by the inability of *cis*-penta-1,3-diene (in contrast to the *trans* isomer) to polymerise or to form a copolymer with butadiene in the presence of several complex catalysts – $(C_2H_5)_2AlCl + VCl_3$ tetrahydrofuran or $VAcac_3$†,[127] $(iso\text{-}C_4H_9)_3Al + TiCl_4$, and $(iso\text{-}C_4H_9)_2AlCl + CoCl_2.C_2H_5OH$ [128] – as well as by the existence of a relation between the composition and the microstructure of the chain in copolymers obtained in the presence of catalytic systems based on compounds of cobalt and of nickel[69,70,124–126].

Data on copolymerisation in the presence of Ziegler catalysts thus show that in this process the polymer chain is neither a free anion nor a cation. The mechanism of the growth reaction is determined by the nature of the catalytic complex, in which the polymer chain occupies a definite position, and chain growth occurs as a stepwise process consisting of two stages – (1) formation of an active centre–monomer complex, and (2) addition of the monomer unit to the chain. In connection with the coordination character of chain growth, the relative activities of monomers are determined to a considerable extent not by polar but by steric factors.

## I. INTRODUCTION

When attempting a chromatographic analysis, the investigator is faced with three main types of problem. The first group relates to the choice of the best procedures and parameters for the separation process, the second to the identification of the components of the mixture to be analysed, and the third to the quantitative interpretation of the gas chromatograms.

The results of calculations of the concentration of the various constituents from the experimental chromatogram depend on correct choice and accurate measurement of the key parameter of the elution curve (particularly when the peaks are only partially resolved), on correct choice of the method of calculating the concentration, and lastly, on correct evaluation of the sensitivity of the detector towards each of the constituents.

The present review is devoted to a discussion of these problems. It is a continuation of our earlier articles[1,2], which dealt with the choice of separation procedures and with the qualitative analysis of mixtures.

A summary of published correction coefficients and peak areas for various substances and different detectors is given at the end of the review, so as to enable the reader to use these values directly in his experimental work.

Throughout this paper, it will be assumed that a differential detector is used.

## II. PARAMETERS OF THE PEAK AND METHODS OF CALCULATION

When a small enough sample is eluted, a distribution of concentrations (called a layer chromatogram) is formed on the sorption layer. Further elution leads to desorption of the wanted constituent. The resulting distribution of concentrations is called an eluate chromatogram.

If the system of detector and recorder used does not distort the curve, the resulting chromatogram differs from the true eluate chromatogram only by a scale factor.

The main parameters of the chromatographic peak (Fig. 1) are[3]:

1. The height $h$, measured by the length of a perpendicular dropped from the peak maximum to the base line.

2. $h'$, the length of a perpendicular dropped to the base line from the intersection of the tangents to the peak.

3. The width of the peak, which can be measured as the distance between points on the peak at a height of 0.5 ($\mu_{0.5}$), 0.75 ($\mu_{0.75}$), 0.9 ($\mu_{0.9}$), or 1/e ($\mu_e$) of the total peak height,

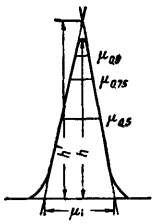

Fig. 1. Parameters of the chromatographic peak.

or alternatively as the distance between the points of inflection ($\mu_p$) or as the intersection ($\mu_i$) on the base line of the tangents at the points of inflection (peak base). It can be readily shown that if the chromatographic peak is sufficiently close to a gaussian distribution curve the following relationships hold between the various $\mu$ values:

$$\mu_e = 1.201\mu_{0.5},$$
$$\mu_{0.75} = 0.645\mu_{0.5},$$
$$\mu_{0.5} = 0.392\mu_{0.5},$$
$$\mu_p = 1.540\mu_{0.5},$$
$$\mu_i = 1.700\mu_{0.5}.$$

4. The peak area $Q$, defined by the outline of the curve and the base line.

5. The retention time $t_R$, the retention volume $V_R$, or the corresponding length $l$ on the chromatogram.

The peak height $h$ is related to the concentration of the substance in the sample. If the column is not overloaded with sample, this relationship is linear, provided of course that the response of the detector is directly proportional to the concentration of the substance in the eluate. However, the peak height is appreciably affected by temperature and by the flow rate of the carrier gas; therefore, the peak height should be selected as the quantitative parameter only if the following conditions are satisfied: (1) high reproducibility of sample size; (2) high stability of temperature and carrier flow; (3) no overloading of the column by the sample; (4) operation in the linear region of the detector and of the recording system.

The use of peak heights for calculating the quantitative composition of a mixture is convenient when the components have small retention times and give narrow peaks on the chromatogram. The method is applicable also to incompletely resolved constituents, provided the band maximum of one component is not affected by its neighbours. Calculations based on peak heights are particularly successful in routine analysis, requiring only moderate precision[4-7]. They are especially convenient in chromatography and in capillary chromatography.

In practice, peak areas are more frequently used as the parameter for calculation. There are various methods for measuring peak areas: planimetry, cutting out and weighing the peak, multiplying the height $h$ by the half-width $\mu_{0.5}$, drawing the tangents to the curve at the points of inflection and calculating the area of the resulting triangle, and the use of integrating devices. The choice of method for measuring peak areas should be guided by the features of the particular elution curve.

When using a planimeter the shape of the curve is immaterial, but the method is inconvenient for very small or very large areas. The precision of the calculation depends very much on subjective factors.

The shape of the peak is likewise unimportant when cutting out and weighing, but in this case significant errors can be introduced by lack of uniformity in the paper as well as by the subjective factor.

The measurement of peak areas as the product of the height $h$ and the half-width $\mu_{0.5}$ is convenient and accurate only if the peaks are symmetrical. Errors are again caused by overloading the column with sample, since the relationship $Q = 1.064h\mu_{0.5}$ (which applies to a gaussian distribution) does not hold when the column is overloaded. The method is difficult to use for small areas of negligible height and long retention time, or for large height and small $t_R$, because the half-width cannot be measured accurately. This method is accurate only when the peaks are adequately resolved.

When the area is measured by multiplying the peak height $h'$ by the base $\mu_i$ (triangle method) the accuracy of the measurement is affected by the shape of the curve and by the care with which the tangents are drawn. Obviously, this method should be used only when the sides of the peak are approximately rectilinear.

Assuming that the chromatographic peak is not very different from a normal gaussian curve, the following method for determining the peak area can be suggested[8]. The equation of this curve is of the form

$$y = \frac{Q}{\sqrt{2\pi}\,\mu_{st}} \times e^{-\frac{1}{2}\left(\frac{x}{\mu_{st}}\right)^2}. \qquad (1)$$

Here $y$ is the ordinate of the curve, measured at a distance $x$ from the ordinate at the maximum; $Q$ is the area of the peak; $\mu_{st}$ is the standard deviation. At the peak maximum, where $x = 0$, $y = h$.

Hence,

$$Q = 2\pi h\mu_{st} = 2.507h\mu_{st}. \qquad (2)$$

The height of the peak is measured directly, and the standard deviation can be determined from the width of the peak measured at various heights, thus:

$$\mu = \mu_{st} \quad \text{at } y = 0.882h,$$
$$\mu = 2\mu_{st} \quad \text{at } y = 0.607h,$$
$$\mu = 3\mu_{st} \quad \text{at } y = 0.324h,$$
$$\mu = 4\mu_{st} \quad \text{at } y = 0.134h, \text{ etc.}$$

Often the chromatographic peaks take the form of somewhat distorted gaussian curves. With asymmetric, biased peaks, for which the centres of the width lie on a straight line at all heights, the area can be calculated by Eqn. (2) just as though the peak were symmetrical[8].

It has been shown[8] that the standard deviation is a linear function of the retention time. Hence it is evident, see Eqn. (2), that the peak area can be measured[9] by using the peak height $h$ and the retention time $t_R$ (or the retention volume $V_R$). It can be readily shown[5] that the quantity $hV_R$ is proportional to the amount of the substance. The half-width of the band, expressed in units of volume, is known to be equal to

$$\omega_{0.5} = 3.33 \times \Gamma_0 \times S\sqrt{\frac{DLx}{\alpha}}, \qquad (3)$$

where $L$ and $S$ are the length and cross-section of the column respectively, $\varkappa$ is the fraction of free volume, $\alpha$ the linear velocity of the carrier gas calculated for the cross-section of the column, $D$ the effective coefficient of longitudinal diffusion, and $\Gamma_0$ the normal Henry coefficient. The retention volume is proportional to the length and cross-section of the column and to the Henry coefficient: $V_R = \Gamma_0 SL$. Cancelling $\Gamma_0 S$ from these two equations we find

$$V_R = \frac{\omega_{0.5}}{3.33}\sqrt{\frac{L\alpha}{D\varkappa}} = A\frac{\omega_{0.5}}{\sqrt{D}}, \quad (4)$$

where

$$A = \frac{\sqrt{L\frac{\alpha}{\varkappa}}}{3.33}.$$

It follows that

$$V_R \times h \sim \frac{Q}{\sqrt{D}}. \quad (5)$$

This method is to be preferred to the others, because it is simpler to measure a retention time than the width of a peak. Eqn. (5) shows that the relationship between $hV_R$ and the amount of a substance in the mixture varies from constituent to constituent due to difference in diffusion coefficient [10]. The method can be used successfully when high precision is not required. It should be noted that the method can be applied to overlapping peaks, whose area is often impossible to evaluate by any other method. All that is necessary in this case is to apply a correction to the peak height, depending on the extent of overlapping (see below for the calculation of the peak height correction).

Various integrating devices are used for measuring peak areas [11]. The mechanical integrator introduces errors into the measurement because it has a high inertia and gives few impulses per square millimetre of area, particularly with small areas and shallow peaks. The same disadvantages are found in the electromechanical integrator. The electronic integrator is much more accurate, but it cannot be used when the components of the mixture are not fully resolved. It should also be remembered that large errors may arise from drift of the base line.

Experimental tests of the various methods have been reported by many workers [4,7,11-15]. It has been shown that all methods give an appreciable error when the peak area is less than 50 mm² (15–25% for peak areas of the order of 25 mm²). The largest errors arise when planimeters or mechanical integrators are used, and the best results are obtained in calculations based on the peak height. When the peak area is about 50–100 mm², practically all the methods are liable to a 10% error, and the accuracy of the results can only be improved by averaging a large number of planimetric measurements. With peak areas above 100 mm² the error is 1–3%, irrespectively of the method.

## Determination of the Parameters of Incompletely Resolved Peaks

Incomplete resolution of the constituents of the mixture distorts the shape of the peaks and degrades the precision of quantitative analytical results. When resolution is not complete, allowance must be made for the presence of one component at the band maximum of another component. The total concentration, measured by the peak height on the chromatogram, is

$$C = C_{1,\max}\, e^{-\rho t_R^2} + C_{2,\max} e^{-\rho(\Delta t - t_R)^2}. \quad (6)$$

In this expression $\rho$ is a parameter which characterises the diffuseness of the band, $t_R$ is the retention time of the peak maximum of the second component, $\Delta t$ is the difference between the retention times of the maxima of the two components.

Starting from Eqn. (6), we can determine the true peak maxima of both components and evaluate the error which arises if the amount of a component is estimated from the apparent height of the peaks found on the chromatogram [16,17].

When the components of a mixture which give symmetrical chromatographic peaks are not fully resolved, the corrected peak heights can be calculated as a function of the extent of overlapping by the method of Stickler and Kovats [17]. Consider, for example, two peaks (Fig. 2) of height $h_1$ and $h_2$ whose maxima are a distance $\Delta l$ apart (measured in units of $\mu_{st}$). The ordinate $y$ of the curve for peak 1 at a distance $\Delta l$ from the maximum is

$$y = h_1 e^{-\frac{1}{2}\left(\frac{\Delta e}{\mu_{st_1}}\right)^2}, \quad \text{where } h_1 = \frac{Q}{\sqrt{2\pi}\,\mu_{st}}. \quad (7)$$

The corrected height of peak 2, allowing for the effect of peak 1, is given by

$$h_2 = \tilde{h}_2 - h_1 \times e^{-\frac{1}{2}\left(\frac{\Delta l}{\mu_{st_1}}\right)^2}, \quad (8)$$

where $\tilde{h}_2$ is the apparent height of the second peak. The area of peak 2 is then

$$Q = \sqrt{2\pi} h_2 \mu_{st_2} = 2.507 h_2 \mu_{st_2}.$$

In these expressions, $\mu_{st_1}$ and $\mu_{st_2}$ are the standard deviations of the first and the second peak respectively.

Usually the correction to the peak height is appreciable if $\Delta l$ is small, and becomes negligible when $\Delta l > 4\mu_{st}$.

When the overlapping peaks are asymmetrical the height correction is obtained as for the case of symmetrical peaks. In general, however, the calculation of the height correction becomes very complicated when asymmetry is present, and involves a number of approximations.

Bartlet and Smith [8] have shown that the two areas corresponding to the individual components can be evaluated with the help of Eqn. (1) even when two substances with similar

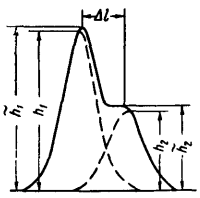

Fig. 2. Symmetrical, partially resolved peaks.

retention volumes give a single broad peak on the chromatogram. These authors used the method [18], and published a plot of the height correction as a function of the distance between the maxima of the overlapping peaks, measured in units of $\mu_{st}$.

Thus, Bartlet and Smith's method gives information on unresolved peaks without any need to choose conditions leading to complete resolution.

Polezzo and Taramasso [19] have proposed a similar method of calculation to give the area of unresolved peaks. They express the corrections to the heights of overlapping peaks in the form

$$a_1 = e^{-\frac{1}{2}\left(\frac{\Delta l}{\mu_{st_1}}\right)^2}, \quad a_2 = e^{-\frac{1}{2}\left(\frac{\Delta l}{\mu_{st_2}}\right)^2}, \tag{9}$$

the corrected peak heights being

$$h_1 = \tilde{h}_1 - h_2 a_2 \text{ and } \tilde{h}_2 = \frac{\tilde{h}_2 - a_1\tilde{h}_1}{1 - c_1 a_2}. \tag{10}$$

In this equation $\tilde{h}_1$ and $\tilde{h}_2$ are the quantities indicated in Fig. 2.

Since $\mu_{st}$ is not easy to measure in practice, it is more convenient to express the area of the peak in terms of other quantities.

We know that $\mu_{st} = 0.424\mu_{0.5}$. Hence

$$C_x = C_{max}\exp(-x^2/0.36\mu_{0.5}^2) \text{ or } C_{max} = \frac{C_x}{\exp(-x^2/0.36\mu_{0.5}^2)}, \tag{11}$$

so that the peak area is given by

$$Q = 1.064\, C_{max}\mu_{0.5} = \frac{1.064\, C_{max}\mu_{0.5}}{\exp(-x^2/0.36\mu_{0.5}^2)}. \tag{12}$$

Analogous formulae can be written in terms of $\mu_{0.75}$, $\mu_{0.9}$, etc.

An alternative method for calculating the areas of unresolved peaks, based on the assumption that the gaussian distribution applies in the case of linear sorption isotherms, was put forward by Zhukhovitskii and coworkers [20]. The area corresponding to a given amount of a component of a mixture is calculated using the equation

$$Q = K_\theta h \mu_{0.5}, \tag{13}$$

where $K_\theta$ is a coefficient, and $\mu_\theta$ is the width of the band at the height $\theta h$. For $\theta$ = 0.5, 0.75, and 0.9 the calculated values of the coefficient $K_\theta$ are 1.064, 1.650, and 2.710 respectively. According to the extent to which the components are separated, the value of $\theta$ should be chosen so that the width of the peak is unaffected by the neighbouring component. This method was tested, and it was shown that satisfactory results can be obtained at different $\theta$ values. However, errors are unavoidable at large $\theta$ because $\mu_{st}$ is small.

An interesting method of quantitative interpretation in the presence of partially resolved components is described by Serfas [21]. The outline of the chromatographic peak is linearised by using a probability scale as ordinate: the elution curve of two partially resolved peaks then consists of a line showing two rectilinear segments joined by a curve. The true outlines of the individual peaks of the two components are obtained by extrapolating the linear portions.

A theoretical method of calculation for unresolved peaks is given in a paper by Grant and Vaughan [22], in which an equation approximately describing the behaviour of three partly resolved peaks is presented. A method for the analysis of close-boiling compounds is based on this equation: the compounds were mostly isomeric, since compounds of similar boiling points but belonging to different classes can usually be separated by suitable choice of stationary phase. The method is used when the two components 1 and 2 give a single peak on the chromatogram, and their total concentration is known. A third substance is chosen such that the distance between the maximum of its chromatographic peak and the maximum of the peak for (1 + 2) is $\Delta l \simeq 3\mu_{st}$, and its peak area is the same as that of (1 + 2). The chromatogram of such a mixture gives a curve (Fig. 3) from which the quantity $h_{1,2,3(min)}/h_3$ can be evaluated: its value is substantially determined by all three components of the mixture. The concentrations of components 1 and 2 which correspond to this value are read off calibration curves constructed for mixtures of known composition.

Fredericks and Brooks [23] measured the areas of unresolved peaks by dropping a perpendicular from the minimum point to the base line and treating this line as the boundary between the two peaks. Their results were in agreement with the gravimetric composition of the mixture, but the method is unsuitable for asymmetric peaks and also for peaks of widely different size.

Bryce [4] has made an interesting study of the measurement of unresolved peak areas. He examined a mixture of benzene, toluene, and *p*-xylene in the ratio of 2 : 3 : 5, giving peaks of equal height on the chromatogram. Straightforward analysis gives complete separation of the peaks. The peaks of a given component were made to overlap by injecting a second sample, the degree of separation being controlled by the interval between the two sample injections. Perpendiculars dropped from the minimum point, and from the intersection of the tangents to the inner sides of the overlapping peaks, were treated as the peak boundary. The latter method of measuring peak areas gave the more accurate results. If, as a result of incomplete separation, one of the sides cannot be distinguished, the internal tangent is drawn symmetrically to the external tangent with respect to a perpendicular dropped from the peak "maximum" to the base line.

To obtain accurate results in the analysis of impurities whose peaks fall on the diffuse trailing edge of the peak of the main constituent, it is not advisable to use the peak height as a measure of concentration. In this case, the

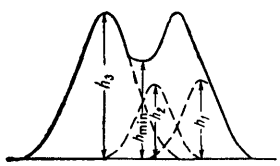

Fig. 3. Incomplete resolution of three components.

peak area is measured[4,24] by extrapolating the tail of the major peak and treating it as the base line of the impurity peak.

## III. METHODS FOR CALCULATING THE COMPOSITION OF A MIXTURE FROM THE CHROMATOGRAM PARAMETERS

The precision of the chromatographic method of analysis depends very much on choosing the most rational method for calculating the proportion of each constituent in the mixture for analysis. We showed in the previous Section how a differential chromatogram can be characterised quantitatively in terms of various peak parameters. By varying these parameters, and by choosing the most appropriate method of calculation, the percentage of any component of the mixture can be found.

The main methods of processing gas chromatograms are: the absolute calibration method, the internal normalisation method, and the internal standard method.

### The Absolute Calibration Method

In the analysis of trace constituents, quantitative interpretation is complicated by the special features of the chromatographic separation procedure. Absolute calibration is the most convenient and accurate method, in this case, for calculating the concentration of the components of interest. When using the absolute calibration method, either the height or the area of the peak can serve as the distinguishing parameters recorded on the chromatogram. The method presents rather stringent requirements as regards analytical procedure, and demands considerable skill and accuracy. The absolute calibration method consists in determining the relationship between the height or the area of the peak for a given component, and the amount of the latter, in a sample of given size[3,25-28]. Calibration is usually carried out by analysing a sample of known volume and accurately known composition. The experimental results are used to plot a graph of the peak height or area against the concentration of that component in the sample, and the concentration of the same component in the unknown mixture is obtained directly from the graph. When the calibration curves are straight lines, it is possible to calculate calibration coefficients which apply over wide limits, and the percentage of the compound can be calculated from the expressions

$$P_i = K\frac{Q_i}{g_i}\times 100 \qquad (14)$$

or

$$P_i = K\frac{h_i}{g_i}\times 100, \qquad (15)$$

where $Q_i$ and $h_i$ are the area and height of the peak, $g_i$ the weight of the component, and $K$ the calibration coefficient.

The accuracy of the quantitative results of the absolute calibration method depends first and foremost on the conditions under which the analysis is carried out and on the operating stability of the chromatographic apparatus. Reliable results are obtained only if the calibration and the analysis itself are carried out under identical conditions. Horn and coworkers[29] have given a detailed discussion of the problems arising from the influence of various factors on the height and area of the peak when calculating calibration coefficients. They showed that the correction factor for the peak height is a sensitive function of the amount of substance, whereas the correction factor for the peak area remains practically constant. In order to simplify the calculations, absolute calibration is often based on the height of the peaks, despite its great sensitivity to changes in experimental parameters. In particular, a one-degree change in the temperature of the column, detector, and connecting tubes can cause an error[24] of 2%. Sverak and Reiser[30], in their work on the determination of small quantities of ether in ethylene using a chromatograph with katharometric detection, allowed for a number of parameters in the formula used for quantitative calculations:

$$C_0 = \frac{KQV_\alpha}{v_n zE}, \qquad (16)$$

where $C_0$ is the concentration of ether (vol.%), $v_n$ the sample volume, $Q$ the peak area, $V_\alpha$ the flow rate of the carrier gas, $z$ the speed of the recorder chart, $E$ the sensitivity of the potentiometer, and $K$ the calibration factor.

It should be noted that calculations with allowance for correction coefficients are justified only as long as the detector response is linear in the concentration of the compound. When this is not true special corrections must be introduced.

### The Internal Normalisation Method

The internal normalisation method consists in bringing the sum of all the peak areas on the chromatogram to 100%. Instead of the peak areas, the product of the peak heights and the corresponding retention times of the components may be used. This method affords only the ratio between the amounts of the components whose peaks appear on the chromatogram, and is therefore valid only if all the constituents of the mixture for analysis are fully eluted. It is common practice to normalise corrected peak areas, that is, peak areas to which a correction for detector sensitivity has been applied. In some cases (for example, in the analysis of liquid hydrocarbons using a thermal conductivity detector with hydrogen or helium as the carrier gas, whose thermal conductivity is considerably higher than that of the substance to be analysed), correction coefficients can be ignored to a first approximation[7,31]. However, significantly higher precision is obtained by taking the correction coefficients into account. There is a wide range of publications[7,31-38] on the effect of various factors on peak areas and peak heights. Thus van de Craats[37] examined the problems associated with flow rate and sample size; Dimbat and coworkers[7] studied the effect of temperature and carrier-gas velocity on the parameters of the peak. The latter workers showed that the area of the peak is a function of the flow rate but does not vary with temperature, whereas the height of the peak depends on the temperature but is practically independent of flow rate. For temperature fluctuations of the order of one degree the relative error of peak area measurements is 0.3%. Ray[38] showed that the error caused by this same temperature variation can be as high as 2.4% when peak heights are used for the calculation. With streaming detectors of the flame ionisation type the height of the peak is very sensitive to the rate of flow of the carrier gas, but the area remains practically constant[39]. The time-constant (or inertia) of the system of detector, bridge, and recorder

must be considered when assessing the precision of the calculations. If the width of the peak is decreased by increasing the flow rate or by raising the temperature, the time-constant begins to have a significant effect and to distort the peak[39,40].

It follows from what has been said that the most satisfactory data on the quantitative composition of mixtures are obtained by using various correction coefficients, depending on the chosen method of detection.

In the internal normalisation method, the concentration (in percentage) of the $i$th component in the mixture to be analysed is calculated by the expression

$$P_i = \frac{K_i Q_i}{\sum_{i=1}^{n} K_i Q_i} \times 100. \qquad (17)$$

To speed up the calculations, some authors advise the use of nomograms[41], computing equipment[42], etc. According to the correction coefficient which was chosen, the concentration of a component found by formula (17) is expressed in weight or molar percentage. These aspects are discussed in greater detail below.

In practice one often has to deal with quite complicated organic mixtures which can only be separated by using multistage analytical procedures. It is obvious that the speed of the carrier gas changes when additional stages are inserted. If the calculation is based on concentration detectors, the corrected peak area should be obtained as the product of the area of the peak, of the correction coefficient, and of the velocity of the carrier gas during elution of the peak in question. Normalisation by multiplying the peak height by the retention time is not adequate in this case. In the analysis of complicated mixtures (petroleum spirit, pyrolysis tar, etc.) Vigdergauz and coworkers[43] used the method of double internal normalisation for quantitatively interpreting the chromatograms obtained at different stages. The first stage of their apparatus is intended to separate narrow fractions in the form of one or several peaks, which are then led to the column of the second stage for more detailed resolution. They showed that the corrected area of the peak of the $i$th component can be determined from the relationship

$$Q_{\text{corr},i} = \frac{KQ_i'' \sum_1^n Q_i'}{\sum_1^n Q_i''}, \qquad (18)$$

where $Q_i''$ is the area of the $i$th peak on the chromatogram of the second separation stage, and $\sum_1^n Q_i'$ and $\sum_1^n Q_i''$ are the sums of the peak areas corresponding to the fraction transferred to the second separation stage obtained on the chromatogram after the first and after the second stage respectively.

The percentage of the wanted component is calculated by the formula

$$P_i = \frac{Q_{\text{corr},i}}{\sum_1^n Q_{\text{corr},i}} \times 100. \qquad (19)$$

Conversion of the components at the detector inlet into carbon dioxide, hydrogen, or methane[44-46] is a very interesting method for the quantitative interpretation of gas chromatograms without previous calibration. The authors claim a number of advantages for this method over alternative methods of calculation, and they state that the precision and the reproducibility of the analytical results are higher.

When the gas-density balance (first described by Martin and James in 1956) is used as a detector, preliminary calibration or the experimental determinatin of correction coefficients are again unnecessary, since the signal of this detector depends only on the ratio of molecular weights of the substance being analysed and of the carrier gas[58]. In the analysis of the light fractions of crude oil (up to and including $C_7$) the measuring error was no more than 1% when a gas-density balance was used[55].

## The Internal Standard Method

The internal standard method, first proposed by Ray[38], relies on adding to the mixture for analysis a known amount of a suitable substance to act as a standard: the height or the area of the peak for the wanted component are then compared with those for the standard. This method is widely used both for major constituents and for the analysis of trace impurities[47,55]. The chosen standard should be a substance which is not contained in the mixture for analysis, which is thermally stable at the temperature of the experiment, and which cannot react with any of the constituents of the sample. At the same time, the standard peak should appear on the chromatogram as close as possible to the peaks of the mixture. The percentage of the $i$th component in the sample can be calculated from the formula

$$P_i = \frac{K_i Q_i}{K_s Q_s} R \times 100, \qquad (20)$$

where $K_i$ and $K_s$ are the correction coefficients for the peak area of the component and of the standard, determined by the sensitivity of the detector, $R$ is the ratio of the weight of internal standard to the weight of the mixture taken for analysis, and $Q_i$ and $Q_s$ are the peak areas of the component and of the standard.

An analogous expression applies to the peak heights. The calibration coefficients are determined by analysing binary mixtures of component and standard. Some workers prefer to plot calibration graphs for all the constituents of the mixture for analysis. Thus, Shlyakhov and coworkers[6], in their analysis of oxygenated hydrocarbons on a capillary column, plotted the ratio of the weight percentage of a given component to that of the standard (on the abscissa axis) against the ratio of the heights of the corresponding peaks (on the ordinate axis). The concentration of every component was determined from these calibration curves, with a mean relative error of 2%. When analysing multicomponent mixtures with a wide range of retention times, more accurate and reproducible results on the quantitative composition are obtained by using several internal standards. Lee and Oliver[56], using two internal standards, estimated small impurities (of the order of tenths of one per cent) of benzene, toluene, and styrene in ethylbenzene to a relative precision of 1–2%. Vlodavets and coworkers[57] used three internal standards for quantitative calculations when developing a method for the chromatographic estimation of acrolein and its dimerisation products.

It is evident from the above examples that the correct choice of method for calculating the composition of a mixture is the key to a successful quantitative analysis.

## IV. CALCULATION OF CORRECTION COEFFICIENTS IN QUANTITATIVE CHROMATOGRAPHIC ANALYSIS

The correct quantitative interpretation of chromatograms requires that the law relating the elution curve to the true ratio of components in the mixture should be known. A situation in which equal quantities of the substances to be separated correspond to equal values of the chosen parameter is exceptional in chromatographic practice. One usually has to apply correction coefficients, which make it possible to deal with the calculation as in the simplest case defined above. With these correction coefficients absolute calibration becomes unnecessary, and because of this many workers have examined the problem of evaluating the coefficients using both experimental and theoretical approaches.

The experimental determination of correction coefficients lags behind the rapidly growing number of substances to which chromatographic analysis is being applied. Furthermore, the experimental correction coefficients need to be critically scrutinised: different workers often report vastly different values which are due to subjective factors as well as to differences in the experimental conditions and procedures[31].

A more rational approach is to seek theoretical relationships between the signal of the detector and the physicochemical properties of the substances to be separated. An "ideal" method of processing the results of a chromatographic analysis would involve very complicated corrections for the distortions of the chromatogram introduced both by the column and by the detecting device.

The distortions introduced by the detector can be divided, on the whole, into two groups[59]: (1) those arising from non-linearity of the detector response as a function of the concentration of the wanted substance in the carrier gas, and (2) dynamical perturbations, caused by the rate of change of concentration in the carrier gas, affecting the sensitivity of the detector.

Obviously, correction coefficients can be tabulated for the entire range of concentrations of the wanted substances only if the calibration plot $y = f(c)$ is rectilinear, that is,

$$y = S_i c, \tag{21}$$

where $y$ is the deflection of the recorder pen, $c$ the concentration of the component in question, and $S_i$ the sensitivity of the detector towards that component.

For the first and the second group of distortions, Eqn. (21) becomes, respectively,

$$y = S_0 + S_1 c + S_2 c^2 + S_3 c^3 + \ldots \tag{22}$$

and

$$y = S_1 c + S_2 \frac{dc}{dt} + S_3 \frac{d^2c}{dt^2} + \ldots . \tag{23}$$

Since Eqn. (21) applies only to a limited range of concentrations (lying, as a rule, in the region of low values of $c$), it is always necessary in practice to estimate the order of magnitude of the error due to non-linearity[60].

A summary of published data on the upper limits of detector linearity is given in Kalmanovskii and Fesenko's paper[40] on detecting devices for gas chromatography.

Among the ways in which the separating part of the apparatus can distort the chromatogram we should list the increase in overall velocity of the flow occurring when the desired component emerges from the column, called the "surge effect" by van de Craats[37]. As a result of this effect, the peak area traced on the chromatogram is smaller than the area corresponding to the measured flow rate.

The author recommends the correction factor

$$f_1 = 1 + \frac{v_s c_s}{100\omega_u} \times \frac{V_2 - V_{gas}}{V_R}, \tag{24}$$

where $v_s$ is the sample size (ml), $c_s$ the concentration of the component in the sample (mole %), $\omega_u$ the width of the peak at the base obtained by drawing tangents (ml), $V_R$ the retention volume of the component (ml), and $V_{gas}$ the volume of gas in the column (ml). He also derives a more precise correction factor:

$$f_2 = 1 + 0.7\,\frac{c_{max}}{100 - c_{max}} \times \frac{V_R - V_{gas}}{V_R}, \tag{25}$$

where $c_{max}$ is the concentration corresponding to the peak maximum.

All these errors, most of which are effectively impossible to control, call for the application of corrections for every type of analytical procedure. However, in practical chromatography the corrections are usually confined to coefficients depending only on the principle of operation of the detector and on the nature of the carrier gas and of the wanted component.

We shall now discuss the methods of determining these correction coefficients, which, when multiplied by the peak areas, convert them into the appropriate gravimetric and molar amounts of substance injected into the column.

According to one school of thought[31], the correction coefficients should always convert the chromatographic results into percentage by weight. However, the present writers prefer to use molar correction coefficients in tabulations, because they reflect most clearly the relation between the signal corresponding to a substance and the chemical nature of the substance.

It is easy to show[43] that the molar correction factor for a given component can be readily converted into a gravimetric factor by the relation

$$\frac{K_w}{K_m} = \frac{M_i}{M_{st}}, \tag{26}$$

where $K_w$ is the gravimetric correction coefficient, $K_m$ the molar correction coefficient, $M_{st}$ the molecular weight of the standard (for which $K_w = K_m = 1$), and $M_i$ the molecular weight of the component.

As we have already pointed out, different substances have practically identical correction coefficients only in special cases. These occur, for example, in the analysis of members of a homologous series using katharometric detection and a light carrier gas (helium or hydrogen). The adequacy of this assumption depends, of course, on the analytical precision required. In every other case the correction coefficients are quite different.

Messner and coworkers[61] showed that for a katharometer detector and helium as the carrier gas a strictly linear relationship exists between the molecular weight and the value of $1/K_m$ for the individual members of homologous series of hydrocarbons, the slope of the resulting straight line decreasing as the degree of branching of the hydrocarbon increases. The following rules were established: $1/K_m$ is smaller for cyclic than for normal hydrocarbons; it is smaller for *ortho*-substituted isomers than

for the *meta*- and *para*-isomers; for normal paraffins $1/K_m$ is higher than for any functional derivatives.

Jamieson[62] has examined a large number of organic compounds, and he has confirmed the rule of Messner and coworkers according to which $1/K_m$ decreases as the branching of the hydrocarbon skeleton increases. He has also shown that this rule is not so strictly followed by polyfunctional derivatives (ethers, hydroxy-, alkoxy-, and ketoxy-ethers).

Jamieson, and also other workers[63,64], showed that with alcohols the relative molar correction varies with the square root of the molecular weight. Iogansen and coworkers[65] found that the correction coefficient for hydrocarbons varies with the 2/3 power of the molecular weight.

Nikelly[66] showed that the plot of correction factor against number of carbon atoms (for the case of a katharometer) is curved, the curvature decreasing in the sequence: alkanes, alkenes, alcohols. From the analytical results for a seven-component mixture of alkenes and alcohols, obtained with temperature programming and by using his own correction coefficients, he estimated an error of 2–4% for each of the components. In the same paper it is shown that the correction coefficients are independent of temperature variation during the analysis.

Similar observations are reported by Baumann and Olund[67], who determined the relation between molar corrections and the normal boiling points in a series of sulphides and thiols.

When a flame ionisation detector is used with hydrocarbons and their derivatives a strictly linear relationship is observed between the relative molar correction and the number of carbon atoms[68].

It should be noted that with many detectors there is no simple systematic relation between the signal and the nature of the substance. Typical of these is Grant's emissivity detector[69], for which the correction coefficients depend on the velocity of the carrier gas and on the absolute amount of substance for analysis. Another characteristic of this detector is that the signal depends very much on the class of compound, and is practically constant within a homologous series. Thus[22], the signal for paraffins and halogenated hydrocarbons relative to benzene is 0.14 and 0.15 respectively, whereas for naphthalene the signal is 2.0–3.0.

## Thermal Conductivity Detector

Most of the work on correction coefficients, both experimental and theoretical, relates to the thermal conductivity detector. The early workers[70,71] assumed that the results of chromatographic analysis are given in molar percentages: thus, Hausdorff[70] considered that when a katharometer is used in conjunction with a light carrier gas the area under the elution curve is proportional to the number of molecules of the substance, and therefore to its molar percentage.

The question of whether the area under the curve on the recorder gives a better approximation to the weight or to the molar percentage has been discussed in several papers[72–76].

More recent work has shown experimentally that in many cases, particularly in the analysis of hydrocarbon mixtures, the area of the peak of a component expressed as a fraction of the total area for all components gives a better approximation to the weight fraction of the component in the sample. However, in most cases the areas under the curve do not correspond either to weight or to molar percentages. This was clearly demonstrated by van de Craats[37], who measured the relative correction factors for the $C_1$–$C_4$ hydrocarbons.

Feish and Engel'gart[72] showed that the correction factors, defined as the peak areas for those hydrocarbons referred to the peak area of n-butane (for equal sample volumes), are equal to the ratio of molecular weights in the zeroth approximation, and to the 3/4 power of the ratio of molecular weights in the first approximation. The first approximation refers to a method in which the standard is chosen to have a molecular weight intermediate between those of the components in the mixture for analysis. In this case the coefficients, calculated as $(M_i/M_{st})^{3/4}$, are approximately the same as those found by van de Craats. At the same time, if the ratio of the areas is taken to the power 4/3 a better approximation to weight percentages is obtained.

The first papers on the determination of correction coefficients were those of Rosie and Grob[34] and Messner and coworkers[61]. Most of the workers who have examined the theoretical aspects of correction coefficients have checked their conclusions against the results of those papers.

Messner and coworkers[61] proposed that the relative molar correction should be expressed in the form

$$\frac{1}{K_M} = A + BM, \qquad (27)$$

where $A$ and $B$ are constants for a given homologous series, and $M$ is the molecular weight.

These workers calculated values of $A$ and $B$ for many classes of organic compounds. Some of their values are tabulated below:

| Series | A | B |
|---|---|---|
| n-Paraffins | 6.7 | 1.35 |
| Methylparaffins | 10.8 | 1.25 |
| α-Olefins | 13.0 | 1.20 |
| n-Alcohols, primary | 34.9 | 0.808 |
| n-Alcohols, secondary | 33.6 | 0.857 |
| n-Alcohols, tertiary | 34.9 | 0.808 |
| Acetates | 37.1 | 0.841 |
| Ketones | 35.9 | 0.881 |

These correction coefficients are independent of concentration over a wide range. A tenfold change (from 1.43 to 0.14) in the molar ratio of diisopropyl ether to benzene had practically no effect on the correction factor. In the same paper it is shown that the correction coefficients are independent of the type of katharometer used (thermistor, or hot wire). Furthermore, it was also established that the correction coefficients for helium and hydrogen are unaffected by change in temperature over a wide range. However, in the case of nitrogen, which shows a strong temperature variation of the correction coefficients, standardisation is particularly difficult. This is especially true of the $C_2$ hydrocarbons, to which the katharometer has practically no sensitivity between 50° and 80°.

As was to be expected, all the workers who studied correction coefficients for katharometers approached the problem by considering changes in thermal conductivity of

the carrier gas as a function of the concentration of the wanted component in the carrier. Keulemans[77] considers that at low concentrations, when the mole fraction ($x$) of the component in the carrier gas is less than $10^{-2}$, the thermal conductivity of the mixture is the sum of the thermal conductivities of the carrier and of the impurity multiplied by the appropriate mole fractions. Then

$$x = \frac{\lambda_1 - \lambda_{12}}{\lambda_1 - \lambda_2}, \quad (28)$$

where $\lambda_1$, $\lambda_2$, and $\lambda_{12}$ are the thermal conductivities of the carrier gas, of the wanted component, and of the mixture respectively. Thus, if the signal is proportional to the change in thermal conductivity ($\lambda_1$ - $\lambda_{12}$), the peak area should lead to an accurate value of the mole fraction when the correction factor $1/(\lambda_1 - \lambda_2)$ is used. However, this is inconsistent with the fact that the area under the elution curve usually corresponds to a weight percentage.

Iogansen[65] takes the same view, and suggests that the molar correction for light hydrocarbons should be calculated by the formula

$$\frac{1}{K_{M_i}} = \frac{\lambda_1 - \lambda_{12}}{\lambda_1 - \lambda_2} \times \sqrt[3]{(M_i/58)^2}, \quad (29)$$

where $M$ is the molecular weight of the wanted hydrocarbon, and 58 the molecular weight of n-butane (taken as standard).

Hinkle and Johnsen[36] propose a correction factor of $\rho^{-2/3}$ to the peak area, where $\rho$ is the vapour density, to give molar percentages. This agrees with Iogansen's conclusion, since

$$\rho = c\left(\frac{\mu c_p}{\lambda}\right)(M)(a)^{-1}, \quad (30)$$

where $c$ is a constant, $\mu$ the absolute viscosity, $\lambda$ the thermal conductivity, $c_p$ and $c_v$ are the specific heats at constant pressure and constant volume, $M$ is the molecular weight, and $a = c_p/c_v$.

Browning and Watts[32] proposed a correction to the peak areas on the basis of the thermal conductivity of the appropriate component. In principle, this correction relies on dividing the peak areas given by the analysis by the thermal conductivities of the corresponding substances, since large peak areas correspond to large thermal conductivities and conversely. Heft has shown[73] that with nitrogen as the carrier gas this correction only makes matters worse.

Littlewood[74], and more recently Mecke and Zirker[75], started from an expression for the thermal conductivity of a mixture derived from the theory of Chapman and Enskog.

Littlewood concluded that the thermal conductivity of the carrier gas, of the component being analysed, and of their mixtures ($\lambda_1$, $\lambda_2$, and $\lambda_{12}$ respectively), and also the mole fraction of the component in the carrier gas ($x_2$), are related to the average diameters of the molecules of the carrier ($\sigma_1$) and of the impurity ($\sigma_2$) by the expression

$$-\frac{1}{\lambda} \times \frac{d\lambda_{12}}{dx_2} = \frac{\sigma_{12}^2}{\sigma_1^2}, \quad (31)$$

where

$$\sigma_{12} = \frac{\sigma_1 + \sigma_2}{2}.$$

To obtain the average molecular diameters needed for the calculation of correction coefficients this worker used some of Rosie and Grob's results on the cross-section of the methyl, methylene, methine, and phenyl groups, and also of the quaternary carbon atom and aromatic hydrogen. Littlewood, on the assumption that the molecular diameter is approximately equal to the sum of the diameters of the constituent elements, calculated correction coefficients (for helium) which were practically indistinguishable from some other results of Rosie and Grob:

| Compound | Relative molar correction | | Compound | Relative molar correction | |
|---|---|---|---|---|---|
| | Rosie and Grob | Littlewood | | Rosie and Grob | Littlewood |
| n-Heptane | 143 | 143 | Ethylbenzene | 129 | 135 |
| n-Octane | 160 | 162 | o-Xylene | 130 | 132 |
| 2-Methylpentane | 120 | 120 | p-Xylene | 131 | 132 |
| 3-Methylpentane | 119 | 120 | Mesitylene | 149 | 148 |

Mecke and Zirker, who also introduced a correction for the change in molecular diameter under the influence of molecular forces, arrived at the same conclusion.

In keeping with Littlewood's assumption, Mecke and Zirker showed (in the case of normal paraffins) that the ratio of the square of the increment in molecular diameter $\Delta d^2_{CH_2}$ to the increment in molecular weight $\Delta M_{CH_2}$ is a constant:

$$\frac{\Delta d^2_{CH_2}}{\Delta M_{CH_2}} = \text{const.} \quad (32)$$

Thus, for the homologous series $A-(CH_2)_n$, where $A$ is a functional group, the square of the average molecular diameter can be calculated by the formula

$$d^2 = d_A^2 + n d^2_{CH_2} = K(A + nM_{CH_2}). \quad (33)$$

The calculation of correction coefficients by the method of Littlewood and of Mecke and Zirker is made much easier by this relationship. The work of these authors is valuable also because it provides an explanation for the observed linear variation of the correction coefficients with molecular weight within a given homologous series, and for the slight deviation from linearity in the first few members (influence of $A$).

Schmauch and Dinerstein[78], and also Hoffman[79], arrived at their molecular correction coefficients from the classical kinetic theory of monatomic gases. According to the former, the sensitivity of the katharometer ($E_0$) is related to the thermal conductivity of the carrier gas ($\lambda_1$) and to that of the mixture ($\lambda_{12}$) by the following expression:

$$E_0 = c\sqrt{\lambda_1}\,\frac{\lambda_1 - \lambda_2}{\lambda_{12}}. \quad (34)$$

To calculate the thermal conductivity of the mixture they applied Vasil'eva's equation

$$\lambda_{12} = \frac{\lambda_1}{1 + A_{12}\left(\frac{1-x}{x}\right)} + \frac{\lambda_2}{1 + A_{21}\left(\frac{x}{1-x}\right)}, \quad (35)$$

where $x$ is the mole fraction, and $A_{12}$ and $A_{21}$ are constants. They conclude that the same correction coefficients can be used over a wide range of concentrations if the difference in thermal conductivity between the substance and the carrier gas is very large (for example, helium or hydrogen carriers, and organic compounds). In other systems, for example, when nitrogen is the carrier and the response is

not linear, a correction is needed for each concentration interval of the test substance.

Hoffman analyses the detector signal into four multiplicative terms: a cell factor, a carrier-gas factor, a molar thermal conductivity change factor, and a concentration factor. From Vasil'eva's equation for the change in molar thermal conductivity, Hoffman obtains

$$F=\frac{\lambda_1-\lambda_2}{\lambda_{12}\,x}=F_0+f_x\,(x\ll 1), \tag{36}$$

where

$$F_0=A_{12}-\frac{\lambda}{A_{12}} \text{ and } \lambda=\frac{\lambda_2}{\lambda_1},$$

$\lambda_1$ and $\lambda_2$ being the thermal conductivities of the pure carrier gas and of the component. Since $x \ll 1$, it follows that $F_0 \simeq F$. The quantity $F_0$ can be neglected in practice, but the quantity $F_{0i}/F_{0st}$, corresponding to the relative molar signal, can be calculated if the data needed to calculate the constants in Vasil'eva's equation are available.

The relative molar corrections obtained by Hoffman for nitrogen, helium, and hydrogen agree strikingly well with the corrections determined experimentally, and also with the results of Messner and coworkers[61], and others. Hoffman showed that the second term (effect of the carrier gas) accounts for only 4–13%. He ascribes the peak inversion which is observed when nitrogen is the carrier to negative $F_0$ values.

Heft[73] explains peak inversion by pointing out that the katharometer response is affected by changes in the specific heat of the mixture of carrier and substance for analysis as well as by thermal conductivity changes. For hydrogen and helium the ratio of these two effects is always much less than unity, whereas for nitrogen the specific heat effect can be much larger than the thermal conductivity effect. This causes cooling of the detector filament, and leads to peak inversion.

As a result of an interesting study of the influence of the specific heat of the components to be analysed on the detector signal, Heft concludes that when nitrogen is used as the carrier gas the areas of the peaks under the elution curve correspond to weight percentages only if one is dealing with members of a homologous series, or with substances having identical specific heats. In all other cases a correction is necessary.

## Gas-Density Balance

This detector, as stated above, is the most suitable for quantitative analysis. Phillips and Timms[58] found that the integral signal for the $i$th substance ($a_i$) depends on the molecular weight $M_i$ as indicated by the equation

$$Q_i=K\,g\left(\frac{M_i-M_0}{M_i}\right), \tag{37}$$

where $M_0$ is the molecular weight of the carrier gas, $g$ the amount of the substance, and $K$ an apparatus constant.

The relative correction coefficient is then

$$K_B=\frac{(M_{st}-M_0)\,M_i}{M_{st}(M_i-M_0)}. \tag{38}$$

Thus, for benzene as the standard and hydrogen as the carrier gas, the correction coefficient for the $i$th compound takes the value

$$K_B=\frac{M_i\times 76}{(M_i-2)\times 78}. \tag{39}$$

The main virtue of this detector is that it does not require tabulated and correction factors. When needed, the factors can always be calculated for any unknown substance provided that its molecular weight is known.

## Flame Ionisation Detector

At the present time, the flame ionisation detector is one of the most satisfactory devices for quantitative analysis by gas chromatography. It provides results which are independent of temperature and of carrier gas, and a large linear range of signals.

However, relatively little has been published on the use of the flame ionisation detector in the quantitative analysis of real mixtures. This is partly due to the fact that the signal depends very significantly on constructional details of the electrodes, burner geometry, flame temperature, etc.

The correction coefficients for the flame ionisation detector are far more sensitive to structural features of the compounds being analysed than are the coefficients for the katharometer[80]

As already pointed out, various authors have obtained a linear relation between the relative molar correction and the number of carbon atoms in the molecule. Altschuller and Clemons[28] showed that the signal of this detector is a linear function of the number of carbon atoms in aromatic hydrocarbons up to $C_{10}$.

One characteristic of the flame ionisation detector is that carbon atoms linked to oxygen or nitrogen contribute practically nothing to the signal given by the compound being examined[81–85]. This is because such a carbon atom does not take part in the combustion, which is the physicochemical basis of the operation of the flame ionisation detector.

Schomburg[68] found a molar correction coefficient (relative to $m$-xylene) varying only over the range 0.59–0.65 for a series of carbonate esters of molecular weight between 116 and 172.

Unfortunately, the special features of the flame ionisation detector limit (or even debar) its application in the analysis of some commercially important substances such as the inert gases, hydrogen, oxygen, carbon monoxide, carbon dioxide, and many others[86].

Schomburg warns[68] against the use of the flame ionisation detector in the analysis of substances whose combustion produces a solid deposit in the burner. For example, a solid residue of boron dioxide is formed in the analysis of alkylborons, and makes quantitative analysis impossible.

Ettre and coworkers[82] showed that the correction coefficients for the flame ionisation detector, like those for for the katharometer, can be calculated by Eqn. (27). Those workers, and also Desty and coworkers[87], obtained correction coefficients for very many organic compounds.

Bredel[88] states that the areas of hydrocarbon peaks are related to the retention times and to the number of carbon

atoms in the molecule by the expression

$$Q = t_R(A\,n + B), \tag{40}$$

where the coefficients $A$ and $B$ are different for different types of column. This author suggests that the peak areas should be corrected by dividing them by the product $t_R n$.

Ongkiehong[83] found that in many cases approximate correction coefficients can be calculated without appreciable loss of analytical precision from the formula

$$K_B = \frac{M_i n_{st}}{n_i M_{st}}, \tag{41}$$

where $M_i$ and $M_{st}$ are the molecular weight of the $i$th compound and that of the standard, and $n_i$ and $n_{st}$ the number of carbon atoms in the molecule of the $i$th compound and of the standard.

These approximate correction coefficients give particularly good results in the analysis of substances containing different functional groups (alcohols, acids, ether, etc.).

Sternberg and coworkers[89], and also Dewar[90], have correlated the detector signal with the structural properties of the substances being analysed.

### β-Ionisation Detector

This very sensitive detector can be used to analyse any compound whose ionisation potential is less than 11.7 eV. One of its characteristics is that the correction coefficients are relatively insensitive to changes in carrier-gas flow and in temperature, and also to the geometry of the apparatus. The integral signal of the β-ionisation detector is proportional to the molecular weight of the substance being analysed, but the recorder deflection is not linear in relation to concentration.

The theory of the β-ionisation detector was first investigated by Lovelock[91]. He showed, by analysing substances belonging to different classes, that the non-linearity of the correction coefficients (relative to pentan-1-ol) as a function of molecular weight varies for substances of different nature. Thus, with the methyl esters of primary fatty acids the correction coefficient decreases sharply with increase of molecular weight up to one hundred, after which it tends to a constant value. A similar behaviour is observed with n-primary alcohols, whereas with ethers and ketones the relative correction coefficient increases sharply over the whole interval of molecular weights (up to 200) which was examined. An increase in the weight correction coefficient with increase in molecular weight was found also in the analysis of non-esterified lower fatty acids[92]. When the molecular weight rises above one hundred the correction coefficient tends to a constant value.

By working with fully halogenated and nitrated hydrocarbons, Lovelock ascribed[93] these anomalies of the β-ionisation detector to the capture of free electrons by suitable groups, such as the carboxyl group, which also explains the results of Böttcher[92] and others.

The formula

$$1/K_M = 2.5 \log n - 1.41, \tag{42}$$

where $n$ is the number of carbon atoms in the molecule, has been suggested for calculating the relative correction factor (with respect to nonanoic acid).

TABLE 1. Molar correction coefficients $K_M$ for the $C_1$–$C_6$ hydrocarbons and light gases (relative to n-butane).

| Component | Carrier gas: hydrogen | | helium | | | nitrogen |

* These and the corresponding numerals in later Tables indicate literature references (Ed. of Translation).

The correction coefficients for the β-ionisation detector, with argon as the carrier gas, have been calculated by Simmons and coworkers[94] and by Durrett and coworkers[95].

Condon and coworkers[96] determined the weight correction factors (relative to n-butanol) for a number of alcohols.

When a gas not susceptible to metastable ionisation is used as the carrier, the sensitivity of this detector approaches that of the katharometer. Under these conditions the relative weight corrections are easily calculated by the formula

$$K_B = \frac{M_i(\sigma_{st} - \sigma_0)}{(\sigma_i - \sigma_0)M_{st}}, \tag{43}$$

where $\sigma_0$, $\sigma_i$, and $\sigma_{st}$ are the ionisation cross-sections of the carrier gas, the wanted compound, and the standard.

Otvos and Stevenson[97] showed that the ionisation cross-sections are additive, and can be calculated from the appropriate increments (which equal 4.16 and 1.00 for carbon and hydrogen respectively).

## Combustion Tube

The quantitative interpretation of gas chromatograms is made easier if a combustion tube is provided as an attachment to the detector. When the components are converted into carbon dioxide or methane, the weight coefficients are readily calculated by formula (41):

$$K_B = \frac{M_i n_{st}}{n_i M_{st}},$$

where $n_i$ is the number of carbon atoms in the molecule of the $i$th component. For benzene as the standard,

$$K_B = \frac{M_i}{n_i} \times 0.077.$$

These correction coefficients are independent of the type of detector and of the nature of the carrier gas.

## Other Detectors

Information has been published on the correction coefficients of other detectors. Wirth[98] and Bredel[99] have shown that the relative molar correction coefficient for the flame temperature detector is the ratio of the heats of combustion. With other detectors there appears to be no simple systematic relationship between the signal and the nature of the substance for analysis[100,101].

## I. INTRODUCTION

Advances in the chemistry and technology of the rarer elements have set research workers a number of problems involving investigations into the state of ions from high-valency elements in solution. Generally, such ions cannot exist in the free state in aqueous solutions, owing to their relatively high ionic potential, and undergo hydrolysis or form complexes with various ligands; the formation of hydrolysed polymeric species is also characteristic of these ions.

The state of ions of high-valency elements greatly affects their reactivity with various reagents and the composition of the reaction products. This is of particular importance in analytical chemistry and in the hydrometallurgical processing of ores where one requires to separate metals, to isolate them from solution, and to obtain compounds or reaction products having a specific composition.

The nature of the reactions between complex ions [for example, $TiO_2^{2+}$, $Zr(OH)_x^{(4-x)+}$, $NbO_2^+$, $MoO_4^{2-}$, $WO_4^{2-}$, etc.] or polymeric species and various ligands, and thus the compositions and properties of the complexes formed, depends to a great extent on the state of the highly-charged ions in solution under given conditions; in addition, there may also be changes in the degree of hydrolysis or polymerisation of high-valency ions during the complex formation process [1].

To elucidate the formation mechanism and the true composition of complexes formed from highly-charged ions we must study the state of the latter under complex-forming conditions, as well as the changes which take place with highly-charged ions in the complex-forming process itself. Only by taking such data into account is it possible to determine that most important characteristic of complexes, their stability constants.

The principal characteristics of the states of high-valency ions in solutions are the sign and magnitude of the charge, the degree of hydrolysis, the polymerisation factor, and the composition and stability of complexes containing different ligands.

These characteristics can be determined by ion-exchange chromatography using ion exchangers having different chemical and physical properties.

## II. QUALITATIVE DETERMINATION OF THE FORM IN WHICH THE ELEMENT BEING STUDIED EXISTS IN SOLUTION

The absorption of the element under investigation by strongly acid cation exchangers is direct evidence of the existence of cationic species in a solution, but if the investigation is carried out in highly acid solutions then the presence of large amounts of foreign ions (for example, $H^+$) can lead to a shift in the equilibrium towards the displacement of ions of the element from the cation exchanger. For example, while it has been established in a number of investigations that $Ti^{IV}$, [2-6] $Zr^{IV}$, [2] and $Mo^{VI}$ [7] are hardly absorbed at all by cation exchangers in 1 *N* HCl, 3 *N* HCl, and 3 *N* $HNO_3$ respectively, electromigration experiments [8-10] have shown convincingly that Ti,[8] Zr,[9] and Mo [10] exist predominantly as cationic species in these media; the predominance of the cationic species $ZrCl^{3+}$, $ZrCl_2^{2+}$, and $ZrCl^+$ in 3 *N* HCl also depends on the stability constants of the zirconium chloro-complexes [11].

Account should be taken of the possibility of disturbing the equilibrium between the various ionic species during the absorption of the element by cation exchangers. For example, at pH 3–5 there is a marked absorption of sexivalent molybdenum ions by cation exchangers [10] although electromigration experiments [7], the determination of the isoelectric point of molybdic acid by a solubility method [7,12] as well as a calculation from the dissociation constants of molybdic acid [13] show that at this acidity practically all the Mo is present as hydrogen molybdate and molybdate ions or as isopolymolybdates [14-16].

Similar complications arise in the absorption by anion exchangers of the element being studied. For example, at pH > 12 $Mo^{VI}$, $Mo^V$, $Ta^V$, and $Ge^{IV}$ are not absorbed by anion exchangers due to competition from $OH^-$ ions although under these conditions these elements occur in solution as monomeric or polymeric anions of molybdic [10,14-16], niobic [17,18], tantalic [17,19,20], and germanic [21] acids. The competing effect of foreign ions can lead to false conclusions, particularly when studying low-stability complexes formed at high ligand concentrations, for under these conditions the ligand itself can be an ion displacer. For example, it has been established in a number of studies that an increase in sulphate ion concentration above a certain level leads to a reduction in the absorption of $Ti^{IV}$, [22] $Zr^{IV}$, [23] and $Nb^V$ [23] by anion exchangers, although electromigration experiments [8,24] show that under these conditions these elements are present in solution as anionic sulphato-complexes.

Similar equilibrium disturbances are found in anion exchange. For example, $Mo^{VI}$ is appreciably absorbed by anion exchangers in 0.2–1.0 *N* nitric acid [7] although molybdenyl cations predominate under these conditions [10].

Furthermore, anion exchangers containing $-NH_2$, =NH, or ≡N groups can absorb metal salt molecules to form complexes with the amino-groups of the resins. Such processes are characteristic of compounds of elements capable of coordinating with nitrogen atoms in various reagents. For example, it has been established that there is marked absorption of Cu, Co, Ni, Cd, and Zn by different types of anion exchangers from weakly acidic solutions, in which cationic species of these elements predominate [25]. The absorption under these conditions is due to the formation of complexes having the composition $[R_2M(H_2O)_2]X$, where R is an anion exchanger containing $-NH_2$, =NH, or ≡N, M a doubly-charged metal cation, and $X^-$ represents $Cl^-$ or $NO_3^-$.

The method of effluent curves is also used for making a qualitative determination of the form in which an element exists in solution [26]. Here one analyses successive individual portions of the test solution flowing from a column containing a cation or anion exchanger. If only ionic species are present in solution, then on passing a known volume of the solution through an ion-exchange column the ions under investigation are found to emerge in the filtrate, their concentration in individual portions of the filtrate increasing gradually and reaching a value equal to that in the initial solution. Such a curve has been obtained, for example, in the absorption of oxalato-complexes of Nb by EDE-10 anion-exchange resin† (curve *1*, Fig. 1) [26]; Nb is not absorbed under these conditions by KU-2 cation-exchange resin‡ (curve *2*, Fig. 1). If neutral molecules are present in solution the substance under investigation is not absorbed by ion exchangers, the effluent curve *2* in Fig. 1 being characteristic of this case. If colloidally dispersed particles predominate in the solution, however, then the adsorption is physical in nature, that is, it is independent of the charge sign of the active groups in the ion exchanger; in this case the effluent curves have the form of curves *3* and *4* in Fig. 1. Similar curves are obtained for colloidally dispersed particles of niobium hydroxide on an anion exchanger (curve *3*) and a cation exchanger (curve *4*) [26].

If there are several forms of the element in solution then it is impossible to detect the presence of the several different species from the first effluent curve, in which

† EDE-10 is a polyfunctional weakly or strongly basic anion-exchange resin prepared by the condensation of polyethylenepolyamines with epichlorohydrin, and contains secondary, tertiary, and quaternary nitrogen groups (Ed. of Translation).

‡ KU-2 is a monofunctional, strongly acid cation-exchange with $-SO_3H$ active groups, prepared by treating a swollen styrene-divinylbenzene copolymer with chlorosulphonic acid, then saponifying the sulphonyl chloride (Ed. of Translation).

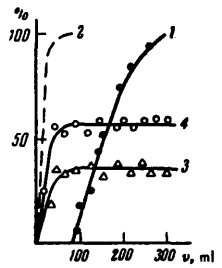

Fig.1. Relationship between the $Nb^V$ concentration in the filtrate and the volume of solution passed through the column (for microconcentrations of niobium)[26]:
1) effluent curve for EDE-10 anion-exchange resin;
2) on KU-2 cation-exchange resin in oxalate solution;
3) effluent curve for EDE-10 anion-exchange resin;
4) on KU-2 cation exchanger in $NaNO_3$ solution.

case "secondary" effluent curves are obtained. For this purpose the filtrate solutions remaining after recording the primary curve are passed through a cation or anion exchanger not containing the ions under investigation. For example, the primary and secondary effluent curves obtained on passing a solution of niobium in 1 *N* $HNO_3$ through an ion exchanger[26] are shown in Fig. 2; the nature of the curves indicates that under these conditions electrically neutral complexes of Nb which are hardly absorbed at all by the cation or anion exchanger (curves *c'*, *a'*, *c''*, *a''*, Fig. 2) and colloidal Nb species whose absorption is physical in nature (curves *c*, *a*, Fig. 2) are present in equilibrium in the solution.

Colloidal species of an element can only be detected by the effluent-curve method in microconcentrations, where the number of colloidal particles physically adsorbed on

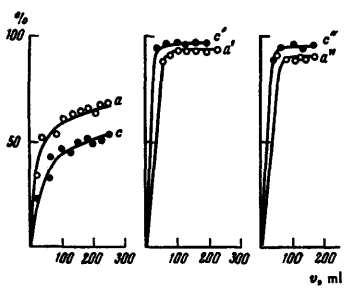

Fig.2. Effluent curves for micro-amounts of niobium in 1 *N* $HNO_3$:[26] *c*), *a*) are the first effluent curves on a cation exchanger (*c*) and an anion exchanger (*a*); *c'*), *a'*) are the secondary effluent curves after the cation exchanger on a cation exchanger (*c'*) and an anion exchanger (*a'*); *c''*), *a''*) are the secondary curves after the anion exchanger on a cation exchanger (*c''*) and an anion exchanger (*a''*).

the surface of the ion-exchanger granules represents an appreciable fraction of the total amount of the element concerned. For these reasons (equilibrium displacement, competition from foreign ions, etc.) the results of investigations by the effluent curve method can indicate only the presence of certain ionic species of the element under investigation in a given system; it is impossible, however, to show that these species predominate in the solution under the given conditions by this method.

## III. DETERMINATION OF THE MAGNITUDE OF THE IONIC CHARGE

Determining the magnitude of the ionic charge of complex ions formed by hydroxo-cations — $TiO^{2+}$, $Zr(OH)_x^{(4-x)+}$, $NbO_2^+$, etc. — can frequently serve as one of the principal methods of establishing the composition and formation mechanism of complex ions in solution.

Over the last 7–8 years the ion-exchange method has been used for determining the charge on the sulphato-complexes of uranyl[28], Ge,[29] Nb, and Ti;[30] the oxalato-complexes of Ge,[31] Zr, and Hf;[32] the chloro-complexes of Ru;[33] and the hydroxo-complexes of Ti,[34] germanate[21], isopolyvanadates[35], vanadyl[36], molybdenyl[7], Zr,[37] Pa,[38] and certain polynuclear complexes of Ru.[39]

The methods for determining the magnitude of the ionic charge can be divided into two groups, the first being based on the equivalence and reversibility of ion-exchange reactions and the second being based on the swelling of ion exchangers during the absorption of ions.

### 1. Methods Based on the Equivalence and Reversibility of Ion-Exchange Reactions

The absorption of the ions of an element under investigation $M^z$ by an ion exchanger loaded with ions $M_1^{z_1}$ having a known charge $z_1$ can be expressed by the equilibrium:

$$z_1 M^z + z\overline{R_{z_1}M_1} \rightleftarrows z_1\overline{R_z M} + z M_1^{z_1}. \quad (1)$$§

This equilibrium can pertain to both cation and anion exchange. Three methods are available for determining the required charge magnitude $z$.

The first method is based on determining the exchange capacity of the ion exchanger for the element being studied $M^z$. For this we must know the total exchange capacity of the ion exchanger for an ion $M_1^{z_1}$ having a known charge $z_1$ and then completely displace the equilibrium (1) to the right by saturating the ion exchanger with the ions being studied $M^z$. The charge $z$ is found from the relationship

$$z = \frac{Q}{G}, \quad (2)$$

where $Q$ is the capacity of a given weight of ion exchanger expressed in g-equiv. of absorbed $M_1^{z_1}$ ions, and $G$ the amount of the element $M^z$ in g-moles absorbed by the same weight of ion exchanger.

This method of determining the charge magnitude can involve substantial errors for a number of reasons, the chief ones being as follows. When determining the exchange capacity of an ion exchanger, $H^+$, $Na^+$, or $Ca^{2+}$ ions (for cation exchangers) and $Cl^-$ ions (for anion

§ Both here and subsequently the bar lines indicate the ion-exchanger phase.

exchangers) are usually used as $M_1^{z_1}$. These ions have relatively small radii and therefore readily penetrate into the pores of the ion exchanger to occupy practically all the active sites. In the absorption of high-valency ions or complex ions and polymeric species, however, which have larger ionic radii, these do not always succeed in occupying all the active sites of the ion exchanger. Furthermore, owing to the absorption of $M^z$ ions the concentration of $M_1^{z_1}$ in solution is increased, which prevents the displacement of equilibrium (1) to the right. All of this can lead to excessively high results in the determination of $z$. Finally, a shift in equilibrium (1) towards ion-exchanger saturation by $M^z$ ions is only possible with a substantial increase in the concentration (or absolute quantity) of the latter; this makes it difficult to determine the charge magnitude at low concentrations of the element.

Thus, a determination of the charge by using the total exchange capacity of an ion exchanger is not always reliable. For example, when using this method to find the charge on the cations of quadrivalent zirconium in perchloric acid solutions it was found[40] that the charge on the zirconium ions is increased on lowering the concentration of $HClO_4$, which contradicts the results obtained[41] by using the stability constants of zirconium hydroxo-complexes[42].

The second method is based on the relationship between the number of $M_1^{z_1}$ ions displaced and the charge magnitude $z$ of the absorbed $M^z$ ions. Experimentally this method is carried out by determining concentration changes for the ions under investigation ($\Delta M^z$) and the displaced ions ($\Delta M_1^{z_1}$) on bringing the solution into contact with an ion exchanger $\overline{R_{z_1}M_1}$. The specific charge is calculated from the relationship

$$z = \frac{\Delta M_1^{z_1}}{\Delta M^z}. \qquad (3)$$

where $\Delta M_1^{z_1}$ is expressed in g-equiv. and $\Delta M^z$ in g-moles.

A necessary condition for obtaining reliable results is sufficient sensitivity in determining $\Delta M^z$ and $\Delta M_1^{z_1}$. Most analytical methods enable element concentrations of $10^{-4}$–$10^{-5}$ M and above to be determined in solution. Frequently, however, the charge magnitude has to be determined in the presence of foreign electrolytes whose concentration considerably exceeds the concentration of the element under investigation. In such cases the ion exchanger must first be saturated with ions of the foreign electrolyte. Consequently, while the element ($M^z$) is being absorbed it dislodges from the ion exchanger the foreign electrolyte ions ($M_1^{z_1}$), whose concentration even before absorption was appreciable. Thus, $\Delta M_1^{z_1}$ must be determined at a substantial concentration of $M_1^{z_1}$, which is only possible if the concentration of $M^z$ ions being absorbed is fairly high. A reliable determination of $\Delta M_1^{z_1}$, is possible by changing the concentration of $M_1^{z_1}$ by at least 10%; therefore in determining the charge magnitude from relationship (3) the concentration of the element being studied should be not less than 10% of the concentration of foreign electrolyte (calculated per g-equiv.).

Table 1 shows the results of charge determinations for $Ti^{IV}$ cations at various pH.[34] The values of $z$ show that at pH < 1.17 doubly-charged titanyl cations $TiO^{2+}$ predominate in solution and on raising the pH hydrolysis occurs to form singly-charged cations¶

$$TiO^{2+} + H_2O \rightleftarrows TiO(OH)^+ + H^+. \qquad (4)$$

¶ The absence of titanium poly-ions in solution under these conditions has been proved by a study of the ion-exchange kinetics and by dialysis[43].

TABLE 1. Magnitude of the charge on $Ti^{IV}$ cations*.

| Initial solution | | | Equilibrium solution | | | $z$ |
|---|---|---|---|---|---|---|
| $pH_1$ | $[H^+]_1$ | $[Ti]$ | $pH_2$ | $[H^+]_2$ | $[Ti]$ | |
| 0.50 | $3.16\cdot10^{-1}$ | $4.95\cdot10^{-2}$ | 0.40 | $3.98\cdot10^{-1}$ | $1.25\cdot10^{-2}$ | 2.21 |
| 1.17 | $6.76\cdot10^{-2}$ | $9.46\cdot10^{-2}$ | 1.05 | $8.91\cdot10^{-2}$ | 0 | 2.24 |
| 1.40 | $3.98\cdot10^{-2}$ | $1.20\cdot10^{-2}$ | 1.33 | $4.68\cdot10^{-2}$ | $5.27\cdot10^{-2}$ | 0.99 |
| 5.75 | $1.78\cdot10^{-6}$ | — | 3.50 | $3.16\cdot10^{-4}$ | — | — |

* All concentrations are molar.

A similar principle is used for determining the charge of anions by using anion exchangers. For example, a study of the absorption of germanate ions by IRA-400 anion-exchange resin in the $OH^-$ and $Cl^-$ forms showed[21] that at pH ≃ 9 the absorption of 2.5 moles Ge leads to the displacement of one g-equiv. of $OH^-$ or $Cl^-$ ions. Thus, under these conditions Ge is present in solution as pentagermanate ions $Ge_5O_{11}^{2-}$ (according to these results).

The third method is based on displacing the equilibrium of reaction (1) [27,28] and consists of studying the effect of varying concentrations of $M_1^{z_1}$ on the absorption of the ions being studied, under the conditions $[\overline{R_{z_1}M_1}] \simeq$ const. In this case the equilibrium constant of (1) is

$$K = \frac{[\overline{R_zM}]^{z_1}\,[M_1^{z_1}]^z}{[M^z]^{z_1}} = (K_d)^{z_1}\,[M_1^{z_1}]^z. \qquad (5)$$

Here $K_d$ is the coefficient for the distribution of element $M^z$ between the ion exchanger and the solution, determined from the relationship

$$K_d = \frac{a}{100-a} \times \frac{v}{m}, \qquad (6)$$

where $a$ is the amount of absorbed element in the equilibrium state (%), $v$ is the volume of solution (ml), and $m$ is the weight of ion exchanger (g).

Eqn. (5) supposes that the ratio of the activity coefficients of $M^z$ ions in solution and in the ion-exchanger phase remains constant over a certain range of concentration. Putting Eqn. (5) in logarithmic form we obtain

$$\log K_d = -\frac{z}{z_1}\log[M_1^{z_1}] + \frac{1}{z_1}\log K. \qquad (7)$$

The ratio $z/z_1$ and thus the charge magnitude $z$, can be found from the slope of the curve of $\log K_d$ against $(-\log[M_1^{z_1}])$.

It was indicated above that the condition $[R_{z_1}M_1] \simeq$ const. must be observed while carrying out this method. This means that the amount of ion exchanger taken for each experiment should be fairly high, so that the absorption of $M^z$ is hardly reflected at all in the amount of ion exchanger in the $[\overline{R_{z_1}M_1}]$ form. A determination of the charge magnitude using Eqn. (7) gives reliable results if the amount of $[\overline{R_{z_1}M_1}]$ is changed by not more than 1–2% during the absorption of $M^z$.

This condition can be written in the following form

$$mQ \geqslant v[M^z]z \times 50, \text{ or}$$

$$[M^z] \leqslant \frac{Q}{50z\ v/m}. \qquad (8)$$

Here $[M^z]$ is the molar concentration of $M^z$ in the solution under investigation prior to contacting it with the ion exchanger, $Q$ is the total exchange capacity of the ion exchanger (mg-equiv. $g^{-1}$), $z$ the expected value of the

charge†, $m$ the mass of ion exchanger (g), and $v$ the volume of solution (ml).

To avoid a substantial change in the volume of the solution, arising from the swelling of the ion exchanger, the experiments are usually carried out by observing the relationship

$$\frac{v}{m} \geqslant 50. \qquad (9)$$

Taking condition (9) into account, the concentration of $M^z$ can be readily calculated from Eqn. (8), which ensures that the determination of $z$ by using Eqn. (7) is reliable.

By way of example, the results of charge determinations on $Ti^{IV}$ cations in perchloric acid solutions[34] are shown in Fig. 3. In this case $M_1^{z_1} = H^+$ ($z_1 = 1$), so that the slope of the curve in Fig. 3 relative to the abscissa axis gives the value of $z$ directly. According to Fig. 3, doubly-charged cations predominate in solution at pH < 1, these clearly being titanyl ions $TiO^{2+}$. At higher pH values hydrolysis occurs to form singly-charged $TiO(OH)^+$ cations, which agrees with the data in Table 1.

It is convenient to use the equivalence of ion exchange to determine the charge magnitude for relatively high concentrations of the ions under investigation (of the order of $10^{-2}$ M and above); at lower concentrations (of the order of $10^{-3}$ M and below) we generally employ the equilibrium displacement method.

## 2. Methods Based on the Swelling of Ion Exchangers

In an investigation of ion exchange on swelling ion exchangers it was found[37] that the exchange selectivity of ions having different valency depends very greatly on the swelling power of the ion exchanger. Therefore the amounts of ions absorbed can be expressed in the exchange isotherm equation as equivalent concentrations by including the specific volume of the swollen resin ($V$) in the equation:

$$\frac{g_1^{1/z_1} V^{1/z_1} \bar{f}_1^{1/z_1}}{g_2^{1/z_2} V^{1/z_2} \bar{f}_2^{1/z_2}} = K \frac{C_1^{1/z_1} f_1^{1/z_1}}{C_2^{1/z_2} f_2^{1/z_2}}. \qquad (10)$$

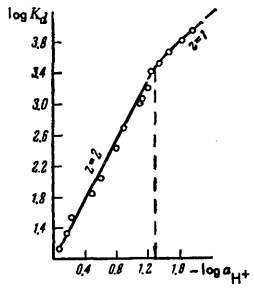

Fig. 3. Effect of the activities of hydrogen ions on the absorption of titanium by KU-2 cation-exchange resin[34]. Initial titanium concentration $2 \times 10^{-4}$ M.

† Usually $z \leqslant 4$ in aqueous solutions.

Here $g_1$, $g_2$ and $\bar{f}_1$, $\bar{f}_2$ are the equivalent amounts of ions absorbed by the ion exchanger and their activity coefficients in the ion-exchanger phase respectively; $C_1$, $C_2$ and $f_1$, $f_2$ are the concentrations and activity coefficients of the exchanging ions in solution respectively; $z_1$ and $z_2$ are the ionic charges.

If one of the exchanging ions is a microcomponent ($g_1$), then the specific capacity of the ion exchanger for the macrocomponent ($g_2$) is equal to the total specific capacity of the resin and the concentration of macrocomponent in solution ($C_2$) will be the constant total concentration of the solution. In this case the activity coefficients of the ions in solution remain constant.

The distribution of microcomponent under investigation between the solution and resin is given by the coefficient:

$$K_{d_1} = \frac{g_1}{C_1} = K' \frac{g^{z_1/z_2} \bar{f}_2^{z_1/z_2}}{C^{z_1/z_2} \bar{f}_1 V^{z_1 - z_2/z_2}}. \qquad (11)$$

Eqn. (11) shows how the distribution coefficient of the element under investigation depends on the specific capacity of the resin ($g$), the total concentration of the solution ($C$), the specific volume of the resin ($V$), and the activity coefficients of the ions in the ion-exchanger phase. It follows from this equation that for $z_1 = z_2$ the distribution coefficient of the element is independent of the swelling power of the resin.

The selectivity in the absorption of the element under investigation on to two resin samples having different swelling powers can be expressed by the relative exchange selectivity coefficient $\beta_1$:

$$\beta_1 = \frac{K_{d_1}^{\mathrm{I}}}{K_{d_1}^{\mathrm{II}}} = \left(\frac{g^{\mathrm{I}}}{g^{\mathrm{II}}}\right)^{z_1/z_2} \left(\frac{V^{\mathrm{II}}}{V^{\mathrm{I}}}\right)^{z_1 - z_2/z_2} \left(\frac{\bar{f}_2^{\mathrm{I}}}{\bar{f}_2^{\mathrm{II}}}\right)^{z_1/z_2} \left(\frac{\bar{f}_1^{\mathrm{II}}}{\bar{f}_1^{\mathrm{I}}}\right). \qquad (12)$$

In this equation the indices I and II relate to resin samples having different swelling powers. It has been found experimentally that the activity coefficients of ions in the resin phase are independent of its swelling power, so that the ratio of the activity coefficients in Eqn. (12) is unity. For investigations in which resins having different swelling powers and the same total specific capacity ($g^{\mathrm{I}} = g^{\mathrm{II}}$) are used, Eqn. (12) assumes the form

$$\frac{K_{d_1}^{\mathrm{I}}}{K_{d_1}^{\mathrm{II}}} = \left(\frac{V^{\mathrm{II}}}{V^{\mathrm{I}}}\right)^{z_1 - z_2/z_2}. \qquad (13)$$

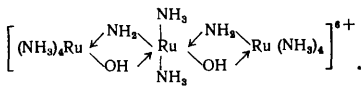
Using univalent ions as the macrocomponent ($z_2 = 1$) the equation for determining the charge has the form:

$$z = \frac{\log \dfrac{K_d^{\mathrm{I}}}{K_d^{\mathrm{II}}}}{\log \dfrac{V^{\mathrm{II}}}{V^{\mathrm{I}}}} + 1. \qquad (14)$$

To determine $z$ we must have two resin samples of different swelling powers and the same specific capacity. In essence the experiment consists of determining the distribution coefficients $K_d^{\mathrm{I}}$ and $K_d^{\mathrm{II}}$ for the element under investigation on the two resin samples under strictly identical conditions; the specific volumes $V^{\mathrm{I}}$ and $V^{\mathrm{II}}$ of the swollen resins are determined pyknometrically under the same conditions. The concentration of the element should be at least 100 times less than the concentration of macrocomponent ions, in order to obtain reliable results.

As an example, the results of charge magnitude determinations for $Zr^{IV}$ ions in nitric acid solutions[37] are presented in Table 2. They show that quadruply-charged $Zr^{4+}$

TABLE 2. Determination of the magnitude of the charge on $Zr^{IV}$ ions as a function of nitric acid concentration[37].



| $[HNO_3]$, $N$ | pH | $K_d^I$ on a resin containing 12% divinylbenzene | $K_d^{II}$ on a resin containing 2% divinylbenzene | $V^I$ ml $g^{-1}$ | $V^{II}$ ml $g^{-1}$ | $z$ |
|---|---|---|---|---|---|---|

| — | 1.8 | 805 | 710 | 0.720 | 1.19 | +1.12 |

ions are formed only over a narrow range of acid concentrations (2–2.5 $N$); the charge is reduced at higher $NHO_3$ concentrations owing to the formation of nitrato-complexes of Zr, and at lower acid concentrations due to the hydrolysis of Zr cations.

### 3. Some Special Aspects of Determining the Charge Magnitude of High-Valency Ions.

High-valency ions generally exhibit a strong tendency towards complex-forming reactions. Therefore, in certain cases, as was indicated earlier, they may be absorbed by ion exchangers by a molecular mechanism, which makes it impossible to determine their charge. To avoid such complications when determining the magnitude of the ionic charge it is necessary to use strongly acid cation exchangers containing active $-SO_3H$ groups (KU-2 or Dowex 50) and strongly basic anion exchangers containing active $\equiv\overset{+}{N}-OH$ groups (AV-17‡ or Dowex 1). These ion exchangers absorb high-valency ions virtually only by an ion-exchange mechanism.

In determining the charge magnitude of poly-ions the treatment of the results obtained by any of the methods described above depends on the method by which the amount of element absorbed by the ion exchanger is determined. If the total amount of absorbed element is determined in g-atoms then the result obtained is the value of the specific charge, that is, the charge attached to one atom of the element concerned in the poly-ion. The determination of the charge magnitude of polygermanate ions[21] mentioned above may be quoted as an example. However, if we determine the amount of absorbed poly-ions of the element under investigation by some method then we obtain the value of the effective (overall) charge of the poly-ion§. This quantity was obtained, for example, in a determination of the charge on the polynuclear complex Ru ion[39].

‡ AV-17 is a strongly basic anion-exchange resin containing quaternary nitrogen groups. It is based on styrene and trimethylamine (Ed. of Translation).

§ In the absence of poly-ions the specific charge is also the effective charge of the complex ion.

In this case the change in the concentration of the polynuclear complex in solution during absorption by a cation exchanger was determined spectrophotometrically from the characteristic maximum in the absorption spectrum of the polynuclear complex.

When low-stability complexes are formed in solution the degree of bonding of a highly-valent element in the complex depends on the excess concentration of ligand (in the case of hydroxo-complexes, on the pH). At the same time the ligand concentration in solution can differ considerably from that in the ion-exchanger phase[45]. For example, it has been found experimentally[46] that for the cation exchanger Dowex 50, with 1–2 $N$ HCl in the aqueous phase, the concentration of HCl in the ion-exchanger phase was 0.09 and 0.2 $N$ respectively. This gives reason to suppose that the state of highly-valent elements in the ion-exchanger phase may differ from that in the solution.

Nevertheless, under certain experimental conditions it is possible to obtain results which will yield the charge magnitude of the ions in solution. Let us suppose that in the absorption of a polymeric action $M_p(OH)_x^{(pq-x)+}$ by a cation exchanger the poly-ion dissociates and there is a change in the degree of hydrolysis, which leads to the formation of a cation $M(OH)_{\frac{x}{p}+y}^{\left(q-\frac{x}{p}-y\right)+}$ in the ion-exchanger phase ($q$ is the valency of the central metal). This process can be represented by the equilibrium

$$M_p(OH)_x^{(pq-x)+} + p\left(q-\frac{x}{p}-y\right)\overline{RH} + py\,H_2O \rightleftarrows \rightleftarrows p\,\overline{R_{q-\frac{x}{p}-y}M(OH)_{\frac{x}{p}+y}} + z\,H^+. \quad (15)$$

A similar equation can be written for any change in the polymerisation factor $p$ or for the similar case of only monomeric ions ($p$ = 1) being present in solution.

The absorption of the complex $M_pA_x^{(pq-x)-}$ by an anion exchanger to form a complex $MA_{\frac{x}{p}+y}^{\left(q-\frac{x}{p}-y\right)-}$ in the ion-exchanger phase can be expressed by the equilibrium

$$M_pA_x^{(pq-x)-} + p\left(q-\frac{x}{p}-y\right)\overline{RA} \rightleftarrows p\,\overline{R_{q-\frac{x}{p}-y}MA_{\frac{x}{p}+y}} + z\,A^-. \quad (16)$$

A similar equation can be written for any change in the polymerisation factor $p$ and the ratio M : A. It is readily seen that in Eqns. (15) and (16) $z = pq - x$, that is, the number of cations or anions displaced by ion exchange is equivalent to the charge in solution of the ions under investigation.

Eqns. (15) and (16) show that to determine the magnitude of the charge on ions present in solution it is necessary to use ion exchangers loaded with ions which are present in the complex ion being studied, or are connected by a chemical equation with ions present in it. In Eqn. (16) these are the $A^-$ ions, in Eqn. (15) they are the $H^+$ ions connected with $OH^-$ ions by the chemical equation $H^+ + OH^- \rightleftharpoons H_2O$.

This condition is not guaranteed when determining the charge on complex ions having high stability, whose composition cannot be changed with differences in ligand concentration in solution and in the ion-exchanger phase.

When determining the charge magnitude of ions one frequently has to deal with solutions containing ions having

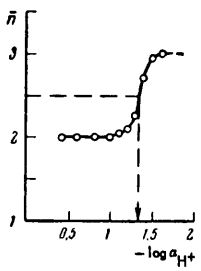

Fig.4. Relationship between $\bar{n}$ and the acidity of the medium in the formation of the hydroxotitanyl complex (calculated from the curve in Fig.3)[34].

different charge magnitudes in equilibrium. On contacting such a solution with an ion exchanger, ions having the higher charge will be absorbed first, and this can lead to a considerable disturbance in the equilibrium between the various ionic species. However, this disturbance in equilibrium is equivalent to the change in the composition of the ions in the ion-exchanger phase, so that by observing the conditions given above we obtain the mean charge magnitude of the ions in solution prior to absorption at given concentration conditions.

The results of charge magnitude determinations for ions can, in certain cases, be used to calculate the instability constants of the complexes. It follows from Eqn. (7) that

$$z = z_1 \frac{\Delta \log K_d}{\Delta \log [M_1^{z_1}]}. \qquad (17)$$

In complex formation involving a metal cation $M^{q+}$ ($q$ being the valency of the metal) the relationship between the Bjerrum formation constant $\bar{n}$ and the charge of the complex ion is expressed by the equation

$$\bar{n} = q - z = q - z_1 \frac{\Delta \log K_d}{\Delta \log [M_1^{z_1}]}. \qquad (18)$$

If a ligand or another ion, whose concentration is proportional to the ligand concentration, is taken as $M_1^{z_1}$ then it is possible to determine the composition of the complexes formed and their instability constants from the relationship

$$\bar{n} = f([M_1^{z_1}]).$$

This method has been used[34] to determine the instability constants of the hydroxotitanyl complex $TiO(OH)^+$. The variation of $K_d$Ti with pH on KU-2 cation-exchange resin in the hydrogen form was studied, that is, the $OH^-$ ion, whose concentration is connected with the $H^+$ concentration by the ionic product of water was taken as $M_1^{z_1}$. The relationship $\bar{n} = f(\text{pH})$ is shown in Fig. 4; the instability constant of the hydroxotitanyl complex, which is numerically equal to the $OH^-$ concentration at $\bar{n} = 2.5$, was found graphically from this curve:

$$K_{\text{instab}} = \frac{[TiO^{2+}][OH^-]}{[TiO(OH)^+]} = 1.5 \times 10^{-3} \text{ at } 18°.$$

A similar result has been obtained by the solubility method[34].

## IV. DETERMINATION OF THE POLYMERISATION FACTOR

Two methods can be used for determining the polymerisation factor by using ion exchangers. The first is based on the fact that ion-exchange processes on synthetic ion exchangers obey the law of mass action[47,48], thus making it possible to use the equilibrium displacement method, which enables the coefficients in the chemical equations to be determined. The second method[48] is based on the rate of diffusion of ions within the cation exchanger being a function of their sizes[49] a study of the ion-exchange kinetics thus enabling one to determine the conditions under which the polymeric species exist in solution and, in certain cases, to judge approximately the polymerisation factor of the ions under investigation.

### 1. The Equilibrium Displacement Method

It has been shown in studies of the polymerisation processes of Zr, Nb, Ta ions[17,50,51] that the polymeric species dissociate during the formation of stable complexes. Synthetic ion exchangers may be considered as macromolecular insoluble reagents[52]; with a fairly stable bond between the element under investigation and the ion exchanger (a high $K_d$ value) it may be assumed that the polymeric species will dissociate in the ion-exchanger phase. In this case the ion-exchange reaction can be expressed by the equation

$$pz\overline{RM_1} + M_p^z \rightleftarrows p\overline{R_zM} + pzM_1, \qquad (19)$$

where $M_1$ is a singly-charged ion and $p$ is the polymerisation factor.

It follows from Eqn. (19) that for $[\overline{RM_1}] \simeq$ const and $[M_1] \simeq$ const the distribution coefficient for the element under investigation ($K_d$) between the solution and the ion exchanger depends on the concentration of $M_p^z$. This enables the polymerisation factor $p$ to be determined from the change in total concentration of the element.

Under these conditions the distribution coefficient assumes the form

$$K_d = \frac{G^p}{[M_p^z]} \times \frac{v}{m}. \qquad (20)$$

Here $G$ is the amount of the element, in g-atoms, absorbed by the ion exchanger under the given conditions, $[M_p^z]$ the equilibrium concentration of poly-ions in solution, $v$ the volume of the solution under investigation (ml), and $m$ the mass of ion exchanger (g).

Eqn. (20) shows that $K_d$ depends on the polymerisation factor $p$; a definite value of the distribution coefficient corresponds to each polymeric species, this remaining constant in a series of experiments in which the concentration of the element under investigation varies, if $p$ is not altered.

The equilibrium concentration of polymeric species in solution can be expressed in terms of the total analytical concentration $C$:

$$[M_p^z] = \frac{1}{p} \times C. \qquad (21)$$

Combining Eqns. (20) and (21) we obtain:

$$K_d = \frac{G^p}{\frac{1}{p} \times C} \times \frac{v}{m}. \qquad (22)$$

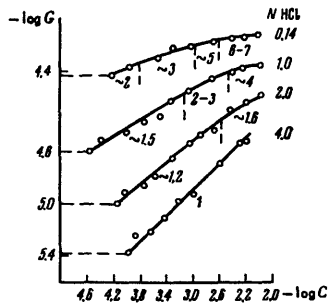

Fig.5. Relationship between the amount of Zr absorbed by KU-1 cation-exchange resin and its equilibrium concentration[48]. The figures under the curves denote the polymerisation factor $p$.

$G$ and $C$ are found experimentally and the ratio $v/m$ is constant in a given series of experiments. Expressing Eqn. (22) in logarithmic form we obtain:

$$p \log G = \log C + \log \frac{1}{p} + \log K'_d. \qquad (23)$$

For a definite constant polymerisation factor ($p$ = const, $K'_d$ = const), Eqn. (23) assumes the form

$$p \log G = \log C + \text{const}. \qquad (24)$$

On plotting $\log G$ against $\log C$ the polymerisation factor $p$ can be determined from the slope of the curve relative to the ordinate axis. If $p$ alters with a change in the concentration ($C$) of $M^z$, then the slope of the curve reflecting the relationship $\log G = f(\log C)$ will alter accordingly.

The results of experiments for $Zr^{IV}$ in perchloric acid solutions[48] are shown in Fig. 5. $H^+$ ions were used as the $M_1$ ions having constant concentration. The experiments were carried out under static conditions using a sulphonated KU-1 cation-exchange resin¶ in the hydrogen form†. The slope of the curves in Fig. 5 relative to the ordinate axis shows that in 4 $N$ $HClO_4$ at zirconium concentrations of $1 \times 10^{-4}$–$1 \times 10^{-2}$ M there are only monomeric species in solution; the polymerisation factor is increased by lowering the acid concentration or increasing the zirconium concentration. Similar results have been obtained by a dialysis method[50].

## 2. Ion-Exchange Kinetics.

Ion-exchange kinetics curves have a varying steepness depending on the rate at which equilibrium is established. A convenient way of comparing the kinetic curves is to determine graphically the time over which half the element being studied is absorbed, compared with the equilibrium state[48]. It has been proposed to call this time the half-equilibrium time and to represent it by $\tau_{\frac{1}{2}}$. Various types of kinetic curves are shown in Fig. 6. Curve *1* corresponds to the absorption by a cation exchanger of $Co^{2+}$ ions, which do not form polymeric species, and curves *2* and *3* to the absorption of zirconium cations for various polymerisation factors. If the transition to the horizontal section on the ion-exchange-kinetics curve occurs over a long interval of time (curve *3*, Fig. 6) then it is necessary to determine the percentage absorption in the equilibrium state ($A$), to read off half this value ($B$) from the ordinate axis and to find the corresponding value of $\tau_{\frac{1}{2}}$ (curve *3*).

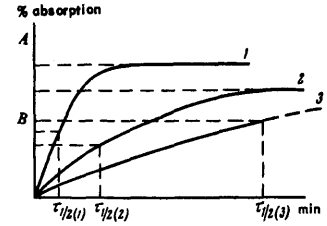

Fig.6. Graphical determination of the half-equilibrium time $\tau_{\frac{1}{2}}$.[48]

TABLE 3. Variation in the polymerisation factor* and the rate of ion exchange of zirconium in perchloric acid solutions[48]. The calculated data obtained from the approximate formula $\tau'_{\frac{1}{2}} p \simeq \tau_{\frac{1}{2}} p'$ are in parentheses.

| $[HClO_4]$, M | Zirconium concentration, M | | | | | |
|---|---|---|---|---|---|---|
| | $1 \times 10^{-2}$ | | $1 \times 10^{-3}$ | | $1 \times 10^{-4}$ | |
| | $\tau_{\frac{1}{2}}$ (min) | $p$ | $\tau_{\frac{1}{2}}$ (min) | $p$ | $\tau_{\frac{1}{2}}$ (min) | $p$ |
| 0.14 | 95 | 8 | 40 | 4 | 22 | 2 |
| 0.50 | 70 | (6) | — | — | 19 | (1.8) |
| 1.0 | 36 | 4 | 28 | 2 | 14 | 1.5 |
| 2.0 | — | 1.6 | 14 | 1.2 | 11 | 1.1 |

* The values of $p$ are taken from Fig.5.

As an illustration, the results of studies on the rate of ion exchange of zirconium cations in perchlorate solutions of KU-1 cation exchanger[48] are shown in Table 3. The data show that the polymerisation factor $p$ and the half-equilibrium time $\tau_{\frac{1}{2}}$ are directly proportional. A similar method has been used in a study of the state of $Ti^{IV}$ in hydrochloric acid solutions[43].

A calculation using the energy characteristics for ion interactions indicates that polyhydroxo-cations are ring-like structures[54]. Therefore it is to be expected that the plot of $\tau_{\frac{1}{2}}$ against $p$ will be a straight line for the formation of polyhydroxo-cations in solution (for example, see Table 3). It is possible that this enables the kinetic method to be used not only for determining the conditions under which poly-ions exist in solution, but also for estimating approximately the mean polymerisation factor of polyhydroxo-cations.

¶ KU-1 is a difunctional, strongly acid cation-exchange resin with $-SO_3H$ and $-OH$ active groups, prepared by the condensation of $p$-phenolsulphonic acid with formaldehyde in acid (Ed. of Translation).

† Zirconium forms fairly stable sulphato-complexes[53], during which the polymeric species dissociate[24]. Therefore it may be assumed that polymeric cations of zirconium dissociate during absorption by a cation exchanger containing active sulphonate groups.

## V. DETERMINATION OF THE COMPOSITION AND STABILITY OF COMPLEXES IN SOLUTION

Ion exchange has been widely used for determining the composition and stability constants of the complexes of many elements, including high-valency elements. For example, it has been used to study the chloro-[11], nitrato-[11,55], sulphato-[56], and oxalato-complexes[57] of $Zr^{IV}$ and $Hf^{IV}$, the complexes of these elements with certain hydroxy-acids[58,59], the chloro-complexes of $Ru^{IV}$,[60] the oxalato-complexes of $Pu^{IV}$,[57] and the nitrato-complexes of $Th^{IV}$.[61]

The theory and practice of studying complex formation under static conditions using cation exchangers[59,62-66] and anion exchangers[66-69], as well as the study of complex formation under dynamic conditions[70-72], are described in sufficient detail in the literature. In this review we shall restrict ourselves merely to setting out the principles of carrying out an experiment and the basic formulae for the methods of Schubert[62-64], Fronaeus[65], and Paramonova[66], which have been most widely used.

Schubert's method[62,63] is used for studying systems in which only one complex, which is not absorbed by a cation exchanger, is formed. An indication of the formation of a single complex over a certain range of ligand concentration is a linear relationship for $1/K_d = f([A^{y-}])$, where $K_d$ is the distribution coefficient of the element under investigation between the cation exchanger and the solution, and $[A^{y-}]$ is the equilibrium ligand concentration. It can be shown[64] that when working with microconcentrations of the element under investigation in the presence of a macroconcentration of singly-charged ions, the stability constant of a complex formed by the reaction $M + nA \rightleftharpoons MA_n$ can be calculated from the formula

$$\beta_n = \frac{[MA_n]}{[M][A]^n} = \frac{K_{d_0}/K_d - 1}{[A]^n}. \quad (25)$$

Here $K_{d_0}$ and $K_d$ are, respectively, the distribution coefficients of the element in the absence of the ligand A and in the presence of different concentrations of it. Putting Eqn. (25) into logarithmic form, we obtain

$$\log(K_{d_0}/K_d - 1) = n\log[A] + \log\beta_n. \quad (26)$$

A graphical plot of relationship (26) enables $n$ to be determined from the slope of the curve relative to the abscissa; the stability constant of the complex is calculated from Eqn. (25).

Fronaeus' method[59,65] is used to study systems in which several complexes are formed, including positively charged complexes which are absorbed by a cation exchanger. An indication of the formation of several complexes over a given range of ligand concentrations is a non-linearity for the relationship $1/K_d = f([A^{y-}])$.

For a reaction between a central ion $M^{q+}$ and a ligand $A^{y-}$ to form the complexes $MA^{(q-y)+}$, $MA_2^{(q-2y)}$, and $MA_3^{(q-3y)}$, of which the first is markedly absorbed by the cation exchanger, the stability constants are calculated from the following equations:

$$\varphi = \frac{K_{d_0}/K_d - 1}{[A]} = \frac{\beta_1 - l + \beta_2[A] + \beta_3[A]^2}{1 + l[A]}, \quad (27)$$

$$f = \frac{K_{d_0}/K_d\{(\beta_1 - l)[A] - 1\} + 1}{[A]^2} = \beta_1\varphi - x, \quad (28)$$

$$x = \beta_2 + \beta_3[A], \quad (29)$$

$$\frac{\Delta f}{\Delta[A]} = \beta_1\frac{\Delta\varphi}{\Delta[A]} - \beta_3. \quad (30)$$

In these equations $K_{d_0}$ and $K_d$ are the distribution coefficients of the element under investigation between the cation exchanger and the solution in the absence and presence of the ligand respectively, [A] is the equilibrium ligand concentration, $\beta_n$ are the cumulative stability constants of the complexes, $l$ is a quantity which takes account of the absorption of the complex $MA^{(q-y)+}$, $\varphi$ and $f$ are the Fronaeus functions, $\Delta\varphi = \varphi - \varphi_0$, $\Delta f = f - f_0$. Experimentally one determines the values of $K_d$ and $K_{d_0}$‡ for a constant ionic strength of the solution observing the condition $[M]_{total} \ll [A^{y-}]$§.

It follows from Eqn. (27) that

$$\lim_{[A]\to 0}\varphi = \beta_1 - l = \varphi_0.$$

Substituting the value of $\beta_1$-$l$ obtained in formula (28) enables the function $f$ to be calculated at different ligand concentrations. The value of $f_0$ is found graphically by extrapolating relationship (28) to zero ligand concentration. By having a number of values of $\varphi$ and $f$ for different ligand concentrations, $\beta_1$ and $\beta_3$ can be determined from Eqn. (30):

$$\lim_{\frac{\Delta\varphi}{\Delta[A]}\to 0}\frac{\Delta f}{\Delta[A]} = -\beta_3, \qquad \frac{\Delta f}{\Delta[A]}\Big/\frac{\Delta\varphi}{\Delta[A]} = \beta_1.$$

$\beta_2$ is calculated from Eqns. (28) and (29).

It is also possible to use the Fronaeus method for calculating stability constants in the more complicated case where four complexes are formed in the system concerned. An example of such a calculation may be found in a paper dealing with the chloro-complexes of $Zr^{IV}$.[11]

Paramonova's absorption curve method[66] provides for the use of both cation and anion exchangers for studying complex formation processes, the method leading to a way of expressing the experimental results which enables data obtained for both types of resin to be compared. In this method one studies the absorption of micro- or semimicro-concentrations of an element by cation and anion exchangers from solutions having constant ionic strength and constant salt composition, but differing from each other in ligand concentration. The experimental results are expressed in relative units of absorption of the element by the cation exchanger $\gamma_+ = g_M/g_M^\circ$ and the anion exchanger $\gamma_- = g_{MA}/g_{MA}^\circ$, where $g_M^\circ$ is the maximal absorption of the element M by the cation exchanger in the absence of ligand A, $g_M$ is the absorption of M by the cation exchanger in the presence of A, $g_{MA}$ is the absorption of M by the anion exchanger from the solution under investigation, and $g_{MA}^\circ$ is the absorption of M by the anion exchanger from a solution in which the concentration of A is so high that the further addition of ligand does not lead to an increase in the absorption of M, since it is already present completely in the form of a coordinatively saturated anionic complex.

‡ $K_{d_0}$ can be determined graphically by extrapolating the relationship $K_d = f([A^{y-}])$ to zero ligand concentration.

§ The total molar concentration of M in the equilibrium solution should not exceed 1–2% of the total molar concentration of $[A^{y-}]$. Furthermore, the concentration of the element under investigation should be considerably less than the concentration of the exchanging ions.

The latter circumstance somewhat limits the range of application of anionic exchange. For low-stability complexes the anionic species are formed only at appreciable ligand concentrations, in which case the ligand may displace anionic complexes of the element under investigation from the anionic exchanger, thus making it difficult to determine $\gamma_-$. In this case, for approximate calculations, the maximum absorption of M attained by the anion exchanger on increasing the concentration of A may be used for $g^{\circ}_{MA}$.

If the concentration of the element under investigation is considerably lower than the concentration of the exchanging ion then it can be shown that $\gamma_+$ and $\gamma_-$ express the fraction of cationic and complex anion species of the element in a given solution. The fraction of the element present in solution in the form of an electrically neutral complex is equal to:

$$\gamma_0 = 1 - \gamma_+ - \gamma_-.$$

When working under static conditions $\gamma_+$ and $\gamma_-$ are calculated from the formula

$$\gamma = \frac{(C_{init} - C)\, C_0}{(C_{init} - C_0)\, C}.$$

Here $C_{init}$ is the concentration of the initial solution, $C$ is the total concentration of M in the equilibrium solution in the presence of the ligand, $C_0$ in the calculation of $\gamma_+$ is the total concentration of M in the solution in equilibrium with the cation exchanger in the absence of the ligand; $C_0$, when calculating $\gamma_-$, is the total concentration of M in the solution in equilibrium with the anion exchanger at that ligand concentration at which all of the element is combined in anionic complexes (or a maximal absorption of M by the anion exchanger is observed).

As an example we present for the simplest cases the formulae for calculating the stability constants of complexes from the experimentally found $\gamma_+$ and $\gamma_-$.

(a) Complex formation taking place according to the equation $M^{z+} + A^{y-} \rightleftharpoons MA^0$. In this case

$$\beta = \frac{[MA^0]}{[M^{z+}][A^{y-}]} = \frac{1-\gamma_+}{\gamma_+[A^{y-}]}. \qquad (31)$$

It follows from Eqn. (31) that the stability constant is numerically equal to $1/[A^{y-}]$ at $\gamma_+ = 0.5$.

(b) Complex formation proceeding according to the scheme $M^{z+} + Ay^- \rightleftharpoons MA^{x-}$ $(y > z)$. In this case

$$\beta = \frac{[MA^{x-}]}{[M^{z+}][A^{y-}]} = \frac{\gamma_-}{\gamma_+[A^{y-}]}. \qquad (32)$$

It follows from Eqn. (32) that $\beta = 1/[A^{y-}]$ at $\gamma_- = \gamma_+$.

(c) Two complexes being formed according to the scheme $M^{z+} + A^{y-} \rightleftharpoons MA^0$, $MA^0 + A^{y-} \rightleftharpoons MA_2^{y-}$. For this system $\beta_1$ is found as in case (a) at those ligand concentrations where there is no anionic complex. The overall stability constant is calculated from the formula

$$\beta_2 = \frac{[MA_2^{y-}]}{[M^{z+}][A^{y-}]^2} = \frac{\gamma_-}{\gamma_+[A^{y-}]^2}. \qquad (33)$$

It follows from Eqn. (33) that $\beta_2 = 1/[A^{y-}]^2$ at $\gamma_- = \gamma_+$.

The methods described above enable the stability constants to be determined for cases where the state of the central ion $M^{q+}$ and the ligand $A^{y-}$ does not change during the complex formation, that is, the reaction between them takes place according to the scheme

$$M^{q+} + nA^{y-} \rightleftarrows MA_n^{(q-yn)}.$$

For complex formation in which hydrolysed cations $M(OH)_x^{(q-x)+}$ participate, the state of the latter may change during complex formation

$$M(OH)_x^{(q-x)+} + nA^{y-} \leftrightarrows M(OH)_{x-n}A_n^{(q+n-yn)} + nOH^-.$$

In this case the above methods only make it possible to determine the equilibrium constants at a given pH.

---o0o---

Arising from certain specific properties of ion exchangers (equivalence of ion exchange, swelling, the diffusion kinetics of exchange) the ion-exchange method can be successfully applied to studying the states of high-valency ions in solution. At the present time ion exchange is the only method which enables the magnitude of the charge on ions in solution to be determined directly by experiment. Ion exchange enables us to study the polymerisation of inorganic compounds in solution in addition to other methods available. In conjunction with other methods ion exchange is a powerful means of studying the complexes of high-valency elements and it enables us to determine the quantitative characteristics of complex formation processes in solution.

## I. INTRODUCTION

In a brief review published a short while ago[1] the first papers on compounds of elements of Group 0 of Mendeleev's Periodic System were considered. The production of a complex of xenon and platinum hexafluoride, $XePtF_6$,[2] of xenon tetrafluoride $XeF_4$,[3-5] and of a radon fluoride of unknown composition[6] was described. Brief mention was also made of the production of xenon difluoride $XeF_2$ [7,8] and xenon hexafluoride $XeF_6$,[9,10] some information was given about the chemical and physical properties of these substances, and the first attempts at a theoretical explanation of the formation of chemical bonds by the atoms of the Group 0 elements[11,12] were discussed.

The first successful investigation stimulated a further, quite intensive development of work in this direction, and in a comparatively short time the experimental and theoretical material has become so voluminous that it seems opportune to attempt to give a more complete review of the present state of the investigations in the field of compounds of the Group 0 elements.

In both the Russian and foreign press a series of articles has appeared already, devoted to complete or partial reviews, sometimes popular in nature[13-31]; however, these articles do not illuminate in sufficient detail all the available material.

The present review covers the literature available to the author up to 1 October 1964. It is expedient to start by considering the compounds of xenon, since the overwhelming majority of studies are devoted to them and at present they are the most thoroughly investigated.

## II. COMPOUNDS OF XENON

### A. Fluorides

1. Xenon difluoride. Several methods for obtaining xenon difluoride $XeF_2$ have been described. Smith[8] synthesised $XeF_2$ by the reaction of gaseous xenon (partial pressure 60 mmHg) and fluorine (240 mmHg) in a nickel circulating system at 400° or above. Weeks and coworkers[32] obtained $XeF_2$ by irradiation of a mixture of fluorine and xenon with ultraviolet light from a high-pressure mercury lamp. Mixtures with $F_2$ : Xe molar ratios from 0.91 to 5.20 were used, circulated in a nickel apparatus with sapphire

windows at room temperature and a pressure of 890–1030 mmHg. The xenon difluoride was condensed in a trap at -78°C; under these conditions pure $XeF_2$ is obtained, but without a trap $XeF_4$ is also formed[33]. Further photochemical reaction of fluorine with $XeF_2$ leads to the formation of $XeF_4$. The quantum yield of $XeF_2$ is 0.3–0.7 but is somewhat less if the pressure is raised, especially the fluorine pressure. The following mechanism is proposed[33] for the photochemical formation of $XeF_2$:

$$F_2+h\nu \rightarrow 2F,$$
$$2F+F_2 \rightarrow 2F_2,$$
$$2F+Xe \rightarrow F_2+Xe,$$
$$F+Xe+F_2 \rightarrow XeF+F_2,$$
$$F+Xe+Xe \rightarrow XeF+Xe,$$
$$XeF+F \rightarrow XeF_2,$$
$$XeF+XeF \rightarrow XeF_2+Xe,$$
$$XeF+XeF \rightarrow 2Xe+F_2.$$

Xenon difluoride is also formed in the irradiation of xenon–fluorine mixtures by $\gamma$-rays from $^{60}Co$ or by high-energy electrons in nickel apparatus[34]. At room temperature and above, mixtures of $XeF_2$ and $XeF_4$ are formed, but at -35°C only $XeF_2$ is obtained.

A method by which pure $XeF_2$ can be obtained in yields of ~ 100 mg $h^{-1}$ was described in detail by Hoppe and coworkers[35]. They passed an electric discharge from an induction coil through mixtures of xenon and fluorine with $Xe : F_2$ molar ratios from 1 : 1 to 1 : 3, at room temperature; $XeF_2$ was condensed on a cold finger at -78°C. The apparatus used is shown schematically in Fig. 1. Xenon from cylinder *1* and fluorine, vaporised from container *2* containing thoroughly purified liquid fluorine, is admitted into reaction vessel *3*, into which pass electrodes from the induction coil, through ground joints. The $XeF_2$ formed in the reaction is condensed on cold finger *4*, cooled by a mixture of alcohol and solid carbon dioxide, and occasionally shaken off into ampoule *5* for weighing.

Khutoretskii and Shpanskii[36] proposed a simple method of synthesising $XeF_2$; they showed that it is formed from the elements at ordinary temperature and increased pressure, with liberation of heat (~ 40–60 kcal $mole^{-1}$) and sometimes even explosively. The experiments were made in nickel, stainless steel, or Monel vessels; fluorine was introduced first into the reactor to a pressure of 18 atm, then xenon was added to a pressure of 35 atm; reaction was almost instantaneous.

A somewhat different method, not employing elemental fluorine, was used by Milligan and Sears[37], who obtained pure $XeF_2$ by passing a high-potential discharge through an

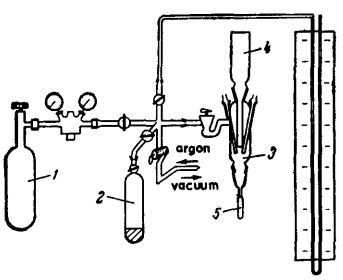

Fig. 1. Apparatus for preparing xenon difluoride[35].

Fig. 2. Crystals of xenon difluoride (a millimetre scale is shown below).

approximately equimolar mixture of xenon and carbon tetrafluoride in a Pyrex glass vessel cooled with a mixture of solid carbon dioxide and acetone, then distilling and recrystallising the reaction products.

The $XeF_2$ in the experiments described above was identified mass-spectrometrically and by chemical analysis.

Xenon difluoride is a colourless solid with vapour pressure 3.8 mmHg at 25°C and 318 mmHg at 100°C.[8,38] It forms excellent gleaming crystals, which grow in a few hours to millimetre dimensions (Fig. 2). The crystals exhibit double refraction. Solid $XeF_2$ melts at ~ 140°C and can be supercooled to 50°C without solidification[38]. At room temperature $XeF_2$ is stable and can be kept in nickel or quartz vessels for a few months[8]. In sealed glass ampoules, $XeF_2$ can be kept at the temperature of solid carbon dioxide for a long time, but at room temperature, even in the dark, it slowly decomposes, possibly as a result of reaction with the glass[35].

Xenon difluoride has a sharp nauseating odour[35]. It reacts vigorously with methanol and slowly with water[35]. It decomposes in solutions of alkalis (NaOH) and dilute acids ($H_2SO_4$) but the reactions are not particularly violent. Iodine is liberated by the action of $XeF_2$ on an acidified solution of potassium iodide or on moist potassium iodide–starch paper. Decomposition of $XeF_2$ takes place even in kerosene, redistilled and dried over metallic sodium[35]. $XeF_2$ dissolves in anhydrous hydrogen fluoride without decomposition; the solubility at 25°C is ~ 10 moles $XeF_2$ in 1000 g HF.[39] Hydrogen at 400°C completely reduces $XeF_2$ to elemental xenon and hydrogen fluoride[15].

Appelman and Malm[40] investigated the chemical properties of aqueous solutions of $XeF_2$ and the ultraviolet absorption spectra of such solutions. Xenon difluoride forms colourless, slowly hydrolysed aqueous solutions in which the $XeF_2$ is probably present as undissociated molecules, which do not form complex anions with fluoride ions. This, follows, firstly, from the low solubility of $XeF_2$ in water (~ 0.15 M at 0°C), and secondly, from the similarity of the spectra shown in Fig. 3 for an aqueous solution of $XeF_2$ at ~ 5°C and for gaseous $XeF_2$ at 30°C.[40,41]

The distribution coefficient of $XeF_2$ between water and carbon tetrachloride is 2.3 and does not change significantly in 1 M $HClO_4$ or in 4 M $KHF_2$. $XeF_2$ solution is a strong oxidant, which rapidly oxidises HCl to $Cl_2$, iodate to periodate, $Ce^{III}$ to $Ce^{IV}$, $Co^{II}$ to $Co^{III}$, and $Ag^{I}$ to $Ag^{II}$. The redox potential of the $Xe-XeF_2$ system in an acid medium is 2.2 V. The half-decomposition life of $XeF_2$ dissolved in water is ~ 7 h at 0°C, in 1 M $HClO_4$ it falls to ~ 5 h, and in 30% HF to ~ 3 h. When $XeF_2$ solution is made alkaline, it rapidly becomes yellow and the solution decomposes; it was suggested[40] that the yellowing is due to the formation of an oxygen compound of xenon(II).

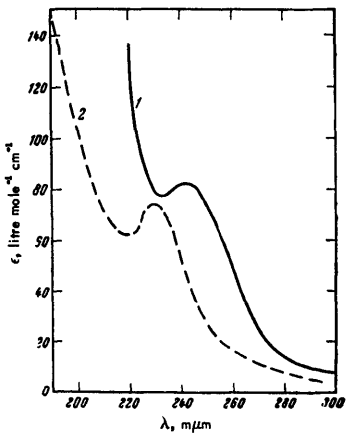

Fig. 3. Ultraviolet absorption spectrum of xenon difluoride: 1) aqueous solution at ~5°C;[40] 2) gas at 30°C.[41]

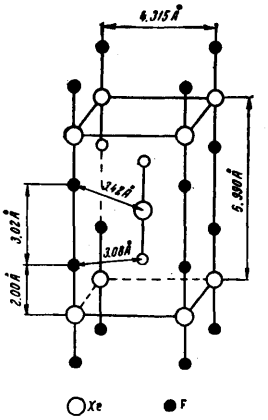

Fig. 4. Crystal structure of xenon difluoride according to neutron diffraction analysis[46].

Xenon difluoride is diamagnetic[35]; its molar magnetic susceptibility is $\chi_M = (40-50) \times 10^{-6}$. The heat of sublimation of crystalline $XeF_2$ is 12.3 ± 0.2 kcal mole$^{-1}$,[42] and was determined from the temperature dependence of the intensity of the spectral bands in the vacuum ultraviolet region of gaseous $XeF_2$ in thermal equilibrium with the crystals[43]. The standard heat of formation of gaseous $XeF_2$, calculated from mass-spectroscopic data, is 37 ± 10 kcal × × mole$^{-1}$,[44] which gives a mean energy of 39 ± 10 kcal × × mole$^{-1}$ for the Xe–F bond in $XeF_2$.

The structure of $XeF_2$ has been studied by X-ray diffraction[45] and neutron diffraction[46] methods. The X-ray studies indicated that $XeF_2$ is tetragonal and has space group $I4/mmm$; the lattice parameters are: $a$ = 4.315 ± ± 0.003, $c$ = 6.990 ± 0.004 Å. The density calculated for two formula units in the unit cell is 4.32 g cm$^{-3}$. The molecule has a linear configuration F–Xe–F and the Xe–F distance is 2.14 ± 0.14 Å.

The neutron diffraction results confirmed these facts, by showing that $XeF_2$ has a body-centred tetragonal lattice (space group $I4/mmm$) of parallel, linear, symmetrical F–Xe–F molecules (Fig. 4). The Xe–F distance is 2.00 ± ± 0.01 Å. Each fluorine atom is associated with another fluorine atom at a distance of 3.02 Å and four fluorines at a distance of 3.08 Å. The least intermolecular Xe–F distance is 3.64 Å.

The infrared spectrum of gaseous $XeF_2$ [8,38] shows two intense bands: at 555 and 213.2 cm$^{-1}$. The first, without a $Q$-branch, relates to the antisymmetric stretching vibration $\nu_3$, and the second, with a distinct $Q$-branch, to the $\nu_2$ bending vibration. A third band, at 1070 cm$^{-1}$, is considered to be a weak $\nu_1 + \nu_3$ combination, including the infrared-inactive band of symmetrical stretching vibrations, $\nu_1$ = 515 cm$^{-1}$.

The $XeF_2$ spectrum is characteristic of a symmetrical linear molecule. The Xe–F interatomic distance, calculated from the $P$–$R$ spacing for $\nu_3$ of 16 cm$^{-1}$ (the maxima of the $P$- and $R$-branches are at 566 and 550 cm$^{-1}$, respectively), is ~1.7 Å. The force constants have been determined: $k_r$ (the constant for the principal stretching vibration) is 2.85, $k_{rr}$ (the constant of stretching interaction) 0.11, and $k_\delta/l^2$ (the constant of bending vibrations)

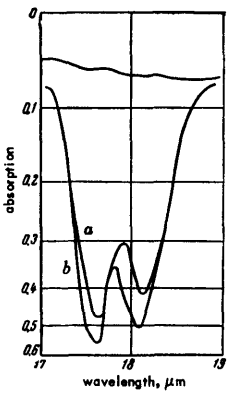

Fig. 5. Infrared spectrum of gaseous xenon difluoride[47]: *a*) pure $XeF_2$; *b*) $XeF_2 + F_2$ (~0.7 kgf cm$^{-2}$).

0.19 mdyn Å$^{-1}$; these values enabled the structure of the $XeF_2$ molecule to be settled (see p. 419).

The main points of the above picture were confirmed by Milligan and Sears[37], who also observed a very weak band at 520 cm$^{-1}$, probably $\nu_1$.

An investigation of the effect of fluorine pressure on the infrared spectrum of $XeF_2$ [47] gave a slightly more accurate $P$–$R$ spacing, 14.2 ± 0.2 cm$^{-1}$, which corresponds to the Xe–F distance of 1.9 Å. The more accurate force constants $k_r$ and $k_{rr}$ are 2.82 and 0.15 mdyn Å$^{-1}$ respectively. Fig. 5 shows the infrared spectrum of gaseous $XeF_2$, according to Smith[47].

The Raman spectrum of solid $XeF_2$ [38] has lines at 108 and 497 cm$^{-1}$. The first is probably a libration frequency, but the second is $\nu_1$. Lines at 548 and 509 cm$^{-1}$ are evidently due to the impurity $XeF_4$.

Investigation of the spectrum of gaseous $XeF_2$ in the far ultraviolet region[43] gave information about the excited electronic levels of the molecule and this was used in

deciding the structure of the $XeF_2$ molecule (see p. 420). Kuznetsov and coworkers[48] investigated the spectrum from a high-frequency discharge through $XeF_2$ vapour; the bands found belonged to $XeF_2$ and XeF molecules.

Nuclear magnetic resonance has also been used in studying $XeF_2$, the investigation being made in anhydrous hydrogen fluoride[49,50] and in the solid state[50]. At room temperature $XeF_2$ enters into exchange with the solvent, but at -19.5°C this exchange is so slow that the measurements are completely feasible. Fig. 6 shows the magnetic resonance spectrum[49] of $XeF_2$ in HF at -20°C and at a frequency of 56.422 MHz. The chemical shift of $^{19}F$ in $XeF_2$ (for a solution in anhydrous HF) is 629 parts per million relative to $F_2$ [50] and 2.3 parts per million relative to HF[50]; the latter quantity at -20°C is also reported[49] to be 3.3 parts per million. The $^{129}Xe-^{19}F$ coupling constant for $XeF_2$ in HF is 5600 Hz [50] or 5690 Hz.[49] The impossibility of observing the $^{131}Xe-^{19}F$ coupling follows from the electrical asymmetry of the $XeF_2$ structure. The results of the nuclear magnetic resonance investigation of $XeF_2$ in HF confirmed that the $XeF_2$ is present in solution mainly as undissociated molecules.

The shielding constant for solid $XeF_2$ is 612 parts per million (relative to $F_2$) and the width of the resonance line is ~ 6.0 G.[50] The results of the nuclear magnetic resonance studies enable a number of views about the electron density distribution in the $XeF_2$ molecule and about the structure of this molecule to be ruled out. The Mössbauer effect in solid $XeF_2$ has also been studied[51,52].

2. Xenon tetrafluoride. A detailed description of the preparation of xenon tetrafluoride by heating a mixture of xenon and fluorine[3,5] was given in the previous review[1], which also included some information about the physical and chemical properties of $XeF_4$.

Another method, which also looks quite promising for the future preparative studies in the field of Group 0 compounds (see pp. 413 and 417) was employed by Kirshenbaum and his coworkers[53,54], who subjected a mixture of xenon and fluorine to the action of an electric discharge. They used an apparatus similar to that employed earlier for the synthesis of the oxygen fluorides $O_3F_2$ and $O_4F_2$ [55-57] (Fig. 7). The diameter of the reactor was 6.5 cm and the distance between the electrodes (dia. 2 cm) 7.5 cm. The mixture of gases with $Xe : F_2 = 1 : 2$ (by volume) was passed at a rate of 136 $cm^3\ h^{-1}$ (under standard conditions) into the reaction vessel cooled to -78°C, and was quantitatively converted into $XeF_4$. The discharge was varied from

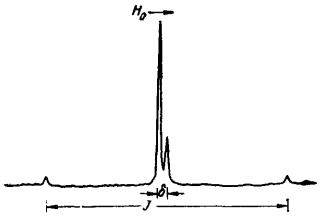

Fig. 6. Magnetic resonance spectrum with high resolution of $^{19}F$ in xenon difluoride at -20°C and frequency 56.422 MHz.[49] The chemical shift of $^{19}F$ relative to $H^{19}F$ is denoted by δ and the spin–spin coupling constant of $^{19}F-^{129}Xe$ is denoted *J*.

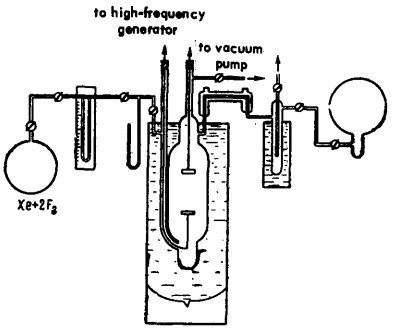

Fig. 7. Apparatus for preparing the fluorides of the Group 0 elements by the electric discharge method[54].

1100 V and 31 mA to 2800 V, 15 mA. In addition to the well-known methods for analysing the reaction products, a new method of determining xenon was employed, based on the quantitative reaction of xenon tetrafluoride with an excess of mercury:

$$XeF_4+4Hg\rightarrow Xe+2Hg_2F_2.$$

Schumacher and Schaefer[58] obtained $XeF_4$ in 97% yield (on Xe) from a mixture of $Xe + 3F_2$, which was circulated in an apparatus (Fig. 8) having a main section heated to 560°C and consisting of a Monel tube furnace packed with pieces of nickel sheet. Up to 20 g $XeF_4$ were obtained in 2 h.

A radiation method has also been used to synthesis $XeF_4$.[59] A mixture of xenon and fluorine in a stainless steel reactor was irradiated with a beam of electrons of energy 1.6 MeV and the reaction products were identified by their infrared spectra, which showed that $XeF_4$ and $XeF_2$ were formed.

The formation of $XeF_4$ (and xenon oxide fluorides) was observed in the reaction of xenon with $OF_2$ in an electric discharge at pressures of 3–62 mmHg and in a nickel tube at 400°C and initial pressure ~ 3.5 atm.[60]

In addition to the chemical properties of xenon tetrafluoride reviewed earlier[1] qualitative investigations[58] have

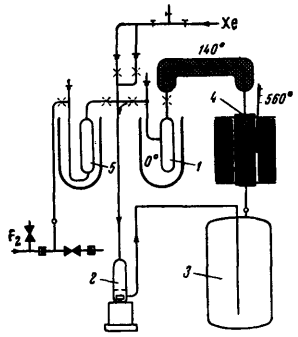

Fig. 8. Apparatus for preparing xenon tetrafluoride by a circulation method[58]:
1) trap at 0°C; 2) Teflon pump; 3) cylinder capacity 4.4 litres; 4) Monel tube furnace packed with nickel sheet; 5) trap.

shown that $XeF_4$ slowly attacks glass with formation of $SiF_4$ and $O_2$; when enclosed in aluminium foil it does not detonate under impact, although mixtures of $XeF_4$ with sugar or sulphur explode like mixtures of these substances with $KClO_3$. On being put on paper or cotton wool, dry $XeF_4$ explodes on heating; $XeF_4$ moistened in air instantly chars paper, which often also ignites spontaneously. Xenon tetrafluoride oxidises, on heating, metallic platinum to $PtF_4$, and possibly to $PtF_6$. $XeF_4$ dissolves in water, glacial acetic acid, concentrated nitric and sulphuric acids, and reacts with these solvents in doing so. In the reaction of $XeF_4$ with $CH_3CO_2H$ or $(CH_3CO)_2O$, a crystalline substance is formed, which the authors[58] think may by xenon acetate. Cyclopentadiene, tetrahydrofuran, dioxan, and ethanol ignite under the action of $XeF_4$; the mixture of vapours often explodes. Acetone does not react immediately with $XeF_4$, but after some time the mixture froths up and the $XeF_4$ dissolves. Petroleum slowly dissolves $XeF_4$, with darkening. In carbon disulphide, carbon tetrachloride, dimethylformamide, diethyl ether, and cyclohexane, $XeF_4$ is insoluble, and it does not react with these substances. $XeF_4$ fumes in air, being hydrolysed to $Xe(OH)_4$. The formation of this compound, which vigorously explodes on being heated to 30–40°C in a vacuum, was noted a little earlier by Bartlett and Rao[61]; according to these authors $Xe(OH)_4$ (or $XeO_2.2H_2O$) is obtained in the hydrolysis of $XeF_4$ by water in an evacuated quartz vessel.

Xenon tetrafluoride dissolves rapidly in potassium iodide solution, with quantitative liberation of xenon[5]:

$$XeF_4+4I^- \rightarrow Xe+2I_2+4F^-.$$

The results of an investigation of the hydrolysis of $XeF_4$ in acid, alkali, and neutral media are not completely reproducible owing to the heterogeneous nature of this reaction. The experimental $Xe:O_2$ ratio found in the reaction products is not 1 : 1, thus indicating a departure from the simple reaction:

$$XeF_4+2H_2O \rightarrow Xe+4HF+O_2.$$

In the hydrolysis of $XeF_4$ in acid and neutral media the yields of xenon and oxygen do not exceed 50 and 70% respectively[62,63]; in 6 M NaOH the yield in each instance is almost quantitative, but the results in 1 M NaOH are the same as in acid and neutral media[63]. Evidently $XeF_4$ disproportionates in solution with the formation of xenon and a soluble compound of xenon(VI). Evaporation of the solution formed by the acid hydrolysis of $XeF_4$ led to the formation of the oxide $XeO_3$ [62] (see p. 414).

The reaction of $XeF_4$ with $SF_4$ leads to the formation of $SF_6$ and elemental xenon; with $O_2F_2$, $XeF_6$ is formed[58]. The reactions of $XeF_4$ with $SbF_5$ and $TaF_5$ give the compounds $XeF_2.2SbF_5$ and $XeF_2.2TaF_5$ [64] (see p. 411); the same compounds are formed in the reaction of $XeF_2$ with the corresponding pentabromides. Xenon tetrafluoride does not react with $BF_3$, NaF, or KF, up to 200°C.[64,65] However, according to Schumacher and Schaefer[58], $XeF_4$ and $BF_3$ form a violet addition product, stable below -100°C.

Xenon tetrafluoride is diamagnetic: the molar magnetic susceptibility at room temperature is $-50.6\times10^{-6}$, but below 240°K the diamagnetism of $XeF_4$ begins, according to Slivnik and coworkers[66], to decrease with fall in temperature. A very close value for the susceptibility, $(-56\pm5)\times10^{-6}$ was found by other authors[67]. Careful measurements of the susceptibility of pure specimens of $XeF_4$ between 77° and 293°K showed, however, that the diamagnetism of $XeF_4$ is independent of temperature in this range; the molar susceptibility of xenon tetrafluoride is $(-53\pm5)\times10^{-6}$; the deviation does not exceed the limits of experimental error[68].

Boudreaux[69] made a theoretical calculation of the magnetic susceptibility of $XeF_4$ in the MO–LCAO approximation, paying special attention to the high-frequency elements of the paramagnetic part of the susceptibility and obtained results which agreed with the experimental data and also confirmed his assumptions concerning the scheme of molecular orbitals[79] (see p. 420).

The problem of the thermodynamic properties of xenon tetrafluoride has received much attention. $XeF_4$ has a high melting point, ~114°C.[15] The heat of sublimation of solid $XeF_4$, determined (just as that for $XeF_2$) from the temperature dependence of the intensity of the spectral bands in the vacuum ultraviolet region of gaseous $XeF_4$ in thermal equilibrium with crystals[43], was found to be $15.3\pm0.2$ kcal mole$^{-1}$.[42]

The heat of formation of solid $XeF_4$ was calculated from the calorimetrically measured heat of reaction of $XeF_4$ with an acidified aqueous solution of potassium iodide[71]. The value found for the standard heat of formation of crystalline $XeF_4$ was -60 kcal mole$^{-1}$, from which the calculated mean energy of the Xe–F bond is 30 kcal. Using the method of reducing $XeF_4$ with hydrogen by the reaction:

$$XeF_4(gas)+2H_2(gas) \rightarrow Xe(gas)+4HF(gas),$$

in an isothermal calorimeter at 120–130°C, preliminary values were found for the heat of formation of gaseous $XeF_4$ and the Xe–F bond energy, -55 kcal mole$^{-1}$ and +32 kcal respectively[72]. The standard heat of formation of gaseous $XeF_4$, calculated from the mass spectrometric result, is $-53\pm5$ kcal mole$^{-1}$,[44] which gives $32\pm2$ kcal for the mean energy of the Xe–F bond.

The heat capacity of solid $XeF_4$ was measured in the temperature range from 20°K to room temperature in an adiabatic calorimeter[73,74]. The preliminary value found for the standard entropy of formation of $XeF_4$ was $\Delta S^\circ = -102.5$ e.u., which, together with the heat of formation[71], gives $\Delta G^\circ = -29.4$ kcal mole$^{-1}$.

The form of the curve of the temperature dependence of heat capacity of $XeF_4$ (Fig. 9) is the same as for molecular crystals, for example, $C_6H_6$, $CO_2$, or $CH_4$. The heat capacity of $XeF_4$ at 298°K is ~28 cal mole$^{-1}$ deg$^{-1}$; the theoretical heat capacity of a molecular crystal of five atoms with six degrees of freedom is ~30 cal mole$^{-1}$deg$^{-1}$.

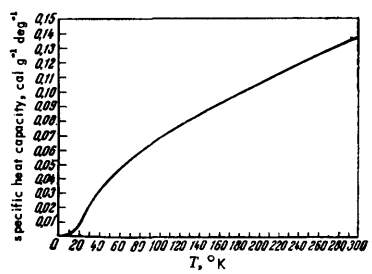

Fig. 9. Curve for the temperature dependence of the specific heat capacity of xenon tetrafluoride[74].

Fig. 10. Crystals of xenon tetrafluoride.

Judging from the heat capacity curve, $XeF_4$ does not undergo phase transformations in the temperature range studied.

From the results on vibrational spectra and structure of $XeF_4$, the thermodynamic functions of $XeF_4$ have been calculated for the range from 50° to 2000°K.[75]

Structural investigations on xenon tetrafluoride have employed X-ray diffraction[45,76-78] and neutron diffraction[79] with single crystals of $XeF_4$ (Fig. 10). The X-ray study[77] showed that $XeF_4$ is monoclinic, space group $P2_1/n$. The lattice parameters of $XeF_4$ are: $a = 5.050$, $b = 5.922$, $c = 5.771$ Å, $\beta = 99.6°$. The density calculated for two formula units in the unit cell is 4.04 g cm$^{-3}$; this agrees with the pyknometric determination[80].

The Xe–F distances are 1.90 and 1.92 Å, the F–Xe–F valency angles are 89.7° and 90.3°. The $XeF_4$ molecule has a square planar configuration with F–F distances of 2.69 and 2.71 Å. The shortest distance between two neighbouring molecules is 3.02 Å.

Neutron diffraction investigation[79] confirmed and somewhat refined the X-ray data. According to the neutron diffraction results, the Xe–F(1) and Xe–F(2) distances are 1.951 and 1.954 Å respectively; the F(1)–Xe–F(2) angle is 90.0 ± 0.1° (Fig. 11). Fig. 12 shows the position of the $XeF_4$ molecules in the crystal.

In a preliminary X-ray structural investigation of $XeF_4$ the existence of yet another polymorphic modification of

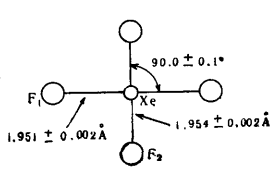

Fig. 11. Crystal structure of xenon tetrafluoride[79].

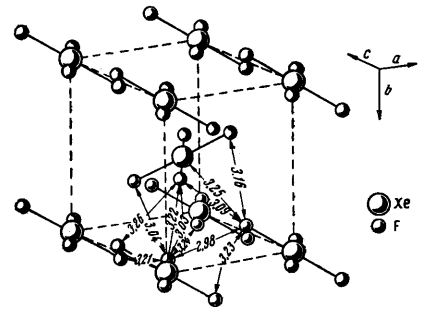

Fig. 12. Crystal structure of xenon tetrafluoride[79].

$XeF_4$ was suggested[76]. Subsequently it was shown[81,82] that this "modification" was really a molecular compound, $XeF_2.XeF_4$. The following parameters were found for this compound, which has the space group $P2_1/c$: $a = 6.64$, $b = 7.33$, $c = 6.40$ Å, $\beta = 92°40'$; for four formula units in the unit cell the density is 4.02 g cm$^{-3}$. In this compound the $XeF_2$ and $XeF_4$ molecules almost completely retain their usual configuration. The least intermolecular Xe–F distance is close to the distances in the $XeF_2$ and $XeF_4$ structures and the least intermolecular F–F distance (2.87 Å), although somewhat less than in these structures, nevertheless corresponds to the uncombined fluorine atoms. The absence of structural indications of the existence of strong bonds between the molecules supports the treatment of $XeF_2.XeF_4$ as a molecular compound.

Gaseous $XeF_4$ has been studied by electron diffraction[83]. The results showed that in the gaseous state the $XeF_4$ molecule has a square planar configuration with Xe–F distance of 1.94 Å.

The vibrational spectra of $XeF_4$ (the infrared spectrum of the gas and the Raman spectrum of the solid) were studied in detail by Claassen and coworkers[84], Figs. 13 and 14 show the spectra and a comparison of the frequencies is given in Table 1.

The results obtained show — in agreement with the structural data — that the $XeF_4$ molecule has a square planar configuration (symmetry $D_{4h}$). From the $Q$–$R$ spacing for $\nu_2$, 11 ± 1 cm$^{-1}$, the Xe–F interatomic distance was evaluated, 1.85 ± 0.2 Å. The force constants were determined: stretching vibrations, 3.00 mdyn Å$^{-1}$; stretching interaction between bonds at right angles,

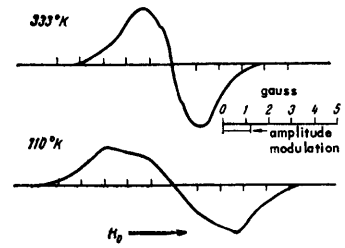

Fig. 16. Nuclear magnetic resonance spectrum of fluorine in xenon tetrafluoride at the frequency 29 MHz.[88]

TABLE 1. Assignment of the frequencies in the vibrational spectra of $XeF_4$.[84]

| | | | | |
|---|---|---|---|---|
| | $a_{1g}$ | $\nu_1$ | RS | 543 $cm^{-1}$ (v.s.) |
| | $a_{2u}$ | $\nu_2$ | IR | 291 $cm^{-1}$ (s.) |
| | $b_{1g}$ | $\nu_3$ | RS | 235 $cm^{-1}$ (w.) |
| | $b_{1u}$ | $\nu_4$ | inactive | 221 $cm^{-1}$ (?) |
| | $b_{2g}$ | $\nu_5$ | RS | 502 $cm^{-1}$ (v.s.) |
| | $e_u$ | $\nu_6$ | IR | 586 $cm^{-1}$ (v.s.) |
| | $e_u$ | $\nu_7$ | IR | 123 $cm^{-1}$ (?) |
| | | $\nu_5+\nu_6$ | IR | 1105 $cm^{-1}$ (w.) |
| | | $\nu_1+\nu_6$ | IR | 1136 $cm^{-1}$ (w.) |

Note. The following abbreviations are used in the table: IR = infrared spectrum of gaseous $XeF_4$; RS = Raman spectrum of solid $XeF_4$; v.s. = very strong; s. = strong; w. = weak intensity of band.

The 442 $cm^{-1}$ band in the Raman spectrum is considered as comprising $2\nu_4$; hence the value 221 $cm^{-1}$ is taken for $\nu_4$.

0.12 mdyn $Å^{-1}$; stretching interaction between oppositely situated bonds, ~0.06 mdyn $Å^{-1}$; the values found were comparable with the corresponding quantities for the $XeF_2$ [8,38] and $PuF_6$ [85] molecules.

The investigation of the spectrum of gaseous $XeF_4$ in the far ultraviolet region[86] made it possible to obtain information about the excited electronic levels of the molecule and these results could be used for assigning the structure of $XeF_4$ (see p. 420). Fig. 15 gives the spectrum.

Nuclear magnetic resonance has also been used for investigating $XeF_4$. The first measurements of the resonance of $^{19}F$ in solid $XeF_4$, made over a wide range of temperatures[87] showed — in accordance with static magnetic measurements[66], a change in the form of the spectrum near 273°K. However, somewhat later these authors refuted their own results[88] and showed that the form of the line was unchanged throughout the whole temperature range investigated (Fig. 16). The asymmetry of the $XeF_4$ spectra is ascribed to the anisotropy of the chemical shift of fluorine[66], and this problem received detailed study[88-93]. The shielding constant for solid $XeF_4$ was 482 parts per million (relative to $F_2$) and the line width ~3.8 G.[50]

Measurements of the magnetic resonance of $^{19}F$ in $XeF_4$ were also made in anhydrous HF.[49,50,94] In the spectrum there was a strong central line with a chemical shift of 175 parts per million relative to HF[49,94] and 454 parts per million relative to $F_2$.[50] Two weak lines on either side of the main line relate to the $^{129}Xe-^{19}F$ coupling. The coupling constant is 3860 Hz. As also in the case of $XeF_2$, the $^{131}Xe-^{19}F$ coupling does not appear in the spectrum; this shows the asymmetry surrounding the xenon nucleus and provides a basis for assuming[50] that the square planar structure of the $XeF_4$ molecule is also retained in solution. As for $XeF_2$, the xenon tetrafluoride is present in solution in HF mainly as undissociated molecules[50].

The information obtained from nuclear magnetic resonance spectra enabled some conclusions to be drawn about the electron density distribution and the structure of the $XeF_4$ molecule. The Mössbauer effect for solid $XeF_4$ was also investigated[51,52]. $^{131}XeF_4$ shows the Szillard-Chalmers effect[95], unlike the clathrate compounds of xenon, in which it is known that xenon does not form chemical bonds. In $\gamma$-irradiation at 77°K with single-crystal $XeF_4$, electron paramagnetic resonance studies showed the existence of an entrapped XeF radical; the spectrum of this radical was interpreted[96,97].

3. Xenon hexafluoride. To prepare xenon hexafluoride $XeF_6$ mixtures of xenon with a large excess of fluorine (Xe : $F_2$ ratios from 1 : 4 to 1 : 20) were heated to 300–700°C

at pressures up to 200 atm in nickel or stainless steel reactors[9,10,98,99]. Xenon hexafluoride is also formed on passing an electric discharge[54] through a 1 : 3 $Xe : F_2$ mixture at -78°C. The specimens of $XeF_6$ obtained by these methods were not completely pure and contained more or less appreciable amounts of $XeF_4$, $XeF_2$, and $XeOF_4$ impurities. Sheft and coworkers[100] proposed a method for obtaining pure crystals of $XeF_6$ based on the fact that unlike the other xenon fluorides and oxide fluorides $XeF_6$ forms a molecular compound with sodium fluoride; this offers the possibility of effectively separating the impurities.

Xenon hexafluoride at room temperature is a colourless crystalline material, m.p. 47.7° ± 0.2°C.[100] Solid $XeF_6$ becomes yellow at 43–43.5°C, and on melting it gives a yellow liquid, but on cooling and solidifying it becomes colourless again[9,100]. The vapour pressure of solid $XeF_6$ is ~ 7 mmHg at 0°C and 30 mmHg at 25°C; $XeF_6$ vapour is pale yellow-grey. $XeF_6$ dissolves in anhydrous HF, the solubility being ~ 10 moles $XeF_6$ in 1000 g HF at 25°C; the yellow solutions are decolorised on cooling[39]. Unlike the analogous solutions of $XeF_2$ and $XeF_4$, solutions of $XeF_6$ in HF exhibit high electrical conductivity (for example, the molar conductance of 0.02 M $XeF_6$ is 147 $\Omega^{-1}$ $cm^{-1}$)[39]; it has been suggested that on dissociation $XeF_5^+$ and $HF_2^-$ ions are formed[15].

With hydrogen at room or slightly higher temperatures, $XeF_6$ is reduced to elemental xenon[9]; mercury at 100°C has the same effect[10]. $XeF_6$ can be kept for a long period in nickel or poly(chlorotrifluoroethylene) vessels but it reacts with quartz at room temperature to form xenon oxide tetrafluoride $XeOF_4$.[9,101] The reaction of $XeF_6$ with $BF_3$ or $AsF_5$ at room temperature leads to the formation of the addition products $XeF_6.BF_3$ and $XeF_6.AsF_5$[102] (see p. 412).

Several important results were obtained in studying the hydrolysis of $XeF_6$. Dudley and coworkers[99] showed that when $XeF_6$ reacts with water a solution exhibiting strong oxidising properties is formed. The reaction of this solution with KI solution leads to the quantitative release of xenon. On this basis it was concluded[99] that xenic acid $Xe(OH)_6$ is formed in the solution. The alkaline hydrolysis of $XeF_6$ leads to the formation of pale yellow solutions, from which stable precipitates of salts of xenic acid are deposited[63,103-106] (see p. 415). Xenon trioxide $XeO_3$ (see p. 414) was obtained by the slow hydrolysis of $XeF_6$ with water vapour at room temperature[107] and $XeOF_4$ is formed in incomplete hydrolysis[108] (see p. 412).

Sheft and Hyman[109] studied the exchange of $^{19}F$ between $XeF_6$ and gaseous fluorine: the rate of exchange (at $XeF_6$ concentration of 0.02 M and 150°C) is a linear function of the fluorine concentration, and on extrapolation the straight line passes through the origin. The results were interpreted as showing the association of $XeF_6$ with a molecule of $F_2$.

Xenon hexafluoride is thermodynamically stable. The reduction of $XeF_6$ by hydrogen according to the reaction:

$$XeF_6(gas) + 3H_2(gas) \rightarrow Xe(gas) + 6HF(gas),$$

in an isothermal calorimeter at 120–130°C was used to find preliminary values of the heat of formation of $XeF_6$ and the energy of the Xe–F bond, -79 kcal $mole^{-1}$ and 31 kcal respectively[72]. Experimental results on the vapour pressure of solid $XeF_6$ were used to derive the vapour pressure equation:

$$\log P_{mm} = 8.155 - 1900/T,$$

from whence the heat of sublimation of $XeF_6$ is found to be 9.15 kcal $mole^{-1}$.[54]

The crystal structure and configuration of the $XeF_6$ molecule have not yet been established. The X-ray and electron diffraction studies are hindered by the relatively high vapour pressure of $XeF_6$ and its reactivity with ordinary capillary materials. Possibly X-ray diffraction studies at low temperatures have a better prospect. Preliminary electron diffraction data[110] are incompatible with the symmetry of the structure of the gaseous molecule.

No light has been cast on the problem of the structure of $XeF_6$ by the investigation of its vibrational spectra[9,10,47,111], which could not be sufficiently fully studied owing to experimental difficulties. In the infrared spectra of $XeF_6$ vapour there are bands at 520, 565, 612, 1100, and 1230 $cm^{-1}$, and in the Raman spectrum of solid $XeF_6$ lines at 582, 635, and 655 $cm^{-1}$. A solution of $XeF_6$ in anhydrous HF showed Raman lines at 620 $cm^{-1}$. The bands of the infrared spectrum have an unusual shape and are anomalously broad. The lines of the Raman spectrum lie in the stretching vibration region.

In view of the impossibility of a reliable allocation of frequencies, the $XeF_6$ spectra do not offer sufficient basis for establishing the structure of the molecule. The principal question under discussion is whether the $XeF_6$ structure is a right octahedron with symmetry $O_h$, similar to other hexafluorides[112], or whether it exhibits lower symmetry. This problem is not devoid of theoretical interest also (see p. 420).

The nuclear magnetic resonance of fluorine in $XeF_6$ was investigated in anhydrous hydrogen fluoride[49,50], and also in the solid and liquid states[50]. In anhydrous HF the rate of exchange of $XeF_6$ with the solvent is so high that only a single broad line is observed in the spectrum. The value of the chemical shift depends considerably on the $XeF_6$ concentration in the solution. On reducing the temperature from 25°C to -13°C the width of the resonance line decreases by ~ 40%. An attempt to resolve the lines of $XeF_6$ and HF by cooling to solid carbon dioxide temperature did not succeed; attempts to find a solvent with which $XeF_6$ would not react were equally unsuccessful[50].

The shielding constant for solid $XeF_6$ is 310 parts per million (relative to $F_2$) and for the liquid, 309 parts per million. The width of the resonance lines of solid and

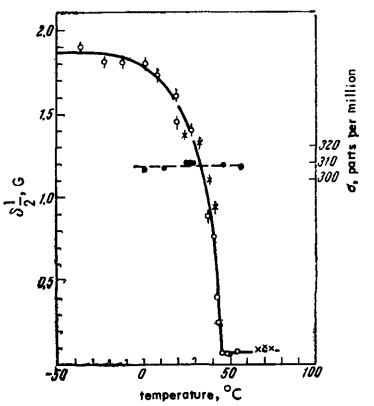

Fig. 17. Effect of temperature on the nuclear magnetic resonance spectrum of $^{19}F$ in solid xenon hexafluoride[50].

liquid $XeF_6$ are ~ 1.9 and ~ 0.14 G respectively. The temperature dependence of the shielding constant and of the line width in the nuclear magnetic resonance spectrum of $^{19}F$ in solid $XeF_6$ is shown in Fig. 17.

4. Other xenon fluorides. By heating a gaseous mixture with the molar ratio $Xe : F_2 = 1 : 16$ at 620°C and 200 atm a yellow substance was obtained whose analysis showed a higher concentration of fluorine than that corresponding to the formula $XeF_6$.[113,114]

After cooling to -78°C the excess of fluorine was evacuated through a trap at liquid nitrogen temperature. In the trap there condensed a yellow substance with a vapour pressure considerably less than that of fluorine, since it remained in the trap even after prolonged evacuation with a mercury diffusion pump.

Analysis of the material, by direct determination of fluorine and finding the xenon by difference, gave an atomic ratio of F : Xe equal to 7.9 ± 0.3 and 8.1 ± 0.1, which closely corresponds to xenon octafluoride $XeF_8$.

In order to trace in greater detail the path of the synthesis the pressure of a reaction mixture with $Xe : F_2 = 1 : 20$ was measured continuously on heating it from 20° to 620°C. The measurements showed clearly that the quantity of combined fluorine exceeds that required for the formation of $XeF_6$. The F : Xe ratio calculated from the pressure measurements was 6.5; the authors[113,114] assume that a mixture of 75% $XeF_6$ + 25% $XeF_8$ was formed.

At room temperature in a sealed glass ampoule the substance obtained is a pale yellow gas which is decolorised in ~ 5 min and attacks the glass. At liquid nitrogen temperature the pale yellow gas is condensed with formation of a yellow solid. In a dilute sodium hydroxide solution the substance is hydrolysed with formation of a yellow solution; the colour is stable for a few hours.

Mass spectrometric studies did not enable the product to be identified although it was suggested earlier[115] that the mass spectrograms obtained indicate the existence of higher fluorides of xenon up to $XeF_8$.

It is interesting to compare the above results with those obtained in investigating the kinetics of the exchange of $^{19}F$ between $XeF_6$ and gaseous fluorine[109]. As noted above (see p. 410), these results show the association of $XeF_6$ with a molecule of $F_2$. A careful study of equilibrium in the xenon–fluorine system[116] gave no indication of the formation of xenon fluorides higher than $XeF_6$.

The same investigation enabled the authors[116] to propose the existence of xenon pentafluoride $XeF_5$. A band at 520 $cm^{-1}$ in the infrared spectrum of $XeF_6$ was also initially ascribed to $XeF_5$; however, this band was observed in the spectrum of pure $XeF_6$.

As noted above, when $XeF_4$ single crystals are irradiated with $^{60}Co$ $\gamma$-rays at -195°C, there is a blue coloration. The electron paramagnetic resonance spectrum of the irradiated crystal has a hyperfine structure, indicating that the xenon atom is bonded with only one fluorine atom, and consequently that the radical XeF is formed[96,97].

In the mass-spectrometric study of $XeF_2$ and $XeF_4$[117,118] a series of fragments ($XeF^+$, $Xe_2F^+$, $Xe_2F_2^+$, $Xe_2F_3^+$, $Xe_2F_5^+$, $Xe_2F_7^+$) were observed, evidently formed in the spectrometer as a result of ionic-molecular association.

Experiments on the reaction of xenon with strong oxidants[119] are also of interest; they lead mainly to the formation of $XeF_2$, but give no indication of the production of any other fluorides.

5. Complex fluorides of xenon. As is well-known[1], the first chemical compound of xenon which was prepared was the complex $XePtF_6$.[2] Subsequently similar compounds were obtained with ruthenium[3] and rhodium[120,121].

A more detailed study of the reactions of xenon with $PtF_6$,[120] made in glass, quartz, and nickel vessels, showed that the products obtained have the composition $Xe(PtF_6)_x$, where $x$ is between 1 and 2. The infrared spectra of these compounds have bands at 652 and 550 $cm^{-1}$, and the spectra for different composition cannot be distinguished.

The complexes of xenon with $PtF_6$ are yellow in thin layers and dark red in bulk. On heating to 115°C the solid becomes vitreous but does not melt below 165°C, at which temperature it decomposes, with formation of $XeF_4$ and a brick-red diamagnetic powder with a composition close to $XePt_2F_{10}$.[120] The X-ray diagrams of a product of composition $XePtF_6$ do not give a diffraction picture and products with greater values of $x$ give complex X-ray diagrams.

The reaction of $XePtF_6$ with rubidium fluoride in iodine pentafluoride gave $RbPtF_6$ containing platinum(V) but reaction of $Xe(PtF_6)_2$ with caesium fluoride under the same conditions gave $CsPtF_6$. These reactions were thought[120] to confirm that $XePtF_6$ and $Xe(PtF_6)_2$ contain platinum(V) and that consequently the first compound should be formulated as $Xe^+[PtF_6]^-$ (this also agrees with the similarity of the infrared spectra of $XePtF_6$, $KPtF_6$ and $O_2PtF_6$) and the second as either a mixture of $XePtF_6$ and $PtF_5$, formed by the reaction:

$$Xe + 2PtF_6 \rightarrow XeF_2 + PtF_5,$$

or as a complex containing platinum(V) and xenon(II).

As for the compound $XePt_2F_{10}$ formed in the pyrolysis of $Xe(PtF_6)_{1.8}$, its reaction with CsF in iodine pentafluoride gives $Cs_2PtF_6$, with platinum(IV). The X-ray diagram of $XePt_2F_{10}$ is complex but does not contain lines which can be ascribed to xenon tetrafluoride, therefore this substance cannot be considered a mixture of $XePtF_6$ and $XeF_4$.

The complex of xenon with $RhF_6$ is characterised by a much closer approach to the 1 : 1 stoichiometric ratio than for that with $PtF_6$.

The formation of products close in composition to $Xe(PtF_6)_2$ in the explosion produced on passing a current through a platinum wire in an atmosphere of fluorine and xenon has been established[122,123].

When $XeF_4$ is dissolved in liquid antimony(V) fluoride, a gas is evolved and a greenish solution is formed, from which a precipitate of a yellow diamagnetic complex $XeF_2 . 2SbF_5$, m.p. 63°C, separates; it sublimes in a vacuum at 60°C. The same compound is formed in the reaction between $XeF_2$ and $SbF_5$. A straw-yellow complex, $XeF_2 . 2TaF_5$, m.p. 81°C is obtained by the action of $TaF_5$ on $XeF_4$; the X-ray powder diagrams of the two complexes indicate their structural similarity. The diamagnetism of $XeF_2 . 2SbF_5$ indicates the formation of a covalent compound of xenon(II) of the type $F_5SbFXeFSbF_5$.[64] $XeF_4$ does not react with $BF_3$ even on heating to 200°C,[64,65] however, from other results[58], $XeF_4$ and $BF_3$ form a violet addition product, stable at a temperature below -100°C.

The action of a glow discharge (6500–7000 V) on a mixture of gaseous xenon and fluorine (molar ratio 2 : 1) in a

glass vessel at -78°C and a pressure below 10 mmHg leads to the formation on the walls of the vessel of a white crystalline substance, stable at -78°C, but decomposing on warming to room temperature, with formation of Xe and $SiF_4$.[124] Analysis of the substance showed the composition $Xe_{2.3}SiF_{5.8}$. Similar experiments with a mixture of xenon with fluorine and $SiF_4$ in the molar ratio 2 : 1 : 1 gave a product with the atomic ratio Xe : Si = 2.2 : 1. It was concluded from these results that a complex $Xe_2SiF_6$ is formed, whose structure can be expressed by the formula $(Xe^+)_2SiF_6^{2-}$.

The analogous reaction of xenon with platinum pentafluoride and fluorine gives a solid which is white to yellow, unstable at room temperature and containing — according to the mass spectrometric and infrared spectroscopic analyses of the decomposition products — xenon and platinum pentafluoride [124].

By heating 0.153 moles $SbF_5$, 0.0435 moles Xe, and 0.0410 moles $F_2$ in a nickel bomb at 250°C for 12 h, a pale yellow solid was obtained which reacts vigorously with water, xenon being liberated. This compound, which is given the composition $XeSbF_6$ [124] does not sublime below 100°C, unlike the other complex with $SbF_5$.

Selig [102] established the formation of addition products of $XeF_6$ and $BF_3$ and of $XeF_6$ and $AsF_5$. At room temperature, $BF_3$ and $XeF_6$ give the compound $XeF_6.BF_3$, which is a white solid, melting at 90°C to a pale yellow viscous liquid. At 20°C the vapour pressure of this addition compound is less than 1 mmHg, but it can be sublimed at this temperature and pressure. The infrared spectrum of solid $XeF_6.BF_3$ at -195°C is complex, but has a broad band with centre close to 1025 $cm^{-1}$, characteristic for the $BF_4^-$ ion. The infrared spectrum of the vapour of the addition compound has bands characteristic of $BF_3$ and $XeF_6$; this signifies partial dissociation in the vapour phase.

The reaction of $XeF_6$ and $AsF_5$ at room temperature also gives a 1 : 1 addition compound — a white solid which does not sublime in a vacuum at room temperature. The Raman spectra of solid $XeF_6.BF_3$ and $XeF_6.AsF_5$ have maxima at 612 and 620 $cm^{-1}$ respectively; it is interesting to note that a solution of $XeF_6$ in anhydrous hydrogen fluoride also gives a maximum in the Raman spectrum at 620 $cm^{-1}$.[39]

The reactivity of the addition products of $XeF_6$ is comparable with that of $XeF_6$ itself. These substances are extremely hygroscopic and although they can be stored in nickel vessels, they react with Pyrex glass. By analogy with the complex $XeF_2.2SbF_5$ (see p. 411), a covalent structure has been proposed for $XeF_6.BF_3$ and $XeF_6.AsF_5$, although an ionic structure of the type $(XeF_5)^+(AsF_6)^-$ cannot be ruled out.

## B. Oxide Fluorides

1. Xenon oxide tetrafluoride. The first indications of the possible existence of xenon oxide tetrafluoride $XeOF_4$ were obtained in the mass-spectrometric investigation of $XeF_4$.[115,117] Then the formation of $XeOF_4$ was established in the reaction of $XeF_6$ with quartz [9,101] and as a result of the slow hydrolysis of $XeF_6$.[101,108]

For the preparation of $XeOF_4$ by the first method [101], $XeF_6$ was condensed in a quartz vessel, this was sealed and then heated to ~50°C. The liquid $XeF_6$ reacted with the $SiO_2$ thus:

$$2\,XeF_6+SiO_2 \rightarrow 2\,XeOF_4+SiF_4.$$

The vessel was cooled to -78°C and the $SiF_4$ evacuated, leaving a colourless liquid in the vessel. In prolonged reaction, a white crystalline precipitate was formed in addition to the liquid; the precipitate was subsequently identified as $XeO_3$.[107] Evidently the reaction proceeds stepwise:

$$2\,XeOF_4+SiO_2 \rightarrow 2XeO_2F_2+SiF_4,$$

$$2XeO_2F_2+SiO_2 \rightarrow 2XeO_3+SiF_4.$$

Smith [108] obtained $XeOF_4$ in the circulating system which he employed for the synthesis of $XeF_2$ (without the heater zone) by the action of air saturated with water vapour, on $XeF_6$ at room temperature. After removing unreacted $XeF_6$ and hydrogen fluoride the yield of $XeOF_4$ was ~80%. In a somewhat different method [101] a known weight of $XeF_6$ was hydrolysed with the accurately calculated quantity of water in accordance with the equation:

$$XeF_6+H_2O \rightarrow XeOF_4+2HF$$

Xenon hexafluoride was condensed in a small nickel vessel at liquid nitrogen temperature, and water in a glass vessel. The two vessels were evacuated to a pressure of $10^{-4}$ mmHg, the water was transferred into a nickel vessel and the latter warmed to room temperature; during this the $XeF_6$ and $H_2O$ were completely converted into the vapour phase and under these conditions there was hydrolysis. After purifying the $XeOF_4$, it was analysed, using the method of reduction by hydrogen:

$$XeOF_4+3H_2 \rightarrow Xe+H_2O+4HF.$$

An analysis was also made by mass spectroscopy.

Xenon oxide tetrafluoride is a colourless liquid stable at room temperature and can be kept in a nickel vessel for several days. It freezes at -41°C.[108] It is reported [101] that its melting point, measured in a sealed quartz capillary, is -28°C. The vapour pressure of $XeOF_4$ is ~8 mmHg at 0°C and ~29 mmHg at 23°C.[101]

The infrared spectrum of $XeOF_4$ vapour and the Raman spectrum of liquid $XeOF_4$ were studied by Smith [47,108] and by Claassen and coworkers [125]. The spectra are shown in Figs. 18 and 19, and the allocation of the frequencies according to Claassen and coworkers [125] in Table 2 (Smith's results [47,108] are only slightly different).

These results support a $XeOF_4$ structure with symmetry $C_{4v}$. The vibrational spectra of $XeOF_4$ and $BrF_5$ [126]

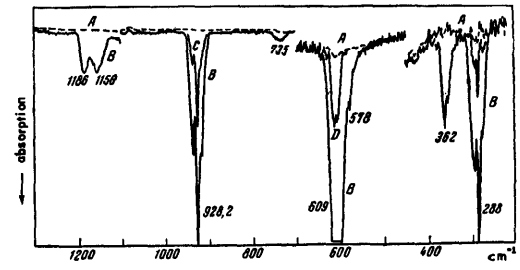

Fig. 18. Infrared spectrum of gaseous $XeOF_4$.[125] Optical path 10 cm: *A*) background; *B*) pressure of 30 mmHg; *C*) pressure of 2 mmHg; *D*) pressure of 1 mmHg.

| | | $\nu_3+\nu_5$ | RS | 818 $cm^{-1}$ (w.) |

Note. The following abbreviations are used in the table: IR = infrared spectrum of gaseous $XeOF_4$; RS = Raman spectrum of liquid $XeOF_4$; p. = polarised; v.s. = very strong; s. = strong; w. = weak; v.w. = very weak intensity of band.

are very similar, and on this basis it was concluded[47,108] that the structures of these compounds are similar; consequently $XeOF_4$ has been given[47,108] the structure of a square pyramid with an atom of oxygen at the apex and the xenon atom is close to the plane of the four fluorine atoms.

The force constants for $XeOF_4$ were calculated[47,108] for idealised valency angles of 90°, and the values found (mdyn $Å^{-1}$) were: Xe–F stretching vibration, 3.20; Xe–O stretching vibration, 7.10; stretching interaction for Xe–F bonds at right angles, 0.12; stretching interaction for Xe–F bonds at 180°, 0.15. The high value of the constant for the stretching vibration of the Xe–O bond indicates that it possesses appreciable double-bond character.

The nuclear magnetic resonance spectra of $^{19}F$ and $^{129}Xe$ in $XeOF_4$ were investigated for liquid $XeOF_4$ [50] and for solutions of $XeOF_4$ in anhydrous hydrogen fluoride[49,127]. The triplet structure of the spectrum of liquid $XeOF_4$, consisting of a central line and a symmetrical doublet, agrees with the structure proposed on the basis of the spectral results. The doublet corresponds to the $^{129}Xe-^{19}F$ interaction; the coupling constant of which is 1086 Hz. The shielding constant is 326 parts per million (relative to $F_2$).[50] The double resonance spectra of $^{19}F$ and $^{129}Xe$ in a solution in anhydrous hydrogen fluoride has been recorded; as for liquid $XeOF_4$, the $^{19}F$ spectrum confirms the views about the equivalency of the four fluorine atoms. The chemical shift of $^{19}F$ is 292 parts per million and that of $^{129}Xe$ is 5511 parts per million (relative to HF). The constant of the $^{129}Xe-^{19}F$ interaction is 1163 Hz.[49,127]

2. Other oxide fluorides. Mass spectrometric investigations[117,118] showed the possibility of the existence of other oxide fluorides of xenon in addition to $XeOF_4$. The oxide fluoride $XeO_2F_2$ was obtained by slow, controlled hydrolysis of $XeF_6$ with subsequent careful separation of the reaction products[118]. The compound was identified mass-spectrometrically[118]. The authors[118] suggested that the hydrolysis of $XeF_6$ proceeds thus:

$$XeF_6+H_2O \rightarrow XeOF_4+2HF,$$
$$XeOF_4+H_2O \rightarrow XeO_2F_2+2HF,$$
$$XeO_2F_2+H_2O \rightarrow XeO_3+2HF.$$

The action of fluorine on xenon at 250–400°C in a flow system, using oxygen or air as carrier gas gave $XeF_2$ plus a little of a more volatile fraction with m.p. 90°C, b.p. ~115°C; in preliminary experiments this fraction was identified as $XeOF_2$.[64]

The oxide fluoride $XeOF_2$ was also prepared by passing an electric discharge through a 1 : 1 mixture of xenon and $OF_2$ at 195°K.[54] Fig. 7 (p. 406) shows the apparatus in which the experiments were made, the pressure in the reaction vessel was 3–62 mmHg and the discharge current was varied between 12 and 32 mA, and the potential between 1200 and 3600 V. The colourless crystals, whose analysis led to the formula $XeOF_2$, were stable at room temperature.

Heating a 1 : 1 mixture of xenon and $OF_2$ at 300–400°C led to the formation of colourless transparent crystals stable at room temperature and which readily sublime and grow to more than 2 mm. Analysis of the crystals gave the empirical formula $Xe_{1.2}O_{1.1}F_{3.0}$, close to the formula $XeOF_3$.[54] It is not clear whether this substance is an individual compound.

C. Oxygen compounds

1. Xenon trioxide. Xenon trioxide $XeO_3$, as noted above, is formed as a result of the neutral or acid hydrolysis of $XeF_4$,[62,128] in the prolonged action of $XeF_6$ on quartz[107] and in the slow hydrolysis of $XeF_6$ by water vapour[107].

The hydrolysis of $XeF_4$ in alkaline, neutral, and acid media was studied by Williamson and Koch[128], who showed that in the last two stages hydrated $XeO_3$ (the degree of

hydration was not found) is formed in the solution and on evaporating the solution at room temperature over barium oxide, colourless crystals are deposited. Analysis of these crystals, carried out by determining the atomic ratio O : Xe in their decomposition products, led to the formula $XeO_3$. The hydrolysis evidently proceeds according to the equation [104]:

$$3XeF_4+6H_2O\rightarrow XeO_3+2Xe+1{,}5O_2+12HF.$$

The mechanism of this reaction can be represented thus [63,104]:

$$2XeF_4+6H_2O \rightarrow 2XeO+XeO_4+12HF,$$
$$2XeO \rightarrow 2Xe+O_2,$$
$$XeO_4 \rightarrow XeO_3+0.5O_2.$$

No one has yet succeeded in establishing the existence of XeO, although a band spectrum observed in the electric discharge was ascribed to this molecule [129]. As regards $XeO_4$, this compound has been obtained and identified [130,131] (see next section).

As a result of the slow hydrolysis of $XeF_6$ at room temperature in the vapour phase, carried out analogously to that described above for $XeOF_4$ (see p. 412), colourless acicular crystals of $XeO_3$ were formed directly [107]. The hydrolysis follows the equation:

$$XeF_6+3H_2O \rightarrow XeO_3+6HF.$$

Xenon trioxide is a colourless involatile crystalline substance. Crystals of $XeO_3$ are strongly hygroscopic and so explosive that there is a great hazard in working with them. $XeO_3$ explodes on rubbing, compression, even on slight heating, and also in contact with cellulose-containing materials; explosions also occur near aqueous solutions. Crystals of $XeO_3$ are considerably less stable under conditions of even very slight humidity than in a dry atmosphere. Because of the risk of explosion ($XeO_3$ is comparable with trinitrotoluene as regards the force of explosion), working with quantities of $XeO_3$ exceeding 50 mg is not recommended [107]. A few hundred milligrammes of $XeO_3$ are sufficient to blow a hole in a Teflon plate 1 cm thick, or to rupture a desiccator [128]. It was noted [128] that preparations of $XeO_3$ obtained by hydrolysis of $XeF_4$ are more stable as regards detonation if the hydrolysis is performed with distilled water in the presence of traces of sulphuric acid (for example, 10 ml $H_2O$ + 4 $\mu$l 1 M $H_2SO_4$ per 1 g $XeF_4$).

The chemical properties of solid $XeO_3$ have been little studied [107]. At a humidity greater than 25% crystals of $XeO_3$ start to deliquesce, bubbles appear in the liquid formed, and the $XeO_3$ is decomposed. When the deliquescing crystals of $XeO_3$ are in contact with copper, the liquid becomes pink and after drying a little dark residue is left. With nickel, a green residue remains. On adding $XeO_3$ to dilute ammonia and drying the solution a precipitate soluble in water is formed, whose infrared spectrum shows the presence of the $NH_4^+$ ion and of another ion absorbing at 790 $cm^{-1}$. This observation could be reproduced only once since usually $XeO_3$ exploded even in direct proximity to the solution.

Aqueous solutions of $XeO_3$ were investigated by Willamson and Koch [128,132] and also by Appelman and Malm [104,106]. The solubility of $XeO_3$ in water exceeds 2 M. [104] Measurements of Raman spectra of such solutions provide a basis for assuming that the dissolved substance is present in solution mainly as the molecule $XeO_3$, [104] but the degree and character of hydration were not established. The chemistry of aqueous solutions of xenon(VI) and xenon(VIII) compounds are considered in detail in the section dealing with xenic acids and their salts (see p. 415).

To determine the heat of formation of $XeO_3$ we measured the heat of explosion of $XeO_3$ calorimetrically [133]. The standard heat of formation of $XeO_3$ was found to be 96 ± 2 kcal $mole^{-1}$. The energy of the Xe–O bond in $XeO_3$ can be evaluated only approximately [143]; it is evidently considerably less than the energy of the Xe–F bond.

The crystal structure of $XeO_3$ was investigated by X-ray diffraction on single crystals [134,135]. Xenon trioxide is orthorhombic with parameters $a$ = 6.163 ± 0.008, $b$ = 8.115 ± ± 0.010, $c$ = 5.234 ± 0.008 Å; space group $P2_12_12_1$; the density calculated for four formulae units in the unit cell is 4.55 g $cm^{-3}$. The $XeO_3$ molecule has the trigonal pyramid configuration; the distances and valency angles are shown in Fig. 20. The least O–O distance between different $XeO_3$ molecules is 2.91 Å, the remaining distances exceed 3.02 Å. Each xenon atom has, as well as the nearest atoms of oxygen, three neighbouring oxygen atoms of adjacent molecules at distances of 2.80, 2.89, and 2.90 Å. It was noted that the crystal structure of $XeO_3$ closely resembles that of $HIO_3$.

The explosibility of $XeO_3$ did not permit the Raman spectrum of this molecule to be investigated. Only the infrared spectrum of a thin film of $XeO_3$ in polyethylene could be recorded [47]. Absorption bands were observed in the 800 and 300 $cm^{-1}$ regions and the principal frequencies were assigned by analogy with $ClO_3^-$, $BrO_3^-$, and $IO_3^-$ ions: $\nu_1(a)$ 770 $cm^{-1}$, $\nu_2(a)$ 311 $cm^{-1}$, $\nu_3(e)$ 820 $cm^{-1}$, and $\nu_4(e)$ 298 $cm^{-1}$. The force constant of the principal stretching vibration (5.66 mdyn $Å^{-1}$) shows the considerable degree of double-bond character of the xenon–oxygen bond in $XeO_3$.

2. Xenon tetroxide. The existence of xenon tetroxide $XeO_4$ was first established by the mass-spectrometric analysis of the gas liberated during the reaction of sodium perxenate with concentrated sulphuric acid [130]. Then $XeO_4$ was obtained in quantities up to 100 mg by the reaction of sulphuric acid with sodium or barium perxenate in a glass U-tube [131]. As a result of the reaction a pale yellow substance condensed in a glass trap cooled by liquid nitrogen, and after its purification by sublimation its analysis indicated the formula $XeO_4$. It was analysed by determining the Xe : $O_2$ ratio in the decomposition products; these were identified by mass spectrometry.

Better yields of $XeO_4$ (34%) were obtained when the reaction was slow; the most satisfactory results were given by

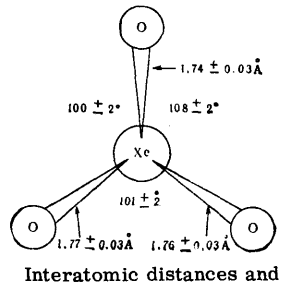

Fig. 20. Interatomic distances and valence angles of the $XeO_3$ molecule according to the X-ray diffraction data [134].

slow addition of the salt (preferably barium perxenate) to the acid cooled to -5°C.

The vapour pressure of $XeO_4$ is 3 mmHg at -35°, 10 mmHg at -16°, and 25 mmHg at 0°C. The specimen could be heated to 0°C only in rare instances; usually the substance decomposed (sometimes with explosion) before reaching this temperature, xenon and oxygen being formed.

Gaseous $XeO_4$ is relatively stable at room temperature also. This enabled its infrared spectrum to be studied (Fig. 21). The two intense bands were found to belong to $XeO_4$ and the weaker bands (marked X in Fig. 21) are obviously due to impurities. The frequencies corresponding to the maxima of the *P*-, *Q*-, and *R*-branches are: 298, 305.7, 314, and 870, 877, 885 $cm^{-1}$. In the infrared spectrum of $XeO_4$ only two frequencies are active: 877 ($\nu_3$) and 305.7 ($\nu_4$); the frequencies $\nu_1$ and $\nu_2$ are inactive. This circumstance and also the triplet structure of both bands, equally also the close similarity of the spectra of $XeO_4$ and $IO_4^-$ provide a basis for assuming that the $XeO_4$ molecule has a tetrahedral structure and symmetry $T_d$, which had been predicted[136] even before the discovery of this compound. From the *Q*–*R* spacing, 16 $cm^{-1}$, the approximate length of the Xe–O bond in $XeO_4$ was found to be 1.6 Å.

3. Xenic acids, xenates, and perxenates. On the basis of the results of studies of the hydrolysis of $XeF_4$ and $XeF_6$ in acid, neutral, and alkaline media, conclusions have been drawn concerning the existence in solution under known conditions of unstable xenic acids: $H_6XeO_6$ with sexivalent xenon, and $H_4XeO_6$ with octovalent xenon. The salts of these acids were separated and named respectively xenates ($Xe^{VI}$) and perxenates ($Xe^{VIII}$).

Closely connected with the work on the isolation and study of salts of xenic acids is the investigation of the chemistry of aqueous solutions of $Xe^{VI}$ and $Xe^{VIII}$ compounds. Study of the chemical properties of solutions of $XeO_3$ showed[128] that even dilute solutions exhibit strong oxidising properties. Table 3 gives some qualitative results.

Koch and Williamson[132] investigated the kinetics of the reaction of aqueous $XeO_3$ with bromide and iodide ions. The reaction follows the equation:

$$XeO_3 \cdot aq + 6H^+ + 9X^- \rightarrow Xe + 3H_2O + 3X_3^- \ (X = Br, I).$$

From the experimental results curves were constructed of the dependence of the optical density on time, the order of the reaction was determined, and the activation energy was found.

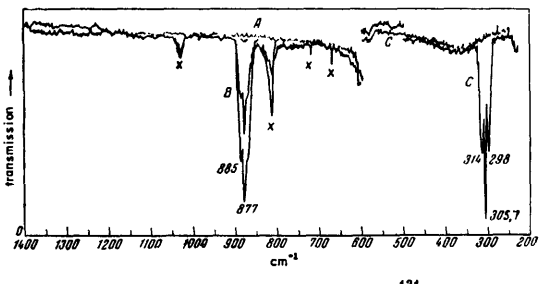

Fig. 21. Infrared spectrum of gaseous $XeO_4$:[131] *A*) background; *B*) optical path 10 cm, pressure unknown; *C*) optical path 10 cm, pressure 8 mmHg.

TABLE 3. Chemical reactions of $XeO_3$.aq.[128]

| Reagent | pH | Product | |
|---|---|---|---|
| $NH_3$ | 6 M $NH_4OH$ | presumably $N_2$ | very vigorous |
| Excess of $I^-$ | 7 or less | $I_3^-$ | rapid |
| 3% $H_2O_2$ | neutral | $O_2$ | very vigorous |
| Excess of $Br^-$ | 1 or less | $Br_2$ | slow |
| $Fe^{2+}$ | neutral | $Fe^{3+}$ | rapid |
| Hg | 1 M $H_2SO_4$ | $Hg_2SO_4$ | rapid |

Appelman and Malm[104], and also Appelman[106] made detailed studies of the chemical properties of solutions of compounds of xenon(VI) and xenon(VIII) using chemical analysis, cryoscopy, conductometry, pH measurement, and spectrophotometry in the ultraviolet region. During this investigation they isolated and characterised several salts of xenic acids.

Solutions of $Xe^{VI}$ are strong oxidants, and there is simultaneous reduction of xenon to the elemental form. Iodide is oxidised by a $Xe^{VI}$ solution to iodine very rapidly in acid solution, but rather slowly at pH > 7, and bromide is rapidly converted into bromine in 1 M HBr, but considerably more slowly at lower $H^+$ and $Br^-$ concentrations. The $Cl^-$ ion is oxidised to $Cl_2$ slowly in 2 M HCl, more rapidly in 3 M HCl, and very rapidly in 6 M HCl. Acid solutions of $Mn^{2+}$ are oxidised to $MnO_2$ in a few hours and after 1–2 d $MnO_4^-$ is formed. In 2 M $HClO_4$, iodine is very slowly converted into iodate. The rate of this reaction is considerably greater in 6 M $HClO_4$; at this concentration of the acid $XeO_3$.aq very slowly oxidises bromine to bromate.

The ultraviolet absorption spectra of $Xe^{VI}$ solutions, according to Appelman and Malm's results[104], differ considerably from those given by Williamson and Koch[128]; the reason for the difference is not clear. On the basis of the pH dependence of the ultraviolet spectra and also the pH titration of $XeO_3$ solutions by alkali, it was concluded[104] that there is the equilibrium:

$$HXeO_4^- \rightleftarrows XeO_3 + OH^-.$$

with an equilibrium constant of $(6.7 \pm 0.5) \times 10^{-4}$ at 25°C. Possibly, however, ions of the type $H_5XeO_6^-$ are formed and also unchanged $XeO_3$ molecules with attached $OH^-$ ions, for example, $XeO_3.OH^-$.[104] $XeO_3$ does not exhibit noticeable basic properties[104].

In the hydrolysis of $XeF_6$ by the action of 2.5 M sodium hydroxide, a solution of $Xe^{VI}$ is formed instantaneously, which then undergoes slow disproportionation accompanied by deposition of a perxenate precipitate; the overall equation is:

$$2XeF_6 + 4Na^+ + 16OH^- \rightarrow Na_4XeO_6 + Xe + O_2 + 12F^- + 8H_2O.$$

The rate of this reaction is different in different experiments (the half-decomposition period varies from 2 to 20 h) and is greater than the disproportionation rate for pure $XeO_3$ in alkaline solution; it has been suggested[104] that the reaction is catalysed by impurities. However, the results of experiments on the disproportionation of solutions with $XeO_3$ concentrations < 0.0003 M in 1–4 M KOH previously treated with ozone to destroy reducing impurities were also non-reproducible.

In the dissolution of $Na_4XeO_6$ in water a strongly alkaline solution is produced (0.0036 M solution has, for example, pH 11.61 at 24°C):

$$Na_4XeO_6+H_2O \rightarrow HXeO_6^{3-}+OH^-+4Na^+.$$

An aqueous solution of $Xe^{VIII}$ slowly liberates oxygen and is converted into $Xe^{VI}$ solution; the rate of this process increases as the pH is reduced and at pH 7 the decomposition is almost instantaneous. The strong and rapid oxidising action of $Xe^{VIII}$ solutions is accompanied by the reduction of $Xe^{VIII}$ to $Xe^{VI}$. $Xe^{VIII}$ solutions oxidise iodide to iodine very rapidly even in 1 M solution of a base; bromide is almost instantaneously oxidised to bromine at pH 9 and less, and chloride is converted into chlorine in dilute acid. The rapid oxidation of $Co^{II}$ into $Co^{III}$ and iodate into periodate takes place both in acid and in alkaline solution.

The results of studying the dependence of ultraviolet spectra of $Xe^{VIII}$ solutions on pH and also the results of pH titrations are explained essentially by the equilibria [104,106]:

$$HXeO_6^{3-}+H^+ \rightleftarrows H_2XeO_6^{2-},$$

$$H_2XeO_6^{2-}+H^+ \rightleftarrows H_3XeO_6^-,$$

$$H_3XeO_6^- \rightarrow HXeO_4^-+0.5O_2+H_2O,$$

$$HXeO_4^-+H^+ \rightarrow XeO_3+H_2O.$$

The equilibrium constant of the reaction:

$$HXeO_6^{3-}+H_2O \rightarrow H_2XeO_6^{2-}+OH^-,$$

is $(2.4 \pm 0.5) \times 10^{-4}$.

The results obtained in investigating solutions of $Xe^{VI}$ and $Xe^{VIII}$ permitted an evaluation of the redox potentials [104]; the results can be expressed by the following schemes:

Acids

$$Xe—1.8—XeO_3—3.0—H_4XeO_6,$$

Bases

$$Xe—0.9—HXeO_4^-—0.9—HXeO_6^-.$$

The oxidising properties of xenic acid $H_6XeO_6$ with respect to a series of vicinal diols and organic alcohols was investigated qualitatively by Jaselskis and Vas [137]. The difference in oxidising action of xenic and iodic acids, which exhibit similar redox potentials, is attributed by these authors to the absence from aqueous solutions of stable oxidation states of xenon below $Xe^{VI}$. This conclusion agrees with the results of an investigation of the polarographic reduction of xenic acid [138]. The reduction of $XeO_3.xH_2O$ at a dropping mercury electrode proceeds in a single stage to xenon; the half-wave potential changes from -0.10 to -0.360 V relative to the $Hg_2SO_4$–Hg electrode, in the pH interval from 4.60 to 8.00. Sodium perxenate in alkaline solution is also reduced in a single stage; the half-wave potential changes from -0.21 to -0.31 V relative to the same electrode, in the pH interval from 10.1 to 11.3. [139]

The nuclear magnetic resonance spectrum of $^{17}O$ in $H_6XeO_6$ solution obtained by hydrolysis of $XeF_6$ showed a single line of width 420 Hz with chemical shift 278 ± 2 parts per million relative to water. The chemical shift which is close to that found earlier for perchloric acid and also for bromate, chlorate, and perchlorate ions, indicates that the xenon–oxygen bond in $H_6XeO_6$ possesses some double-bond nature [140].

As already noted repeatedly, $Xe^{VIII}$ deposits precipitates of stable perxenates — salts of the acid $H_4XeO_6$ — which in many instances have been isolated and investigated.

Malm and coworkers [63] made the first experiments on the preparation of sodium perxenate. To a weighed portion of $XeF_6$, sublimed into a Pyrex glass vessel at a temperature close to that of liquid nitrogen, a large excess of 2 M NaOH was slowly added, the mixture was heated to room temperature, diluted with an equal quantity of water, and kept for about a day. The initial yellow colour of the solution gradually paled and a white precipitate came down; its analysis led to the formula intermediate between $Na_4XeO_6.2H_2O$ and $Na_6XeO_7.H_2O$. The yield of the product reached 80%. The substance obtained was completely stable, could be kept without change at room temperature and was decomposed with liberation of xenon and oxygen above 300°C, by which temperature the salt had not melted. The solubility of the dry salt in water at 25°C was 7 g litre$^{-1}$.

Further investigations [104] showed that this product contained sodium fluoride as an impurity. Purer preparations were obtained by ozonisation of a solution of $XeO_3$ in 1 M NaOH. The precipitation of sodium perxenate takes place in this almost quantitatively. The solubility of sodium perxenate in water is 0.025 M at room temperature, which permits the excess of base to be readily washed from the precipitate. The substance obtained is a white crystalline powder of composition $Na_4XeO_6$, containing from 0.6 to 6 molecules of crystallisation water per 1 g-atom Xe, depending on the conditions of drying, and a little sodium carbonate. Sodium perxenate is completely stable at room temperature, is dehydrated to the anhydrous salt at ~100°C and decomposes vigorously at 360°C. [141]

The reaction of 0.2 M $Ba(OH)_2$ with 0.007 M $XeO_3$ followed by drying in a stream of nitrogen, grinding and repeat drying in a vacuum over magnesium perchlorate gave a white stable product of empirical composition $Ba_2XeO_6.1.5H_2O.0.05BaCO_3$. As with the sodium salt, barium perxenate is stable at room temperature and is decomposed at ~300°C. [141] It is almost insoluble in water; at room temperature a saturated solution has a total concentration of only $2.3 \times 10^{-5}$ M. [104]

Potassium perxenate could not be obtained by hydrolysis of $XeF_6$ with KOH solution, by disproportionation of a solution of $Xe^{VI}$ in KOH and by ozonisation of a solution of $Xe^{VI}$ in KOH; a salt $K_4XeO_6.2XeO_3$ was isolated [104]. However, $K_4XeO_6.9H_2O$ was obtained by the action of a little solid potassium permanganate on concentrated KOH solution, holding the solution at 70°C for 3 d (until the colour disappeared) and adding xenic acid (obtained by dissolving $XeO_3$) at 0°C in a vacuum [142].

Yellow uranyl and lead perxenates and black silver perxenate were obtained by the action of solid sodium perxenate on aqueous solutions of uranyl, lead, and silver nitrates [143]. Furthermore, there are reports of the preparation of calcium, lithium, and caesium perxenates [144].

The attempts of Appelman and Malm [104] to obtain barium xenate were unsuccessful, but Kirshenbaum and Grosse [105] prepared it and also reported the results of preliminary experiments on the preparation of the sodium and potassium salts of xenic acids.

The initial preparations of $H_6XeO_6$ were obtained by slow hydrolysis of $XeF_4$ or xenon oxide fluorides with water at 0°C. Removal of HF was effected by shaking the solution with a small excess of $CaCO_3$ or $Ca(OH)_2$ at 0°C; $CaF_2$ was formed, which was readily removed from the reaction zone. Solutions of $H_6XeO_6$ can be kept at temperatures from -20° to -30°C without decomposition for a few weeks [105].

On adding a solution of 3 moles $Ba(OH)_2$ to 1 mole $H_6XeO_6$ at 0°C a white amorphous precipitate was obtained, whose analysis gave the formula $Ba_3XeO_6$.[105] The yield of $Ba_3XeO_6$ reached almost 100% when the solution of the base was added rapidly enough to prevent decomposition of the acid.

Barium xenate is very poorly soluble in water: 0.25 g × × litre$^{-1}$ at 20°C. At room temperature $Ba_3XeO_6$ is completely stable; slow decomposition starts at 125° and ends at 250°C. The decomposition of $Ba_3XeO_6$ follows the reaction:

$$Ba_3XeO_6 \rightarrow 3BaO+Xe+1.5O_2.$$

Sodium and potassium xenates have also been obtained[105], but have not been characterised completely. These salts are also stable at room temperature for at least a few months.

With the aim of determining the structure and configuration of the perxenate ion X-ray diffraction investigations have been made of $Na_4XeO_6.6H_2O$,[145] $Na_4XeO_6.8H_2O$,[146] and $K_4XeO_6.9H_2O$.[142] The results showed that these perxenates are orthorhombic and that the $XeO_6^{4-}$ ion has the configuration of a regular octahedron: the mean Xe–O distance is 1.84 Å in $Na_4XeO_6.6H_2O$, 1.875 Å in $Na_4XeO_6.8H_2O$, and 1.86 Å in $K_4XeO_6.9H_2O$.

The investigation of the infrared spectra of the sodium, uranyl, lead, and silver perxenates[143] showed that all these compounds have an intense absorption band in the region 650–680 cm$^{-1}$, the position of which is independent of the nature of the cation. This band is related to the principal vibration of the $XeO_6$ octahedral group, which agrees with the results of the structural investigation.

The structural and spectrographic information and equally the results of studies of the Mössbauer effect in sodium perxenate[51,52], have been used to judge the structure of the perxenate ion.

The first investigation of the physiological action of compounds of Group 0 elements was made using sodium perxenate as example, by Finkel and coworkers[147]. They studied the metabolic and toxicological effects of injections of an aqueous solution of sodium perxenate on mice. It was established that sodium perxenate is of average toxicity in intravenous injection; the lethal does lie between 15 and 30 mg kg$^{-1}$. The perxenate introduced is rapidly reduced to elemental xenon, the bulk of which is lost from the body a few minutes after injection.

## III. COMPOUNDS OF RADON AND KRYPTON

### A. Radon Fluorides

The production of a stable radon fluoride of unknown composition[6] was described in the previous review[1]. In addition, there are indications of a volatile radon hexafluoride[148], which has still not been confirmed.

### B. Krypton Compounds

1. Krypton tetrafluoride. After the preparation of compounds of xenon and radon, the natural interest concerned the problem of the possibility of preparing compounds of other Group 0 elements, above all those of krypton.

Experiments on the reaction of krypton with platinum and ruthenium hexafluoride on heating to 50°C were unsuccessful[121]. Attempts to prepare krypton fluorides by the reaction of gaseous krypton and fluorine at 400–500°C in a nickel vessel and also by irradiating mixtures of these gases with ultraviolet light at -60°C were also unfruitful[32].

Krypton tetrafluoride $KrF_4$ was obtained[54,149] by the action of an electric discharge on a mixture of krypton and fluorine. The experimental method was the same as was used in preparing xenon tetrafluoride (see p. 406). A 1 : 2 mixture (by volume) of krypton and fluorine was passed at 7–12 mmHg and at a rate of 125 cm$^3$ h$^{-1}$ (s.t.p.) into a reactor cooled to -188°C by a mixture of liquid oxygen and nitrogen; the current was 24–37 mA and the potential 700–2200 V. The krypton tetrafluoride, whose yield reached 100% in isolated experiments, was deposited on the glass walls of the reactor as a white solid. After removing the unreacted krypton and fluorine by evacuation at -78°C, (as well as silicon tetrafluoride and oxygen), the $KrF_4$ was sublimed at -30° to -40°C into a glass vessel in which was dry powdered KF (as a getter for HF).

Krypton tetrafluoride forms colourless transparent crystals (Fig. 22). Thermally, $KrF_4$ is less stable than $XeF_4$, but at -78°C it can be kept without decomposition for several weeks. At 20° in a poly(chlorotrifluoroethylene) vessel with copper taps, $KrF_4$ slowly decomposes; it decomposes rapidly by the reaction:

$$KrF_4 \rightarrow Kr+2F_2,$$

at 60°C; the method of analysing $KrF_4$ is based on this reaction.

The temperature dependence of the vapour pressure of $KrF_4$ is expressed by the equation:

$$\log P_{mm} = 8.531 - 1930/T.$$

Fig. 23 shows the corresponding curve together with the vapour pressure curve of $XeF_6$ (see p. 410) for comparison. The heat of sublimation of $KrF_4$ is found to be 8840 ± ± 300 cal mole$^{-1}$ by extrapolating to the sublimation temperature (at 760 mmHg), ~70°C.

The physical properties of $KrF_4$ have been insufficiently studied†. The ions $KrF^+$ and $Kr^+$ have been observed in

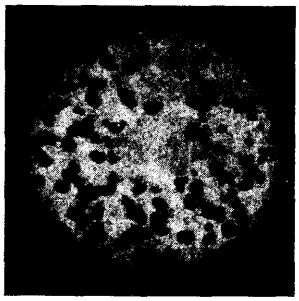

Fig. 22. Crystals of xenon tetrafluoride.

† The reader may like to consult F. Schreiner, J. G. Malm, and J. C. Hindman, J. Amer. Chem. Soc., 87, 25 (1965) who show that the preparation believed to yield $KrF_4$ actually gives $KrF_2$ (Ed. of Translation).

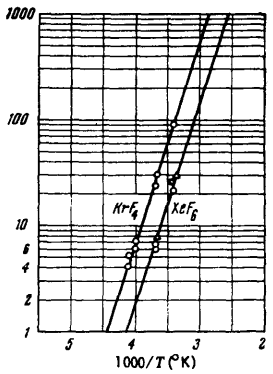

Fig. 23. Vapour pressure curves for $KrF_4$ [149] and $XeF_6$. [54]

the mass spectrum of $KrF_4$. [150] In the nuclear magnetic resonance spectrum of $^{19}F$ in krypton tetrafluoride dissolved in anhydrous HF a single $^{19}F$ resonance line was observed [151], with a chemical shift of 254 parts per million with respect to HF. On the basis of the nuclear resonance spectrum it was concluded [151] that the fluorine atoms in $KrF_4$ are equivalent and that exchange with the solvent does not take place to any significant extent. The absence of hyperfine structure obviously indicates a planar or pyramidal structure for the $KrF_4$ molecule.

2. Krypton difluoride. The first successful experiments on the preparation of krypton difluoride $KrF_2$ [152,153] employed the matrix-isolation technique [154]. A gaseous mixture with a molar ratio $F_2 : Kr : Ar = 1 : 70 : 220$ was slowly precipitated on a caesium fluoride window at 20°K. After recording the infrared spectrum of a specimen it was irradiated with the focussed light of a medium-pressure mercury lamp and the infrared spectrum again recorded. After it had been irradiated for 3 h a specimen gave an infrared spectrum with two absorption bands: at 580 $cm^{-1}$ (half-width ~3.5 $cm^{-1}$, optical density 0.19) and at 236 $cm^{-1}$ (optical density 0.04).

For the confirmation of the assignment of these bands to krypton difluoride, photolysis experiments were made under the same conditions with mixtures of fluorine and argon and of fluorine, xenon, and argon. In the first case there was no absorption, and in the second the spectrum showed the formation of $XeF_2$ and a trace of $XeF_4$.

The bands at 580 and 236 $cm^{-1}$ in the infrared spectrum of $KrF_2$ belong respectively to the asymmetric stretching vibration $\nu_3$ and the bending vibration $\nu_4$ of a linear symmetric molecule. The values calculated for the force constants ($k_\gamma - k_{\gamma\gamma} = 2.59$; $k_\gamma + k_{\gamma\gamma} = 2.91$; $k_\delta/l^2 = 0.21$ mdyn $Å^{-1}$) were close to those found for $XeF_2$ (see p. 405)‡.

The preparation of $KrF_2$ in amounts of ~100 mg was brought about by subjecting a mixture of krypton and fluorine to a beam of electrons with energy 150 MeV at -150°C in a nickel vessel [155]. When the reaction had finished, the unreacted krypton and fluorine were evacuated and the $KrF_2$ was frozen out in a quartz trap at solid carbon dioxide or liquid air temperatures. At these temperatures $KrF_2$ is a fine white powder. $KrF_2$ sublimes under gentle heating without noticeable decomposition; in one experiment a colourless crystal measuring ~1 mm was obtained. This crystal did not change appreciably in 5 min at room temperature, and then suddenly decomposed with a small explosion.

The composition of the specimens was determined by decomposing them with mercury and analysing the decomposition products. Difficulties were encountered in measuring the vapour pressure of $KrF_2$, owing to the instability of this compound, but it was established that at -40°C the vapour pressure is 1.5–2 mmHg. [155]

An X-ray investigation of $KrF_2$ showed [156] that krypton difluoride is tetragonal with parameters $a = 6.533$ and $c = 5.831$ Å; the density for four formula units in the unit cell is 3.24 g $cm^{-3}$. It was noted that $KrF_2$ is not isostructural with $XeF_2$. Because crystals of $KrF_2$ decompose appreciably on irradiation, the X-ray diagrams were insufficiently sharp.

3. The complex of krypton difluoride with antimony pentafluoride. During the interaction of $KrF_2$ with antimony pentafluoride at -20°C in glass or poly(chlorotrifluoroethylene) vessels a white crystalline substance, whose analysis led to the formula $KrF_2.2SbF_5$, was formed [157]. It dissolves in an excess of $SbF_5$ at room temperature with the formation of a transparent, pale yellow solution, from which, after evacuation of the solvent at 25°C, the original complex separated again.

The complex $KrF_2.2SbF_5$ is considerably more stable and much less volatile than the initial krypton difluoride. It melts at ~50°C, but in the liquid state it decomposes rapidly with the formation of $SbF_5$, krypton, and fluorine. As might have been expected, the complex is exceptionally reactive and ignites organic materials with explosion. Solutions of the complex in antimony pentafluoride decompose slowly at 25°C; they are also quite reactive and attack poly(chlorotrifluoroethylene). The hydrolysis of the complex in a base or weak acid leads to the formation of not only krypton and oxygen, but also considerable amounts of $OF_2$. In the infrared spectrum of $KrF_2.2SbF_5$ a strong characteristic band was observed at 813 $cm^{-1}$ and another strong, but badly resolved band in the region 600–700 $cm^{-1}$.

Preliminary experiments also showed that $KrF_2$ combines with $AsF_5$ at -78°C, but the addition product formed is very unstable and could not be isolated [157].

4. Kryptic acid and its barium salt. The hydrolysis of $KrF_4$ at room temperature proceeds almost quantitatively by the equation:

$$KrF_4 + 2H_2O \rightarrow Kr + O_2 + 4HF.$$

However, when hydrolysis takes place slowly at temperatures from -30° to -40°C the aqueous solution formed contains a very slight trace of a compound which exhibits oxidising properties and releases iodine from an acidified iodide solution. As careful experiments on the hydrolysis of $KrF_4$ with ice at -30°C showed [158], the solution after hydrolysis then contains 2–3 mole % kryptic acid, which oxidises potassium iodide solution by the reaction:

$$KrO_3 \cdot xH_2O + 6KI + 6HCl \rightarrow Kr + 3I_2 + 6KCl + (3+x)\,H_2O\,.$$

‡ The reader should refer to H. H. Claassen, G. L. Goodman, J. G. Malm, and F. Schreiner, J. Chem. Phys., 42, 1229 (1965) (Ed. of Translation).

The question of the valency of krypton in this acid, and consequently the formula of the acid, is still open.

To prepare the barium salt of kryptic acid[158], $KrF_4$ was hydrolysed at 0–5°C by $Ba(OH)_2$ solution. During the reaction gas was evolved and a white precipitate separated; it contained $BaF_2$ and barium kryptate. The precipitate was filtered off, washed with small portions of ice water, and dried at 0°C. The dry preparation is stable at room temperature, starts to decompose at ~50°C, and decomposes completely at 200°C. The results of chemical and mass spectrometric analyses of the gases evolved during the preparation, and also of the decomposition products of barium kryptate, agree with the formula $BaKrO_4$; the decomposition of the kryptate proceeds thus:

$$BaKrO_4 \rightarrow BaO + Kr + 1.5O_2,$$

and the reaction with acidified KI solution:

$$BaKrO_4 + 8HCl + 6KI \rightarrow BaCl_2 + 6KCl + 3I_2 + Kr + 4H_2O.$$

The yield of $BaKrO_4$ is ~7% , and the product contains $BaF_2$ ~ 95, $BaKrO_4$ ~ 5%. On the basis of studies of the salts of xenic and kryptic acids it is suggested that xenon and krypton may exist in nature not only in the atmosphere but also in hydrothermal minerals and in the oceans[105,158].

## IV. THE CHEMICAL BONDS IN COMPOUNDS OF THE ELEMENTS OF GROUP 0

The first attempts at a theoretical description of the chemical bonds in the compounds of the elements of Group 0, made even before the discovery of these compounds, were those of Pauling[159] and Pimentel[160], who used the methods of valency bonds[159] and molecular orbitals[160]. Today, when as a result of the preparation of several compounds of xenon and krypton and the investigation of their chemical and physical properties it is already possible to make some generalisation about the experimental material, a considerable number of theoretical studies have appeared which are devoted to explaining the structure and the nature of the chemical bonds in these compounds[11,12,38,47,136,161–184].

Allen's model[11], based on calculation of the correlation effects in pairs of electrons with antiparallel spins was developed to some extent in the later work of Allen himself[161] and also in Michels' work[162]. However, this model was subjected to serious criticism by Coulson[163], in his review of the theories of the chemical bond in compounds of the elements of Group 0. Nevertheless it must be stated that with the aid of the correlation model the linear configuration of the $XeF_2$ molecule and the square planar structure of the $XeF_4$ molecule were first explained successfully.

The valency bond method with allowance for the hybridisation with participation of the *d* electrons of xenon was used by Allen and Horrocks[12] to explain the linear and square structures of $XeF_4$ and $XeF_4$ and to predict the configuration of certain (then as yet unobtained) xenon oxide fluorides. In a somewhat altered form this approach, together with the use of molecular orbitals (MO) was employed by Bersohn[164]. Gillespie[136] has made the most detailed application of the valence bond method to the compounds of xenon and the other elements of Group 0; with a view to explaining and predicting the configuration of the known and still unknown molecules and also to evaluate the bond lengths in these molecules by comparison with the interhalogen compounds. According to Gillespie, eight of the electrons of the outer shell of the Xe atom and one electron of each F atom (or two electrons of an O atom) form pairs, which either form bonds between the atoms or exist as lone pairs. The form of the molecule is eventually determined by the degree and character of the electrostatic repulsion of unshared pairs, of ordinary Xe–F bonds and of Xe=O double bonds. For example, the distribution of ten electrons (two ordinary bonds and three unshared pairs) in $XeF_2$, 12 electrons (four ordinary bonds and two unshared pairs) in $XeF_4$, and 14 electrons (four ordinary bonds, one double bond, and one unshared pair) in $XeOF_4$ leads to the known structures of these molecules. This theory predicts a distorted octahedral structure for $XeF_6$. The interatomic distances Xe–F in $XeF_2$ and $XeF_4$, and Xe–O in $XeO_3$, which were estimated, agree well with the experimental values.

Smith[38,47] came to analogous conclusions, reducing to a minimum the part played by ionic bonds in xenon fluorides, on the basis of an analysis of the vibrational spectra. Smith showed that for $XeF_2$ and $XeF_4$ the ratio of the constant valency interaction to a constant principal valence vibration is considerably less than for the $ICl_2^-$ ion, the bonds in which are considered to be essentially ionic[185,186] and on this basis it was concluded that covalent bonds with participation of *d* orbitals play an extremely important part in xenon fluorides. According to this view, the structure of $XeF_6$ cannot be octahedral. Smith rejects the consideration of the bond in $XeF_2$ from the standpoint of the resonance of the $F–Xe^+F^-$ and $F^-Xe^+–F$ structures, but Coulson[163], in considering this possibility in greater detail, concluded that it leads to a charge distribution in agreement with the experimental results.

The MO method, in which delocalised MO are constructed from the atomic 5*p* orbital of xenon and the 2*p* orbital of fluorine (without any participation of the *d* orbital), was employed by Rundle[165], using his earlier proposal to treat the structure of the interhalogen compounds with the aid of three-centre four-electron bonds. For example, for the $XeF_2$ molecule three MO's are obtained: bonding, non-bonding, and antibonding, in which the first two are occupied by pairs of electrons. In $XeF_4$ there are two choices of such orbitals, and in $XeF_6$ three. In accordance with this the $XeF_6$ molecule is given an octahedral structure. By comparing $XeF_4$ with $IF_5$, Rundle evaluated some thermodynamic and structural characteristics of $XeF_4$ and these values agreed satisfactorily with the experimental data.

Rundle's ideas have been developed further in subsequent studies[166–174] in some of which[167–173] there is a more quantitative approach. The calculations of Lohr and Lipscomb[170,171] by the MO–LCAO method, in which the MO were constructed with allowance for the 2*s* and 2*p* orbitals of fluorine and the 4*d*, 5*s*, and 5*p* orbitals of xenon, showed that the 4*d* electrons of xenon played a very small part in the bonds. According to Lohr and Lipscomb[171] $KrF_4$ should be stable but $ArF_4$ unstable; in both cases the calculations were carried out assuming a square planar structure for the molecule.

Hinze and Pitzer[167] also concluded that there was hardly any participation of the *d* orbitals in the bond formation. Jortner and coworkers[168,169] using the same model in principle, as Rundle, employed the semiempirical MO–LCAO method and concluded that the bond in xenon fluorides is described with the aid of delocalised MO's, which are formed by a combination of the 5*p* σ orbitals of xenon and the 2*p* σ orbitals of fluorine. The results of the authors'

theoretical calculations[168,169] were compared with spectroscopic data for $XeF_2$ and $XeF_4$ in the far ultraviolet region[43,86] and also the results of determinations of the heats of sublimation of these fluorides[42]. The experimental results agree with the proposed model; comparison of theoretical and experimental data led the authors[168,169] to conclude that the essential contribution to the stability of crystalline $XeF_2$ and $XeF_4$ is provided by electrostatic interaction, due to the transfer of charge from the xenon atom to the fluorine atoms. The ionic character of the halides of the Group 0 elements also follows from Waters and Gray's calculations[172], made within the framework of the simple MO method.

Some authors have used the MO method with allowance for the *d* orbitals of xenon. Boudreaux[70] studied the 5*p*, 5*d*, 6*s*, and 6*p* orbitals of xenon and the 2*p* orbitals of fluorine and showed that the bond in $XeF_4$ has mainly a *p* character, but partially *d* and *s* character. The results of his calculations of the magnetic susceptibility of $XeF_4$ [69] agree with the experimental results and confirm his proposed model. The scheme of MO's proposed by Israéli[175,176] was also constructed with allowance for the *d* orbitals of xenon. In this case qualitative consideration led to agreement with the experimental results on the geometrical configuration of the xenon fluorides.

Nesbet[177] proposed that the bond in the xenon fluorides is similar to the mechanism of indirect exchange in the antiferromagnetic oxides of type MnO. Nesbet's ideas and conclusions were criticised by Allen[161].

The work of Bilham and Linnett[178] was devoted to the approximate calculation of $XeF_2$ by the valency bond method with allowance for four electrons and the island $F^+Xe^{2+}F^+$. The wave functions of the molecule are constructed from the $2p_z$ orbitals of two fluorine atoms and one $5p_z$ orbital of a xenon atom in the assumed linear structure of the molecule. Calculations for $XeF_6$, made by the MO–LCAO method, led to an octahedral structure for this molecule[179]. The electronic structure of the kryptates and xenates was considered by Urch[180]. The ion $XeO_6^{4-}$, in all probability, exhibits octahedral symmetry. In this problem there is no difference between the MO method and the valency bond method.

The above ideas were subject to some criticism both from theoretical positions and also by comparison with experimental results[110,163,181,183]. Coulson[163] discussed the merits and deficiencies of the various models and came to a conclusion that the correlation model[11] and the models using the hybridisation of the *d* electrons[12] (in this case the excitation energy of the electrons to the *d* level is too high) were inapplicable; Coulson considered that both the MO theory and the valence bond theory with allowance for resonance in the structure (see p. 419) are suitable for describing the chemical bonds in the compounds of the Group 0 elements. Both these theories give a charge distribution of $F^{-\frac{1}{2}}-Xe^{+1}-F^{-\frac{1}{2}}$ for $XeF_2$; in $XeF_4$ and $XeF_6$ the charge migration is somewhat less. Such a charge distribution agrees with the results derived from investigations of the nuclear magnetic resonance[49,50,91–94,187,188].

Hemmerlich[181] and Noyes[183] consider the most acceptable treatment from the position of the theory of three-centre four-electron MO.[165,169] This theory well explains the spatial configuration of the compounds of xenon and gives interatomic distances in these compounds which agree satisfactorily with the experimental values. The considerable degree of ionicity of the bonds in the xenon fluorides, resulting from this consideration, also agrees with the experimental results. Thus the essential role of ionic bonds in xenon fluorides is demonstrated by the chemical shifts measured by the nuclear magnetic resonance method (Fig. 24); for $XeF_4$ this is also apparent from the asymmetry of the resonance lines (see p. 409). The results of a study of the Mössbauer effect in the xenon fluorides[51,52], the heats of sublimation of $XeF_2$ and $XeF_4$,[42,168,169], and certain other physical and chemical properties of xenon compounds have also been interpreted from this viewpoint.

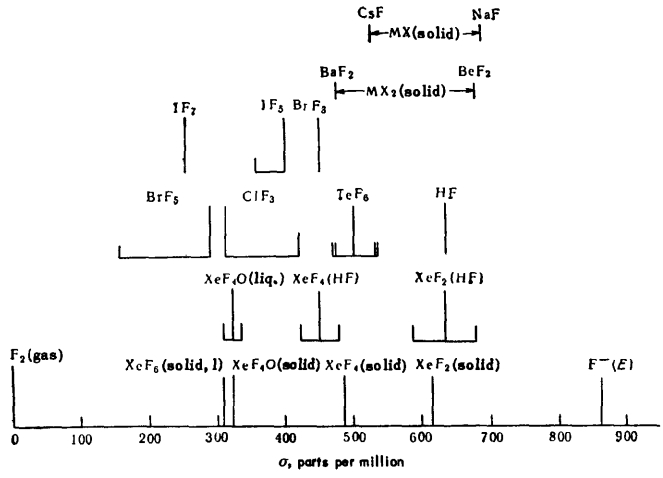

Fig. 24. Shielding constants σ for some fluorides[50].

Consideration by the valence bond method also gave a series of results agreeing with the experimental data[136]. In general, in most instances the MO theory and the valence bond theory lead to the same configuration and this agrees with experiment. The essential difference between the methods considered occurs, however, in the case of $XeF_6$. For this molecule the valence bond theory leads to a non-octahedral structure, whereas consideration by the MO method leads to regular octahedral structure. Unfortunately the experimental results have still not made possible the solution of this question.

Each of the theories has, naturally, its merits and its drawbacks; Coulson[163], for example, notes that the valence bond theory is simpler and more graphic, but states that the MO method is more suitable for considering different electron transitions. The most important conclusion, which can be drawn on the basis of the theoretical discussions, is the absence of a necessity to postulate any new type of bond for the compounds of the Group 0 elements and the possiblity of a semiquantitative explanation of the experimental facts with the assistance of existing theoretical concepts.

## V. SOME THERMODYNAMIC CONSIDERATIONS

One of the most astonishing experimental facts revealed in the process of investigating xenon compounds, was the thermodynamic stability of many of these compounds. The standard heat of formation of gaseous $XeF_2$ is $-37 \pm 10$ kcal × × $mole^{-1}$.[44] Evaluation of this value for solid $XeF_2$ from spectrographic data led to the value -20 kcal $mole^{-1}$,[116] but Hoppe[189], as the result of a comparison of the bond

energies of the xenon fluorides and the halogen fluorides, concluded that it should be greater. For $XeF_4$, $\Delta H^\circ$ = = -60 kcal mole$^{-1}$,[71] and $\Delta G^\circ$ = -29.4 kcal mole$^{-1}$. For $XeF_5$, $\Delta H^\circ$ = -79 kcal mole$^{-1}$.[72] The xenon oxides, however, are thermodynamically unstable.

Some investigators attempted, by more or less complex calculations, to evaluate the thermodynamic stability of Group 0 element compounds not yet obtained and so to decide the question of the possibility of obtaining these or other compounds. Waters and Gray[172] calculated by the simple MO method, the energy of formation from the elements and the energy of dissociation of the halides of the Group 0 elements. They found the following values (in kcal mole$^{-1}$) for the dissociation energy: $XeF_4$ 123.1, $KrF_4$ 23.5, $ArF_4$ -30.7, $NeF_4$ -507.1, $XeCl_4$ -50.9, $KrCl_4$ -137.4, $XeF_2$ 11.1, $KrF_2$ -5.3, $XeCl_2$ -42.9. Bartlett[18,190] started principally from a comparison of the mean bond energies of the compounds of the Group 0 elements with other halides and oxides. He evaluated the mean bond energy (in kcal): $KrF_2 \sim 30$, $KrF_4 \sim 19$, $KrF_6 \sim 18$, and $XeCl_4 \sim 10$, and concluded that the first three were exothermic and the fourth endothermic.

Although the results of all the calculations demonstrate sufficiently convincingly the thermodynamic instability of the compounds of even argon, Pimentel and Spratley[173,191] consider that the existence of a helium fluoride $HeF_2$ is possible; these authors calculated the infrared spectrum of the hypothetical molecule $HeF_2$ and considered possible methods for obtaining $HeF_2$ based on the $\beta$ discharge of tritium nuclei, the irradiation of lithium fluoride with slow neutrons and the bombardment of metal fluorides with $\alpha$ particles[191]. Noyes[183] briefly considered various possibilities for the formation of still unknown compounds of Group 0 elements and proposed for these elements the group name "aerogens".

## VI. POSSIBLE APPLICATIONS

The interest in the compounds of the elements of Group 0 is obviously not due solely to their theoretical importance. It must be supposed that such broad development in the investigations also had some practical aims. Unfortunately this question has only been touched upon and then in very few works.

The question of the potential applications of the compounds of Group 0 elements has received the most detailed consideration in the article by Pomeroy[192]. He noted the important part played by the xenon isotopes $^{133}Xe$ and especially $^{135}Xe$, which exhibits a very large cross-section for the capture of thermal neutrons ($> 10^6$ barns) in industrial nuclear energy and briefly considered the possiblity of using them as solid, and not gaseous compounds. On the other hand, there is the interesting possibility of recovering radioactive xenon and krypton, formed in the operation of a nuclear reactor, as fluorides or other compounds of low volatility.

The xenon fluorides can serve as "stores" of xenon and fluorine; it is possible that they will show promise as oxidants for rocket fuels[14,192]. The regeneration of xenon from its fluorides, particularly the complex ones, can prove to be a good method of obtaining pure xenon. The possibility of an analogous use of krypton fluorides is not excluded, although their instability can create obvious difficulties.

The xenon oxides very easily detonate and are highly explosive; it is possible that their ability to explode without leaving traces of solid substances can be utilised[14,192].

Compounds of xenon, especially the xenates and perxenates, may find many uses as oxidants in carrying out various processes[192].

Finally, it can be suggested that if the radon fluorides prove to be involatile they will find wider application in radiation therapy than gaseous radon, the use of which sometimes is hazardous[14].

Undoubtedly in the very near future a profitable use will be found for the compounds of the elements of Group 0. Even now for inorganic chemistry the immense value of the discovery and study of these substances is completely indisputable, and it is possible, finally, to visualise a further wide development of manifold investigations in this interesting and promising field.

## NOTE ADDED IN PROOF

Whilst this article was in the press several papers dealing with the compounds of the elements of Group 0 were published; they include both reviews[193-201] and original work[202-210].

## 1. INTRODUCTION

Decaborane† is one of the most interesting representatives of the boron hydrides, information about which before the nineteen-fifties was restricted to Stock's unique monograph [1].

After World War II, in connection with the vigorous development of reaction propulsion for aviation there arose the need to devise a more effective aviation fuel than hydrocarbons. The high calorific value of boron hydrides served as an impetus to the intensive investigation of the chemistry of decaborane, the most stable boron hydride. In view of the complex constitution of decaborane the establishment of its structure was the first task.

This problem was solved by the combined forces of a large group of physicists and chemists.

This review surveys all the main literature on the chemistry of decaborane and also that on the structure and reactivity of its stable derivatives — anions of the $B_{10}H_{10}^{2-}$ type, barenes (carboranes), etc.

† Strictly, decaborane(14), according to the nomenclature recommended in the Preliminary Report of the Advisory Committee presented at the 125th Meeting of the American Chemical Society, 25th March, 1954. This nomenclature has been used where possible in this translation (Ed. of Translation).

## 2. STRUCTURE AND REACTIVITY OF DECABORANE

For long the structure of the boron hydrides was one of the principal unsolved problems of structural chemistry. Although decaborane is a solid crystalline compound and was studied by X-ray diffraction, the few attempts in this direction ended in failure, because of the complexity of the structure [2]. Finally Kasper and coworkers [3] succeeded in solving the problem in 1950, despite a series of difficulties, for example, the absence of heavy atoms from the decaborane molecule.

It was shown that the ordered structure of the unit cell of the crystal consists of eight units ($a$ = 14.45, $b$ = 20.88, $c$ = 5.68 Å). The $x$, $y$ coordinates of the boron atoms were determined from the initial map obtained for the electron density in the $\rho_z(x', y')$ plane. The $z$ coordinate was then found by trial and error. The use of the electron density method enabled the coordinates of the boron atoms to be defined accurately and the coordinates of the hydrogen atoms to be found. It transpired that ten of these were attached to the ten boron atoms by an ordinary bond and the other four act as bridges between six boron atoms.

Subsequently [4] a more accurate structure was deduced by the method of least squares. It appeared (see Fig. 1) that the skeleton of the molecule consists of two pentagonal pyramids linked by a common edge of the bases.

The molecule has a centre of symmetry and two perpendicular axes of the second order. It can be shown that the boron atoms in the skeleton occupy 10 of the 12 vertices of a slightly deformed icosahedron.

The structure obtained now required explanation from the standpoint of electronic theory, since it did not fit into the framework of the elementary bond theory. The first significant step towards the solution of this problem was the application of the three-centre bond theory to the structure [5]. The starting point for the calculations was two main assumptions: (1) each boron atom gives three electrons and four $2sp^3$ hybridised orbitals, and each hydrogen atom a 1$s$ orbital and one electron; (2) in addition, six boron atoms give one $2sp^3$ orbital and half an electron to each B–H–B bond. As a result it was found that the boron skeleton contains two σ bonds (between atoms 2 and 6, 4 and 9) and six three-centre bonds. Four of these are three-centre central bonds — between the atoms $B_{(10)}-B_{(1)}-B_{(5)}$; $B_{(1)}-B_{(2)}-B_{(3)}$, $B_{(1)}-B_{(4)}-B_{(8)}$, and $B_{(8)}-B_{(9)}-B_{(7)}$ — which are characterised by the direction of three atomic orbitals of boron to the centre of the triangle and the existence of one bonding and two non-bonding orbitals. The other two are open three-centre bonds — between the atoms $B_{(10)}-B_{(4)}-B_{(8)}$ and $B_{(5)}-B_{(2)}-B_{(7)}$ — which are characterised by a special direction of the constituent orbitals of boron and by the presence of bonding, non-bonding, and antibonding orbitals. Despite the undoubted importance of these theoretical concepts, they were insufficiently precise in reflecting the electronic structure of decaborane and led to an incorrect determination of the charges of the boron atoms.

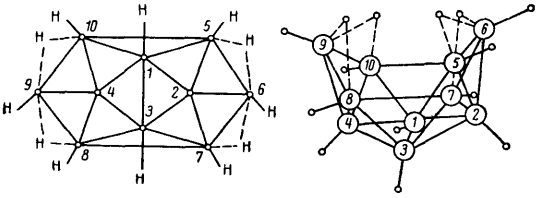

Fig. 1. Structure of the decaborane molecule.

The use of the standard calculation by the LCAO–MO single-electron method, assuming that 16 electrons and 22 atomic orbitals bond the boron skeleton was more fruitful [6]. The following distribution of the formal charge was obtained by calculation of eight wave functions for the given boron skeleton:

| $B_2$, $B_4$ | $B_5$, $B_7$ | $B_8$, $B_{10}$ | $B_1$, $B_3$ | $B_6$, $B_9$ |
|---|---|---|---|---|
| −0.254$e$ | −0.031$e$ | | +0.046$e$ | +0.268$e$ |

Starting from the distribution of the formal charge and the structure of the boron skeleton, the dipole moment was found, which agrees well with the value found experimentally [7].

The introduction of a correction with an allowance of 0.2$e$ negative charge on the bridging hydrogen atoms leads to the final distribution:

| $B_2$, $B_4$ | $B_1$, $B_3$ | $B_5$, $B_7$, $B_8$, $B_{10}$ | $B_6$, $B_9$ |
|---|---|---|---|
| −0.254$e$ | +0.046$e$ | +0.069$e$ | +0.268$e$ |

Although the calculation of the charges by the LCAO–MO method (even the latest improved values [8]) agrees with the chemical and physical properties of decaborane much better than the method of localised three-centre orbitals, the great difference in charges between the atoms 1, 3 and 2, 4:

| $B_2$, $B_4$ | $B_1$, $B_3$ | $B_5$, $B_7$, $B_8$, $B_{10}$ | $B_6$, $B_9$ |
|---|---|---|---|
| −0.329$e$ | −0.102$e$ | +0.011$e$ | +0.410$e$ |

does not agree with the chemical results and the electronic model [9], which requires further study.

One of the interesting features of decaborane is the presence of four three-centre B–H–B bonds. The nuclear magnetic resonance spectra and theoretical calculations showed [10] that bridge atoms of hydrogen in decaborane are more electropositive than the terminal ones. This is because after departure of the bridge proton the electron pair is employed in the formation of a new B–B bond, instead of the B–H–B bond, so that radical changes in the structure do not take place. As a result of this, decaborane is a strong acid [11] giving various salts with bases.

Furthermore, decaborane participates in interesting exchange reactions with nucleophilic reagents at the $B_{(6)}$ and $B_{(9)}$ atoms, which carry considerable positive charge. For these reactions (for example, with acetonitrile) the liberation of 1 mole hydrogen per 2 moles reacting base with an unshared pair of electrons is remarkable, the compound $B_{10}H_{12}L_2$ being formed with a changed electron balance. Reddy and Lipscomb [12,13], in establishing the structure of the diacetonitrile derivative of decaborane by X-ray diffraction, demonstrated a very small change in the B–B and C–C–N distances compared with the initial decaborane and acetonitrile.

Dickerson and Lipscomb [14] predicted the existence of then unknown stable boron hydrides, and subsequently the existence of stable anions based on boron hydrides was predicted [15]. One of the most interesting anions predicted was $B_{10}H_{14}^{2-}$, the existence of which was confirmed [13] by the preparation of $B_{10}H_{14}Na_2$, since of all the boron hydrides only decaborane is able to add on two electrons, giving a satisfactory valence structure [15].

The bis(acetonitrile) product $B_{10}H_{12}(CNCH_3)_2$ can be considered as a derivative of this anion having two B–H–B bonds between the atoms 7, 8 and 5, 10 and the two $BH_2$ groups at atoms 6 and 9. The suggested mechanism [13] presupposes the formation of two open three-centre bonds, $B_{(5)}-B_{(6)}-B_{(7)}$ and $B_{(10)}-B_{(9)}-B_{(8)}$ instead of four bridge bonds – with the formation of two new bridge bonds, $B_{(5)}-H-B_{(10)}$ and $B_{(7)}-H-B_{(8)}$ – as a result of which a molecule of hydrogen is detached and at the $B_{(6)}$ and $B_{(9)}$ atoms is released by the orbital occupying the unshared electron pair of the attacking base (Fig. 2).

Furthermore, it is suggested [16] that bis(acetonitrile)-decaborane exists in solution in two tautomeric forms in which the acetonitrile groups are either in the terminal positions, as described above, or occupy the place of two bridge hydrogen atoms. This suggestion was formulated on the basis of the different nuclear magnetic resonance spectra of solutions of $B_{10}H_{12}(CH_3CN)_2$ in acetonitrile and in dimethylformamide.

On the other hand, in view of the presence of negative charges on atoms 2 and 4, in principle decaborane should participate in electrophilic substitution reactions. Stock himself showed [1] that on reaction with halogens decaborane is halogenated. Comparatively recently [17] the structure of an halogeno-derivative was established for the first time, using X-ray diffraction – diiododecaborane. Having found the presence of a second-order axis in the molecule and by using the probable B–I distance (the sum of the covalent radii), the authors calculated the I–I distances for all possible pairs of positions at which the iodine atoms are situated symmetrically relative to the second-order axis (5 pairs) and compared these quantities with the value found experimentally (6.25 Å). Positions 2 and 4 satisfied these requirements, the I–I distance then being 6.21 Å. All this supports the hypothesis of the electrophilic mechanism of iodination of decaborane at the places with maximal electron density.

Due to the non-uniform charge distribution in the molecule, decaborane can also act as a donor of hydride ions. For example, it reduces acetals and ortho-esters to ethers on heating [18].

Although Kasper and coworkers provided sufficient evidence for the structure of decaborane, it has been investigated carefully by many physicochemical methods. The principal merit of these methods, one which they retain unaltered in decaborane chemistry, is the possibility of determining the characteristics of all the types of hydrogen bonds in the molecule. This permits the determination of the mobility of the B–H bonds in different types of reactions and rapid establishment of the structure of the products obtained.

Shoolery made the first interpretation of the proton and $^{11}B$ nuclear magnetic resonance spectra of decaborane, in 1955 [19]. In this and subsequent investigations [20,21] it was found that the $^{11}B$ nuclear resonance spectrum (Fig. 3*a*) consists of a high-field doublet and a low-field triplet (ratio of intensities 1 : 4), the latter being, in its turn, the result of the overlap of two doublets of the same intensity.

It was shown that the high-frequency doublet of the spectrum belongs to the vertex atoms $B_{(2)}$ and $B_{(4)}$, the central doublet of the triplet to the equivalent atoms $B_{(5)}$, $B_{(7)}$, $B_{(8)}$, and $B_{(10)}$, and the low-field doublet to the atoms $B_{(1)}$, $B_{(3)}$, $B_{(6)}$, and $B_{(9)}$. The last is not completely understood, since these four boron atoms are not equivalent. Actually, the nuclear magnetic resonance spectrum of perdeuterodecaborane [21] (Fig. 3*d*) – in which, because of the weak B–D spin–spin coupling, the number of peaks should equal the number of types of boron atoms in the molecule – showed distinct splitting of the low-field peak into two. Hence the low-field triplet in the nuclear magnetic resonance spectrum of decaborane can be considered as the result of superposition of three doublets with an intensity ratio of 1 : 1 : 2.

The proton spectrum of decaborane (Fig. 3*b*) is a resolved multiplet, with the following interpretation [19]. It is suggested that it consists of two quartets displaced relative to one another, and on these is superimposed a multiplet in the high-field region, which belongs to the bridge protons. The small quartet (shifted to the right) belongs to the two protons bonded with the vertex boron atoms, and the large one to the eight remaining protons. Attempts to interpret this spectrum by saturation of the signal of the proton nuclear magnetic resonance and by excitation of $^{11}B$ at the frequency 9.6257 MHz (double resonance), that is, by cancelling the B–H spin interaction, led to the spectrum represented in Fig. 3*c*. [20] It was shown that the high-field singlet of the spectrum belongs to the bridge protons, the low-field doublet to all the terminal protons except the "vertex" ones, and the plateau between them to the "vertex" protons. The low-field doublet is the result of the overlap of two peaks of the same intensity [21], in which the high-field singlet of the doublet belongs to four equivalent protons at $B_{(5)}$, $B_{(7)}$, $B_{(8)}$, and $B_{(10)}$, and the low-field component may in its turn be a split singlet – protons at $B_{(1)}$, $B_{(3)}$, $B_{(6)}$, and $B_{(9)}$.

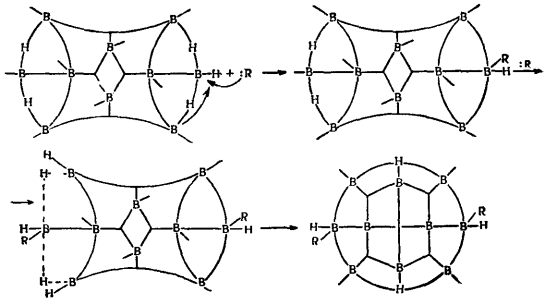

Fig. 2. Mechanism of reaction of decaborane with nucleophilic agents.

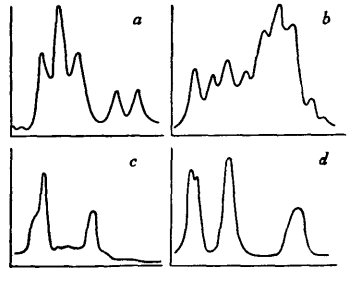

Fig. 3. Nuclear magnetic resonance spectra of decaborane and perdeuterodecaborane.

Hence in the study of the proton and $^{11}B$ nuclear magnetic resonance spectra of decaborane the hydrogen bridge atoms can easily be distinguished from the terminal ones and the "vertex" terminal hydrogens from the "non-vertex" ones. To distinguish the $B_{(5)}$, $B_{(7)}$, $B_{(8)}$, and $B_{(10)}$ hydrogen atoms from $B_{(1)}$, $B_{(3)}$, $B_{(6)}$, and $B_{(9)}$ is more laborious, and the direct establishment of the position of the hydrogen in positions 6 and 9 is almost impossible, compared with 1 and 3.

The use of infrared spectroscopy to study decaborane does not give better results. It was shown [22,23] that the valency vibrations of all the B–H terminal bonds of the molecule (as in the other boron hydrides) produces an absorption band in the spectrum in the region 2350–2630 $cm^{-1}$, mainly in the form of badly resolved multiplets. The valency vibrations of the B–H–B bridge bonds produce an absorption band in the 1600–2220 $cm^{-1}$ region. However, it seems impossible to distinguish by this method the "non-vertex" from the "vertex" B–H terminal bonds, since the deformation vibrations of the latter produce a band in the 900 $cm^{-1}$ region. The deformation vibrations of the "non-vertex" B–H bonds are difficult to determine, but they are evidently in the 1075–1010 $cm^{-1}$ region.

The mass spectrum of decaborane contains several peaks from unity to one hundred and twenty-four [24]. The theoretically calculated monoisotopic spectrum showed that the maximal mass peak corresponds with the ion of decaborane with *six hydrogen atoms removed.* As this number agrees with the number of terminal hydrogen atoms at the boron atoms which participate in the formation of hydrogen bridges, the authors consider that these hydrogens are the most labile in the molecule (in the sense of ionisation by electrons).

From the near ultraviolet absorption spectrum of decaborane [25] (in the gas phase from 90° to 140°C, in solution at room temperature, and in crystals at 4–4.2°K), the mean value of the minimum energy required for the first electron transition was 3.90 ± 0.1 eV. It is difficult to determine the existence of another electronically excited state of somewhat higher energy, since it is masked by the first transition.

Thermochemical calculations [26] give the following values for the dissociation energies of the various types of bond in decaborane: B–H (σ bond) 93.1 kcal per bond; B–B (σ bond) 83.1 kcal per bond; B–H–B (three-centre bond) 107.2 kcal per bond; B–B–B (three-centre bond) 97.7 kcal per bond.

Decaborane in diamagnetic. Its specific magnetic susceptibility, determined experimentally, is $(-116 \pm 1.5) \times \times 10^{-6}$.

The difference between the measured value and that calculated on the basis of the magnetic susceptibilities of boron and hydrogen ($-108 \times 10^{-6}$) is obviously due to the presence in the molecule of the bridge atoms of hydrogen.

The dipole moment of decaborane, determined by the Debye and Guggenheim methods, is between 3.17 D (in carbon disulphide solution) and 3.62 D (in benzene solution) [7].

## 3. DEUTERIUM EXCHANGE IN DECABORANE

Information about the deuteration of decaborane is extremely contradictory. Thus in investigating the nucleophilic reaction of deuterium exchange of decaborane with $D_2O$ and DCl at room temperature in solvents — Lewis bases (dioxan and water) — Hawthorne and Miller [27,28] showed that the hydrogen bridge atoms are exchanged first. The analysis was made using infrared spectra; it was first demonstrated that in what was known synthetically to be perdeuterodecaborane the stretching vibrations of the B–D bonds lie in the 1925 $cm^{-1}$ region and those of the B–D–B bonds in the 1400 $cm^{-1}$ region (in decaborane itself, 2565 and 1800–2140 $cm^{-1}$ respectively). The second stage of the reaction was the slow exchange of deuterium bridges with terminal hydrogen atoms bound to the atoms $B_{(5)}$, $B_{(7)}$, $B_{(8)}$, and $B_{(10)}$. In this process, the maximum exchange was eight protons with $D_2O$ and only about six with DCl.

Shapiro and coworkers [29], in studying the kinetics of this reaction, confirmed that the first act is the exchange of the bridge hydrogen atoms, with a subsequent slow migration of deuterium to the atoms $B_{(5)}$, $B_{(7)}$, $B_{(8)}$, and $B_{(10)}$. However, there is concurrent deuteration in the $B_{(6)}$ and $B_{(9)}$ terminal positions. If specimens of $B_{10}H_{10}D_4$ are isolated from the reaction medium and dissolved in anhydrous dioxan, then there is only regrouping of D atoms in the $B_{(5)}$, $B_{(7)}$, $B_{(8)}$, and $B_{(10)}$ positions.

According to the suggested mechanism, deuterium exchange in decaborane takes place with participation of the Lewis acids and bases. The authors think that the first act is the transfer of the electron pair of the Lewis base to the sixth and ninth boron atoms. In this, the bridge hydrogen atom becomes terminally bound with the neighbouring boron atom ("equatorial") and is rapidly exchanged with deuterium from $D_2O$. The deuterium subsequently entering into the molecule can be exchanged with the terminal hydrogen atoms at $B_{(5)}$, $B_{(7)}$, $B_{(8)}$, and $B_{(10)}$.

The terminal hydrogen atoms at $B_{(6)}$ and $B_{(9)}$ are exchanged intramolecularly in the complex of $D_2O$ with these boron atoms.

The proposed mechanism seems sufficiently satisfactory since it explains why in the case of DCl in dioxan less atoms of deuterium are exchanged than in the case of $D_2O$ [29] — here intramolecular exchange at the $B_{(6)}$ and $B_{(9)}$ terminal positions is impossible. However, Shapiro further maintains that the deuterium exchange with $D_2O$ in aqueous dioxan during prolonged interaction is quantitative, giving in a sense nucleophilic substitution, since the boron atoms 2, 4, 1, and 3 carry a significant negative charge. In methylene dichloride the deuteration of decaborane with $D_2O$ goes only in the bridge positions and the deuteration with DCl does not take place at all [27]. Sodium tridecahydrodecaborate($1^-$) exchanges only the bridge hydrogens with DCl. [28] In carrying out electrophilic deuteration of decaborane with DCl in carbon disulphide in the presence of aluminium chloride (at room temperature), Dupont and Hawthorne [30] showed that the reaction proceeds at the terminal hydrogen atoms bonded with the most negative atoms $B_{(2)}$, $B_{(4)}$, $B_{(1)}$, and $B_{(3)}$ and stops at this. The $B_{10}H_{10}D_4$ obtained does not exchange deuterium atoms for hydrogen on interaction with HCl, but reacts with DCl in dioxan almost to complete exchange, giving perdeuterodecaborane. This communication was published in refutation of a previous one [31], where it was maintained that in this reaction there is exchange of six hydrogen atoms in positions 2, 4, 5, 7, 8, and 10.

Apart from the methods described above, partly deuterated decaborane can be obtained by pyrolysis of partly deuterated diborane [32], there then being a statistical distribution of the deuterium in the molecule. A second

method is to heat decaborane with perdeuterodiborane at 100°. As the infrared spectra show, the exchange here is entirely in the terminal positions. Recently[33] an interesting paper reported isotopic exchange of boron atoms between [$^{10}$B]diborane and ordinary $B_{10}H_{13}Na$, in which all ten boron atoms of the decaborane skeleton participate (62.7% of the $^{10}$B is in the recovered diborane). It is suggested that the exchange takes place by formation and splitting of the intermediate anion $B_{11}H_{16}^-$, having the structure of an incomplete icosahedron.

## 4. PYROLYSIS OF DECABORANE

Stock himself noted[1] the stability of decaborane in the absence of oxygen at elevated temperature (up to 170°C), but a detailed investigation of the pyrolysis of decaborane has been made only recently.

Beachell and Haugh[34] showed that at 170–238° the main product is a polymeric hydride, containing, according to the infrared spectra, decaborane units. Volatile products other than hydrogen were not observed. These results were confirmed by Siegel and Mack[35] who isolated a polymeric product of composition $(BH)_x$ after pyrolysis at 200–250°C. They found that the pyrolysis rate rises sharply with temperature within the limits stated.

Finally, Owen[36] made a complete kinetic investigation of pyrolysis in the gas phase at 220°, 230°, and 250°C and various initial decaborane pressures (from 60 to 600 mmHg) and proposed a complete mechanism for the reaction:

$$B_{10}H_{14} + B_{10}H_{14} \rightleftarrows B_{10}H_{14}^* + B_{10}H_{14}, \quad (1)$$

$$B_{10}H_{14}^* \rightleftarrows B_{10}H_{12} + H_2, \quad (2)$$

$$B_{10}H_{14} + B_{10}H_{12} \rightleftarrows B_{20}H_{24} + H_2, \quad (3)$$

$$B_{20}H_{24}\ (\text{gas}) \rightleftarrows B_{20}H_{24}\ (\text{solid}), \quad (4)$$

$$2B_{20}H_{24} \rightleftarrows H_2 + \text{involatile solid hydrides}. \quad (5)$$

He showed that the pyrolysis is a first-order reaction with respect to decaborane and Eqn. (2) is the rate-determining stage for the reaction. This dependence is strictly obeyed for the first 60% of the conversion, but as the decaborane concentration falls the rate of reaction (3) approaches the rate of reaction (2) and the overall order becomes greater than first. An attempt was made to isolate the intermediate hydride $B_{20}H_{24}$ from the pyrolysis products at 230°C; a viscous liquid with a very low vapour pressure and an infrared spectrum similar to that of decaborane was obtained. It was shown by deuteration[34] that in the polymerisation of decaborane the terminal, not the bridge, hydrogen atoms are preferentially removed. Moreover, in carrying out the pyrolysis in the presence of ethyl bromide the main product was 2-ethyldecaborane[36]. The authors to suggested that the initial stage of the pyrolysis is the detachment of hydrogen atoms from the "vertex" positions.

The thermal interaction of diborane with decaborane was an interesting reaction. On passing diborane into molten decaborane (100°C), the liberation of hydrogen and the formation of a yellow crystalline product[37] were noted. Diborane itself under these conditions does not change. The following reaction mechanism was proposed on the basis of an analysis of the proton nuclear magnetic resonance spectrum, infrared spectra, and mass-spectra:

$$B_2H_6 + B_{10}H_{14} \rightarrow (BH)_{12} + 4H_2,$$

$$(BH)_{12} \rightarrow B_nH_{n-x} + \frac{x}{2}H_2.$$

The authors think that the $(BH)_{12}$ structure is a complete icosahedron in which the bridge hydrogen bonds are replaced by a $B_2H_2$ "cap". The polymer consists of chains of icosahedra. This is confirmed by the absence of intermediate boron hydrides between $B_{10}H_{14}$ and $B_2H_6$ and by the presence of tetraborane and hexaborane — the hydrolysis products of decaborane itself — in the hydrolysis of the polymer.

## 5. HYDROLYSIS, ALCOHOLYSIS, AND THIOLYSIS

As noted above, Stock[1] found that decaborane is slowly hydrolysed by water on heating. Later this reaction was studied in detail by Atteberry[38], who made a kinetic investigation of the hydrolysis of decaborane by water at 80° and 100°C. It was shown to be a first-order reaction:

$$B_{10}H_{14} + 30H_2O \rightarrow 10B(OH)_3 + 22H_2,$$

the rate constants being:

$$K_{100} = 4.27 \times 10^{-5}\ s^{-1} \quad \text{and} \quad K_{80} = 1.43 \times 10^{-5}\ s^{-1},$$

and the energy of activation $E_a$ = 14.5 kcal mole$^{-1}$.

On the basis that the activation energy agrees with the quantity found by Guter and Schaeffer[39] for the initial dissociation of decaborane in aqueous dioxan, the author concluded that the most probable mechanism was the ionic-dipolar hydroxylation of boron–hydrogen bonds.

A reaction of interest in this connection is the alcoholysis of decaborane by alcohols, of which there have been several kinetic studies:

$$B_{10}H_{14} + 30ROH \rightarrow 10B(OR)_3 + 22H_2.$$

Beachell and Meeker found[40] that the reaction of decaborane with primary alcohols is second order overall, first order in each of the components. The rate constants and activation energies were determined; there was an increase in the rate constant with the number of carbon atoms in the primary alcohols from 2 to 5. A more detailed study of this reaction with a larger number of alcohols[41] showed that is proceeds through the intermediate donor–aceptor complex $B_{10}H_{14}$.HOR. It appeared that the rate of alcoholysis by halogenated alcohols decreases as the halogen atom approaches along the carbon chain towards the OH group and increases as a $CH_3$ group approaches. The alcoholysis of decaborane by phenol is much slower than that by cyclopentanol. On the basis of these results and also in connection with the previously observed increase in alcoholysis rate with increase in the number of carbon atoms in the primary alcohol it was concluded that the decisive factor in alcoholysis is the inductive and not the steric effect. The stages determining the reaction rate are the breaking of the O–H bond in the $B_{10}H_{14}$.HOR complex, since there is a strong isotope effect on replacing alcohol by deuteroalcohol. A radical mechanism has been proposed for the breaking of the O–H bond, since in the case of an ionic mechanism:

$$B_{10}H_{14}HOR \rightleftarrows [B_{10}H_{14}OR]^- + H^+,$$

the addition of a base would rapidly shift the equilibrium to the right, that is, the reaction rate would be greatly increased. However, the addition of bases only slightly retards the process, which suggests that the second mechanism is impossible.

Thiols also destroy the decaborane molecule[42]. Thus on boiling in butanethiol for a few days, decaborane is converted quantitatively into tributyl thioborate. The reaction

with lower thiols necessitates heating in a autoclave, since at lower temperatures the reaction is very slow:

$$B_{10}H_{14} + 30RSH \rightarrow 10B(SR)_3 + 22H_2.$$

## 6. DECABORANE AS AN ACID

It was noted earlier that to a greater extent than the other boron hydrides decaborane is a dual reagent: in some reactions it behaves as a donor of hydride ions and in others as an acid, dissociating to $H^+$ ions. Guter and Schaeffer[39] found that the curve for the titration of a solution of decaborane in protolytic solvents (alcohol, aqueous alcohol, aqueous dioxan, 0.1 *N* NaOH) is characteristic for a strong monobasic acid. Two possible mechanisms for the formation of the acid are suggested:

$$B_{10}H_{14} + H_2O \rightarrow [B_{10}H_{14}OH]^- + H^+ \text{ (solution)},$$
$$B_{10}H_{14} \rightarrow [B_{10}H_{13}]^- + H^+ \text{ (solution)}.$$

In acetonitrile, decaborane behaves as a weak acid with $pK_a = 3.5$ and in dimethylformamide as a strong acid, the first potential jump being observed at pH 1.2 and the second at pH 6. It is thought that this difference is due to the different electron-donor properties of the solvents, which are stronger in the case of dimethylformamide[43]. However, according to Griffiths and Williams[44] the difference in the titration curves of decaborane in acetonitrile and dimethylformamide is due to the existence in the latter of dimethylamine impurity. In the pure solvents the curves are identical.

The acid properties of decaborane, that is, the presence in it of mobile protonised hydrogen atoms, forms a basis for its reaction with methylenetriphenylphosphorane and trimethylammoniomethylenide, as a result of which substituted phosphonium and ammonium salts with the anion $B_{10}H_{13}^-$ are obtained[45,46]:

$$(C_6H_5)_3P{=}CH_2 + B_{10}H_{14} \rightarrow [(C_6H_5)_3P^+CH_3]\,B_{10}H_{13}^-,$$
$$(CH_3)_3N^+{-}CH_2^- + B_{10}H_{14} \rightarrow [(CH_3)_4N^+]\,B_{10}H_{13}^-.$$

## 7. DECABORANE GRIGNARD REAGENTS AND SODIUM TRIDECAHYDRODECABORATE(1⁻)

The acidic properties of decaborane explain the ease of formation of its metal derivatives with sodium and magnesium, from which alkyldecaboranes were obtained in turn.

The magnesium derivative was first obtained by Siegel and coworkers[47] in 1958. They studied the reaction of decaborane with methylmagnesium iodide in ether and found that when an excess of decaborane was used a monomangesium derivative was produced:

$$B_{10}H_{14} + CH_3MgI \xrightarrow{\text{ether}} B_{10}H_{13}MgI + CH_4,$$

and when the methylmagnesium iodide was in excess, a dimagnesium derivative, $B_{10}H_{12}(MgI)_2$.

In hydrolysis with moist ether decaborane is regenerated. Benzyldecaborane is obtained by the reaction of decaborane Grignard reagent with benzyl chioride:

$$B_{10}H_{13}MgI + 2C_6H_5CH_2Cl \rightarrow B_{10}H_{13}CH_2C_6H_5 + C_6H_5CH_2I + MgCl_2.$$

The investigation of this compound by infrared spectroscopy and the $^{11}B$ nuclear magnetic resonance did not allow the authors to discover the precise position of the benzyl group in the decaborane molecule but positions 2 and 4 are excluded because the high-field doublet does not change in intensity compared with that for decaborane.

Dunstan and coworkers[48] made a special study of this reaction and found that in the reaction of decaborane with ethylmagnesium iodide a little ethyldecaborane is formed in addition to the magnesium iodide tridecahydrodecaborate(1⁻), and on subsequent addition of dimethyl sulphate to the decaborane Grignard reagent equal amounts of two isometic methyldecaboranes are formed.

In interpreting the $^{11}B$ nuclear magnetic resonance spectra the authors assigned to the products the structures of 5- and 6-methyldecaboranes. Benzyldecaborane, obtained by the method described above, was also given the structure of the 6-derivative.

It was shown that of the ordinary alkyl halides only benzyl bromide and chloride[49] and allyl bromide[50] undergo condensation with the decaborane Grignard reagent. In the case of alkyl fluorides and trialkyloxonium salts, various alkyldecaboranes were obtained with good yields[49]:

$$B_{10}H_{13}MgX + RF \rightarrow B_{10}H_{13}R + MgFX,$$
$$B_{10}H_{13}MgX + R_3O^+X^- \quad B_{10}H_{13}R + R_2O + MgX_2.$$

Attempts were made to reveal the structure of the decaborane Grignard reagent by infrared and ultraviolet spectra. It was shown that the infrared spectrum of $B_{10}H_{13}MgI$ is very similar to the spectrum of methylmagnesium iodide; the ultraviolet spectra also showed great similarity. From these results the authors gave magnesium iodide tridecahydrodecaborate(1⁻) the following structure:

and

A convenient reagent for the preparation of alkyldecaboranes is sodium tridecahydrodecaborate(1⁻), which can be obtained by the action of such reagents as sodium, sodium hydride, sodium amide, sodium tetrahydroborate, and dry powdered sodium hydroxide in ether on decaborane[51]:

$$B_{10}H_{14} + NaH \xrightarrow{\text{ether}} B_{10}H_{13}Na + H_2.$$

By carying out this reaction with decaborane with deuterated bridges it was shown that one of the bridge hydrogen atoms is substituted:

$$B_{10}H_{10}D_4 + NaH \xrightarrow{\text{ether}} B_{10}H_{10}D_3Na + HD.$$

The action of benzyl bromide in ether on sodium tridecahydrodecaborate(1⁻) gives benzyldecaborane identical with that obtained from the decaborane Grignard reagent, as described above. The deuteration of benzyldecaborane with $D_2O$ in dioxan showed that four deuterium atoms were rapidly introduced into the molecule, and this is evidence of the rearrangement of the benzyl group from a bridge position to a terminal one. There are only two possibilities for such regrouping: in the 6- or the 5-position. The nuclear magnetic resonance spectrum showed unambigously that the benzyl group is in position 6.

Sodium tridecahydrodecaborate(1⁻) boiled in ether with dimethyl and diethyl sulphate gives the same products as magnesium iodide tridecahydrodecaborate(1⁻), that is, a mixture of the 5- and 6-methyl- or 5- and 6-ethyl-decaboranes[52]. Reaction with iodine in ether at -80°C gave a

mixture of products, consisting of decaborane, ethoxydecaborane, and ethoxyiododecaborane [51]:

$$B_{10}H_{13}Na \xrightarrow[-80^\circ]{\text{ether}} B_{10}H_{13}I + B_{10}H_{14} + B_{10}H_{13}OC_2H_5 + B_{10}H_{12}IOC_2H_5.$$

By using various ethers in this reaction, various alkoxydecaboranes can be obtained [53]. The precise position of the RO group could not be established, but the $^{11}B$ nuclear magnetic resonance spectrum excludes substitution at boron atoms 2 and 4.

Finally, sodium tridecahydrodecaborate(1$^-$) reacts with chloro(diphenyl)phosphine, forming a phosphorus(III) compound [54]:

$$B_{10}H_{13}Na + (C_6H_5)_2PCl \rightarrow B_{10}H_{13}P(C_6H_5)_2 + NaCl.$$

## 8. NUCLEOPHILIC SUBSTITUTION IN DECABORANE

It was noted earlier that hydrolysis and alcoholysis of decaborane take place through an intermediate complex, $B_{10}H_{14}.HOR$. This complex is formed because, despite the high degree of symmetry and stability, the decaborane molecule is an electron-deficient system striving to make up the deficiency from molecules having unshared pairs. This property of decaborane appears in many reactions with various nucleophilic reagents.

For example, a solution of decaborane in acetone at low temperatures gives a $^{11}B$ nuclear magnetic resonance spectrum in which the low-field doublet is degenerate, which indicates the formation of a complex at positions 6 and 9 in the decaborane molecule. On raising the temperature to room temperature or above, the spectrum becomes identical with that in benzene, that is, the complex is decomposed into the initial components [55].

Stock himself noted [1] that decaborane reacts with liquid ammonia, adding up to six molecules of the latter; on heating, the ammonia molecules are split off in stages, and later the decaborane structure is broken down and hydrogen released.

Fitch and Laubengayer [56] studied in detail the reaction of decaborane with dimethylamine at low temperature [56]:

$$B_{10}H_{14} + n(CH_3)_2NH \rightarrow [(CH_3)_2NH]_n.B_{10}H_{14}.$$

By studying the reaction kinetics, the existence of addition compounds with four and five molecules of dimethylamine per molecule of decaborane has been demonstrated. They are very unstable compounds and decompose with formation of dimethylamine and lower addition products even at low temperatures (-60° to 40°C)‡. The addition products with $n$ = 1, 2, or 3 are rather stable and were characterised by X-ray diffraction. Treatment of the addition products with water formed decaborane again. In an excess of dimethylamine at elevated temperatures decaborane undergoes aminolysis with liberation of hydrogen and destruction of the skeleton; in particular, a crystalline product with the ratio B : N = 9 : 1 has been identified.

Interestingly, for most amines at elevated temperature the reaction proceeds with liberation of hydrogen and formation of complexes of the type $B_{10}H_{12}.2L$. The addition products obtained and isolated at low temperatures decompose only by splitting off the amine but without releasing hydrogen. This was confirmed by Burkardt and Fetter [57] for the pyridine derivatives. Under these conditions the addition products $B_{10}H_{14}.2BrC_5H_4N$ and $B_{10}H_{14}.3C_5H_5N$ were obtained, stable on heating to 100°. Investigation of the reaction of decaborane with substituted anilines [32] showed that in every case of the reaction of an amine (*p*-anisidine, *p*-toluidine, *p*-chloroaniline, *N*-methylaniline, *NN*-dimethylaniline) with decaborane at room temperature 1 mole hydrogen is liberated per 1 mole decaborane:

$$B_{10}H_{14} + 2RC_6H_4NH_2 \rightarrow B_{10}H_{12}.(RC_6H_4NH_2)_2 + H_2.$$

Alkylpyridines and alkylquinolines at room temperature dissolve decaborane without releasing hydrogen, giving strongly coloured solutions from which a solid is slowly precipitated. The same reaction in pentane proceeds with evolution of hydrogen. Aliphatic amines give solid products without evolution of hydrogen even in pentane. The reaction with diethylthiourea proceeds with liberation of hydrogen and the formation of a stable crystalline substance, $B_{10}H_{12}[(C_2H_5NH)_2CS]_2$. [58]

A method for the direct colorimetric determination of decaborane has been developed, based on the formation of orange-red solutions with *NN*-diethylnicotinamide with an absorption maximum in the 430–500 mμm region [59]. The value of this method is that neither other boron compounds, nor proteins hinder the determination. The method is applicable to solutions in aqueous systems (for example, blood plasma), and this defines its practical value in view of the considerable toxicity of decaborane.

Nitriles, as substances with very weak basic properties, react with decaborane on heating, hydrogen being liberated [60,61]:

$$B_{10}H_{14} + 2RC{\equiv}N \rightarrow B_{10}H_{12}.(RCN)_2 + H_2,$$

and crystalline products precipitated. The bis(acetonitrile) complex, which is involatile and stable in air, melts with decomposition above 200°C, is diamagnetic, and soluble in acetonitrile. The structure of the substance was determined by X-ray analysis [13]. It was shown that the acetonitrile ligands are in positions 6 and 9. This agrees completely with the fact that these are the most electropositive atoms in the decaborane molecule.

Besides the above nitrogen compounds, amides and cyanamides can enter into reactions analogous to those with nitriles, and so can many Lewis bases not containing nitrogen, such as sulphides, phosphines, phosphites, thiophosphites, ethers, alkylphosphinic acids [alkylphosphonic acids or even alkyl hydrogen phosphonates may be meant (Ed. of Translation)], arsines, and sulphoxides [62–67]. They all have the formula $B_{10}H_{12}L_2$ (where L is the Lewis base) and a structure which is obviously analogous to that of bis(acetonitrile)decaborane.

All the complexes of this type are covalent compounds, as is shown by a study of their infrared and $^{11}B$ nuclear magnetic resonance spectra, compared with those of the ionic complex $[B_{10}H_{10}]^{2-}.2(C_2H_5)_3\overset{+}{N}H$. [63]

On the basis of complexes of decaborane with phosphines, polymers of the type [67]:

$$[-OP(C_6H_5)_2.B_{10}H_{12}P(C_6H_5)_2-]_x.$$

have been obtained [68].

Kinetic investigation of the reactions of decaborane with various nitriles and sulphides [69] in dioxan at 70–80°C showed that this reaction is first order with respect to each of the reagents and of second order overall. Electron-donor substituents in nitriles and sulphides increase the

‡ These figures appear to be in error; see Fitch and Laubengayer [56] (Ed. of Translation).

reaction rate, electron-acceptor constituents decrease it. The following reaction scheme is proposed:

$$B_{10}H_{14}+L \underset{}{\overset{\text{rapid}}{\rightleftharpoons}} B_{10}H_{14}L \xrightarrow{\text{slow}} H_2+B_{10}H_{13}L \xrightarrow[\text{rapid}]{L} B_{10}H_{13}L_2.$$

Not only uncharged molecules, but also anions can act as complex-forming agents in this reaction[64-70]. For example, hydrogen is also liberated in the reaction of decaborane in ether with sodium cyanide:

$$NaCN+B_{10}H_{14}R_2 \xrightarrow{25^\circ} [NaB_{10}H_{14}CN] \rightarrow NaB_{10}H_{12}CN+H_2.$$

An ionic compound is formed in which the CN group is obviously situated at one of the boron atoms 6 or 9. The salts $B_{10}H_{11}X^-$, where X = NCO, SCN, $OCH_3$, and $C(CN)_3$, have also been obtained. $^{11}B$ nuclear magnetic resonance spectra have shown that all the decaborane complexes of type $B_{10}H_{12}.2L$ and $B_{10}H_{12}.L^-$ are isostructural and are derivatives of the ion $B_{10}H_{14}^{2-}$.

A convenient method has been developed[71] for obtaining the anion $B_{10}H_{14}^{2-}$ by the reaction of decaborane with an aqueous solution of potassium tetrahydroborate:

$$B_{10}H_{14}+H_2O \rightleftarrows B_{10}H_{13}^-+H_3O^+,$$
$$B_{10}H_{13}^-+BH_4^- \rightleftarrows B_{10}H_{14}^{2-}+[BH_3],$$
$$[BH_3]+3H_2O \xrightarrow{\text{rapid}} B(OH)_3+3H_2.$$

$Rb_2B_{10}H_{14}$ and $Cs_2B_{10}H_{14}$ were isolated. The reaction of decaborane with sodium tetrahydroborate in Diglyme [di-(2-methoxyethyl) ether (Ed. of Translation)] at the boiling point is a simple method for preparing[72] the dianion $B_{12}H_{12}^{2-}$. The reaction follows the scheme:

$$B_{10}H_{14}+BH_4^-+R_2O \rightarrow B_{10}H_{13}^-+R_2O\cdot BH_3+H_2;$$
$$B_{10}H_{13}^-+R_2O\cdot BH_3 \rightarrow B_{11}H_{14}^-+H_2+R_2O;$$
$$B_{11}H_{14}^-+BH_4^- \rightarrow B_{12}H_{12}^{2-}+3H_2.$$

The first stage takes place at room temperature, the second at 90°, and the last at the boiling point of Diglyme.

Donor–acceptor complexes including the $B_{10}H_{12}$ unit in their composition undergo characteristic ligand-exchange reactions[10,19,66]:

$$B_{10}H_{12}\cdot 2L'+2L \rightarrow B_{10}H_{12}\cdot 2L+2L',$$

in which the displacement sequence obviously depends on the strength of the base. Thus Hawthorne and Pitochelly[62] found the following displacement order for acetonitrile, diethylcyanamide, and triphenylphosphine:

$$B_{10}H_{12}(CH_3CN)_2 \xrightarrow{2\,(C_2H_5)_2NCN} B_{10}H_{12}[(C_2H_5)_2NCN]_2 \xrightarrow{2P\,(C_6H_5)_3} B_{10}H_{12}[P(C_6H_5)_3]_2.$$

The reverse reactions do not take place.

A series of pyridine complexes of decaborane were obtained by analogous reaction of the dimethyl sulphide complex with substituted pyridines[73]. Since some of these products are coloured the authors suggest the interaction of the pyridine $\pi$ electron with the three-centre bonds in $B_{10}H_{12}^{2-}$.

Subsequent investigations of the exchange reactions of bis(acetonitrile)decaborane showed that in its reaction with triethylamine in boiling benzene two products with the same overall formula $B_{10}H_{12}.[N(C_2H_5)_3]_2$ should be expected[74]. One of these is a covalent compound of the general type $B_{10}H_{10}.L_2$, and the other the saltlike compound $B_{10}H_{10}^{2-}.2[NH(C_2H_5)_3]^+$. Unlike the first compound, the latter is confirmed by deuterium exchange with $D_2O$, is insoluble in organic solvents, and soluble in water; in aqueous solutions the $NH(C_2H_5)_3^+$ is exchanged for other cations:

$$B_{10}H_{10}^{2-}\cdot 2NH(C_2H_5)_3^+ + N(CH_3)_4^+Cl^- \rightarrow B_{10}H_{10}^{2-}\cdot N(CH_3)_4^+ + NH^+(C_2H_5)_3Cl^-.$$

It was found[75] that substituted decaboranes also form (like decaborane) complexes with Lewis bases. Thus 2-bromodecaborane reacts with acetonitrile, diethyl sulphide, and triphenylphosphine to give corresponding complexes:

$$2\text{-}B_{10}H_{13}Br \xrightarrow{\begin{array}{l}(C_2H_5)_2S\\ CH_3CN\\ (C_6H_5)_3P\end{array}} \begin{array}{l}[(C_2H_5)_2S]_2B_{10}H_{11}Br\\ (CH_3CN)_2B_{10}H_{11}Br\\ [(C_6H_5)_3P]_2B_{10}H_{11}Br\end{array}.$$

Monoethyldecaborane, containing 60% 2-ethyl- and 40% 1-ethyl-decaborane, is also readily converted into analogous complexes.

However, it has been noted[75] that boiling 2-iododecaborane with triethylamine in benzene yields not only the salt mentioned, $B_{10}H_{10}[NH(C_2H_5)_3]_2$, but also $B_{12}H_{12}[NH(C_2H_5)_3]_2$, which can also exchange cations, giving, for example, $K_2B_{12}H_{12}$.

2-Bromodecaborane also forms a complex with triethylamine[75], $B_{12}H_{12}[NH(C_2H_5)_3]_2$. However, bis(triethylammonium) nonahydrobromodecaborate is readily obtained by the action of triethylamine in benzene at 20° on $[(C_2H_5)_2S]_2B_{10}H_{11}Br$:

$$[(C_2H_5)_2S]_2B_{10}H_{11}Br+2N(C_2H_5)_3 \rightarrow [(C_2H_5)_3NH]B_{10}H_9Br.$$

A similar product is formed on heating $B_{10}H_{13}Br$ with trimethylamine in boiling toluene. Monoethyldecaborane and triethylamine in toluene give

$$[(C_2H_5)_3NH]_2B_{10}H_9C_2H_5,$$

in high yield.

The symmetry of the stable anion $B_{10}H_{10}^{2-}$ has been demonstrated and an icosahedral structure has been proposed for it.

Hawthorne and coworkers[76] have observed that in the reaction of the disulphide complex of decaborane with ethanol $B_9H_{13}(SR_2)$, a derivative of nonaborane(15) $B_9H_{15}$ is formed. An analogous reaction with the acetonitrile complex takes place thus:

$$B_{10}H_{12}(CH_3CN)_2+2C_2H_5OH \rightarrow B_9H_{12}(CH_3-\underset{\underset{OC_2H_5}{|}}{C}=NH)+CH_3CN+H_2+B(OC_2H_5)_3.$$

Organic sulphide ligands in the last type of compound can be replaced by other ligands:

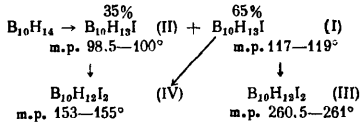
$$B_9H_{13}(SR_2)+X \rightarrow B_9H_{13}X+SR_2,$$

where X = $CH_3CN$; $R_3N$; $R_2NH$; $RNH_2$; $R_2NCN$, $P(C_6H_5)_3$. When a sulphide complex of nonaborane(15) is treated with methylenetriphenylphosphane, a salt of the $B_9H_{12}^-$ anion is formed:

$$B_9H_{13}(SR_2)+(C_6H_5)_3P{=}CH_2 \rightarrow [(C_6H_5)_3PCH_3]^+[B_9H_{12}]^-+SR_2.$$

The direct alkylation of decaborane by methyllithium and ethyllithium can also be classified as nucleophilic reactions. A mixture of the mono- and di-substituted derivatives is formed[77], which was separated by preparative gas–liquid chromatography and the structure of the

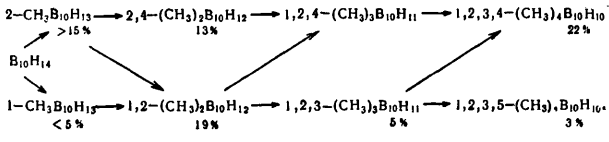
products was established by $^{11}B$ nuclear magnetic resonance spectra. They are the 5- and 6-alkyl and the 6,9- and 6,5(8)-dialkyl derivatives. These results agree completely with the electron density distribution at the boron atoms of decaborane: 2, 4 > 1, 3 > 5, 7, 8, 10 > 6, 9.



The most electropositive positions, 6 and 9, are the first to undergo nucleophilic attack by alkyllithiums, then 5, 7, 8, and 10; the 2, 4 and 1, 3 positions do not participate in the reaction at all.

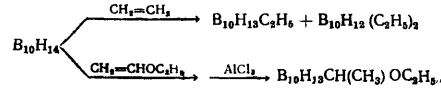
## 9. ELECTROPHILIC SUBSTITUTIONS

As well as nucleophilic substitutions, decaborane is also characterised by electrophilic substitutions. From the electronic non-equivalence of the boron atoms in the decaborane molecule, it is to be expected that electrophilic agents would attack positions 2, 4 and 1, 3.



Stock was the first to observe, in 1914, that halogens do not destroy the structure of the decaborane molecule, but only replace from one to three hydrogen atoms by halogen. By heating decaborane with iodine at 100°, diiododecaborane $B_{10}H_{12}I_2$ was obtained and isolated in the pure state. Bromination and iodination under mild conditions gave monobromodecaborane and two monoiododecaboranes[78]. In the $^{11}B$ nuclear magnetic resonance spectra of the monobromo-derivative and the high-melting monoiodido-derivative a triplet in the low field is unchanged and a doublet in the high field is altered, the intensity of one of the peaks being decreased. This indicates that the halogen atom is in position 2 in both compounds. The spectrum of the low-melting monoiodido-complex shows a decrease in the high-field part of the triplet, belonging to atoms 5, 7, 8, and 10, whereas the low-field doublet is unchanged. Consequently, this substance must be 5-iododecaborane. The formation of this product can be explained by the parallel reaction of radical substitution[78].

Iodination was studied in greater detail by Hillman[79]. He iodinated separately decaborane itself and the monoiododecaboranes which were obtained:



It was established, by deuterium exchange and the earlier X-ray structural analysis of 2,4-diiodo-derivative[17] (III), that compounds (I), (II), and (IV) are respectively 2-iodo-, 5-iodo-, and 2,5-diiodo-decaborane.

Williams and coworkers[80,81] studied the electrophilic alkylation of decaborane under the conditions of the Friedels–Craft reaction. On heating decaborane with methyl bromide in the presence of aluminium chloride in carbon disulphide in a sealed ampoule for 36 h, a mixture of polymethylated decaboranes was obtained:

Alkyldecaboranes, especially ethyldecaboranes, have been obtained by another method, the pyrolysis of ethyldiboranes[82]. 5-Ethyldecaborane (and other products) was isolated from the reaction mixture.

Decaborane adds on to ethyl vinyl ether and the lower alkenes in the presence of aluminium halides[83,84]:

The reaction takes place in a medium of an inert organic solvent. The products are liquids and have been proposed as additives to high-energy rocket fuels.

Finally, decaborane is alkylated by alkyl halides in the presence of metal halides to give a mixture of alkyldecaboranes[85].

## 10. THE STABLE ANION $B_{10}H_{10}^{2-}$

In 1959 Hawthorne and Pitochelly[74] reported that bis-(acetonitrile)decaborane reacts in two ways with tertiary amines, giving either the covalent compound $B_{10}H_{12}[N(C_2H_5)_3]_2$ or the ionic $B_{10}H_{10}^{2-}[HN^+(C_2H_5)_3]_2$, insoluble in organic solvents. This reacts with tetramethylammonium chloride, giving $B_{10}H_{10}^{2-}[\dot{N}(CH_3)_4]_2$.

The absence of $BH_2$ groups and hydrogen bridge atoms was shown by infrared spectra[86]. The $^{11}B$ nuclear magnetic resonance spectrum showed the presence of only two types of boron atom, in the ratio 8 : 2. These results indicate that the system is of high symmetry.

It was suggested[86] that the structure of the $B_{10}H_{10}^{2-}$ anion consists of two $B_5H_5$ "groups" — tetragonal pyramids, joined to one another by their bases. Hence the molecule contains two "vertex" and eight "equatorial" boron atoms. This structure was confirmed experimentally. Dobrott and Lipscomb[87] made an X-ray diffraction study of the salt $Cu_2B_{10}H_{10}$. The calculations showed that there are three types of B–B distance in the anion (Fig. 4): (1) the distance between the vertex boron atoms and the atoms lying in the base of the pyramid (1.73 ± 0.02 Å); (2) the distance between the atoms lying in the base of each pyramid (1.86 ± 0.03 Å); (3) the distance between atoms lying in the bases of pyramids ("equatorial belt", 1.815 ± ± 0.015 Å).

The calculated bond orders agree well with the data obtained by the LCAO–MO method[88] and are 0.56, 0.40, and 0.51 respectively. The Cu–B distance varies from 2.13, to 2.33 Å, which greatly hinders the calculations. From these results and from the B–Cu–B angle found (46°) the authors think a three-centre bond between the copper atom and the B–B edge the most probable (*sp* hybridisation of copper).

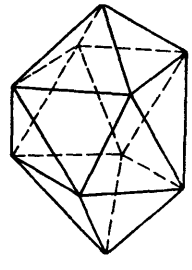


Fig. 4. Structure of the $B_{10}H_{10}^{2-}$ anion.

Calculation of the $B_{10}H_{10}^{2-}$ anion by the LCAO–MO method[88] showed that the vertex atoms are the most electropositive and are the first to be attacked by electrophilic agents.

A mechanism for the formation of the $B_{10}H_{10}^{2-}$ anion from bis(acetonitrile)decaborane has been proposed (Fig. 5).[89] The two bridge hydrogen atoms in bis(acetonitrile)decaborane leave as protons, giving a transition state containing two filled two-centre orbitals between the boron atoms 5 and 10, and 7 and 8. This transition state is stabilised by ejection of the ligands from positions 6 and 9. There is then a general rearrangement of the molecule in which the vertices of the polyhedron formed should be positions 10 and 7 or 5 and 8. This was confirmed by the nuclear magnetic resonance spectra of $B_{10}H_{10}^{2-}$ and $B_{10}H_6D_4^{2-}$, obtained from $B_{10}H_{10}D_4$ with deuterium in positions 1, 2, 3, and 4. The spectra showed the absence of deuterium from the vertex positions of the anion. The infrared spectra confirmed that the anion $B_{10}H_{10}^{2-}$ does not undergo deuterium exchange with $D_2O$ or $(C_2H_5)_3ND$.

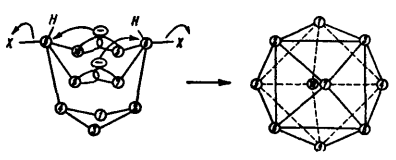
Salts of the anion $B_{10}H_{10}^{2-}$ (and also $B_{12}H_{12}^{2-}$) exhibit an astonishing stability with respect to strong acids, bases, and oxidants. They do not react with hot sodium hydroxide, but acids convert them into the acid $B_{10}H_{10}(H_3O)_2 \cdot xH_2O$, which is stronger than sulphuric acid[90]. Many different salts of the anions $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ have been obtained.

In aqueous and or alcoholic solutions, the anion $B_{10}H_{10}^{2-}$ reacts smoothly with chlorine, bromine, and iodine, giving derivatives in which from one to ten hydrogen atoms have been replaced by halogen[91]. It is suggested that such halogenation takes place by radicals. Thus, $B_{10}H_2Cl_8^{2-}$, $B_{10}H_3Br_7^{2-}$, $B_{10}H_7I_3^{2-}$, $B_{10}H_6I_4^{2-}$, $B_{10}H_4I_6^{2-}$, $B_{10}Cl_{10}^{2-}$, $B_{10}Br_{10}^{2-}$, and $B_{10}I_{10}^{2-}$ have been obtained. Halide derivatives of the anion containing other substituents have also been obtained, for example, $B_{10}Cl_9COC_6H_5^{2-}$ and $B_{10}H_2Cl_6[S(CH_3)_2]_2$. The anion $B_{12}H_{12}^{2-}$ undergoes analogous reactions. The halogenated compounds are strong acids, show great stability to acids and bases, and high thermal stability. $Cs_2B_{10}Cl_{10}$ loses only 4% of its weight when heated in a vacuum at 600°C; $B_{10}H_3Br_7^{2-}$ is unchanged after 1 h with $CH_3ONa$ in boiling methanol; $B_{10}H_7I_3^{2-}$ is inert to a solution of $KNH_2$ in liquid ammonia, but gives $B_{10}H_{10}^{2-}$ by the action of potassium in liquid ammonia. The crystalline acid $(H_3O)_2B_{10}Cl_{10} \cdot .5H_2O$ is reversibly dehydrated in a vacuum at 150°:

$$(H_3O)_2B_{10}Cl_{10} \cdot 5H_2O \rightleftarrows 3H_2O + (H_3O)_2B_{10}Cl_{10} \cdot 2H_2O.$$

Irreversible decomposition starts above 200° and a new compound is formed: octachlorononaborane(9), $B_9HCl_8$. Its properties have been studied[92], especially its conversion into the anion $B_9Cl_8H^{2-}$.

The caesium salt of the $B_{10}H_{10}^{2-}$ anion is unchanged after heating to 810°C. Some salts of $B_{10}H_{10}^{2-}$ are coloured; thus the pyridinium salt is yellow[93].



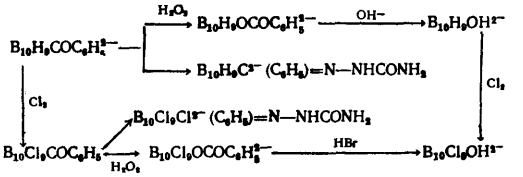


Fig. 5. Mechanism of formation of the $B_{10}H_{10}^{2-}$ anion from bis(acetonitrile)decaborane.

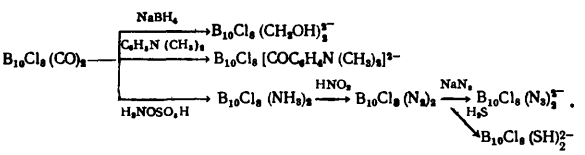
Benzoyl chloride reacts with $B_{10}H_{10}(H_3O)_2$, giving the anion $B_{10}H_9COC_6H_5^{2-}$, which takes part in various reactions[90]:

Amides react with the anion in acid medium, for example:

$$B_{10}H_{10}^{2-} \xrightarrow[[H^+]]{HCON(CH_3)_2} B_{10}H_9^{2-}OCHO + B_{10}H_9N^{2-}.$$

$B_{10}H_{10}^{2-}$ also reacts with donor compounds oxygen- and sulphur-containing compounds. The acid $B_{10}H_{10}(H_3O)_2$ hydroborates styrene. Furthermore the anion reacts with dimethyl sulphoxide:



$$B_{10}H_{10}^{2-} + 2(CH_3)_2SO \rightarrow B_{10}H_8[S(CH_3)_2]_2 + H_2O.$$

The mechanism of this reaction is obviously electrophilic under the conditions of an electrophilic reaction; the $S(CH_3)_2$ group occupies the vertex positions (according to the nuclear magnetic resonance spectra). Under these conditions deuteration also takes place at the vertex atoms.

In the treatment of the $B_{10}H_{10}^{2-}$ anion with a large excess of aqueous nitrous acid with subsequent reduction of the precipitate formed, using sodium tetrahydroborate in methanol, a diazonium derivative is formed, $B_{10}H_8(N_2)_2$.[94] The action on this of amines, nitriles, ammonia, and carbon monoxide at 115–140°C releases nitrogen and gives the corresponding $B_{10}H_8L_2$. On carrying out the reaction with carbon monoxide in the presence of cyclohexane, $C_6H_{11}B_{10}H_7(CO)_2$ and $(C_6H_{11})_2B_{10}H_6(CO)_2$ are formed. This reaction proceeds by a free radical mechanism. The carbonyl derivative $B_{10}H_8(CO)_2$ exhibits very interesting chemical properties:

$$B_{10}H_8(CO)_2 + \begin{cases} 2CH_3OH \rightleftarrows (H^+)_2B_{10}H_8(COOCH_3)_2^{2-} \\ 4NH_3 \rightarrow (NH_4^+)_2B_{10}H_8(CONH_2)_2^{2-} \\ LiAlH_4 \rightarrow B_{10}H_8(CH_3)_2^{2-} \\ NaN_3 \rightarrow B_{10}H_8(NCO)_2^{2-} \\ H_2O + H_2NOSO_3H \rightarrow B_{10}H_8(NH_3)_2 + 2CO_2. \end{cases}$$

On heating above 300° the caesium salt $Cs_2B_{10}H_8(CONH_2)_2$ is dehydrated to $Cs_2B_{10}H_8(CN)_2$. On halogenating $B_{10}H_8(CO)_2$ in water, $B_{10}Cl_8(CO)_2$ and $B_{10}Br_8(CO)_2$ are obtained. The octachloro-derivatives undergo the following reactions:

In the oxidation of the $B_{10}H_{10}^{2-}$ anion, two new anions of the same composition, but different structure (A and B), ($B_{20}H_{18}^{2-}$) were obtained. The first anion (A) was obtained by oxidation of the triethylammonium salt of $B_{10}H_{10}^{2-}$ by the $Fe^{3+}$ ion in aqueous solution[95]. The second anion (B) was obtained by oxidation of the triethylammonium salt of $B_{10}H_{10}^{2-}$ with a cold aqueous solution of $Ce^{4+}$.[96] Study of the

nuclear magnetic resonance spectra of the freshly prepared anions showed that they consist of two unchanged polyhedra of the $B_{10}H_{10}^{2-}$ initial ion joined to one another by hydrogen bridge atoms.

Because ion B is quantitatively converted into ion A in an aqueous solution containing catalytic amounts of hydrochloric acid, it is thought that ion B is formed as the result of attack by the $Ce^{4+}$ ion on the more negative vertex atoms of the initial anion. The authors [96] think that the acid catalysis of the isomerisation of B into A takes place without rupture of the bridging bonds by the simple migration of the polyhedra relative to one another.

After passing an ethanol solution of the triethylammonium salt of A through an acid ion-exchange resin, evaporating off the ethanol, and adding water to an ethereal solution of the residue, rapid hydrolysis, accompanied by liberation of hydrogen, is observed [95]. As a result, a new hydride, stable in air was obtained, $B_{18}H_{22}$, acting as a strong acid and containing bridge and terminal hydrogen bonds (according to the infrared spectra).

There is a very interesting reaction between the triethylammonium salt of $B_{10}H_{10}^{2-}$ and nitrogen oxides [97]. By oxidation of the salt with nitrogen dioxide in aqueous acetonitrile or by nitrogen monoxide in the presence of $Fe^{3+}$ the compound $B_{14}H_{12}NO[NH(C_2H_5)_3]_2$ was obtained, and by passing $NO_2$ into 10% aqueous acetonitrile solution of the initial substance, two other such compounds, $B_{10}H_6(NO)_2N(CH_3)_4$ and $B_{10}H_4(NO)_3N(CH_3)_4$, were isolated. The NO group here is reduced to the $NH_2$ group by Raney nickel.

It is obvious that the study of the properties of the $B_{10}H_{10}^{2-}$ anion undertaken in recent years — like the study of the properties of decaborane, other higher hydrides, and other anions — is only the start of a larger investigation, judging from the quite interesting and unexpected discoveries in the field of polyhedral molecules having a main skeleton of boron atoms.

## 11. CARBORANES

In the middle of 1962, Onak and coworkers reported [98] that pentaborane(9) reacts with alkynes (propyne, butyne, and pentyne) in the presence of 2,6-dimethylpyridine, giving compounds with the general formula $B_4C_nH_{2n+4}$:

$$B_5H_9 + R{-}C{\equiv}C{-}R_1 + \text{2,6-dimethylpyridine} \rightarrow$$
$$\rightarrow B_4H_6C_2RR_1 + \text{2,6-dimethylpyridine}.BH_3$$

Side reactions include the cleavage of pentaborane with the formation of two moles of amine.$BH_3$ complex and $(BH)_x$ polymer.

The proton and $^{11}B$ spectra of the class of compounds obtained agree with the structure shown in Fig. 6.

The high-field doublet of the $^{11}B$ nuclear magnetic resonance spectrum is reminiscent of the same doublet, which corresponds to the vertex atom in hexaborane. The low-field doublet corresponds to the boron atoms in hexaborane lying in the base. However, in view of the fact that this doublet is split in the proportion 2 : 1, the non-equivalence of the boron atoms lying at the base of the structure of the compounds obtained is confirmed.

The proton spectrum consists of two overlapping quadruplets in the ratio 3 : 1 (a vertex proton and three lying in the base) and an unresolved multiplet, corresponding to the bridge hydrogens.

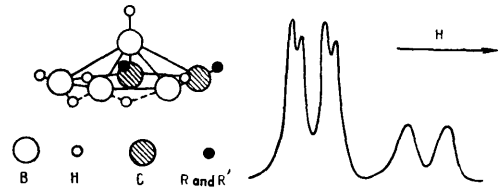


Fig. 6. Structure and $^{11}B$ nuclear magnetic resonance spectrum of dihydrocarborane(4),

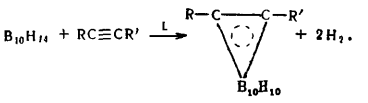
Shapiro and coworkers [99] isolated $B_3C_2H_5$ from the mixture of products obtained by repeated circulation of an equimolecular mixture of pentaborane(9) and acetylene through a silent discharge apparatus (15 kV) at room temperature. The substance obtained (m.p. -126.4°, b.p.-3.7°C) is stable in air and unchanged on contact with acetone, trimethylamine, $CO_2$, and water at room temperature.

A study of the deuterium exchange of this compound with $B_2D_6$ showed that only three of the hydrogen atoms bound to boron atoms exchange with deuterium.

The infrared spectrum of $B_3C_2H_5$ shows a highly symmetrical molecule (the band in the 2800–3300 $cm^{-1}$ region, belonging to the C–H bonds, is absent). The spectrum includes bands corresponding to the stretching vibrations of the terminal B–H bonds (but not B–H–B bridges), stretching vibrations of B–B bonds (in the 780 $cm^{-1}$ region) and B–C bonds (in the 1000–1100 $cm^{-1}$ region). The proton nuclear magnetic resonance spectrum suggests the existence in the molecule of two types of proton: those attached to carbon atoms (singlet) and those attached to equivalent boron atoms (quadruplet). The $^{11}B$ nuclear magnetic resonance spectrum shows a single type of boron atom (single doublet).

The information obtained suggests [98] a trigonal bipyramid as the most probable structure of the $B_3C_2H_5$ molecule, in which all the boron atoms lie in a single plane and the carbon atoms are perpendicular to it.

The compounds of the general formula $B_nC_2H_{2n+2}$ were named carboranes. It was suggested [100] that the polyhedral molecules of the carboranes constitute a superaromatic system, since they satisfy the requirements of the existing theory of aromaticity.



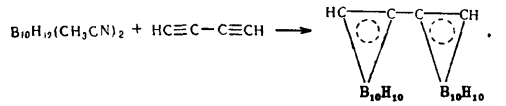
On the basis of the attractive LCAO–MO calculations, great stability was predicted for this class of compound and an ability to participate in electrophilic and nucleophilic substitutions. However, the position of the most electropositive and electronegative atoms could not be found from the calculations.

In view of the stability of the well-known icosahedral ion $B_{12}H_{12}^{2-}$, which is isostructural with the proposed carborane $B_{10}H_{12}C_2$, it was suggested that the latter should exist and might contain three normal $\sigma$ bonds and ten three-centre bonds in the skeleton, analogous to $B_{12}H_{12}^{2-}$. Possible models for intramolecular migrations of the boron atoms in $B_{10}H_{12}C_2$ through an intermediate cuboctahedral structure were considered [101].

Three groups of investigators recently published communications about the synthesis of $B_{10}H_{12}C_2$ and many of its derivatives (saturated and unsaturated hydrocarbons,

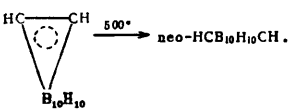
halogenoalkyl compounds, alcohols, acids and their derivatives, amines, ketones, ethers, etc.)[102-106]. The first member of the series $B_{10}H_{10}C_2H_2$, was named barene by Soviet chemists, carborane-10 by the Americans.

Barene and its derivatives were synthesised by the reaction of decaborane with acetylenic compounds in the presence of certain Lewis bases, which form with decaborane the $B_{10}H_{12}L_2$ complexes described above:



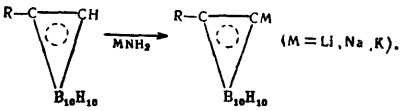
It has been shown[102] that the reaction takes place in two stages: first decaborane and the Lewis base give the complex $B_{10}H_{12}L_2$, which then reacts with the acetylene compound:

$$B_{10}H_{14} + 2L \rightarrow B_{10}H_{12}L_2 + H_2;$$



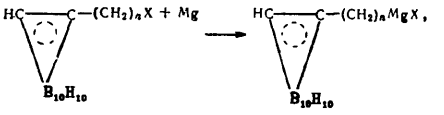
$$B_{10}H_{12}L_2 + RC{\equiv}CR' \rightarrow B_{10}H_{10}C_2RR' + H_2 + 2L.$$

Previously prepared complexes can be introduced into the reaction for the preparation of barenes. $CH_3CN$, $(C_2H_5)_2S$, $(C_2H_5)_3As$, $HCON(CH_3)_2$, $CH_3CON(CH_3)_2$, and $C_6H_5N(CH_3)_2$ are among the catalysts which have been used. A bisbarenyl compound has also been obtained[107]:

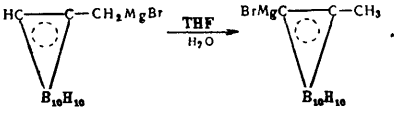


In the formation of a barene (carborane) from $B_{10}H_{12}L_2$ and acetylene a molecule of hydrogen is liberated[103] from the two bridge hydrogen atoms in $B_{10}H_{12}L_2$ – between $B_{(5)}$ and $B_{(10)}$, $B_{(7)}$ and $B_{(8)}$. The structure of the barenes has still not been finally established. A study of their structure using the example of di(bromomethyl)barene by X-ray diffraction showed that the decaborane structure is mainly retained[108]. From X-ray diffraction studies of *B*-octachlorobarene[109], $B_{10}H_2Cl_8C_2H_2$, obtained by chlorinating barene with ultraviolet irradiation, a structure close to icosahedral has been proposed (the isoelectronic structure of a right icosahedron of the dianion $B_{12}H_{12}^{2-}$). The C–C distance is 1.68 ± 0.02 Å and each carbon atom of the nucleus is bound by two three-electron bonds with four neighbouring boron atoms. Isomers of barene were also obtained.

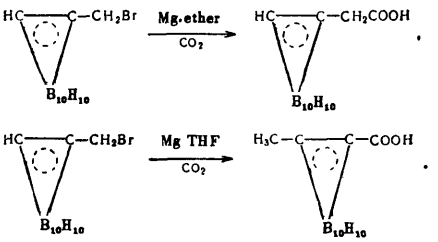
Neocarborane was obtained[110] by heating barene at 465–500°C:



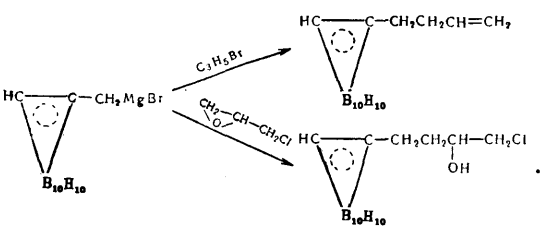
The structure of this isomer has also not been finally established. From studies of the $^{11}B$ nuclear magnetic resonance spectrum of neo-$B_{10}Cl_{10}C_2H_2$ it was suggested[111] that neocarborane has an icosahedral structure with carbon atoms in a "meta"-position (not bound with one another), as Lipscomb had already proposed[101]. On heating neocarborane at 615°C for 17 h, another isomer was isolated, termed "para"-carborane (it was suggested that the carbon atoms in it are in a "para"-position in the icosahedral structure)[112].



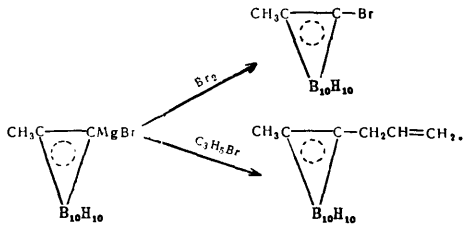
Barene has great thermal stability and is stable to the action of strong acids, several oxidants, and bases. The characteristic property of the barene nucleus is its electron-acceptor behaviour, which has a great effect on the chemical properties of barene compounds. It was shown that the barene nucleus deactivates a double bond towards addition reactions, inhibits nucleophilic substitutions at halogenomethyl derivatives, makes possible metallation at C–H, increases the strength of barenecarboxylic acids, etc.[103,113,114]. Many reactions of barene and its derivatives have been studied. It has been found that barene and its monosubstituted derivatives are metallated at a carbon of the nucleus by the action of alkyllithiums[115,116], sodium amide in boiling toluene[117], and alkali metal amides in liquid ammonia[118]:



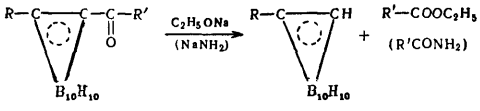
Barene forms both mono- and di-metal derivatives. With magnesium in ether or tetrahydrofuran, the halogenoalkyl derivatives form Grignard reagents[103,104,116]:



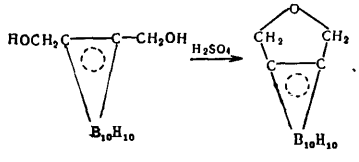
It has been shown that baren-1-ylmethylmagnesium bromide in tetrahydrofuran is isomerised into 1-methylbaren-2-ylmagnesium bromide[114,116]:



The carbonation of Grignard reagents from barenylmethyl bromide, prepared in either absolute ether or in tetrahydrofuran, has given the difficultly obtainable barenylacetic acid and methylbarenecarboxylic acid, respectively[119]:

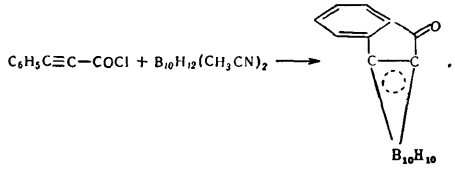


The barene Grignard reagents react with allyl bromide, epichlorhydrin, and bromine in the usual way:

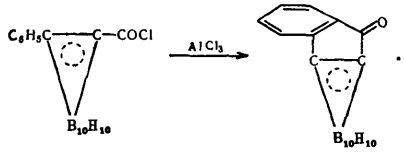


On hydrolysis, these Grignard reagents form alkyl derivatives of barene.

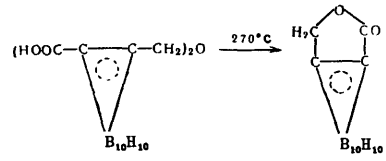
With esters of barenecarboxylic and barenedicarboxylic acids and barenyl phenyl ketones, it was shown that by the action of sodium ethoxide in absolute alcohol and sodium amide in liquid ammonia, rupture of the C–C bond takes place, because of the strong electron acceptor influence of the barene nucleus on the one hand and of the carbonyl group on the other [120,121]:



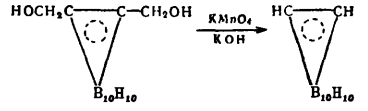
where R = H, $CH_3$, COOH; R′ = $OC_2H_5$, $C_6H_5$, $NH_2$.



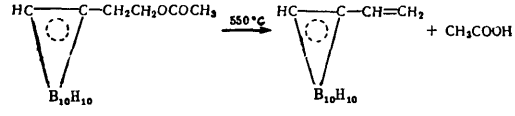
An interesting property of disubstituted barenes is their ease of cyclisation into three-membered exo-rings. When di(hydroxymethyl)barene is heated with sulphuric acid, a cyclic ether is readily formed [114,116]:



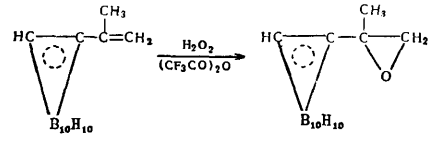
In the reaction of phenylpropynoyl chloride with bis(acetonitrile)decaborane, a cyclic ketone is smoothly formed [122]:



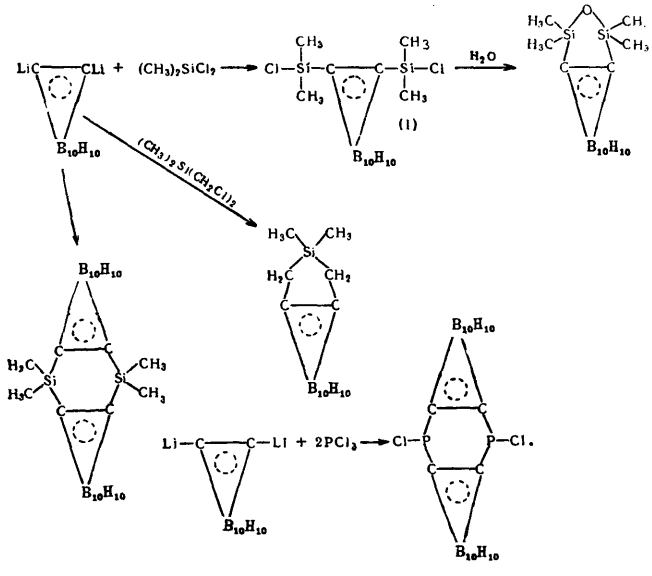
This same ketone is obtained from phenylbarenylcarbonyl chloride by the action of aluminium chloride:



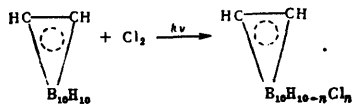
There is an interesting reaction when dicarboxylic acids are heated [123]:



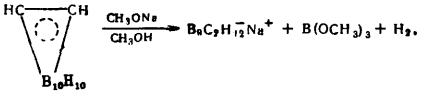
When alcohols of the barene series are oxidised in acid or alkaline media, acids of the barene series are obtained. Di(hydroxymethyl)barene and hydroxymethylbarene are exceptions, which form barene when oxidised by alkaline permanganate [103,114]:



When the acetates of the barene alcohols are heated above 500°C, acetic acid is lost, and unsaturated compounds are obtained [116]:



The action of peroxy-acids on the unsaturated compounds yields the corresponding oxides [104,116]:



Several organoelemental compounds of the barene series have been prepared from the lithium derivatives: those of phosphorus, silicon, tin, and mercury [116,124,125]. The heterocyclic systems containing silicon and phosphorus are interesting [124,125]:

It has been shown that barene [126,127] and phenylbarene [126] are chlorinated under the action of ultraviolet light at the boron atoms, with formation of *B*-chloroderivatives:

Polyhalogenobarenes from the di- to the decachloro-derivative have been obtained. It is reported [127] that undecachloro-derivative $B_{10}Cl_{10}C_2HCl$ has been made. *B*-Decachlorobarene and phenyl-*B*-decachlorobarene are rather strong acids and dissolve in aqueous alkali solutions [124]. Dodecachlorobarene was obtained by the action of chlorine on the alkali solution of *B*-decachlorobarene [126]. On reaction with alkyl halides in the presence of aluminium chloride, barene compounds are alkylated at boron atoms [128]. The action of strong bases on barenes liberates one mole of hydrogen and forms water-soluble salts of dicarboundecylcarboranes [114,129]:

The chemistry of neocarboranes has been studied little, but in their properties they are close to barenes. Metallation occurs by the action of butyllithium [110]:

The lithium derivatives undergo the usual reactions: carboxylation with $CO_2$, formation of alcohols with aldehydes, alkylation with alkyl halides. The oxidation of di(hydroxymethyl)neocarborane by alkaline permanganate takes place analogously to the oxidation of di(hydroxymethyl)barene:

neo-$B_{10}Cl_{10}C_2H_2$ was obtained by the chlorination of neocarborane under the action of ultraviolet light [111]. The investigation of barene and its derivatives has opened a new, interesting chapter in the chemistry of the organic compounds of boron.

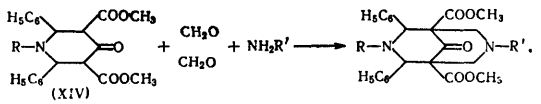
# SYNTHETIC DIAZA- AND AZA-BICYCLIC SYSTEMS WITH NON-BRIDGEHEAD NITROGEN ATOMS

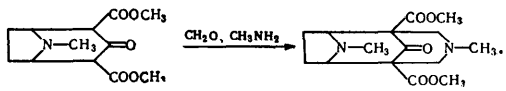
M. V. Rubtsov and E. S. Nikitskaya

## Introduction

Recently a large number of papers have been published on the chemical and biological studies of synthetic diaza- and aza-bicyclic systems with non-bridgehead nitrogen atoms. According to their chemical structure, these bicyclic systems may be divided into the following groups:



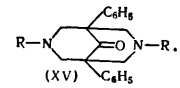
Aza- and diaza-bicyclic compounds are very interesting pharmacologically, since many of them exhibit biological activity and may be used for the investigation and preparation of new drugs. In this connection it appeared useful to give a systematic account of work dealing with the methods of synthesis of the above bicyclic systems, their chemical properties, and pharmacological activity. The present article does not include natural compounds of the tropane series and their synthetic derivatives, since a number of reviews dealing with them already exist[1-4].



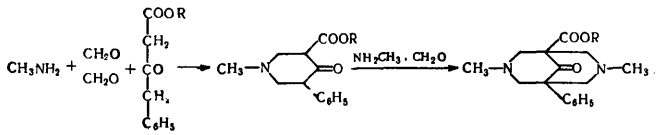
## 3,7-Diazabicyclo[3,3,1]nonane (I)

The derivatives of 3,7-diazabicyclo[3,3,1] nonane can be divided into two subgroups: 9-oxo-3,7-diazabicyclo[3,3,1]-nonanes or bispidones and the 3,7-diazabicyclo[3,3,1]nonanes themselves or bispidines. The methods available for the preparation of the two subgroups are different; bispidines cannot be obtained from bispidones.

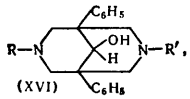
Bispidones. Derivatives of 9-oxo-3,7-diazabicyclo-[3,3,1]nonane were first synthesised by Mannich and Mohs[5] by the condensation of substituted piperidonedicarboxylic ester (XIV) with formaldehyde and primary amines:



Compound (XIV) was obtained by the reaction of acetonedicarboxylic ester with the appropriate aldehyde and alkylamines[6-8]. The bicyclic system forms very readily at room temperature in aqueous alcoholic medium with a yield of 60–70%. By choosing appropriate derivatives of piperidine and alkylamines, it is possible to obtain easily various bispidones[9]†. Under these conditions the dimethyl ester of tropinonedicarboxylic acid yields a tricyclic system — the dimethyl ester of 6,8-ethylene-3,7-dimethyl-9--oxo-3,7-diazabicyclo[3,3,1]nonane-1,5-dicarboxylic acid:

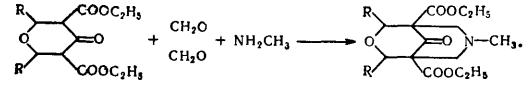


When an attempt was made to prepare a substituted γ-piperidone by the condensation of diphenylacetone, formaldehyde, and ammonia, the sole product isolated was 9-oxo-1,5-diphenyl-3,7-diazabicyclo[3,3,1]nonane[12].

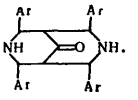


By using various alkylamines in the reaction with diphenylacetone, the authors of these investigations obtained a nunber of bispidone derivatives with the general formula (XV), where R = $CH_3CO$, $CH_3$, n-$C_2H_7$, $C_6H_5CH_2$, $HOCH_2CH_2$, and $ClCH_2CH_2$.

Similar results were obtained also by other workers[13], who allowed γ-phenylacetoacetic ester to react with methylamine and formaldehyde and instead of the expected product (3,5-dialkoxycarbonylphenyl-*N*-methylpiperidone), obtained bispidone derivatives, which are the products of the further interaction of the piperidone with formaldehyde and the amine:

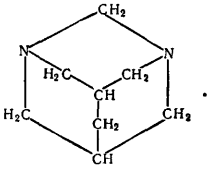


Numerous bispidone derivatives with the general formula (XVI) have been obtained by Chiavarelli and coworkers[14,15] by the condensation of diphenylacetone with formaldehyde and alkylamines followed by reduction of the ketones to alcohols with lithium aluminium hydride:

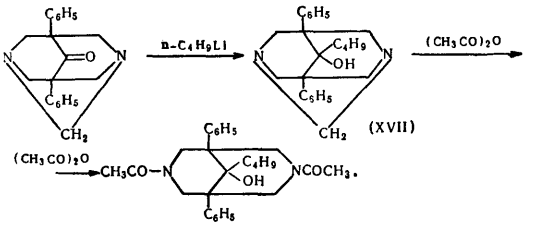


where R = R′ = $C_2H_5$, iso-$C_3H_7$, n-$C_4H_9$, $CH_3$, H, $ClCH_2CO$, $R_2NCH_2CO$, etc.

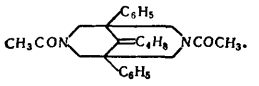
† A similar reaction[10] has been carried out with pyran derivatives[11]:



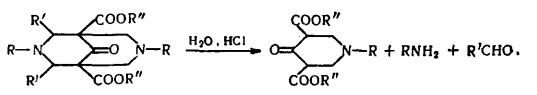
2,4,6,8-Tetraarylbispidones have been prepared by the reaction of acetone and ammonium acetate with benzaldehyde and *p*-methylbenzaldehyde[16]:



These were then reduced to the corresponding 9-bispidols.

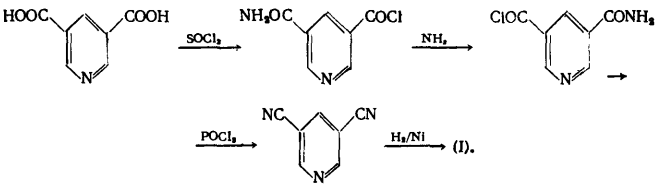


Certain diphenyl derivatives of diazaadamantane exhibit strychninelike activity[17-19]. This led to increased interest in bispidone, which is an intermediate in the synthesis of diazaadamantane:

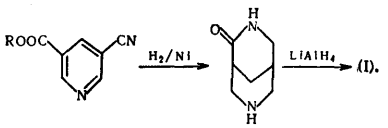


Substituted bispidones are readily obtained by the cleavage of diazaadamantane derivatives. Thus reaction of 9-oxodiazaadamantane with lithium alkyls yields tertiary alcohols, which on reaction with acetic hydride are cleaved with the formation of the *NN*-diazetyl derivative of 9-bispidol[18]:

When acetyl chloride acts upon compound (XVII), a molecule of water is split off and the ring is cleaved at the same time with the formation of an unsaturated compound[18]:



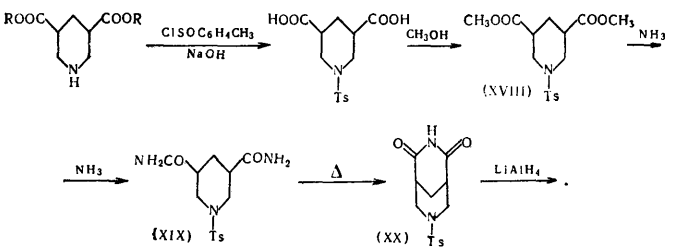
In a non-aqueous medium bispidones form dihydrochlorides, but one molecule of hydrogen chloride is easily lost (the hydrochloride "fumes"). The monohydrochloride is stable and almost insoluble in water. The carbonyl group does not undergo the characteristic reactions, and is not reduced in the presence of palladium or platinum black; on hydrogenation in methanol in the presence of palladium black, the molecule is cleaved with formation of an alkylamine and an aldehyde. Bispidones are readily hydrolysed to the corresponding piperidones, alkylamines, and aldehydes. Hydrolysis takes place even on boiling in water but the reaction is faster in the presence of acids, the substituted ring being cleaved as a rule[5,9]:



The pharmacological activity of bispidones has not been adequately investigated. Compounds with the general formula (XV) are weak anaesthetics and analgesics[12]. Among derivatives with the structure (XVI), compounds with antiarrhythmic activity have been found[14].

Bispidines. As stated above bispidone derivatives do not undergo reactions characteristic of the carbonyl group and are not reduced to bispidine derivatives. For this reason, the latter must be synthesised by different methods.

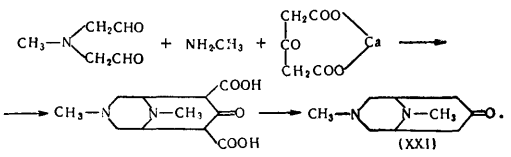
In an attempt to synthesise cytisine, the molecule of which incorporates bispidine, Bohlman and coworkers[20] obtained the latter from pyridine-3,5-dicarboxylic acid:



The yield of bispidine was 15%. When pyridine-3,5-dicarboxylic acid was replaced by 5-alkoxycarbonyl-3--cyano pyridine, compound (I) was again obtained[21]:

Galinovsky and Langer[22] obtained bispidine in 40% yield by heating 3,5-dibromomethylpiperidine with an alcoholic solution of ammonia in a sealed tube.

Bispidine may be synthesised from the diester of piperidine-3,5-dicarboxylic acid[23]:

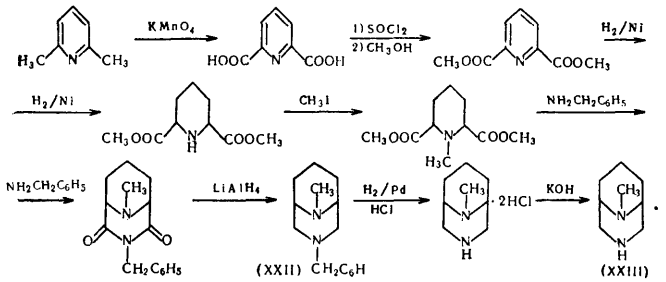


Reaction of the ester (XVIII) with boiling benzylamine gave a 95% yield of the extremely stable dibenzylamide which could not be cyclised into bispidine derivatives: for this reason the *trans*-configuration was attributed to this compound.

The ease of cyclisation of compound (XIX), which is obtained at low temperatures, and the impossibility of cyclising the dibenzylamide of *N*-tosylpiperidine-3,5-dicarboxylic acid, which is obtained at a high temperature, suggests that in the first case the formation of the diamide is preceded by the conversion of the *trans*-form of the ester (XVIII) into the *cis*-form and, conversely, in the preparation of the dibenzylamide at a high temperature the *cis*--form of the ester (XVIII) is converted into the *trans*-form. In subsequent papers the possibility of obtaining the cyclic imide (XX) directly from the ammonium salt of *N*-tosylpiperidine-3,5-dicarboxylic acid was indicated[24].

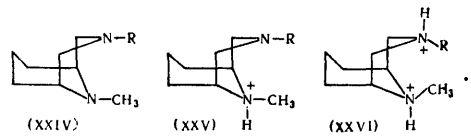
Bispidine consists of colourless crystals which avidly attract moisture and can be distilled in the form of a liquid hydrate. It is a strong diacidic base with an odour resembling that of piperidine. There are no data in the literature on the pharmacology of bispidine derivatives.

3,9-Diazabicyclo[3,3,1]nonane(II)



This bicyclic system was first obtained by Blount and Robinson[25] from methylaminodiacetaldehyde[26], methylamine, and the calcium salt of acetonedicarboxylic acid, the yield being 7.5%:

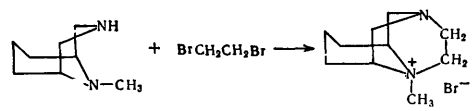
(XXI)



The reaction was continued to prepare the ketone (XXI).

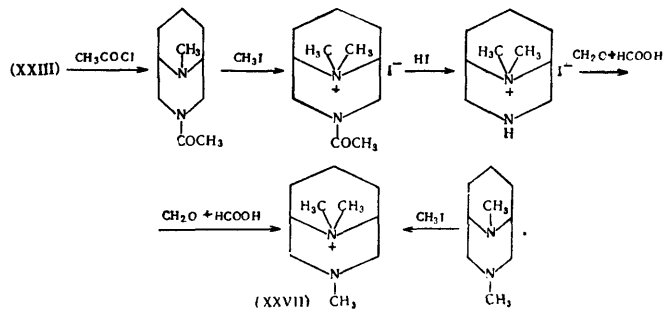
Barnes and Fales synthesised 9-methyl-3,9-diazabicyclo[3,3,1]nonane from 2,6-lutidine[27]:

(XXII) (XXIII)



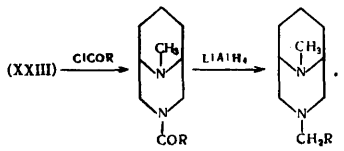
They established that the benzyl derivative (XXII) forms only the monomethiodide and the monopicrate, while 9-methyl-3,9-diazabicyclo[3,3,1]nonane (XXIII) yields both the dihydrochloride and the dipicrate. They explain this difference in behaviour by steric factors, and suggest that these compounds are most likely to have the configuration (XXIV):

(XXIV) (XXV) (XXVI)



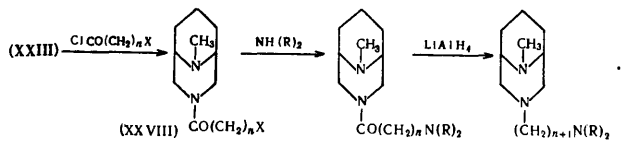
There is no steric hindrance in the formation of the mono-salt both when R = H and when R = $CH_2C_6H_5$ as in compound (XXV). However, the formation of the di-salt (XXVI) is impossible in the latter case because of steric hindrance, which occurs when methyl and benzyl groups approach one another. The steric hindrance is eliminated when the benzyl group in position 3 is replaced by hydrogen.

In order to prove the suggested configuration, Fales and Barnes synthesised 9-methyl-3,9-diazabicyclo[3,3,1,2$^{3-9}$]-undecane[28]:



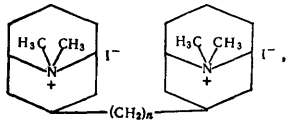
and demonstrated its structure by chemical reactions and by infrared spectroscopy.

The non-equivalence of the two nitrogen atoms in the bicyclic system (II) was noted also by other workers[29], and it has been shown that the formation of the mono-quaternary salt occurs at the nitrogen in position 9.[30] To form this salt, 9-methyl-3,9-diazabicyclo[3,3,1]nonane was acetylated, the acetyl derivative was converted into the quaternary salt, and the latter was then deacetylated and methylated with a mixture of formic acid and formaldehyde:



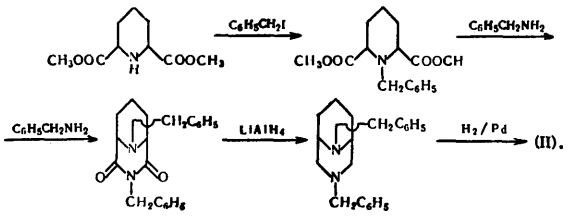
(XXVII)

The resulting quaternary salt (XXVII) proved to be identical with the methiodide of 3,9-dimethyl-3,9-diazabicyclo[3,3,1]-nonane prepared by the direct reaction of 3,9-dimethyl-3,9--diazabicyclo[3,3,1]nonane with methyl iodide. Derivatives of 9-methyl-3,9-diazabicyclo[3,3,1]nonane containing acyl, alkyl, hydroxyalkyl, carboxyalkyl, alkylaminoalkyl, and other groups at the nitrogen atom in position 3 have been synthesised recently for the purpose of pharmacological study[29]. The synthesis started with compound (XXIII) and the acid chlorides:



The amides thus obtained were then reduced with lithium aluminium hydride to the corresponding amines. The synthesis of 3-alkylaminoalkyl derivatives was achieved by the reaction of compound (XXIII) with the acid chlorides of halogeno-acids with subsequent substitution of the halogen in compound (XXVIII) by the dialkylamino-group and the reduction of the carbamoyl group with lithium aluminium hydride:

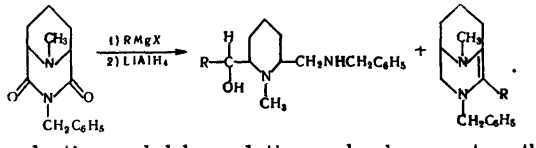
(XXVIII)



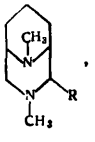
The dihydrochloride (XXIII) exhibits nicotine like activity, i.e. it stimulates ganglia[31]. Any substituent in position 3, starting with the methyl group, converts the compound into a ganglion-blocking agent. Apart from the ganglion-blocking effect, curarelike activity also appears. The greatest interest attaches to the dihydrochloride of 3,9-dimethyl-3,9-diazabicyclo[3,3,1]nonane which has approximately one twentieth of the ganglion-blocking activity of hexamethonium and is only 50% less active than the curarelike preparation diplacin which is used in the Soviet Union. When these compounds are converted into quaternary salts the ganglion-blocking and curarelike activities are intensified.

The series of symmetrical bis-quaternary salts with the general formula

is interesting. The tertiary bases were obtained by reducing the amides prepared by the reaction of compound (XXIII) with acid dichlorides[29] or the acid chlorides of halogeno--substituted acids[32]. The most active preparation, with the experimentally most pronounced curarelike activity, proved to be the symmetrical bis-quaternary salt with $n$ = 4.[31] It is somewhat more active than decamethonium and twenty times more active than diplacin.



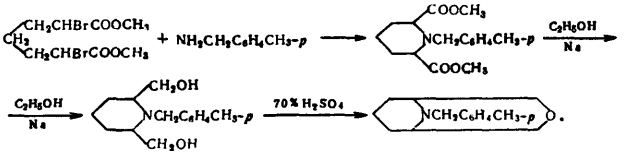
Unsubstituted 3,9-diazabicyclo[3,3,1]nonane (II) was obtained as follows[30]:



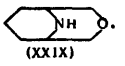
The reaction is carried out with benzyl iodide, benzyl chloride not reacting under similar conditions. The subsequent stages of the synthesis are similar to those in the synthesis of compound (XXIII).

Compound (II) is a homologue of piperazine and like the latter exhibits antihelminthic activity, which, however, is much weaker than in that of piperazine.

The synthesis of 3,9-diazabicyclo[3,3,1]nonane derivatives with substituents in position 2 does not take place smoothly[33]. The use for this purpose of the reaction between alkylmagnesium halides and cyclic imides[34] with subsequent reduction of the reaction products with lithium aluminium chloride yields mainly piperidine derivatives; unsaturated bicyclic compounds with a substituent in position 2 are obtained in only a very small yield:



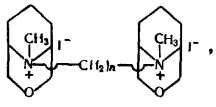
Their reduction and debenzylation and subsequent methylation at the nitrogen atom yields the compounds



where R = $CH_3$ and $C_2H_5$.

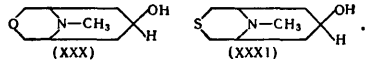
3-Oxa(thia, selena)-9-azabicyclo[3,3,1]nonane (III)

The bicyclic system of 3-oxa-9-azabicyclo[3,3,1]nonane was obtained for the first time as 9-($p$-methylbenzyl)-3--oxa-9-azabicyclo[3,3,1]nonane[35]:

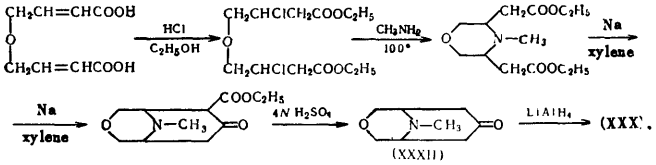


The study of 3-oxa-9-azabicyclo[3,3,1]nonane (XXIX) and its derivatives was begun in 1959 [36,37]:

The starting material for its synthesis was the diethyl ester of piperidine-2,6-dicarboxylic acid[38], whose reduction with lithium aluminium hydride yielded 2,6-dihydroxymethylpiperidine, which was cyclised to compound (XXIX) with 70% sulphuric acid. The cyclisation takes place with 50% yield and is accompanied by extensive charring.



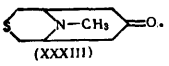
A number of derivatives of compound (XXIX) have been obtained with alkyl, acyl, alkylaminoacyl, and alkylaminoalkyl substituents at the nitrogen atom, including compounds whose acyl and alkyl substituents incorporated pharmacologically active systems such as phenothiazine, quinazolone, morpholine, and others. Ethers and esters of 9-($\gamma$-hydroxypropyl)- and 9-($\delta$-hydroxybutyl)-3-oxa-9--azabicyclo[3,3,1]nonane and the symmetrical bis-quaternary salts with the general formula



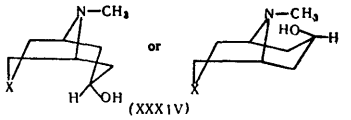
have also been prepared.

Some of these compounds exhibit nicotinelike activity and in large doses also traces of curarelike activity; none of these compounds are of practical interest.

The 7-hydroxy-derivatives of this bicyclic compound (XXX) and its thia-analogue (XXXI) proved to be more interesting[39].

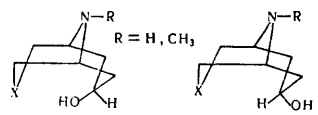


Starting from $\omega$-carboxyallyl ether, 9-methyl-3-oxa-9--azabicyclo[3,1,3]nonan-7-one (XXXII) was obtained as follows:



The overall yield of compound (XXXII) with respect to the $\omega$-carboxyallyl ether was 21%. The yield is low because the diethyl ester of 1-methylmorpholine-2,6-diacetic acid is formed as a mixture of the *cis*- and *trans*-isomers and only the *cis*-isomer cyclises into the bicyclic compound. Reduction of compound (XXXII) yielded compound (XXX).

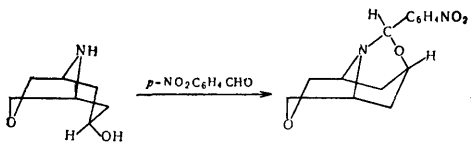
Compound (XXXI) was synthesised by the method of Blount and Robinson[26] (see p. 441). Best results were obtained when the reaction was carried out in a weakly acid medium (pH 4). The ketone (XXXIII) was reduced to the alcohol with lithium aluminium hydride, only one isomer being isolated.



The *cis*-configuration (XXXIV) has been wrongly attributed to compounds (XXX) and (XXXI) obtained by the reduction of the ketones (XXXII) and (XXXIII):

(XXXIV)

(XXXIVa, X = O), (XXXIVb, X = S).

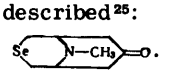


Zirkle and coworkers[40] studied the reduction of the ketones (XXXII) and (XXXIII) and the isolation in a pure form of the *cis*- and *trans*-isomers (XXX) and (XXXI). They reduced the ketones (XXXII) and (XXXIII) in different ways. When compound (XXXII) was reduced by means of a nickel catalyst in alcohol or ruthenium oxide in acetic acid, the main product was the axial (*trans*-)isomer (XXXVb, R = $CH_3$). The other isomer was obtained on reduction of compound (XXXII) with sodium in pentanol and on epimerisation of the axial isomer in the presence of aluminium isopropoxide. The isomer formed on epimerisation (XXXVIb, R = $CH_3$) is probably more stable and therefore its hydroxyl should be in the equatorial position.

(XXXV) (XXXVI)

(XXXVa, X = S), (XXXVIa, X = S),
(XXXVb, X = O), (XXXVIb, X = O).

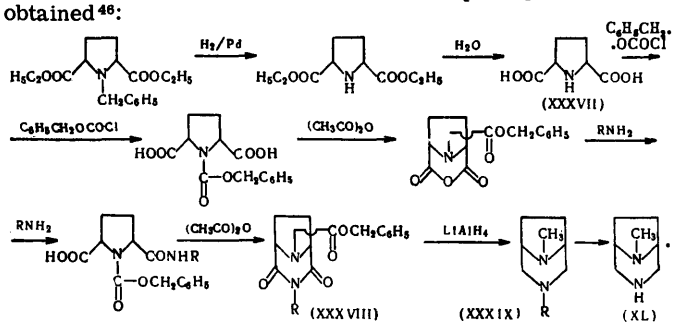
The configuration of the epimers was demonstrated by the method of acyl migration which has been used in similar cases to study the steric structure of compounds of the tropane series[41-43]. Both epimeric alcohols (XXXVb, R = $CH_3$) and (XXXVIb, R = $CH_3$), were demethylated, and the nor-compounds were benzoylated and then heated in an acid medium. In this reaction the *N*-benzoyl derivative of the equatorial (*cis*)isomer (XXXVIb, R = H) isomerised to the *O*-benzoyl derivative while the axial (*trans*-)isomer (XXXVb, R = H) remained unchanged. In addition, the equatorial isomer formed a cyclic compound with *p*-nitrobenzaldehyde[44]:



while the axial isomer charred under these conditions.

Because of the presence of sulphur, the thia-bicyclic ketone (XXXIII) does not undergo catalytic hydrogenation, but it is reduced with sodium in pentanol, the product being the equatorial (*cis*-)isomer (XXXVIa, R = $CH_3$). Reduction of the ketones (XXXII) and (XXXIII) with lithium aluminium hydride yields the axial (*trans*-)isomers (XXXVa, R = $CH_3$) and (XXXVb, R = $CH_3$).

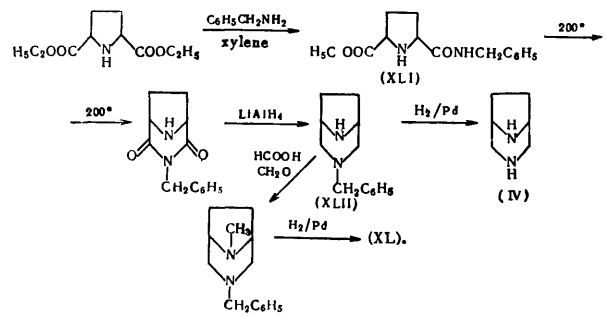
A number of esters of compounds (XXX) and (XXXI) with diphenylacetic, benzilic, and other acids have been obtained[39,40]. Among these compounds the benzylic acid ester of compound (XXX), which exhibits considerable spasmolytic and high anaesthetic activity, is the most interesting[45]. In addition, it proved effective in the treatment of gastric ulcers and Parkinson's disease[40,45].



The synthesis of 9-methyl-3-selena-9-azabicyclo[3,3,1]-nonan-7-one has been described[25]:

No data concerning its biological properties have been given.

## 3,8-Diazabicyclo[3,2,1]octane (IV)



Bicyclic systems containing the pyrrolidine and piperidine rings are biologically very interesting, since they are similar to tropane and contain the piperazine ring, which is a component of many physiologically active substances. Numerous attempts to synthesise compounds of this series remained unsuccessful for a long time. It was not until 1961 that 8-methyl-3,8-diazabicyclo[3,2,1]octane was obtained[46]:

The acid (XXXVII) could be obtained from the ester only by using water as the hydrolytic agent In acid and alkaline media the pyrrolidine ring is cleaved. Since the acid (XXXVII) is very soluble in water and virtually insoluble in alcohol, it was isolated as the 1-benzyloxycarbonyl derivative, which was then converted into the anhydride using acetic anhydride. Reaction of the anhydride with alkylamines yielded monoamides, which on boiling with acetic anhydride were converted into the cyclic imides (XXXVIII). The imides were reduced with lithium aluminium hydride, the benzyloxycarbonyl group being converted into the methyl group.

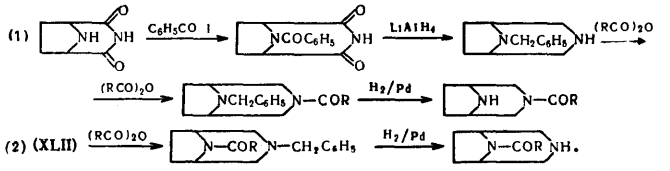
Benzylamine was used to prepare 8-methyl-3,8-diazabicyclo[3,2,1]octane (XL). In this case reduction with lithium aluminium hydride gave 3-benzyl-8-methyl-3,8-diazabicyclo[3,2,1]octane (XXXIX, R = $CH_2C_6H_5$), which was debenzylated in the presence of palladium.

Later a simpler synthesis was developed for compound (XL), which permitted also the preparation of the unsubstituted bicyclic compound (IV) [47]:

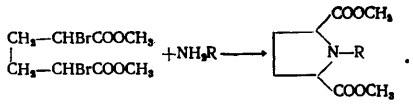
While in the first procedure, involving seven stages, the yield of compound (XL) was 16%, in the second procedure, consisting of five stages, the yield increased to 25%.[48] A more detailed study of the thermal cyclisation of the ester-amide (XLI) led to the isolation from the reaction mixture of two other substances[49]. One of these was the benzylimide of 1-ethylpyrrolidine-2,5-dicarboxylic acid and the other proved to be the *trans*-form of the ester-amide (XLI).

Derivatives of compound (XL) containing alkyl, aralkyl, and acyl groups in position 3 have been obtained. Like the derivatives of 3,9-diazabicyclo[3,3,1]nonane, the 3-alkyl derivatives of compound (XL) give only mono-quaternary salts, the quaternary nitrogen being in position 8.

Pharmacological study has established that 3-substituted derivatives of compound (XL) are antagonists of acetylcholine, 8-methyl-3-($\alpha$-methyltropoyl)-3,8-diazabicyclo[3,2,1]octane showing the greatest activity[50]:



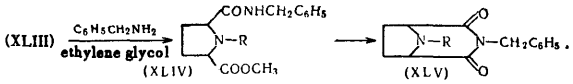
To compare the pharmacological activity of the 3-substituted derivatives of compound (XL) with their 8-isomers, a number of compounds having the following general formula were obtained[51]:



Here R is an acyl or an alkyl group. It was found that, in contrast to the 3-isomers, the 8-acyl derivatives exhibit analgesic activity, 3-methyl-8-propionyl-3,8-diazabicyclo[3,2,1]octane being the most effective.

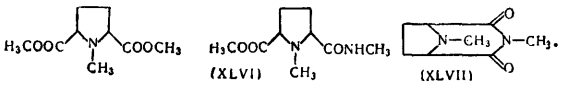
Investigation of the properties of the 3- and 8-acyl derivatives of 3,8-diazabicyclo[3,2,1]octane showed that the acyl residue in position 8 migrates to position 3 under the influence of temperature or alkaline reagents[52]. The opposite migration has not been observed.

The 3- and 8-acyl derivatives required for this purpose can be obtained as follows:



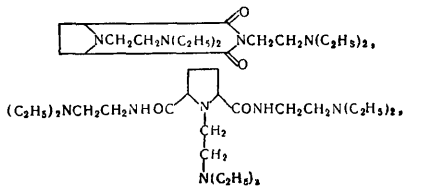
In the synthesis of the derivatives of 3,8-diazabicyclo[3,2,1]-octane a special study was made of the pyrrolidine ring closure reaction[53]:

(XLIII)



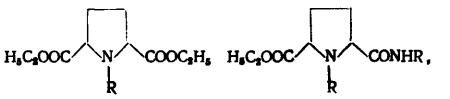
$\alpha\alpha'$-Dibromoadipic acid is shown to be a mixture of isomers[54-56]. In order to obtain from this acid 1-substituted *cis*-pyrrolidine-2,5-dicarboxylic ester (XLIII), the *meso*-form must be used in the reaction, the racemate being less suitable. In the reaction of the *meso*-form of $\alpha\alpha'$-dibromoadipic acid with aniline in a mixture of benzene and nitromethane 1-phenylpyrrolidine-2,5-dicarboxylic ester forms in 70% yield. The *cis*- and *trans*-isomers, in the proportions of three to one, can be separated by fractional crystallisation and by chromatography. Under the same condition the racemate of $\alpha\alpha'$-dibromoadipate gives compound (XLIII) in 10% yield, which can be separated into equal amounts of the *cis*- and *trans*-isomers.

Study of the synthesis of the imide (XLV) showed[53] that not only cyclisation but also the formation of the ester--amide (XLIV) proceeds with considerable difficulty:



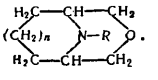
The product required can be obtained only when the reaction with benzylamine is carried out in boiling ethylene glycol in the presence of metallic sodium, followed by distillation of the reaction mixture without prior removal of the catalyst. During the distillation the cyclisation with the formation of compound (XLV) goes to completion, the yield of (XLV) being 40% from *cis*- (XLIII) and 12% from *trans*-(XLIII).

Schipper and Boehme[57] published interesting observations in 1961. They showed that in the reaction of dimethyl $\alpha\alpha'$-dibromoadipate with methylamine in the ratio 1 : 3 three products are formed:



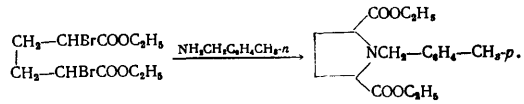
Compound (XLVII) can also be obtained in 50% yield on heating the ester-amide (XLVI) to 180°. Reduction of compound (XLVII) with lithium aluminium hydride yields, 3,8--dimethyl-3,8-diazabicyclo[3,2,1]octane.

The reaction of $\alpha\alpha'$-dibromoadipate proceeds in different ways with different alkylamines. For example, when $\beta$-diethylaminoethylamine is used, a mixture of the bicyclic compound and the diamide is formed:



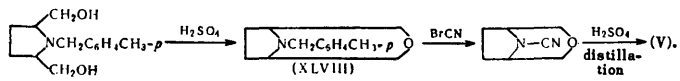
whereas with benzylamine or n-butylamine the reaction products are the ester and the ester-amide:

where R = n-$C_4H_9$ or $C_6H_5CH_2$.



## 3-Oxa-8-azabicyclo[3,2,1]octane (V)

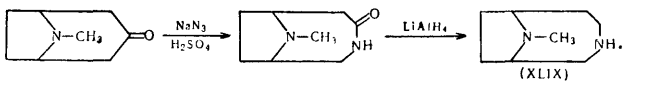
3-Oxa-8-azabicyclo[3,2,1]octane was obtained by Braun and Leistner[35], who synthesised a number of bicyclic derivatives of morpholine having the general formula



The simplest representative of this series, morpholinopyrrolidine or 3-oxa-8-azabicyclo[3,2,1]octane, was synthesised from diethyl *meso*-$\alpha\alpha'$-dibromoadipate and

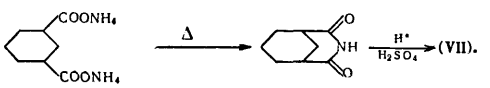
*p*-methylbenzylamine via the 1-(*p*-methylbenzyl)pyrrolidine-2,5-dicarboxylic ester:

The latter was reduced with sodium in alcohol to the corresponding diol which was cyclised with 70% sulphuric acid at 175° into 8-(*p*-methylbenzyl)-3-oxa-8-azabicyclo[3,2,1]-octane (XLVIII):



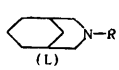
To prepare the nor-compound, the *p*-methylbenzyl derivative (XLVIII) was allowed to react with cyanogen bromide, the cyano-derivative being subsequently saponified with 25% sulphuric acid.

Like morpholinopiperidine (XXIX), morpholinopyrrolidine (V) shows little pharmacological activity[35].



## 3,9-Diazabicyclo[4,2,1]nonane (VI)

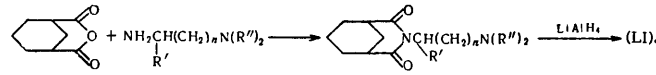
In 1960 a short note was published concerning the synthesis of 9-methyl-3,9-diazabicyclo[4,2,1]nonane (XLIX) as the starting material for the preparation of pharmacologically active substances[58]. The synthesis was achieved by treating tropinone with sodium azide in sulphuric acid with subsequent reduction of the cyclic amide formed with lithium aluminium hydride. The yield of compound (XLIX) was 51% with respect to tropinone.



## 3-Azabicyclo[3,3,1]nonane (VII)

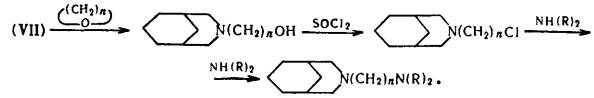
Compound (VII) was first prepared by the dry distillation of ammonium hexahydroisophthalate, the imide formed being subsequently reduced at a lead cathode in 65% sulphuric acid[59]:

The yield of compound (VII) was only 17%, probably as a result of the hydrolysis of the imide during the reduction process.

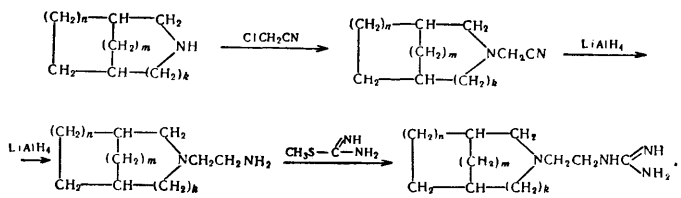


In recent years a number of papers have been published on the synthesis of derivatives of compound (VII). Compounds having the general formula (L) have been obtained[60]:

where R = $CH_3$, $C_2H_5$, $CH(CH_3)_2$, $CH_2CH{=}CH_2$, NO, etc., and also the mono- and bis-quaternary salts (LI)[61]:



where $n$ = 1, 2, and 3, R′ = H and $CH_3$, and $N(R'')_2$ = $N(CH_3)_2$, $N(C_2H_5)_2$, pyrrolidyl, morpholinyl, etc. These compounds were synthesised by the reaction of compound (VII) with alkyl halides[60] or by the reaction of hexahydroisophthalic acid or its anhydride with the corresponding amines and subsequent reduction of the resulting imides with lithium aluminium hydride[61,62]:

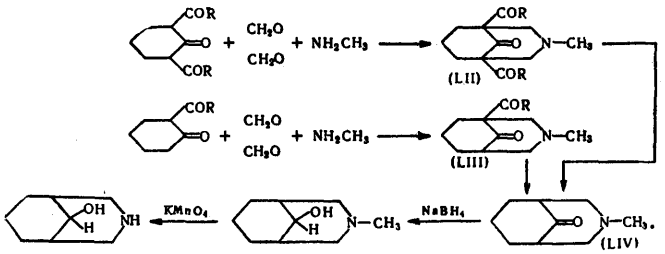


Later it was shown that substituted derivatives of (VII) can form from the di(*p*-toluenesulphonate) ester of 1,3-dihydroxymethylcyclohexane and the corresponding amine[63].

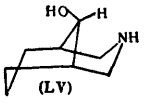
Compounds (LI) in which $n$ = 1 and R′ = $CH_3$ do not form bis-quaternary salts because of steric hindrance. The other compounds form mono-quaternary salts at 20°and bis-quaternary salts at 80–90°. Compounds (LI) in which $n$ = 1or 2 and R′ = H can be obtained by the reaction of compound (VII) with epoxyethylene and epoxypropene followed by treatment of the resulting alcohols with thionyl chloride and secondary amines[61]:

The compounds obtained[61] exhibit considerable ganglion-blocking activity, the most interesting being 3-(γ-dimethylaminopropyl)-3-azabicyclo[3,3,1]nonane methiodide[61] and 3-(ω-dimethylaminopentyl)-3-azabicyclo[3,3,1]nonane[64]. It is noteworthy that similar compounds containing an even number of methylene groups have been found by Rice and Grogan to have little activity[65].

Later studies showed[66-68] that certain derivatives of compound (VII) and also of its structural isomer 3-azabicyclo[3,2,2]nonane exhibit hypotensive properties. Among these 3-(β-guanidinoethyl) derivatives proved to be especially active, preliminary data showing that in the intensity and duration of the activity they are not inferior to guanethidine[66]‡. The synthesis of 3-(β-guanidinoethyl)-3-azabicyclo[3,3,1]nonane and its analogues were achieved as follows:

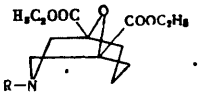


The azabicycloalkanes were converted into *N*-cyanomethyl derivatives and the latter were reduced with lithium aluminium hydride and then allowed to react with *S*-methylisothiourea.



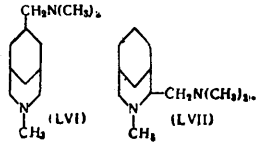
Derivatives of compound (VII) may be synthesised also by the Mannich reaction[71-75]. 9-Hydroxy-3-azabicyclo-

‡ Among the derivatives of 3-azabicyclo[3,2,2]nonane, a structural isomer of compound (VII), compounds have been obtained recently capable of giving rise to hypotonia, salivation, and convulsions[69,70].

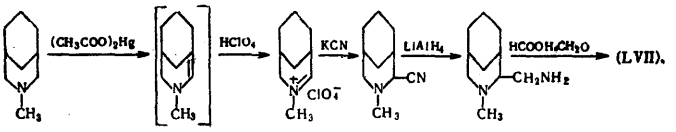


[3,3,1]nonane was obtained by this method from cyclohexanone derivatives[71]:

Condensation of diethyl cyclohexanone-2,6-dicarboxylate and ethyl cyclohexanone-2-carboxylate with formaldehyde and methylamine yields the diethyl ester (LII) and the ethyl ester (LIII). The amides of the acids can be used in the reaction instead of the esters. Hydrolysis and decarboxylation of compounds (LII) and (LIII) give compound (LIV); this can be reduced with sodium borohydride to the corresponding alcohol, which can be demethylated with an alkaline solution of potassium permanganate to 9-hydroxy-3-azabicyclo[3,3,1]nonane or isopseudogranatoline, the latter compound probably having the *trans*-configuration (LV), since it does not form a cyclic product with *p*-nitrobenzaldehyde[44]:

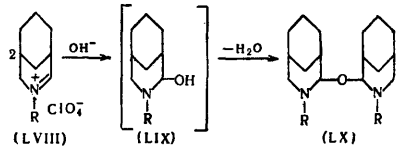


Study of the formation of compound (LII) by the Mannich reaction[72,73] showed that, depending on the temperature (25° or 100°), one of two compounds, differing in their boiling points but identical in all other properties and having the composition of compound (LII), is obtained. They are probably the *cis*- and *trans*-isomers with respect to the ethoxycarbonyl groups§. Compounds of this type must have the chair–chair structure:

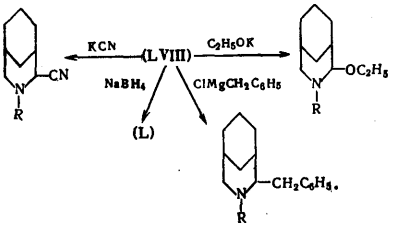


Their carbonyl groups do not give the characteristic reactions, which is evidently due to steric hindrance[73]. Hydrolysis and decarboxylation of both isomers yield the same ketone (LIV), which forms an oxime and can be reduced by the Wolff–Kishner method to compound (L, R = $CH_3$).

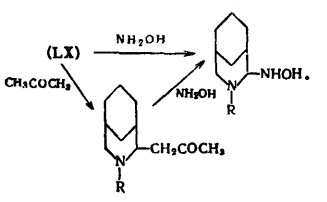
Other derivatives of 3-azabicyclo[3,3,1]nonane which have been synthesised are the 7- and 2-dimethylaminoethyl compounds[76]:



Compound (LVI) was obtained from cyclohexane-1,3,5-tricarboxylic acid, which was converted by dry ammonia at 200–220° into its monoamide, monoimide. The latter was reduced with lithium aluminium hydride and methylated with a mixture of formic acid and formaldehyde to give compound (LVI). Compound (LVII) was synthesised as follows:

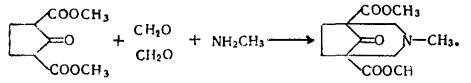


3-Methyl-3-azabicyclo[3,3,1]nonane was dehydrogenated at 80° with a solution of mercury acetate in 5% acetic acid; the unsaturated compound, isolated as the perchlorate, was converted by the action of an aqueous solution of potassium cyanide into 2-cyano-3-methyl-3-azabicyclo[3,3,1]nonane. The latter was reduced with lithium aluminium hydride and methylated with a mixture of formic acid and formaldehyde to give compound (LVII). No data on the pharmacological activity of thesecompounds have been published.

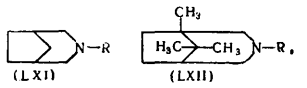


Schneider and Götz[77] found that, on being acted upon by sodium hydroxide, perchlorates of the type of (LVIII) do not form the hydroxy-derivative (LIX) but the dimeric compound (LX):

Reaction of compound (LVIII) with various nucleophilic agents gives 2-substituted derivatives of 3-alkyl-3-azabicyclo[3,3,1]nonane: 2-ethoxy-derivative with potassium ethoxide, 2-cyano-derivative with potassium cyanide, and 2-benzyl derivative with benzylmagnesium chloride. Reduction of compound (LVIII) with sodium borohydride gives compound (L).

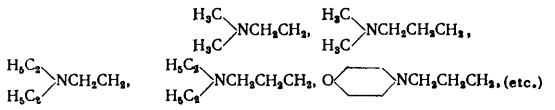


The dimer (LX) also reacts with nucleophilic agents, forming monomeric 2-substituted derivatives: reaction with hydroxylamine in absolute alcohol gives 3-alkyl-2--hydroxyamino-3-azabicyclo[3,3,1]nonane and the reaction with acetone gives a ketone which on being acted upon by hydroxylamine does not give an oxime but the hydroxylamino-derivative:

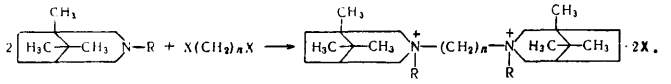


§ This does not appear to be possible (Ed. of Translation).

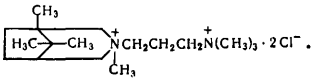
3-Azabicyclo[3,2,1]octane (VIII)



Derivatives of compound (VIII) can be obtained by the Mannich reaction from the cyclopentanone-1,5-dicarboxylic ester[75,78]:



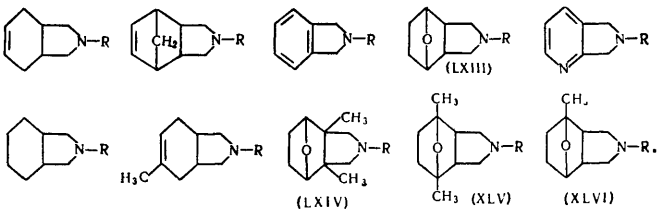
Another synthetic pathway for compound (VIII) is based on the use of the anhydride of *cis*-1,3-cyclopentanedicarboxylic acid[79] or the camphoric anhydride, which is converted into bicyclic amines via the corresponding imides[80-82]. Depending on the initial anhydride and amine, compounds having the structures (LXI) and (LXII) are formed:



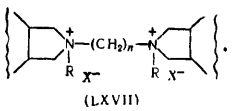
where R = alkyl,

Reaction of 3-alkyl-1,8,8-trimethyl-3-azabicyclo[3,3,1]-nonane with $\alpha\omega$-dihalogenoalkanes gave symmetrical bis--quaternary salts[80]:

Pharmacological investigation of the compounds synthesised showed that the tertiary bases are inactive, while the quaternary salts show hypotensive activity[83,84]. No differences were observed between the (+)- and (±)-forms. 3-($\gamma$-Diethylaminopropyl)-1,8,8-trimethyl-3-azabicyclo-[3,2,1]octane was found to have the greatest activity[84]:

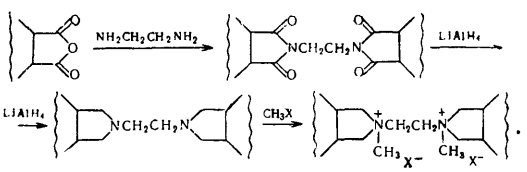


This substance exhibits pronounced hypotensive activity and also depressive activity on the central nervous system.

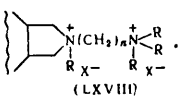


3-Azabicyclo[4,3,0]nonane (IX)

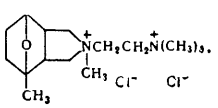
3-Azabicyclo[4,3,0]nonanes or isoindolines have been synthesised in different ways. Thus Tiffeneau and coworkers[85] obtained *N*-isopentylisoindoline by the reaction of *o*-bromomethylbenzyl bromide with diisopentylamine. In a similar way Braun and coworkers[86,87] obtained isoindoline and a number of its derivatives.



Substituted isoindolines are most simply obtained by the reduction of the imides of 1,2-dicarboxylic acids[88-91] which in turn are synthesised from the anhydrides of the corresponding dicarboxylic acids and alkylamines[92]. The following derivatives of isoindoline have been synthesised:

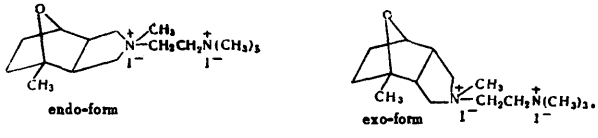


The amines used were dimethylamino-, diethylamino-, morpholino-, and piperidino-ethylamines, and others. The resulting bicyclic amines were converted into asymmetric and symmetric bis-quaternary salts (LXVII) [93] by standard methods[80]:

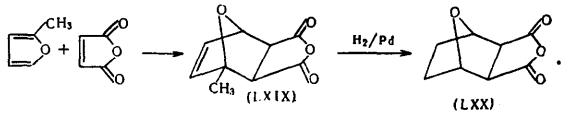


The quaternary salts are readily obtained when $n$ = 3 and more; when $n$ = 2 only one end of the dihalogenoalkane reacts with the amine. In this case, in order to obtain symmetric bis-quaternary salts, the corresponding anhydride of the dicarboxylic acid is allowed to react with ethylenediamine, the condensation product being reduced with lithium aluminium hydride and converted into the quaternary salt by means of methyl iodide:

Substituted acid imides and their methiodides are pharmacologically inactive. The isoindoline bases are only weakly active, but their conversion into bis-quaternary salts yields compounds with pronounced hypotensive activity and low toxicity. Compounds (LXVII) and (LXVIII), with $n$ = 2 or 3 and R = $CH_3$ or $C_2H_5$, and compounds with an oxygen bridge (LXIII–LXVI) exhibit very powerful hypotensive properties.

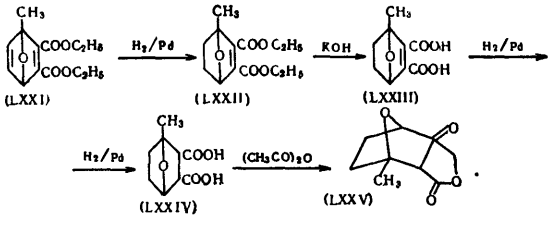


Among all the compounds of this series which have been investigated, preparation H-2 proved to be the most effective[94,95]:



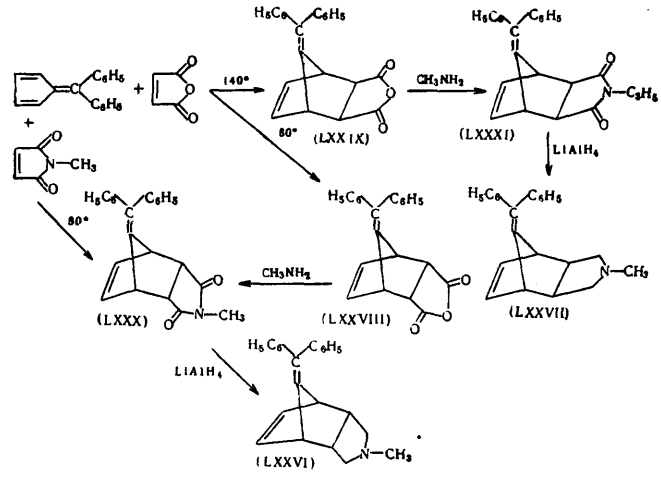
It is much more active and less toxic than hexamethonium. From their study of the structure of preparation H-2 (as

the dimethiodide), Rice and Grogan concluded that this compound can exist in one of two forms[96]:



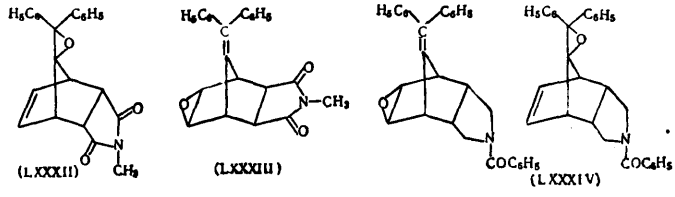
They synthesised both isomers and investigated their pharmacological properties. The synthesis was based on phthalic anhydride derivatives of different configurations. Condensation of maleic anhydride and 2-methylfuran gave the addition product (LXIX)[97] with the *exo*-configuration[98]:

Its reduction yields *exo*-perhydrophthalic anhydride (LXX).



The condensation of diethyl acetylene-1,2-dicarboxylate acid with 2-methylfuran gives the addition product (LXXI)[99,100]:

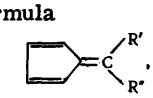
On catalytic hydrogenation of compounds (LXXI), one mole of hydrogen adds on to give compound (LXXII), which can be hydrolysed to the acid (LXXIII). Reduction of compound (LXXIII) yields *endo-cis*-perhydrophthalic acid (LXXIV), which can be converted into the anhydride (LXXV) by treatment with acetic anhydride and acetyl chloride. The acid obtained from the anhydride (LXX) is not identical with the acid (LXXIV), just as the anhydride (LXX) is not identical with the anhydride (LXXV). Taking into account the work of Woodward and Baer[98], it may be assumed that the anhydride (LXXV) has the *endo*-form.



The anhydrides (LXX) and (LXXV) were allowed to react with dimethylaminoethylamine, the resulting imides being reduced with lithium aluminium hydride and converted into bis-quaternary salts. The pharmacological activity of the two compounds proved to be equally high[94].

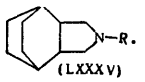
In 1962 Poos and coworkers[101] synthesised the *endo*- and *exo*-isomers of 8-diphenylmethylene-2-methyltetrahydro-4,7-methanoisoindoline (LXXVI) and (LXXVII) and a number of its derivatives, starting from the corresponding fulvenes, by a method similar to that described above. Condensation of diphenylfulvene and maleic anhydride at 80° gives predominantly the *endo*-form of the addition product (LXXVIII), and at 140° the *exo*-form (LXXIX).[102] Condensation of diphenylfulvene with *N*-methylmaleimide at 80° gave only one addition product (LXXX), which proved to be identical with the compound formed on reaction of compound (LXXVIII) with methylamine, i.e. it has the *endo*-configuration. Subsequent reduction of compound (LXXX) with lithium aluminium hydride gave *endo*-8-diphenylmethylene-2-methyltetrahydro-4,7-methanoisoindoline (LXXVI):

The *exo*-derivative (LXXVII) was synthesised in a similar way via the *exo*-form of the addition product (LXXIX), by the reaction of the latter with methylamine followed by the reduction of *exo*-8-diphenylmethylene-2-methyltetrahydro-4,7-methanoisoindoline-1,3-dione (LXXXI), with lithium aluminium hydride to give compound (LXXVII).



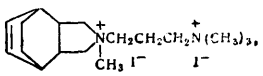
The unusual features of the reactions of compounds (LXXX) and (LXXXI) with perbenzoic acid are also noteworthy[103]. Compound (LXXX) forms an oxygen bridge at the double bond outside the ring to give compound (LXXXII), while compound (LXXXI) forms only the ring epoxide (LXXXIII):

However, the reaction of *endo*-8-diphenylmethylene-2-benzoyltetrahydro-4,7-methanoisoindoline with perbenzoic acid yields a mixture of epoxides (LXXXIV). Selective epoxide formation is probably due to the configuration of the molecule and the presence of the amide group.



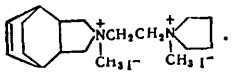
Compound (LXXVI) exhibits pronounced peripheral and central anticholinergic activity. Compound (LXXVII) is somewhat less active.

The authors also prepared a number of compounds, predominantly of the *endo*-series, using different fulvenes having the general formula



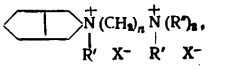
where R′ = R″ = $CH_3$(1), R′ = $C_6H_5$ and R″ = $CH_3$(2), R′ = = $C_6H_5$ and R″ = *p*-$C_6H_4Cl$(3), R′ = $C_6H_5$ and R″ = *m*-$CF_3C_6H_4$(4), R′ = $C_6H_5$ and R″ = *o*-$CH_3C_6H_4$(5), and R′ = $C_6H_5$ and R″ = 2-$C_5H_4N$(6). The compounds obtained included some with anticholinergic activity, but much weaker than that of compound (LXXVI).

Introduction of an ethylene group across positions 4 and 7 of the isoindoline system somewhat alters the mode of action of the substances. For example, among compounds with the general formula (LXXXV), which were obtained by Japanese investigators [104-106],



(LXXXV)

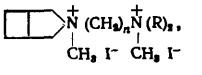
Some were found to have ganglion-blocking activity, for example the dimethiodide of 2-($\gamma$-dimethylaminopropyl)--4,7-ethanotetrahydroisoindoline:



and the dimethiodide of 2-($\beta$-pyrrolidin-1-ylethyl)-4,7--ethanotetrahydroisoindoline:

3-Azabicyclo[3,3,0]octane (X)

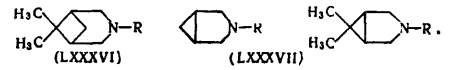
Hypotensive activity, ranging from moderate to high, is shown by the following systems: 3-azabicyclo[3,2,1]-octane, 1,8,8-trimethyl-3-azabicyclo[3,2,1]octane, 3-azabicyclo[3,2,0]heptane, and also various modifications of the cyclic systems of isoindoline — 3-azabicyclo[4,3,0]-nonane [80,81,92,93,96,107]. However, the derivatives of 3-azabicyclo[3,3,1]nonane proved to have little or no activity [65]. The sharp difference in activity between compounds (IX) and (VII) led investigators to synthesise derivatives of compound (X) [108] to compare their pharmacological activity with that of 3-azabicyclo[3,2,1]octane.



The starting material was the anhydride of *cis*-cyclopentane-1,2-dicarboxylic acid [109], which was converted into the corresponding derivative of compound (X) in the usual way — by reaction with amines followed by reduction with lithium aluminium hydride. The bis-quaternary amines obtained in this way were readily converted into bis-quaternary salts:

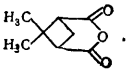
with marked hypotensive activity. Thus there is no difference in the mode of action and activity of 3-azabicyclo-[3,2,1]octanes and 3-azabicyclo[3,3,0]octanes.

3-Azabicyclo[3,2,0]heptane (XI)



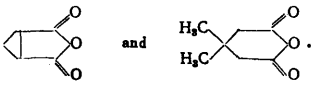
Derivatives of this bicyclic compound were first obtained in 1957 [107] from the anhydride of cyclobutane-1,2--dicarboxylic acid [110], which was converted in the usual way, by reaction with appropriate amines, into a substituted imide and then the corresponding amine. The bis--quaternary salts of this series of compounds exhibit hypotensive activity, the most active among them being, as in the case of isoindolines, substances with the general formula

where $n$ = 2 or 3 and R = $CH_3$ or $C_2H_5$.



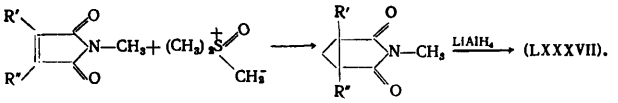
3-Azabicyclo[3,1,1]heptane (XII) and 3-Azabicyclo[3,1,0]-hexane (XIII)

The pharmacologically active bicyclic monoaza-systems which have been described above, can be classified as polymethylenepiperidines and polymethylenepyrrolidines with bridges consisting of 2, 3, and 4 methylene groups. Rice and coworkers synthesised the piperidine (LXXXVI) and pyrrolidine (LXXXVII) derivatives with a bridge containing one methylene group only [111]:



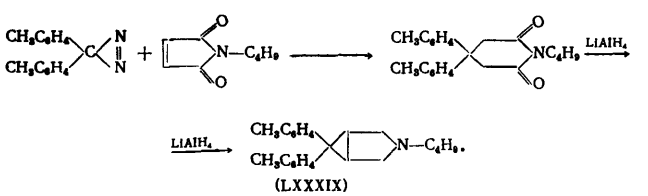
(LXXXVI) (LXXXVII)

The derivative (LXXXVI) was obtained in the usual way from the norpinic anhydride (LXXXVIII). [112]



(LXXXVIII)

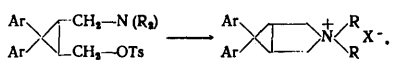
The synthesis of compound (LXXXVII) was based on the anhydrides [113,114]



A recent paper describes a new synthesis of cyclopropane-1,2-dicarboximides [115], which consisted in the reaction of substituted *N*-methylmaleimides with trimethylsulphoxonium ylid [116]:

The 3-substituted derivatives of compound (LXXXVII) readily yield bis-quaternary salts, in contrast to the 3-substituted derivatives of compound (LXXXVI) which form bis-quaternary salts only at high temperatures and pressures. A similar difference in behaviour as regards quaternisation was noted earlier for other bicyclic systems containing pyrrolidine and piperidine rings [61,65,81,93].

Among the derivatives of the bicyclic compounds considered here, only the quaternary ammonium salts proved to be active. The dimethiodide of 3-($\gamma$-dimethylaminopropyl)-3-azabicyclo[3,1,0]hexane shows no activity, that of its 6,6-dimethyl homologue is higher, but the highest activity is shown by derivatives of compound (LXXXVI).



The synthesis of 3-butyl-6,6-ditolyl-3-azabicyclo[3,1,0]-hexane (LXXXIX), involving the reaction of diaryldiazomethane, with *N*-substituted maleimide followed by reduction with lithium aluminium hydride to compound (LXXXIX), was described in 1962. [117]

(LXXXIX)

Similar compounds can be obtained as quaternary salts by the cyclisation of 3-aminoalkyl-1,1-diaryl-2-hydroxy-

methylcyclopropane in the presence of *p*-toluenesulphonyl chloride:

If the tertiary amino-group consists of a piperidine or morpholine residue, spiro-quaternary salts are formed.

Pharmacological study of these compounds showed that the bicyclic imides are inactive; their reduction to the amines results in the appearance of some local anaesthetic and analgesic activity. The quaternary salts are somewhat more active than the tertiary bases, but they are not of practical interest either.

# POLYMERISATION CONCEPTS IN THE CHEMISTRY OF CEMENTS

Yu. S. Cherkinskii

## 1. INTRODUCTION

The chief chemical elements present in cements are silicon, aluminium, oxygen, and calcium. In the inorganic world, silicon exhibits a remarkable ability to form polymeric chains[1]. These include the homochain polymer formed by elementary silicon, and a large number of heterochain polymers, of which the silicic acids and their salts — the silicates — are most widely encountered in nature and also in practical applications[2-8].

Aluminium is a metallic element but the great majority of its oxygen compounds, e.g. compounds such as corundum and hydrargillite, are heterochain polymers[2,9-13].

Oxygen in the polymeric chains formed by various elements acts as a bridge, and only in the peroxides is it capable of forming a homochain, consisting of two atoms[1].

Calcium on the other hand behaves as a cation.

Since the chief elements present in cements are capable of forming inorganic polymer chains, there is every justification for assuming that polymerisation and depolymerisation processes will also take place in the preparation and hardening of cement.

The ideas of Le Châtelier, subsequently developed by many workers, made it possible to understand the basis of the mechanism of the hardening of inorganic binding agents. In most work devoted to this question, the substance taken as standard model was gypsum — a compound which is not polymeric in character. In some cases, macromolecular compounds were also used as models. While drawing the analogy between the mechanisms of the hardening of cement and joiners' glue or silica gel, however, the supporters of the colloid theory (Michaelis and Kühl) saw in these substances only the high degree of dispersion, the high specific surface, and the ability to take part in sorption processes[14,15].

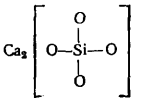
Modern theoretical views on the mechanism of the hydration hardening of cement are based on the concepts of physicochemical mechanics, whose basis principles were developed by Rebinder[16,17].

Work by Bernal[18], Belov and coworkers[19,20], and others established that the products of the hydration hardening of Portland cement contain isolated units of calcium hydrosilicates and compounds containing chains of condensed silicon–oxygen tetrahedra, i.e. polysiloxane chains. The periodicity of the manifestation of binding properties, related to Mendeleev's Table, was established by Zhuravlev[21] and confirmed by Moshchanskii[22].

In an examination of cement and concrete from the viewpoint of the chemistry of macromolecular compounds, Korshak and Mozgova[2] put forward the idea that "cement and concrete contain inorganic silicate polymers". The suggestion that silicate cements be regarded as three-dimensional polymers had been put forward earlier, in

less explicit form[11]. More recently the question of polymerisation has been raised with increasing frequency in papers devoted to inorganic binding agents[23-29].

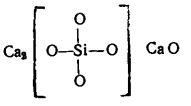
The basic questions of the chemistry of Portland cement and alumina cement are considered below from the viewpoint of polymerisation reactions.



## 2. PORTLAND CEMENT

The raw material used for the preparation of Portland cement contains, firstly, elements capable of forming macromolecular compounds with oxygen (chiefly silicon and aluminium) and, secondly, an element (calcium) which acts as a cation.

Silicon and aluminium are introduced into the charge in the form of natural (clays, loams, or clay shales) or synthetic (e.g. the waste materials from the production of aluminium from nephelite) macromolecular compounds whose structure has a definite influence on the preparation of the clinker[30-33]. Calcium is introduced into the charge in the form of lime or limestone.



Preparation of cement. It is possible to distinguish the following main stages in the firing of the charge: (1) drying and preheating; (2) depolymerisation; (3) ionic solution; (4) cooling. From the viewpoint of polymerisation theories, the second and third stages are the most important and the most complex.

The second stage, which gives a monomeric silicon–oxygen compound by the thermal depolymerisation of the original polysiloxane (polyaluminosiloxane) in the presence of oxygen and calcium ions, is a *necessary* stage in the preparation of the binding agent, but this stage is still *insufficient* for the preparation of a binding agent which hardens rapidly. The process taking place in the solid phase[34] at this stage leads to the formation of belite, the chief component of which is calcium orthosilicate — a monomeric silicon–oxygen compound[35-38]

or $2CaO \cdot SiO_2$.

The preparation of the highly active binding agent alite, whose chief component is again the monomeric silicon–oxygen compound $3CaO.SiO_2$ or[38-42]

takes place in the third stage as a result of a liquid-phase process. This stage can be defined more precisely as the ionic solution stage[43-47]. This subdivision of the process of clinker preparation is not contradicted by a large amount of experimental data[48-54].

In the preparation of Portland cement, the macromolecular component of the charge — clay — is heated to a high temperature. Clay also forms ceramic tile. In the preparation of Portland cement, however, the clay is converted not into water-resistant ceramic but into a substance which exhibits new binding properties.

What is changed during the high-temperature transformation of the clay and at what stage does the change take place?

The first stage in the transformation of the original polyaluminosiloxane (the clay minerals) is evidently of the same general type in both cases and involves thermal depolymerisation.

The two processes differ in the subsequent stage, in which in the first case the products of the degradation of the polyaluminosiloxane are converted into inorganic macromolecular compounds of a new type as a result of thermal polymerisation (polyrecombination) on cooling. These include a vitreous phase, mullite, and certain other substances which form the basis of ceramics and porcelain. Depolymerisation in the case of kaolinite, for example, begins in the range of the endothermic effect (520–600°), whereas polyrecombination takes place at 900–1000° and is responsible for a sharp exothermic effect[55-59].

In the preparation of cement, the changes in the polymers taking place in a medium of calcium ions (and oxygen) stops at the depolymerisation stage, and the resulting monomeric silicon–oxygen groups (and polyaluminooxane chains) are fixed by the calcium ions, which prevent polymerisation in the melt during cooling.

Thus the changes in the silicon–oxygen component of a Portland cement charge are described by the left-hand side of the scheme illustrated in Fig. 1.

Clinker. The hydraulic activity of Portland cement clinker is determined chiefly by the presence of monomeric silicon–oxygen compounds taken in the form of the calcium salts (or strontium or barium salts[21]). Increase in the defect nature of the structure leads to an increase in the activity of the binding agent[41,60].

Reaction with water. The reaction of cement with water (with chemistry of the hardening process) is described by the right-hand side of the scheme (Fig. 1).

In the reaction of clinker (here and subsequently we shall refer to the silicate component, namely dicalcium silicate, but it should be noted that the aluminate and ferrite components also play some part in Portland cement) with water leads, as a result of the hydrolysis of calcium orthosilicate, to the formation of orthosilicic acid[61-63]:

$$Ca_2SiO_4 + 4H_2O \rightarrow 2Ca^{2+} + 4OH^- + H_4SiO_4, \quad (1)$$

which is an extremely unstable compound.

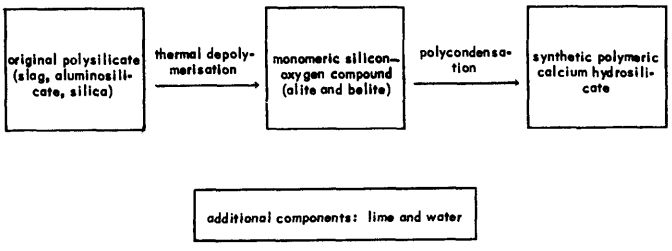


Fig. 1. Polymeric changes undergone by the silicate component of Portland cement.

Under the conditions of setting, the orthosilicic acid formed takes part in reactions of salt formation and polycondensation.

a. Salt formation:

$$\equiv Si-O^-H^+ + Ca^{2+} + 2OH^- \rightleftarrows \equiv Si-O^-Ca^{2+} + OH^- + H_2O. \quad (2)$$

This reaction involves the calcium ions which were liberated as a result of the hydrolysis of calcium orthosilicate, and also the "excess of lime" in $C_3S$. [64-66]. Under ordinary conditions, however, the hydrolysis is irreversible and reaction (2), when orthosilicate is taken as the original silicic acid, leads to the formation of acid salts of the afwillite type [67]. Orthosilicate is formed only under conditions of extremely high temperatures and pressures [67-68].

b. The polycondensation reaction is represented in general form by the equation

$$HO-\underset{\underset{OH}{|}}{\overset{OH}{|}}{Si}-OH + HO-\underset{\underset{OH}{|}}{\overset{OH}{|}}{Si}-OH \rightleftarrows HO-\underset{\underset{OH}{|}}{\overset{OH}{|}}{Si}-O-\underset{\underset{OH}{|}}{\overset{OH}{|}}{Si}-OH + H_2O, \quad (3)$$

or, in the limit,

$$n Si(OH)_4 \rightleftarrows (SiO_2)_n (OH)_m + p H_2O, \quad (4)$$

where $m \to 0$ and $p = \frac{4n - m}{2}$.

Opinions differ regarding the details of the mechanism of the polycondensation reaction [69-73] and the probability of condensation of $H_3SiO_4^-$ ions in alkaline medium has also been noted [74,75].

Reactions (2) and (3) take place simultaneously and the direction of the chemical reactions is decided by competition between these two types (ionic and molecular) of chemical change.

A vast amount of practical experience and experimental and theoretical data [76] indicate that the tendency of orthosilicic acid to undergo polycondensation is so great that this molecular reaction is one of the chief reactions determining the chemistry of the aqueous hardening of Portland cement and, in particular, the behaviour of cement block kept in water.

The equilibrium for the polycondensation reaction always tends to be displaced towards the formation of polymeric silicates; this takes place at the first opportunity, and in the limit leads to the formation of silica $(SiO_2)_n$. In the presence of calcium ions, however, monomeric calcium hydrosilicates (acid salts of orthosilicic acid), e.g. afwillite and the alpha-hydrate of $C_2S$, and polymeric hydrosilicates (salts of di- and poly-silicic acids) are formed. According to the phase diagram for the $CaO-SiO_2-H_2O$ system at normal temperature [18], hydrosilicates with a molar $CaO : SiO_2$ ratio less than 5 : 3 are polymeric, although polymeric calcium silicates (hillebrandite) with higher $CaO : SiO_2$ ratios are also known.

Calcium hydrosilicates. The composition and structure of individual calcium hydrosilicates in a number of cases have been established with certainty and in other cases they have been assumed [20,77,78]. On the basis of polymerisation principles, calcium hydrosilicates can be divided into two main groups: low-molecular and macromolecular (or simply polymeric).

Low-molecular calcium hydrosilicates include compounds with a monomeric or dimeric silicon–oxygen anion.

a. Compounds containing a monomeric silicon–oxygen anion include, for example, afwillite $Ca_3[SiO_3(OH)].2H_2O$ [79] and the alpha-hydrate of $C_2S$. [38] Afwillite and other calcium hydrosilicates containing an individual silicon–oxygen group and consisting of a definite combination of Si tetrahedra and hydroxide and calcium ions are the first members of a polymer homologous series of calcium polyhydrosiloxanates, whose existence is possible under conditions where the active degrading action of the calcium ions is a maximum.

b. Compounds with a dimeric silicon–oxygen anion include those of the cuspidine type $Ca_4[(Si_2O_7)(OH, F)_2]$. [80,81]

These hydrosilicates can be regarded as the second members of the above polymer homologous series. Calcium hydrosilicate containing a diorthosilicate anion obeys the crystal-chemical laws covered by the second chapter of "The Crystal Chemistry of Silicates Containing Large Cations". [19] It can therefore be regarded as the first member in a series of crystallographically and chemically similar calcium hydrosilicates in which the individual or linked diorthosilicate units are situated in the electric field of the calcium ions.

It is possible to assume the existence of the various [67] subsequent members of the polymer homologous series of calcium polyhydrosiloxanates, but it is more important to turn attention to the macromolecular compounds whose molecular or, more accurately, ionic weight amounts to several thousand units.

Macromolecular calcium hydrosilicates have ordered or disordered structures. Compounds with ordered structure include xonotlite $Ca_6(Si_6O_{17})(OH)_2$, [82,83] nekoite $Ca_3(Si_6O_{15}).2H_2O$, [84] and tobermorite $Ca_{10}(Si_{12}O_{31}).(OH)_6.nH_2O$. [66,85,86]

The first type of hydrosilicate has a polymeric silicon–oxygen anion in the form of linked six-unit rings [82]; the silicon–oxygen chain of hydrosilicates of the nekoite type consists of alternating eight-membered and double five-membered rings [84]. The chain in tobermorite is made up of doubled xonotlite chains which fit over one another in the condensation process to form corrugated layers [80].

Examination of polymeric calcium hydrosilicates shows that the structure of the silicon–oxygen chain may be comparatively simple or extremely complex.

The even greater complexity of the structure of the silicon–oxygen polymeric anion produced in the polycondensation process or on rearrangement of the ordered structure makes it impossible to determine the structure by existing crystallographic and chemical methods. These calcium hydrosilicates are combined in a subgroup of polymers with disordered structure. They include the gel-like phase and the X, Y, and Z phases [77,78].

Polymeric hydrosilicates and some properties of concrete. Belov attributes the cementing properties to polymeric hydrosilicates of the xonotlite type [42,80]. On the other hand, it has been noted [20] that the strength of cements decreases with the formation and increase in the quantity of the low-molecular readily-crystallising afwillite and the alpha-hydrate of $C_2S$.

The concentration of polymeric calcium hydrosilicates can be increased artificially; this increases the bending strength of the concrete but decreases the rate of hardening[87,88]. In practice, this is usually achieved by introducing, with the clinker, substances capable of forming polymeric hydrosilicates under the conditions of setting. These substances include silica gel, pozzolana, and diatomite, i.e. familiar mineral additives.

The chemical changes undergone by these additives are also defined by the scheme given in Fig. 1 with the fundamental difference that in this case the depolymerisation of the polysiloxane takes place as a result of the hydrolysis (hydrolytic depolymerisation) of the –Si–O–Si– siloxane bond under the influence of aqueous calcium hydroxide solution[89-93]. The depolymerisation leads to the formation of orthosilicic acid, which condenses according to the mechanism described above; the excess of the silicon–oxygen component makes it possible to increase the quantity of polymeric phase. Similar processes also take place in the preparation of autoclave silicate concretes[77]; the activation of the silicon–oxygen component as a result of the increase in temperature makes it possible to utilise effectively both calcium orthosilicate and metasilicate as well as silica[94].

The most important property of Portland cement — its hydraulic resistance — is determined by the ability of the original clinker materials and their hydrolysis products to form polymeric compounds — polymeric calcium hydrosilicates — since of the ionic and covalent bonds present in the products obtained by hydration hardening, only the covalent bond is sufficiently resistant to the action of the polar solvent water. Although in actual fact the quantity of polymeric silicates (crystalline silicates and the "amorphous" gel-like phase) in cement block is small, the thick network of siloxane chains formed when the cement block comes into contact with water is capable of blocking to a considerable extent the ionogenic components — lime and calcium ions; these are chemisorbed by the polymeric silicate, which prevents them from coming into contact with water and dissolving.

Methods of increasing the quantity of polymeric phase. One possible method of increasing the concentration of polymeric calcium hydrosilicates in concrete involves the use of active mineral additives. Autoclave silicate concretes and limestone–pozzolana concretes also contain a high concentration of polymeric calcium hydrosilicates.

The polymerisation reaction scheme (Fig. 1) may facilitate the search for other methods of preparing inorganic polymeric materials of the silicate–concrete type.

## 3. ALUMINA CEMENT

Raw material. The raw materials used for the preparation of alumina cement[38,95,96] include, firstly, polymeric coordination compounds of aluminium, such as hydrargillite, boehmite, and diaspore[9,11,12,97-104], and, partly, of iron (haematite), together with a small quantity of a silicate component which we shall not consider in this Section. The second component is lime (limestone).

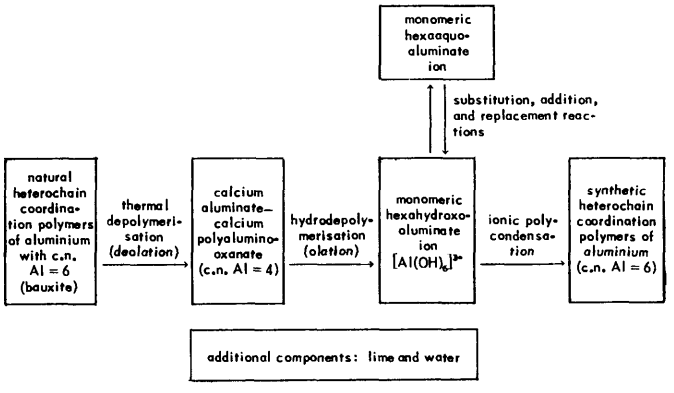
Preparation of cement. After the first preliminary stage involving drying, the second stage of the preparation of cement at temperatures up to approximately 500–600° involves the removal of water from hydrated forms of aluminium, i.e. deolation of hydrargillite (polyaluminodiolane) takes place. With further heating in the presence of $Ca^{2+}$ ions and oxygen, thermal depolymerisation takes place (see scheme in Fig. 2), accompanied by a change in the coordination number (c.n.) of the aluminium atoms from 6 to 4 and leading to the formation of calcium polyaluminooxanate (c.n. Al = 4) containing the chain

or, which is the same thing: $CaO.Al_2O_3$, CA, or $Ca(AlO_2)_2$. The formation of $Ca(AlO_2)_2$ takes place in the liquid phase and it is suggested[105] that the melt contains complex ions. Cooling of the melt is accompanied by thermal polymerisation of calcium aluminooxanates.

Clinker. The instability of oxygen compounds of aluminium with c.n. Al = 4 and their tendency to undergo conversion into stable oxygen compounds with c.n. Al = 6 are the chief factors determining the activity of alumina cement clinker, in which the chief component is calcium polyaluminooxanate (c.n. Al = 4).

Reaction with water. The first stage in the reaction of calcium aluminate (calcium polyaluminooxanate) with water involves rupture of the $^4Al–O–^4Al$ aluminooxane bond as a result of hydration, or more accurately as a result of the olation reaction specific for coordination compounds of aluminium (c.n. Al = 4).[98] During olation, the aluminooxane bond is first converted into the diol bond $R–Al<^{OH}_{OH}>Al–R'$, after which chain rupture takes place with the formation of two hydroxyl groups at the ends of the chain

During olation, the coordination number of the aluminium atom increases from 4 to 6 and the calcium ions go into solution.



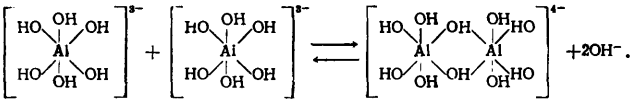


Fig. 2. Polymeric changes undergone by the aluminate component of alumina cement.

At the end of the first stage, further development of the olation process takes place, leading in the limit to the complete degradation of the polyaluminooxane (c.n. Al = 4) with the formation of a monomeric hydrated compound of aluminium with c.n. Al = 6, namely the $[Al(OH)_6]^{3-}$ anion.

Main reactions and compounds obtained. In order to picture the possible reactions in which the hexahydroxoaluminate ion may take part, we may recall that according to the modern theory of hydro-complexes [98,106,107], the amphoteric nature of aluminium hydroxide (hydrargillite) is expressed by the equation

$$[Al(OH)_6]^{3-} \overset{H_3O^+}{\rightleftharpoons} [Al(OH)_3(H_2O)_3] \overset{H_3O^+}{\rightleftharpoons} [Al(H_2O)_6]^{3+}.$$
$$\Big\| \; n\,[Al(OH)_3]_n$$
hydrargillite

The hexahydroxoaluminate ions undergo ionic condensation, probably according to the equation [108]

The dimeric ion undergoes further condensation with a monomeric ion with the formation of a trimer, hexamer, etc.; the hexamer undergoes ring closure and in the limit forms aluminium hydroxide — hydrargillite — a planar polymer with a reticulate structure made up of linked six-membered rings.

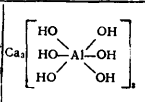
Both the monomeric and the more complex anions react with cations, particularly the $Ca^{2+}$ ion, to form salts, some of which are listed in Table 1, which gives complex compounds of aluminium in which the aluminium atom is present in a complex anion and in which only the limiting member of the series — hydrargillite — is neutral.

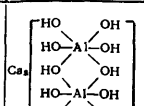
Hydrargillite exhibits one other characteristic feature. It is the most stable hydrated compound of aluminium in the biosphere [109].

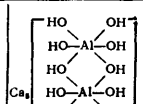
It may therefore be stated that in the limit the reaction of calcium aluminate with water when $Ca^{2+}$ ions are deficient, leads to the formation of hydrargillite.

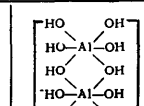
In an examination of the behaviour of the monomeric $[Al(OH)_6]^{3-}$ ion, it should be noted that the $OH^-$ groups in the inner coordination sphere of the aluminium atom may be replaced by univalent ($Cl^-$, $F^-$) or multivalent anions.

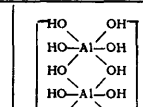
An important case in the chemistry of cement is that where the ligand is orthosilicic acid. In this case, inner-sphere substitution taking place under hydrothermal conditions [110] leads to the formation of a separate series of hydrogarnets and, in the limit, of the garnet grossular [the fraction indicates the proportion of the $(SiO_4)^{4-}$ ligand corresponding to one Al atom in the complex] (see p. 456).

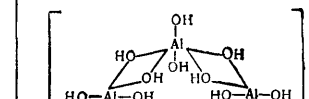






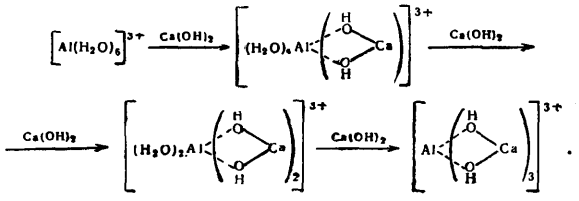






$$[Al(OH_6)]_2Ca_3 \equiv 3CaO \cdot Al_2O_3 \cdot 6H_2O \rightarrow$$
$$\rightarrow [(OH)_6Al(SiO_4)_{1/4}]_2Ca_3 \equiv 3CaO\ Al_2O_3 \cdot {}^1/_3SiO_2 \cdot 5H_2O \rightarrow$$
$$\rightarrow [(OH)_4Al(SiO_4)_{2/4}]_2Ca_3 \equiv 3CaO \cdot Al_2O_3 \cdot SiO_2 \cdot 4H_2O \rightarrow$$
$$\rightarrow [(OH)_2Al(SiO_4)_{3/4}]_2Ca_3 \equiv 3CaO \cdot Al_2O_3 \cdot 1^1/_2SiO_2 \cdot 3H_2O \rightarrow$$
$$\rightarrow [(OH)_2Al(SiO_4)_{1/4}]_2Ca_3 \equiv 3CaO \cdot Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O \rightarrow$$
$$\rightarrow [(OH)\,Al(SiO_4)_{3/4}]_2Ca_3 \equiv 3CaO \cdot Al_2O_3 \cdot 2^1/_2SiO_2 \cdot H_2O \rightarrow$$
$$\rightarrow [Al(SiO_4)_{6/4}]_2Ca_3 \equiv 3CaO \cdot Al_2O_3 \cdot 3SiO_2.$$

That this process is correct is confirmed by the preparation of the first, third (plazolite), fourth, fifth, and seventh compounds [111-113]; compounds with compositions close to those of the second [114,115] and sixth [111] compounds have also been prepared. The second and subsequent garnets are polymeric: the inner coordination spheres of the Al atom are joined by $(SiO_4)^{4-}$ groups.



In addition, because of the amphoteric nature of aluminium, formation of the $[Al(H_2O)_6]^{3+}$ ion is also possible (see scheme in Fig. 2).

The behaviour of the $[Al(H_2O)_6]^{3+}$ cation, which is capable of forming salts with anions, differs fundamentally from that of $[Al(OH)_6]^{3-}$. First of all it should be noted that in calcium hydroxide and calcium sulphate solutions coordination compounds are formed, as a result of inner-sphere substitution, in which two aquo-groups in the inner-sphere

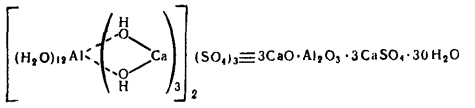
TABLE 1. Series of aluminodiolanes.

| Type | Anion | | | | | | |
|---|---|---|---|---|---|---|---|
| | monomeric | dimeric | trimeric | tetrameric | pentameric | hexameric | polymeric |
| Ratio OH/Al | 6 | 5 | 4.67 | 4.5 | 4.4 | 4 | 3 |
| *Oxide formula* | $3CaO \cdot Al_2O_3 \cdot 6H_2O$ | $2CaO \cdot Al_2O_3 \cdot 5H_2O$ | $5CaO \cdot 3Al_2O_3 \cdot 14H_2O$ | $3CaO \cdot 2Al_2O_3 \cdot 9H_2O$ | $7CaO \cdot 5Al_2O_3 \cdot 22H_2O$ | $CaO \cdot Al_2O_3 \cdot 6H_2O$ | $Al_2O_3 \cdot 3H_2O$ |
| Chemical structural formula |  |  |  |  |  |  | hydrargillite (hydrated aluminium oxide) $[Al(OH)_3]_n$ |

of the central atom are replaced by one molecule of calcium hydroxide, which occupies two coordination positions:

The calcium hydroxide molecules present in the inner coordination sphere of the Al atom in the calcium hydroaluminates formed during the hydration of alumina cement can be characterised as "combined lime".

When the complex cation is considered from the viewpoint of the octahedral model, a number of possibilities arise. The two calcium hydroxide molecules may be present in the complex in either the *trans*- or *cis*-positions; in the latter case, optically active forms are produced.



The complex containing three calcium hydroxide molecules should also exist in the form of mirror isomers or a racemate.

The $[Al(H_2O)_6]^{3+}$ cation or its derivatives containing calcium hydroxide molecules react with anions to give compounds with $[Al(OH)_6]^{3-}$, $OH^-$, $Cl^-$, $SO_4^{2-}$, etc. in the outer coordination sphere.

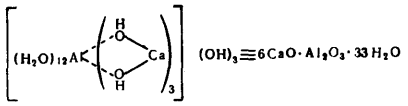


Table 2 gives complex cations which contain a central aluminium atom and can be regarded as derivatives of the $[Al(H_2O)_6]^{3+}$ ion. Thus the water present in the "oxide" formulae should be regarded as water of constitution, removal of which (particular attention must be paid to the possibility of hydrate isomerism) leads to breakdown of the coordination compound.

Calcium hydroaluminates containing much larger quantities of water are also known.

Deval's salt [116]

and hexacalcium hydroaluminate

are super-complex compounds [117] in which the coordination sphere of the Al atom contains 12 "additional" water molecules.

Thus in the products of the hydration hardening of monocalcium aluminate it is necessary to distinguish the following [118].

1. Products of the incomplete hydration (olation) of monocalcium aluminate — calcium polyaluminooxanate with c.n. Al = 4.

TABLE 2. Most important hydroaluminates containing the Al atom in a complex cation.

| Cation | Anion | | | |
|---|---|---|---|---|
| | $[Al(OH)_6]^{3-}$ | $(OH)^-$ | $Cl^-$ | $(SO_4)^{2-}$ |
|  | $Al(OH)_3$ (hydrargillite) | $Al(OH)_3$ (hydrargillite) | $AlCl_3 \cdot 12H_2O$ | $Al_2(SO_4)_3 \cdot 12H_2O$ |
|  | $CaO \cdot Al_2O_3 \cdot 8H_2O$ | $2CaO \cdot Al_2O_3 \cdot 13H_2O$ | — | $2CaO \cdot Al_2O_3 \cdot 3H_2SO_4 \cdot 7H_2O$ |
|  *trans*- and *di-cis*-forms | $2CaO \cdot Al_2O_3 \cdot 7H_2O$ | $4CaO \cdot Al_2O_3 \cdot 11H_2O$ ($\alpha$-, $\beta$-, and $\gamma$-forms, hydrocalumite) | — | $CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 8H_2O$ |
|  *di-cis*-forms | $3CaO \cdot Al_2O_3 \cdot 6H_2O$ | $6CaO \cdot Al_2O_3 \cdot 9H_2O$ | $3CaO \cdot Al_2O_3 \cdot 3CaCl_2 \cdot 6H_2O$ | $3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 6H_2O$ |

2. Coordination compounds of aluminium in which the aluminium atom (c.n. Al = 6) is present in a complex *anion*: (a) aluminolanes — monomeric (cubic $3CaO.Al_2O_3.6H_2O$), dimeric, and in the limit polymeric (hydrargillite) coordination compounds of aluminium; (b) inner-sphere substitution products in which the inner coordination sphere of the aluminium atom contains the ligands $Cl^-$, $(SiO_4)^{4-}$ — in the latter case the products are garnets and hydrogarnets (it is necessary to distinguish polymeric forms).

3. Coordination compounds of aluminium in which the aluminium is present in a complex *cation*, surrounded by $H_2O$ and $Ca(OH)_2$ ligands. This group includes hydrocalumite, calcium hydrochloroaluminate and hydrosulphoaluminate, etc.

4. Products obtained as a result of the deolation of hydrargillite, e.g. boehmite.

Additives to the cement. Since the polymeric components of concrete based on alumina cement are polyaluminodiolanes, hydrated forms of aluminium are used as characteristically active hydraulic additives to alumina cement.

Tervalent iron, like aluminium, is capable of forming polymeric coordination compounds [118], so that hydrated and oxide forms of iron, and also calcium ferrites, have no harmful action in alumina cement.

## SUMMARY

The ability of oxygen compounds of silicon and aluminium to undergo polymerisation and depolymerisation has a marked influence on the preparation of cement clinker, the reaction of the latter with water, and the properties of concretes. Polymeric compounds are present in the products of hydration hardening and also in the original raw material and the hydraulic additives. It is these polymeric compounds which determine to a considerable extent the technological methods for the processing of the raw material and the properties of cements and concretes. All this indicates that macromolecular compounds and inorganic binding agents (cements) are similar in character. The

main characteristic feature common to these two groups of substances is the presence of chains formed by covalently bound atoms.

In view of the important part played by polymeric substances in cements and concretes, the chemistry of Portland cement and alumina cement is an important field of the chemistry of silicon and aluminium polymers. The chemistry of cements leads to new synthetic procedures in the chemistry of macromolecular compounds.

Cements have their own characteristic features, shown only by this type of substance, so that the group of inorganic binding agents includes both cements and gypsum, magnesia, and lime binding agents.

During the hydration hardening of all inorganic binding agents, a fundamentally new disperse phase — new formations — not previously present in the system are formed from aqueous solution (the water not only acts as a dispersion medium but also takes direct part in the chemical reaction). The part played by the processes leading to the formation of the crystalline aggregate, in particular cement block, in the technological processes for the production of concretes is so great that up to the present the main attention has been directed to these processes. The similarity of these processes for a variety of substances has led to their classification as inorganic binding agents.

At the same time it is convenient to distinguish inorganic binding agents according to the possibility of formation and actual formation of polymeric chains; the latter are characteristic of Portland cement and alumina cement but not of gypsum.

Thus in an examination of inorganic binding agents (cements) it is necessary to take account of the dual nature of the chemical bonding (ionic and covalent) as a result of which the atoms joined to one another are capable of forming polymeric chains in these substances, and also of the chemical and physicochemical processes taking place during the preparation and hydration hardening of the binding agent. This becomes possible if cements are approached from the viewpoint of polymerisation and crystallisation theories[28]. A one-sided approach to cements will not reveal the great variety in their properties.

# GRAFT COPOLYMERS OF CELLULOSE AND ITS DERIVATIVES

R. M. Livshits and Z. A. Rogovin

## CONTENTS

I. Introduction 459
II. Synthesis of graft copolymers by polycondensation 460
III. Synthesis of graft copolymers by the interaction of two polymers 460
IV. Synthesis of graft copolymers by the polymerisation of rings 461
V. Synthesis of graft copolymers by ionic polymerisation 461
VI. Synthesis of graft copolymers by radical polymerisation 461
1. Synthesis of graft copolymers by chain transfer 461
2. Synthesis of graft copolymers by the copolymerisation of unsaturated esters of cellulose with vinyl monomers 462
3. Mechanicochemical method of synthesising block and graft copolymers 463
4. Synthesis of graft copolymers under the influence of radiation 463
5. Synthesis of graft copolymers by the preliminary introduction of groups which break down to form macroradicals 465
6. Synthesis of graft copolymers on redox systems in which the polymer acts as reducing agent 466

## I. INTRODUCTION

The controlled modification of the properties of cellulose and its derivatives by the synthesis of graft copolymers based on them undoubtedly provides one of the most promising and effective methods for improving the quality and extending the range of application of cellulosic materials.

Several cellulosic materials possessing valuable new properties have already been obtained by the synthesis of graft copolymers. For example, cellulosic materials which are completely resistant to the action of microorganisms can be prepared by grafting on various carbon-chain polymers, and improved stability to light and heat is achieved by the synthesis of graft copolymers with polyacrylonitrile. Non-flammable cellulosic materials can be obtained by the grafting on of polymers containing phosphorus or chlorine; the grafting of water-repellent carbon-chain or silicon-containing polymers confers water-repellent properties and improved resistance to acids. The synthesis of graft copolymers of cellulose with a definite class of synthetic polymers makes it possible to

have cellulosic materials possessing specific new properties, in particular ion-exchange and bactericidal properties. The possibility of a controlled variation in the properties of cellulosic materials by the synthesis of graft copolymers is responsible for the interest taken by research workers in this method of modifying the properties of cellulose and its derivatives [1-16].

It is possible to envisage two main ways in which graft copolymers of cellulose and its esters can be synthesised — (1) by the synthesis of graft copolymers which are then processed into materials (fibres, films, etc.), and (2) by direct grafting to ready-made articles.

Each of these methods has its advantages and disadvantages. The advantages of the first method are — (*a*) the production in most cases of materials (fibres, films) having improved physical and mechanical properties, since in this case not only the macromolecules of the original cellulose derivative but also graft chains of synthetic polymers are involved in forming the supermolecular structures, and (*b*) the possibility of using a mixture of the graft copolymer and the homopolymer joined to it. A serious defect of the method is the impossibility of using it to obtain fibres and films of graft copolymers of cellulose, since such products are not usually soluble and do not show viscous flow.

The second method is considerably more promising and versatile. If certain requirements, indicated below, are satisfied, this method may find wide practical application in the immediate future. A method of synthesising graft copolymers which is acceptable in practice for the modification of ready-made goods must evidently satisfy the following requirements: (1) graft copolymerisation should occur without formation of the homopolymer; in isolated cases the homopolymer may be formed directly on the cellulosic material (not in the reaction medium), and then the homopolymer should not be removable when the goods are in service; (2) the synthesis of graft copolymers must be achieved without the use of organic solvents; and (3) the grafting process should not be accompanied by appreciable degradation of cellulose or its derivatives. It is also desirable that the method should permit ready control of the length and number of the graft chains, so that the properties of the graft copolymers can be varied without changing their composition.

In principle the synthesis of graft copolymers, like that of polymers in general, can be effected by the known reactions of polycondensation, polymerisation of rings, and chain polymerisation. A specific method for the synthesis of graft copolymers is the possibility of their production by the interaction of two polymers.

Below are considered the principal methods which have been proposed for the synthesis of graft copolymers of cellulose. These methods can be employed also to obtain graft copolymers based on other macromolecular compounds. The present review is confined to results obtained in the synthesis of graft copolymers of cellulose and its derivatives.

## II. SYNTHESIS OF GRAFT COPOLYMERS BY POLYCONDENSATION

Rogovin and his coworkers have synthesised graft copolymers of cellulose and its esters with polyamides by polycondensation of the monomer as a result of interaction with the functional group of the cellulose derivatives.

Polycondensation of methyl 7-aminoheptanoate, in the presence of methyl ethers of carboxy-containing polysaccharides (carboxymethylcellulose, dicarboxycellulose, alginic acid) or their amides with methyl 7-aminoheptanoate, yields graft copolymers of the cellulose derivatives with polyamides, together with a large quantity of the homopolyamide [17,18]. The reaction takes place according to the scheme

$$\text{poly-saccharide}\text{—}COOCH_3 + nH_2N(CH_2)_6COOCH_3 \xrightarrow[Ar]{100-110^\circ} \text{polysaccharide}\text{—}CONH(CH_2)_6COOCH_3 \rightarrow$$
$$\rightarrow \text{polysaccharide}\text{—}CO[NH(CH_2)_6CO]_xOCH_3 + H[NH(CH_2)_6CO]_yOCH_3 + (n-2)\,CH_3OH \quad (1)$$
(where $x+y=n$).

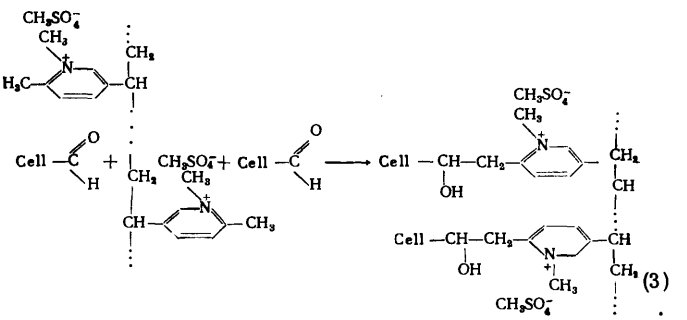
Graft copolymers of cellulose and polyamides have been synthesised [18] by treating cellulose with the hydrochloride of 7-aminoheptanoyl chloride in an organic base

$$\text{Cell}\text{—}OH + nClOC(CH_2)_6NH_2\cdot HCl \rightarrow$$
$$\rightarrow \text{Cell}\text{—}OCO(CH_2)_6NH[CO(CH_2)_6NH]_xH + H[NH(CH_2)_6CO]_yOH + nHCl \quad (2)$$
(where $x+y=n$).

When sodium cellulose xanthate is employed as starting material, the process can be carried out at the interface [18].

The complicated preparation of the initial cellulosic derivatives, the necessity of employing organic solvents, and the formation of a considerable quantity of homopolymer together with the graft copolymer at the present time prevent the practical application of these methods of synthesising graft copolymers.

## III. SYNTHESIS OF GRAFT COPOLYMERS BY THE INTERACTION OF TWO POLYMERS



The chief advantage of this method is the possibility of synthesising graft copolymers having main and graft chains of specified length. The method is used to obtain graft copolymers based on synthetic polymers, but finds limited application for the modification of cellulosic derivatives.

Graft copolymers having a main chain of cellulose and protein side-chains have been obtained by condensation. These products are of great interest for polymer chemistry. In order to synthesise cellulose–protein graft copolymers, cellulose azide is condensed with proteins containing free amino-groups:

$$\text{Cell}\text{—}CON_3 + H_2N\text{—}\text{Prot} \rightarrow \text{Cell}\text{—}CONH\text{—}\text{Prot}.$$

Graft copolymers differing in composition can be obtained according to the concentrations of the two components in the reaction mixture. If the concentration of protein is considerably increased, insoluble products are formed [19].

Copolymers of three-dimensional structure have been synthesised by the interaction of cellulose acetate toluene-*p*-sulphonate and dialdehydocellulose with poly-2-methyl-5-vinylpyridine or a quaternary salt thereof [20]. When dialdehydocellulose is used, the reaction proceeds according to the scheme

(3)

Reaction between cellulose acetate toluene-*p*-sulphonate and poly-2-methyl-5-vinylpyridine is brought about by a method similar to that used to synthesise graft copolymers of poly(vinyl chloride) and methylvinylpyridine rubber[21]. Practical application of this method for the modification of cellulose is made difficult by the complexity of the synthesis of the initial cellulose derivatives and the insolubility of the final product.

## IV. SYNTHESIS OF GRAFT COPOLYMERS BY THE POLYMERISATION OF RINGS

When strained rings (ethylene oxide, ethyleneimine, β-propiolactone) are polymerised in the presence of alkali-cellulose, homopolymerisation and formation of cellulose ethers are probably accompanied by the formation of graft copolymers[22-25]:

$$\text{Cell}-\text{OH}+n\text{CH}_2\!-\!\text{CH}_2 \begin{cases} \rightarrow \text{Cell}-\text{O}(\text{CH}_2\text{CH}_2\text{O})_x\text{H} \\ \rightarrow \text{Cell}-\text{OCH}_2\text{CH}_2\text{OH} \end{cases} \quad (4)$$

Formation of a graft copolymer by the interaction of aziridine (ethyleneimine) and alkali-cellulose has been demonstrated experimentally by isolating the grafted polyethyleneimine by hydrolysis of the cellulose followed by esterification of the glucopyranose end-group with benzoyl chloride[26]. The degree of polymerisation of the isolated polymer did not exceed 6.

It is of interest to undertake similar investigations on the products formed by cellulose with oxiran (ethylene oxide). The simplicity of their preparation and their several valuable properties (in particular solubility in water) of such products have provided reasons for their practical utilisation[27].

Graft copolymers of cellulose and polyethyleneimine are also of definite practical interest for obtaining cellulosic materials possessing specific properties (bactericidal power, non-flammability, etc.).[26,28-30] A final conclusion concerning the advisability of the practical application of products formed by the interaction of cellulose with ethyleneimine may be reached after determining the relative quantities of monomer which have reacted with the cellulose and have been used up in homopolymerisation.

American research workers, having studied the conditions for the synthesis of derivatives of cellulose and poly-β-propiolactone, and also the properties of these products, concluded that their practical application would serve no useful purpose[31-34].

The principal defect in the above methods for synthesising graft copolymers is the considerable loss of monomer by homopolymerisation.

Rogovin and Wu Jung-jui proposed a method for obtaining graft copolymers of carboxymethylcellulose and polycaprolactam which excludes formation of the homopolyamide[35]. Synthesis of the graft copolymer is effected by polymerising caprolactam in the presence of chloroformylmethylcellulose and sodium caprolactam. In the first stage of the reaction an imide of caprolactam and carboxymethylcellulose is formed, with polymerisation of the caprolactam, in the presence of which graft copolymers are formed:

$$\text{Cell}-\text{OCH}_2\text{COCl} \xrightarrow{\text{NaN}(\text{CH}_2)_5\text{CO}} \text{Cell}-\text{OCH}_2\text{CON}(\text{CH}_2)_5\text{CO} \xrightarrow[70-80^\circ,\ \text{Ar}]{n\text{HN}(\text{CH}_2)_5\text{CO}} \xrightarrow[70-80^\circ,\ \text{Ar}]{n\text{HN}(\text{CH}_2)_5\text{CO}} \text{Cell}-\text{OCH}_2\text{CO}[\text{HN}(\text{CH}_2)_5\text{CO}]_{n-1}\text{N}(\text{CH}_2)_5\text{CO}. \quad (5)$$

The employment of chloroformylmethylcellulose and sodium caprolactam for the synthesis of graft copolymers by this method precludes its practical application, although the synthesis of graft copolymers of cellulose and polyamides is of considerable interest.

## V. SYNTHESIS OF GRAFT COPOLYMERS BY IONIC POLYMERISATION

Only one attempt has been reported[36] to use ionic polymerisation to modify cellulose with carbon-chain polymers. The cellulosic material is wetted out at low temperatures in a solution of boron trifluoride in an organic solvent (boron trifluoride forms a complex with cellulose), and then the material is placed in the monomer. However, the paper gives no evidence to indicate the formation of a graft copolymer.

Ionic polymerisation can probably be used to obtain graft copolymers of cellulose by a scheme suggested for the synthesis of block copolymers of poly(ethylene oxide)[37] (with hydroxyethylcellulose as starting material). The complexity of the process for obtaining the starting materials and the necessity of carrying out the reaction in an organic solvent or in the 100% monomer make the method unpromising for practical application.

## VI. SYNTHESIS OF GRAFT COPOLYMERS BY RADICAL POLYMERISATION

The modification of cellulosic materials by the synthesis of graft copolymers by radical polymerisation has been investigated most. The following methods may be used — (1) chain transfer, (2) copolymerisation of unsaturated esters of cellulose with vinyl monomers, (3) a mechanico-chemical method, (4) exposure to high-energy and low-energy particles, (5) preliminary introduction of groups which break down to form macroradicals, and (6) by redox systems in which the polymer acts as reductant.

### 1. Synthesis of Graft Copolymers by Chain Transfer

The synthesis of graft copolymers by chain transfer presupposes that, as a result of detachment of a labile atom by interaction with a radical, the polymer molecule is converted into a macroradical capable of initiating the graft copolymerisation of a vinyl monomer in contact with it.

In principle chain transfer to a polymer can be effected by the interaction of (*a*) a growing macroradical or (*b*) an initiator radical with the polymer macromolecule. The composition of the product of graft copolymerisation will depend on which of these two mechanisms of chain transfer is operating. It is therefore useful to examine the two possibilities separately, but it must be borne in mind that such separation is arbitrary, and cases may occur in which chain transfer is accomplished by both mechanisms.

(*a*) Synthesis of graft copolymers by chain transfer from a growing macroradical. We include here those methods of graft copolymerisation in which an initiator is added to a solution of the monomer containing the polymer. Under these conditions interaction of the initiator radicals is thermodynamically more favourable with the monomer than with the polymer.

Graft copolymers have been synthesised by the initiated polymerisation of acrylonitrile in the presence of starch[38], methylcellulose, gelatin, cellulose acetates[39], and hydroxyethylcellulose[40].

A systematic investigation of the effect of process conditions on the quantity of homopolymer formed during the graft copolymerisation of 2-methyl-5-vinylpyridine and cellulose has been made by Kryazhev and Rogovin[41]. The efficiency of chain transfer to the polymer is increased if the reaction is carried out with the cellulose in a considerably swollen state. Even in this case, however, the quantity of monomer involved in graft copolymerisation does not exceed 25% of that which has reacted.

To improve the efficiency of chain transfer, groups containing labile atoms are introduced into the cellulose macromolecule, which markedly increases the possibility of this process. Mixed esters of cellulose with acetic and 11-bromoundecanoic acids[1] or cellulose preparations containing thiol groups[42,43] are used for this purpose.

The preliminary introduction of thiol groups for the synthesis of graft copolymers was first suggested by Gluckman[44,45]. J. J. Hermans and his coworkers obtained products containing thiol groups by treating modified cellulose and secondary cellulose acetate with ethylene sulphide. Graft copolymers can be obtained by the polymerisation of vinyl monomers in the presence of such esters[42,43]. The efficiency of chain transfer with preparations containing thiol groups is five times that with materials which have not been treated with ethylene sulphide.

In all cases of the synthesis of graft copolymers by chain transfer from a growing macroradical a considerable quantity of homopolymer is formed, which, together with the need to introduce groups to ensure a high efficiency of chain transfer, prevents the practical application of these methods.

(*b*) Synthesis of graft copolymers by chain transfer from initiator radicals. Chain transfer from initiator radicals is considerably more useful than the above. It probably occurs in the polymerisation of vinyl monomers in the presence of cellulose on the $Fe^{2+}$–$H_2O_2$ redox system[46–53]. In this case formation of a cellulose macroradical probably occurs by the following mechanism

$$Fe^{2+}+H_2O_2 \rightarrow Fe^{3+}+OH^-+\dot{O}H,$$

$$\text{Cell}-OH+\dot{O}H \rightarrow \text{Cell}-O^{\bullet}+H_2O. \qquad (6)$$

Graft copolymerisation takes place when a cellulosic material is wetted out in a solution containing $Fe^{2+}$ ions and then immersed in a solution of a monomer containing 0.03% of hydrogen peroxide. Under the conditions chosen, however, the quantity of monomer involved in graft copolymerisation does not exceed 12.5% of the amount which has reacted[47]. The formation of considerable quantities of homopolymer is probably due to diffusion of $Fe^{2+}$ ions into the aqueous solution, where homopolymerisation of the monomer is initiated. The efficiency of chain transfer is considerably increased if the initiator or a component of the redox system is bound to the cellulosic material by a salt link, and its diffusion into the monomer solution is impeded. In this case initiator radicals are formed directly on the cellulosic material, and the probability of their interacting with the cellulose macromolecules is increased. This principle forms the basis of the method for synthesising graft copolymers proposed by Bridgeford, in which a cellulose preparation containing a small quantity of carboxy-groups is wetted with a solution of an iron(II) salt (when $Fe^{2+}$ is sorbed by the carboxy-groups of the cellulose) and, after excess $Fe^{2+}$ cations have been eluted, is immersed in an aqueous solution or an emulsion of the monomer containing hydrogen peroxide insufficient to initiate polymerisation in the absence of $Fe^{2+}$ ions. In this case formation of homopolymer in the reaction medium is not observed[53]. The efficiency of graft copolymerisation is determined by the nature of the cellulosic material. The amount of homopolymer formed within the cellulosic material is considerably lower with hydrocellulose fibres than with cotton fibres, constituting only 4–5% of the monomer which has reacted.

Chain transfer from initiator radicals also occurs when potassium peroxodisulphate is employed as initiator under conditions which make diffusion of the initiator into the monomer solution difficult[6,54,55]. The possibility of formation of a cellulose macroradical by interaction of the cellulose with radicals produced by decomposition of the persulphate is confirmed by investigations with alcohols of low molecular weight. When aqueous solutions containing peroxodisulphate ions are heated, these ions break down according to the equation[56]

$$S_2O_8^{2-} \rightarrow 2SO_4^{-}. \qquad (7)$$

When $K_2S_2O_8$ decomposes in the presence of an alcohol, $SO_4^{-}\cdot$ ion-radicals react with the alcohol molecule according to the equation[56–58]

$$CH_3OH+SO_4^{-}\cdot \rightarrow \dot{C}H_2OH+HSO_4^{-}. \qquad (8)$$

The probability of reaction (8) diminishes in the presence of a free-radical acceptor (monomer). Thus the synthesis of graft copolymers of cellulose is possible on reaction under conditions which impede interaction of $SO_4^{-}\cdot$ with the monomer. In fact, if a cellulosic material is wetted with a solution of potassium peroxodisulphate and then brought into contact with a monomer (by being kept in the monomer vapour or immersed in the pure monomer) under conditions which make diffusion of $S_2O_8^{2-}$ or $SO_4^{-}\cdot$ into the monomer phase difficult, graft copolymers of various compositions can be synthesised[54,55].

When graft copolymers are synthesised by chain transfer from initiator radicals, homopolymer is formed only directly on the cellulosic material. Therefore such methods can be expected to be applied in practice for the modification of ready-made goods in cases in which the presence of homopolymer on the cellulosic material does not impair the properties of the resulting materials in service. Among the defects of these methods must be reckoned the difficulty of controlling the degree of polymerisation and the number of graft chains.

## 2. Synthesis of Graft Copolymers by the Copolymerisation of Unsaturated Esters of Cellulose with Vinyl Monomers

The synthesis of graft copolymers by this method is based on the fact that, in the presence of initiators of radical polymerisation, the double bond of the polymer is opened to form a macroradical, which initiates polymerisation of the monomer or combines with the growing macroradical of the monomer. Both processes result in the formation of a graft copolymer. The presence of an initiator in the system makes simultaneous homopolymerisation of the monomer possible. Thus a considerable quantity of homopolymer is formed in all cases of graft copolymerisation by this method.

The possibility of synthesising graft copolymers by the copolymerisation of unsaturated esters of cellulose with various vinyl monomers was first pointed out by Ushakov[59]. Berlin and Makarova developed a method for preparing cellulose acetate methacrylates by the acetylation of cellulose monomethacrylate with acetic anhydride or by the esterification of secondary cellulose acetate with methacrylic anhydride. The resulting mixed esters of cellulose are copolymerised in the presence of benzoyl peroxide with methyl methacrylate and ethylene dimethacrylate to form graft copolymers of three-dimensional structure[60]. Graft copolymers containing 6–8% of polystyrene have been synthesised[61] by the copolymerisation with styrene of mixed esters of cellulose containing unsaturated bonds. Grafting is accompanied by the formation of a large quantity of homopolymer. Unsaturated groups are readily introduced into the macromolecule of cellulose nitrates by treating their solutions with

$$\left[\begin{array}{l}-ONO_2\\-ONO_2\\-OH\end{array}\right. + OCNRNHCOOCH{=}CH_2 \rightarrow \left[\begin{array}{l}-ONO_2\\-ONO_2\\-OCONHRNHCOOCH{=}CH_2\end{array}\right. \quad (9)$$

Graft copolymers are formed by the polymerisation of acrylonitrile in solutions of modified cellulose nitrates[62].

The formation of a considerable quantity of homopolymer, the low yields of graft copolymer, and the need for preliminary treatment of the cellulose to introduce unsaturated groups evidently make the synthesis of graft copolymers by this method unpromising.

## 3. Mechanicochemical Method of Synthesising Block and Graft Copolymers

The degradation of cellulose and its derivatives by mechanical energy is accompanied by the formation, at the ends of the newly produced chains, of free macroradicals[63] capable of initiating the block copolymerisation of monomers in contact with them. Formation of a macroradical by rupture of a bond with a substituent results in the formation of graft copolymers. The mechanicochemical method is the only method for the synthesis of block copolymers of polysaccharides which has yet been put into practice under laboratory conditions.

Ceresa obtained methylcellulose–polyacrylonitrile, ethylcellulose–poly(methyl methacrylate), benzylcellulose–polystyrene, and cellulose acetate–poly(vinyl acetate) block copolymers by vigorous grinding of the polymers, plasticised with the monomer, in the absence of atmospheric oxygen[64]. He prepared block copolymers also by swelling cellulose acetates in acrylonitrile[64]. Block copolymers of water-soluble polysaccharides are obtained by repeatedly freezing and thawing out aqueous emulsions of the polymer and monomer[64–66]. Block copolymers can probably be obtained also by the intense mechanical working of thermoplastic cellulose ethers with other thermoplastic polymers (as a result of the combination of macroradicals of the different polymers). In the synthesis of block copolymers by this method, a complicated mixture of products is obtained, containing both homopolymers and block and graft copolymers.

This last fact, the difficulties associated with controlling the composition and size of the blocks, and the impossibility of employing this procedure for modifying ready-made goods have so far prevented the practical realisation of these methods for modifying cellulose and its derivatives.

## 4. Synthesis of Graft Copolymers under the Influence of Radiation

(*a*) Synthesis of graft copolymers by exposure to high-energy particles. When cellulose[67,68], its ethers and esters[69], and other polysaccharides[70] are irradiated with high-energy particles, the main process is degradation. Completely water-soluble products are formed by the exposure of cellulose[68] to a dosage of only ~ 100 Mr. Degradation under the influence of radiation takes place by a free-radical mechanism. The formation of macroradicals of cellulose and its derivatives by the action of high-energy particles can be used to initiate graft copolymerisation. Depending on the conditions, there are four ways in which graft copolymers can be synthesised by this method — (i) simultaneous irradiation of polymer and monomer in the absence of air, (ii) simultaneous irradiation of polymer and monomer in air, (iii) irradiation of the polymer in an inert gas atmosphere with subsequent interaction with the monomer, and (iv) irradiation of the monomer in the presence of air with subsequent interaction with the monomer.

(i) When polymer and monomer are exposed together in the absence of air, graft copolymerisation is initiated by macroradicals of the polymer formed under the influence of the high-energy particles. In the synthesis of graft copolymers of cellulose, macroradicals can be formed either at the end of a chain (by cleavage of the bond between monomeric units in the cellulose macromolecule) or in the middle of a chain[67–69,71].

Rupture of the bond between monomeric units should result in the formation of considerable quantities of block copolymers together with the graft copolymers.

(ii) When polymer and monomer are irradiated together in air, graft copolymerisation is initiated both by macroradicals formed by the direct action of radiation and by macroradicals resulting from the breakdown of peroxy- or hydroperoxy-groups formed by the addition of oxygen to macroradicals obtained in the first stage of irradiation.

When graft copolymers are synthesised by simultaneous irradiation of polymer and monomer, considerable quantities of the homopolymer are formed, since production of polymer macroradicals is accompanied by that of radicals of low molecular weight as a result of exposure of the monomer, and these initiate homopolymerisation[72–84]. One procedure for the simultaneous exposure of polymer and monomer is to irradiate the polymer swollen in the monomer. In this case the homopolymer is formed only on the treated polymer, not in the reaction medium, as is observed when the polymer is irradiated in the monomer solution[85]. One of the most acceptable ways of synthesising graft copolymers by the simultaneous irradiation of polymer and monomer is probably to expose the polymer in the presence of the monomer vapour (vapour-phase copolymerisation)[86,87].

The synthesis of graft copolymers by the irradiation of polymer and monomer together probably involves the formation of strongly branched polymers, since the possibility remains that a macroradical capable of initiating polymerisation will be formed on the grafted chain[88]. Swelling of the cellulosic material is of great importance for the reaction to be efficient, since it increases the rate of diffusion of the monomer. Usmanov and his coworkers investigated the graft copolymerisation of cellulose with acrylonitrile. The reaction was carried out by irradiating

cellulose suspended in a solution of acrylonitrile in water, methanol, or benzene or in pure acrylonitrile. A graft copolymer was obtained only when the cellulose was swollen (no grafting occurred when cellulose was exposed in benzene solution)[72]. Other workers have noted the effect of degree of swelling on rate of graft copolymerisation[71,74,75]. Shapiro and Stannett found that the rate of the graft copolymerisation of cellulose with vinyl monomers is increased by increasing the water content of the reaction medium[74]. Leavitt suggested that the effect of water is not limited to increasing the degree of swelling of the cellulosic material, but involves the generation of OH radicals on irradiation, which split off a hydrogen atom from the cellulose macromolecule to form a cellulose macroradical, as is presumably confirmed by the possibility of the "cross-linking" of water-soluble ethers of cellulose and gelatin in the presence of water. No cross-linking effect is observed when the dried polymers are irradiated[89].

(iii) When cellulose is irradiated in an atmosphere of an inert gas, "long-lived" macroradicals are formed (cellulose which has been exposed in the absence of atmospheric oxygen gives paramagnetic resonance signals for several days after irradiation)[88], which initiate graft copolymerisation on subsequent interaction with a monomer[71,76,90-92]. However, degradation of the cellulose is more intense in this case than on exposure in the presence of a monomer which is an acceptor for free radicals[71].

(iv) When a polymer is irradiated in air, peroxy- or hydroperoxy-groups are formed, which on subsequent heating in the presence of a monomer break down and initiate graft copolymerisation[77,90,91]. Thus exposure of the polymer in the presence of air can be regarded as one way of introducing hydroperoxy-groups; the synthesis of graft copolymers by means of these groups is discussed below. Irradiation of the polymer with subsequent interaction with the monomer has certain technical advantages compared with the above procedure, since it permits the processes of irradiation and of subsequent grafting to be separated.

Wide practical application of methods for synthesising graft copolymers based on the use of ionising irradiation with particles of high energy is made difficult by the absence of methods for eliminating secondary processes resulting in the formation of homopolymer, degradation of the initial polymer, and the production of strongly branched graft copolymers, as well as by the difficulties involved in ensuring the safety of the process.

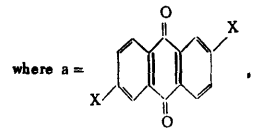
This last obstacle largely disappears when graft copolymerisation is induced by ultraviolet radiation or by radiation of longer wavelength in the presence of sensitisers. Carrying out grafting by this method enables considerable degradation of the polymer to be eliminated, which, together with its safety, constitutes the advantage of this method of synthesising graft copolymers.

(*b*) Synthesis of graft copolymers by means of low-energy particles. A systematic investigation of graft copolymerisation induced by visible light in the presence of anthraquinonoid dyes as sensitisers have been undertaken by Geacintov[93,94].

The mechanism of graft copolymerisation in the presence of sensitisers is that radiation of a wavelength absorbed by the sensitiser excites its molecule to a state in which it reacts with the polymer, converting the latter into a macroradical which initiates graft copolymerisation. Interaction between the excited sensitiser molecule and the monomer results in the formation of a radical of low molecular weight, which initiates homopolymerisation.

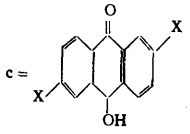
When an anthraquinonoid dye is employed as sensitiser, the mechanism of the process can be represented as follows:

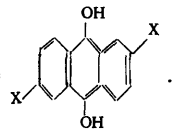
$$AQ^a + h\nu \longrightarrow AQ^{*b}, \quad (10)$$



$$AQ^{*b} + \text{Cell}\!>\!\underset{\displaystyle H}{\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}} \longrightarrow AQH^c\cdot + \text{Cell}\!>\!\overset{\displaystyle OH}{\overset{|}{C}}\cdot, \quad (11)$$

$$\text{Cell}\!>\!\overset{\displaystyle OH}{\overset{|}{C}}\cdot + n CH_2{=}CHR \longrightarrow \text{Cell}\!>\!\overset{\displaystyle OH}{\overset{|}{C}}\!-\!(CH_2\!-\!CHR)_n, \quad (12)$$





$$AQ^{*b} + CH_2{=}CHR \rightarrow AQH^c\cdot + CH_2{=}\dot{C}R, \quad (13)$$

$$CH_2{=}\dot{C}R + (n-1)\,CH_2{=}CHR \rightarrow (CH_2\!-\!CHR)_n, \quad (14)$$

$$2\,AQH^c\cdot \rightarrow AQH_2^d + AQ^a, \quad (15)$$

where a =  ,

the X being groups which confer on the sensitiser solubility in water ($SO_3Na$) or organic solvents, b is an excited sensitiser molecule,

c =  , d =  .

Such a mechanism is supported by work on related systems using alcohols of low molecular weight[6].

The rate of graft copolymerisation by this method is greater in the presence of air than in an inert gas, since in the presence of oxygen the above reactions are accompanied by the formation of peroxides, hydroperoxides, or both, which break down to form a cellulose macroradical[93].

Graft copolymerisation by this method is carried out under conditions of considerable swelling of the cellulose (in a solution of the monomer in a mixture of dimethylformamide and water or in an aqueous solution of the monomer) with minimum concentrations of the sensitiser (up to 0.01 M). The quantity of monomer grafted on is proportional to the time of exposure and the concentration of the dye.

Geacintov employed the above method to synthesise graft copolymers of cellulose with polyacrylonitrile, poly(vinyl acetate), polystyrene, and poly(methyl methacrylate), employing as starting material regenerated cellulose film, paper, etc.

A considerable amount of homopolymer — cf. reactions (13) and (14) — is formed in all cases of the synthesis of graft copolymers by this method. A further defect of the method is the difficulty of controlling the length and number of graft chains.

5. Synthesis of Graft Copolymers by the Preliminary Introduction of Groups which Break Down to Form Macroradicals

Under certain conditions hydroperoxy(or peroxy)-, diazo-, azonitrile, and diazoamino-groups break down to form radicals capable of initiating the polymerisation of vinyl monomers in contact with them[95-100]. If these groups are chemically combined with a polymer molecule, their decomposition produces macroradicals which initiate graft copolymerisation.

The synthesis of graft copolymers of cellulose and its derivatives is effected only by first introducing hydroperoxy- and diazo-groups into the cellulose macromolecule.

(*a*) Synthesis of graft copolymers of cellulose and its derivatives by the preliminary introduction of hydroperoxy-groups. Hydroperoxy- or peroxy-groups can be introduced into the macromolecule of cellulose and its ethers by treating the polymer with ammonium peroxodisulphate[101], irradiating it with high- and low-energy particles in the presence of air[77,99,102], and also by passing a stream of air through a solution of the cellulose ether containing azoisobutyronitrile[103] or a stream of oxygen or oxygen enriched with ozone[99,100,104,105]. The oxidation of cellulose and its derivatives for the purpose of introducing peroxy- or hydroperoxy-groups is almost always accompanied by considerable degradation of the polymer[102,103,105].

Ozonisation is a method frequently employed in laboratory investigations for introducing hydroperoxy-groups. The rate of accumulation of peroxy- and/or hydroperoxy--groups during ozonisation is increased by the presence of water, although hydrogen peroxide is not formed under the experimental conditions[106].

When a stream of oxygen containing 6% of ozone is passed through a cellulosic material, it is possible after 6 h to introduce 1 peroxy-group per 20 monomeric units. Peroxy-groups introduced into cellulose do not break down at 20° even on storage of the oxidised cellulose for 3 months. Appreciable diminution in the content of available oxygen is observed only at 75–80°; at 100° complete breakdown of peroxy-groups occurs after 2 h.[99]

A systematic investigation of ozonisation and of the properties of oxidised cellulose acetates has been made by Radchenko and his coworkers[105].

When cellulose preparations containing hydroperoxy--groups are heated in the presence of a monomer at 80–100°, the groups break down to form a macroradical, which initiates graft copolymerisation, and a hydroxy--radical, which causes homopolymerisation of the monomer:

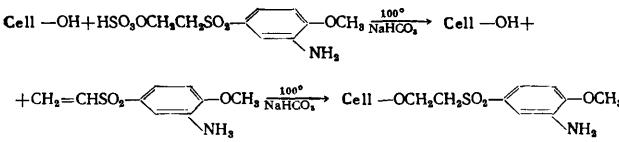
$$\text{Cell}-\text{OOH} \rightarrow \text{Cell}-\text{O}^{\cdot} + {}^{\cdot}\text{OH}. \qquad (16)$$

In the presence of metals of variable valency the hydroxy--radical is reduced to a hydroxide ion:

p l l o pe h y lf e xycl l ot r p/d u d l f l l l ht

The preliminary introduction of hydroperoxy-groups and/or peroxy-groups into the polymer has been used to synthesise graft copolymers of cellulose with polyacrylonitrile, polystyrene[99], poly(methyl methacrylate), poly-(vinyl acetate), and polyvinylpyridine, of cellulose nitrates with poly(butyl methacrylate)[102], of benzyl- and ethyl--cellulose with polystyrene, and of carboxymethylcellulose with polyacrylonitrile[92].

This method has the advantages that it makes possible the synthesis of graft copolymers based on almost any derivative of cellulose, the number of grafted chains can be readily varied (by varying the content of available oxygen in the polymer), and the process is comparatively simple to carry out. Among its disadvantages are the formation of a certain amount of homopolymer together with the graft copolymer, and the degradation of the original polymer on oxidation. These defects can be eliminated by using preparations of cellulose containing a small quantity of diazo--groups.



(*b*) Synthesis of graft copolymers by the preliminary introduction of diazo-groups. This method was suggested almost simultaneously and independently by Richards[107] and by Rogovin[108]. According to Richards, aromatic amino-groups can be introduced by treating alkali-cellulose with *p*-amino-ω-chloroacetophenone

$$\text{Cell}-\text{ONa}+\text{ClCH}_2\text{COC}_6\text{H}_4\text{NH}_2 \rightarrow \text{Cell}-\text{OCH}_2\text{COC}_6\text{H}_4\text{NH}_2, \qquad (18)$$

or by heating an aqueous solution of the sodium salt of carboxymethylcellulose with a solution of *p*-aminochloroacetophenone in dimethylformamide:

$$\text{Cell}-\text{OCH}_2\text{COONa}+\text{ClCH}_2\text{COC}_6\text{H}_4\text{NH}_2 \rightarrow \text{Cell}-\text{OCH}_2\text{COOCH}_2\text{COC}_6\text{H}_4\text{NH}_2. \qquad (19)$$

Rogovin et al. proposed a simpler single-stage method for introducing aromatic amino-groups into the cellulose macromolecule. When cellulose is treated in weakly alkaline medium at 100° with a 2-sulphonylethyl sulphate, the sulphate group is split off, and a vinylsulphonyl group is formed which, in the nascent state, adds on to the hydroxy--groups of the cellulose molecule to form a cellulose ether (Michael reaction). To introduce aromatic amino-groups into the cellulose macromolecule, use was made of the water-soluble sulphuric esters of 2-(3-amino-4-methoxyphenylsulphonyl)ethanol and 2-*p*-aminophenylsulphonylethanol. The alkylation of cellulose proceeds according to the scheme

(20)

Diazotisation of the cellulose macromolecule effects the introduction of diazo-groups, which break down on subsequent heating to form a macroradical, which initiates graft

the Cl· radical into a $Cl^-$ ion, and they are probably involved in chain termination by interaction of the growing macroradical with the oxidised form of the metal cation:

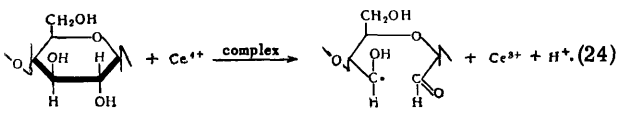
$$\text{Cell}-OAr{N_2}Cl+Fe^{2+} \rightarrow \text{Cell}-OAr^{\cdot}+N_2+Cl^-+Fe^{3+}, \quad (22)$$

$$-CH_2-\dot{C}HR+Fe^{3+} \rightarrow -CH=CHR+Fe^{2+}+H^+. \quad (23)$$

In order to synthesise graft copolymers by this method it is sufficient to obtain a cellulose ether having $\gamma = 3-10$. The quantity of polymer grafted depends on the activity of the radical formed, the degree of alkylation, and the nature of the initial monomer [108]. This method has been used to synthesise graft copolymers of cellulose with polyacrylonitrile, poly(vinylidene chloride), poly(methyl methacrylate), and polyacrylic and polyvinylphosphinic acids. In no case is the homopolymer formed [107-114].

It must be noted that the synthesis of graft copolymers by this method always yields coloured products [108]. The probable explanation is that the main reaction of diazotisation of the amino-groups with subsequent formation of a macroradical is accompanied by azo-coupling, in which some of the unchanged amino-groups take part.

In spite of the considerable advantages of this method (the possibility of synthesising graft copolymers from aqueous solutions or aqueous emulsions of the polymer without homopolymer formation, and the ease of regulating the number of graft chains), the necessity of first introducing aromatic amino-groups, with the associated considerable consumption of a relatively expensive compound and the production of coloured materials, prevents the widespread practical application of this method.



The synthesis of graft copolymers of cellulose and its derivatives on redox systems in which the cellulose or its derivative acts as reducing agent is a considerably more promising method.

### 6. Synthesis of Graft Copolymers on Redox Systems in which the Polymer Acts as Reducing Agent

The principle underlying the synthesis is that the oxidation with some oxidising agents of polymers containing reducing groups involves a stage in which macroradicals are formed; these are capable of initiating the graft copolymerisation of vinyl monomers in contact with them.

This principle was first exploited for the synthesis of graft copolymers by Mino, who proposed a quadrivalent cerium salt as oxidant [115]. This method has been investigated systematically by Japanese workers [116-127] and in our laboratory [128-136]. Work has also been done on the oxidation of compounds of low molecular weight [137-141], as well as of poly(vinyl alcohol) [142] and cellulose [120], with $Ce^{4+}$ ions, and on the polymerisation of vinyl monomers on redox systems formed by an alcohol of low molecular weight with $Ce^{4+}$. [140,143,144]

The initiation of the graft copolymerisation of cellulose by this method takes place according to the scheme

This mechanism of initiation is supported by the following experimental results:

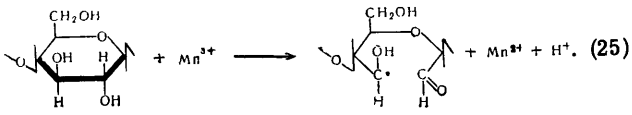
(i) In all cases of the oxidation of alcohols of low and high molecular weight, and of polymerisation by means of alcohol–$Ce^{4+}$ redox systems, a complex of reductant and oxidant is formed, the rate of oxidation being determined by the rate of disproportionation of this complex [140].

(ii) The oxidation of compounds containing a glycol grouping by cerium(IV) salts involves the intermediate formation of free radicals, with cleavage of the bond between the carbon atoms having attached hydroxy-groups [138,140,142].

(iii) Polymers synthesised on the redox system formed by an alcohol of low molecular weight with $Ce^{4+}$ contain a terminal hydroxy-group [145].

(iv) When highly substituted methyl ethers of cellulose containing no free glycol groups are employed as initial polymer, graft copolymers cannot be synthesised, whereas with methylcelluloses of low degree of substitution graft copolymerisation is rapid [131].

Termination of the material chain is achieved in this method mainly by interaction of the growing macroradical with an oxidant cation. This hypothesis is supported by the lack of dependence of reaction velocity on initiator concentration and the almost complete absence of homopolymer formation [115,128,146]. By this method it is possible to vary the number and degree of polymerisation of the graft chains without changing the total quantity of graft component [133].

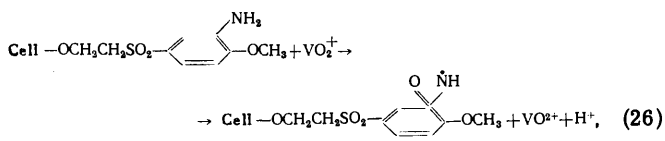


It must be noted that the use of cerium(IV) salts for the synthesis of graft copolymers may cause polymerisation of the monomer even in the absence of a reducing agent. However, polymerisation of the monomer begins after a definite induction period, whereas oxidation of the polymer, and hence initiation of graft copolymerisation, take place without an induction period. Thus by keeping the duration of the synthesis shorter then the induction period it is possible to obtain graft copolymers practically without formation of homopolymer. The synthesis of graft copolymers using cerium(IV) salts is carried out in aqueous solutions or aqueous emulsions of the monomer with minimum amounts of oxidant [128,129]. This method has already been employed to synthesise copolymers of cellulose with polyacrylonitrile [120,121,128,132,147,148], poly(methyl methacrylate) [117,119,133], poly(vinyl acetate) [118], poly(butyl acrylate) [136], polystyrene [122], polyacrylamide [116,148], poly-(2,3-epoxypropyl methacrylate) [123,145], and poly(methyl acrylate) [121,148], and of cellulose nitrates and acetates with poly(methyl acrylate) [130,134].

The appearance of Mino and Kaizerman's paper stimulated attempts to find other redox systems, not involving the use of the scarce and expensive cerium salts.

Japanese workers have proposed the use of potassium permanganate and cobalt(III) salts [127] for the synthesis of graft copolymers of polyvinyl alcohol, starch, and block copolymers containing the terminal hydroxy-groups of a polyethylene glycol, and sodium periodate [149] or cobalt(III) salts [127] for the synthesis of graft copolymers of cellulose. Graft copolymerisation by means of these oxidants is accompanied by the formation of considerable quantities of homopolymer, resulting from oxidation of the monomers with formation of radicals of low molecular weight.

Rogovin and Livshits suggested the use of manganese(III) pyrophosphate [150] for the synthesis of graft copolymers of cellulose, and vanadium(V) compounds [151-154] for modified cellulosic preparations containing small quantities of aromatic amino-groups or aldehyde groups.



When manganese(III) pyrophosphate is used, initiation of graft copolymerisation is effected, as with cerium(IV) salts, by free-radical oxidation of a glycol group in the cellulose macromolecule [154], and chain termination occurs by interaction between the growing macroradical and an oxidant cation.

(25)

With manganese(III) pyrophosphate as oxidising agent, as with cerium(IV) salts, graft copolymers can be synthesised without homopolymer formation, and also without the use of organic solvents, while the number and length of the graft chains can be readily varied by changing the oxidant concentration. A further advantage of using the pyrophosphate is its ready availability.

In the synthesis of a graft copolymer based on modified cellulose preparations containing aromatic amino-groups — the ether of cellulose and 2-(3-amino-4-methoxyphenylsulphonyl)ethanol — with vanadium(V) compounds as oxidants, initiation of graft copolymerisation is accomplished according to the scheme

(26)

and chain termination is probably represented by the equation

(27)

In the synthesis of graft copolymers of modified cellulose preparations containing aromatic amino-groups or aldehyde groups, with a vanadium(V) compound as oxidant, formation of homopolymer does not occur, however long the contact between oxidising agent and monomer, if the conditions have been chosen correctly, in contrast to what occurs in methods involving the use of $Ce^{4+}$ or $Mn^{3+}$. This together with the ready availability of the oxidising agent constitutes an important advantage of this method, since it enables the process to be carried out continuously using aqueous solutions or emulsions of the monomer. One defect of the method is the necessity of first introducing a small quantity of amino-groups or aldehyde groups into the cellulosic materials. The method is applicable not only to cellulose but also to all other polymers containing these groups.

From this survey of the various methods for synthesising graft copolymers of cellulose and its derivatives we can conclude that the most promising methods are — (1) syntheses of graft copolymers on redox systems in which the polymer acts as reductant, and (2) in several cases chain transfer from initiator radicals.

In spite of the considerable amount of research on the synthesis of graft copolymers of cellulose and its derivatives, several fundamental questions relating to the characterisation and properties of graft copolymers have not yet been settled. Systematic investigations have still not been made to elucidate the effect of the conditions of graft copolymerisation on the length and number of graft chains, and especially on the quantity of cellulose entering into the graft copolymer. The quantity of homopolymer formed from the synthetic compound of high molecular weight has been determined in most published work, but the fact that not all the cellulose macromolecules become incorporated in the graft copolymer has been ignored. The quantity of cellulose homopolymer undoubtedly has an important influence on the properties of the products resulting from grafting. Nor has the effect of the degree of polymerisation and the number of graft chains on the properties of graft copolymers of cellulose and its derivatives been investigated, except in one paper [133]. Carrying out the reaction in a heterogeneous medium, as is almost always the case in grafting to cellulose and its derivatives, results in the production of graft copolymers containing a small number of graft chains of high molecular weight (with degrees of polymerisation up to 30 000), and sometimes, therefore, graft copolymers do not differ in their fundamental properties from mechanical mixtures of the homopolymers. The development of methods yielding graft copolymers having a small number of relatively short graft chains is an urgent task. An investigation of these questions has recently been undertaken in our laboratory.

---o0o---

Since this paper was submitted to the Editors, several publications have appeared on the synthesis of graft copolymers of cellulose by the radiation method [155-164], by the use of cerium salts [165-171], by chain transfer from initiator radicals [172-174], and by ionic polymerisation [175,176]. Several papers have been published on the properties of graft copolymers of cellulose and its derivatives [168,173,174,176-179].

# REACTION GAS CHROMATOGRAPHY IN ANALYSIS

V. G. Berezkin and O. L. Gorshunov

CONTENTS

1. Introduction 470
2. Pyrolysis 471
3. Cracking 473
4. Hydrogenation and dehydrogenation 473
5. Dehydration and decarboxylation 474
6. Esterification 474
7. Saponification 475
8. Formation of non-volatile compounds 475
9. Oxidation of organic compounds 477
10. Determination of water 478
11. Qualitative chemical reactions 478

## 1. INTRODUCTION

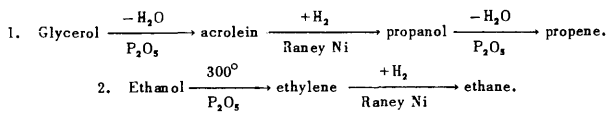
Gas chromatography is now an effective method for the analysis of organic and inorganic compounds. Fairly frequently, however, particularly in the analysis of complex organic mixtures, the oridinary methods of gas chromatography are unsatisfactory.

The efficiency of gas chromatography as an analytical method can be increased considerably by the simultaneous use of chromatographic separation and chemical reactions. Chemical reactions in gas chromatography can be carried out for different purposes, in particular: (1) the analysis of substances for which direct use of the methods of gas chromatography is impossible (e.g. the analysis of polymers, non-volatile compounds, etc.); (2) the reduction of a difficult analytical problem to a simpler problem which has previously been resolved (e.g. the conversion of alcohols into alkenes or alkanes or esters of nitrous acid, followed by chromatographic analysis of the reaction products); (3) the identification of peaks due to unknown components by the use of group (individual) selective absorbers (e.g. sulphuric acid for the absorption of alkenes from hydrocarbons) or group qualitative reactions; and (4) the simplification of quantitative calculations and increase in the sensitivity and accuracy of analysis by the conversion of all the organic compounds being analysed into one or two simple compounds at the outlet from the separating column (e.g. conversion to carbon dioxide and water or hydrogen with the use of a thermal-conductivity detector).

Thus the use of chemical reactions in gas chromatography is extending appreciably the range of the ordinary chromatographic separation and exhibits a number of specific features. It is therefore appropriate to deal with the use of chemical reactions in gas chromatography as a separate field — reaction gas chromatography. This term was first used by Drawert[1,2], who at first, however, gave a too narrow definition of reaction gas chromatography, restricting himself to the case where the substance being analysed undergoes changes in a reaction vessel placed before the separating column (in order to convert the compounds being analysed into definite compounds whose chromatographic analysis presents no difficulties).

In a later paper, Drawert[3] correctly pointed out that in a wider sense the term "reaction gas chromatography" can be taken to mean the use of chemical reactions together with chromatographic separation. It is necessary only to emphasise that the chemical changes should take place in a single chromatographic scheme. The present review considers only the analytical applications of the combined use of chemical reactions and chromatographic separation. Another important independent field of reaction gas chromatography involves the study of the kinetics and mechanism of chemical reactions under chromatographic conditions. Work on these lines, which is now being successfully developed, was begun by Roginskii and coworkers[4,5].

A promising development is the use of the mathematical methods of the theory of reactions under chromatographic conditions to determine the initial concentration of a substance in a specimen, some components of which undergo chemical changes as a result of chemical reactions in the chromatographic column.



Thus analytical reaction gas chromatography is a form of gas chromatography in which chemical reactions in a single gas-phase chromatographic process are used for analytical purposes. The chemical reactions may take

place in special reaction vessels placed before, after, or directly inside the column or between two chromatographic columns. When a special reaction vessel is introduced into a chromatographic set-up, there is a possibility that the efficiency of separation will be reduced. These fears generally prove groundless, however, since the chromatographic characteristics of the packing of the reaction vessel and column do not generally differ greatly from one another, and the length of the reaction vessel amounts to only a small percentage of the length of the chromatographic column.

No published papers have referred to a decrease in the efficiency of separation. For a quantitative estimate of the decrease in the efficiency using chromatograms obtained with and without a reaction vessel[6], we calculated the number of theoretical plates. The calculation showed that there is no decrease in the efficiency of separation.

Table 1 gives a classification of known reaction gas chromatography procedures according to the given chromatographic set-up (position of reaction vessel) and according to the types of chemical reaction used.

In a number of cases it is convenient to effect different chemical reactions simultaneously in a single analysis by using a multistage reaction vessel. For example, for the determination of alcohol and glycerol in dilute aqueous solutions, Drawert et al.[3] used a complex multistage reaction vessel in which the following chemical changes took place:

The gas-chromatographic determination of the products formed (propene and ethane) presents no difficulties and can be carried out using simpler apparatus than that required for the determination of the original compounds (glycerol and ethanol). The combined use of several chemical reactions has also been described[7]. The fractions leaving the gas chromatograph were oxidised on a platinum catalyst, and the oxidation products were studied by qualitative reactions for sulphur, nitrogen, and halogens. A positive qualitative test indicated the presence of the elements detected in the molecule of the original compound.

TABLE 1. Chemical reactions and chromatographic set-ups*.

| Types of chemical change | Position of reaction vessel in gas-chromatographic set-up | | |
|---|---|---|---|
| | reaction vessel before column | reaction vessel—column | reaction vessel after column |
| Pyrolysis | 10—30, 31—36 | | |
| Hydrogenation and dehydrogenation | 1, 2, 3, 8, 39—43 | | |
| Dehydration and decarboxylation | 2, 3, 39, 40 | | |
| Esterification | 1, 2, 3, 39, 40, 44 | 9 | |
| Saponification | | | 45 |
| Formation of non-volatile compounds | 6, 48, 49, 46 | | 47 |
| Oxidation | 8, 37, 38 | | 52—64 |

| Cracking | | | |
| Study of reactions under chromatographic conditions | | 4.5 | 37—39 |
| Reduction | 65, 66 | | |

* The numbers give the literature references.

To detect traces of inorganic gases (carbon monoxide, oxygen, etc.) by means of the highly sensitive flame-ionisation detector, the inorganic gases are converted quantitatively into compounds which can be measured by this detector. An example is the gas-chromatographic method for determining oxygen by means of a flame-ionisation detector after the quantitative conversion of the oxygen to carbon monoxide over carbon and reduction of the carbon monoxide to methane in a current of hydrogen over a nickel catalyst[8].

Different chemical reactions and different set-ups can be used in reaction gas chromatography, depending on the type of problems to be solved. Thus pyrolysis, hydrogenation, dehydration, esterification, and other chemical changes are usually employed for the analysis of non-volatile substances and for the conversion of polar, unstable, or non-volatile substances, which are difficult to study chromatographically, into compounds which are determined more easily. In this case the reaction vessel is generally placed before the chromatographic column.

Reactions involving oxidation, reduction, cracking, and the formation of non-volatile compounds, and also qualitative colour reactions, are often used to simplify quantitative calculations, to increase sensitivity, and for the identification of peaks due to the compounds being studied. In this case the reaction vessel is usually placed after the column, either before the detector or (when qualitative reactions are being carried out) after the detector. In some cases the chromatographic set-up contains no special reaction vessel and the reaction takes place directly in the column. Thus Anders and Mannering[9] introduced acetic or propionic anhydride into a chromatographic column immediately after a specimen of alkaloids and steroids and their derivatives. Under these conditions many of the compounds being analysed formed esters (acetates or propionates) directly in the column.

Thus the aims and purposes of the study determine not only the position of the reaction vessel in the general gas-chromatographic set-up, its shape, and the constructional details, but also the type of chemical reaction used.

The use of various types of chemical reaction in reaction gas chromatography is examined below.

## 2. PYROLYSIS

Pyrolysis is widely used in reaction gas chromatography for the identification of polymers, the study of the composition of copolymers, the identification of individual functional groups (e.g. benzene nuclei) in the molecules of non-volatile compounds, and the identification of isomeric paraffinic hydrocarbons.

A combination of the controlled pyrolysis of non-volatile compounds with gas-chromatographic determination of the product spectrum opens up the possibility of rapid identification of non-volatile compounds.

It has been shown[10-15] that under certain pyrolysis conditions, solid non-volatile substances decompose in a specific fashion and that analysis of the products enables certain conclusions to be reached regarding the structure and composition of the original substances.

The pyrolysis is carried out in a special assembly mounted before the separating column. The substance being studied is deposited beforehand on a metallic (platinum or, less frequently, nichrome) filament, wound to

form a spiral or mesh. After the spiral carrying the substance has been introduced into the gas stream, the spiral is heated rapidly by an electric current. The resulting pyrolysis products pass to the chromatographic column and are recorded by the detector at the outlet from the column.

Fig. 1 shows a typical pyrolysis cell. In some cases[16-19] the pyrolysis is carried out in a tube heated to high temperature.

The use of a special cell for the rapid pyrolysis of non-volatile substances on an incandescent filament has certain advantages over the method involving prolonged pyrolysis in a heated tube: (1) small quantities of the specimen (milli- or micro-grammes) are required for the analysis; (2) the method is rapid; and (3) the part played by secondary reactions in the formation of pyrolysis products is reduced.

The method of depositing the specimen on the filament is determined by the nature of the specimen. Solid soluble substances are deposited in a thin layer from solution on one or two rings in the centre of the spiral, and insoluble substances are deposited in the form of an aqueous suspension. The spiral with the specimen is then dried by means of an infrared lamp until the solvent is completely removed.

It is not always possible to achieve complete removal of the solvent, and the pyrolysis products of the solvent are generally present in the chromatograms together with the pyrolysis products of the substances being studied[20,21].

In another method[13,14,21,22] pyrolysis is carried out in a special boat of inert material (porcelain or quartz), which is brought rapidly into the hot zone. The quantity of volatile products and the weight of residue are found by weighing the boat.

By carrying out the pyrolysis in a boat, it is also possible to control accurately the pyrolysis process, to analyse liquid and solid specimens, and to determine the resulting products chromatographically. The temperature of pyrolysis is varied over a wide range, from 150° to 950°, depending on the nature of the substances being studied. The optimum pyrolysis temperature is found empirically. The temperature dependence of the yield of pyrolysis products from butyl methacrylate (Fig. 2) shows that, under the given conditions of pyrolysis in the boat, the optimum pyrolysis temperature is ~500°.

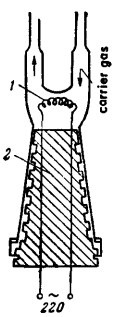

Fig. 1. Pyrolysis cell:
1) nichrome spiral with specimen; 2) Teflon block.

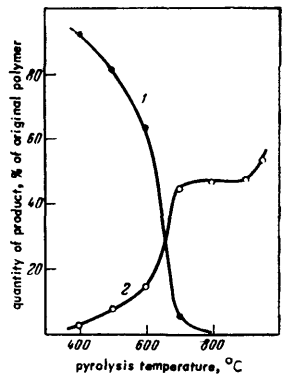

Fig. 2. Dependence of the yield of pyrolysis products from butyl methacrylate on the pyrolysis temperature:
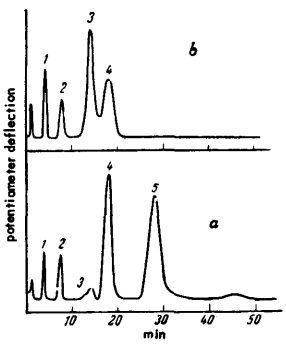
1) butyl methacrylate monomer; 2) gaseous products ($CO + CO_2$).

The method involving pyrolysis can be used successfully to study the structure and composition of solid, liquid, and gaseous substances. For example, in the pyrolysis of polymers of the methyl methacrylate type and other acrylates[14,16,23-25] the original monomers are formed as chief product. The method involving pyrolysis has been used for the analysis of a number of copolymers (of styrene with methyl methacrylate[26] and of ethylene with vinyl acetate and ethyl acrylate[27,28], etc.) and polymers (polyurethane[17], polyethylene, polypropylene[29], etc.). Pyrolysis in gas chromatography has also been used to establish the structure of non-volatile compounds such as natural oils[6-8] and medicinal products[10-12,15,30]. As an example, Fig. 3 gives the chromatograms of the pyrolysis products from natural barbituric acids. It can be seen from Fig. 3 that the compounds of the same class give identical pyrolysis products.

Study of the pyrolysis products from a large number of high-boiling aromatic compounds (~100)[19] showed that a combination of pyrolysis with subsequent chromatographic analysis of the products provides a reliable method for detecting benzene rings in the compounds being analysed,



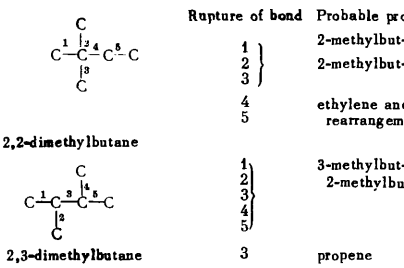


Fig. 3. Chromatograms of the pyrolysis products from the sodium salts of barbituric acid derivatives. Analysis conditions: 30% squalane on Celite 545, 100°:
*a*) luminal, *b*) eudon; 1) benzene; 2) toluene; 3) ethylbenzene; 4) *o*-xylene; 5) propylbenzene.

since the benzene nuclei are not broken down during the thermal decomposition of the substances, and the decomposition products contain aromatic compounds. Thus, for example, in the pyrolysis of benzyl alcohol, benzyl benzoate, and benzyl phenylacetate, the chief products are benzene, toluene, and carbon dioxide (Fig. 4). The pyrolysis was carried out in a short quartz tube filled with chromosorb (~2 g) and connected to the chromatographic column.

Hyden[31] proposed the use of the pyrolysis method for the gas-chromatographic analysis of thermally unstable compounds. For example, in the water–di-t-butyl peroxide system at 310° the peroxide decomposes almost instantaneously and the thermal decomposition products can be used for its qualitative identification. The method can be used for the quantitative analysis of the peroxide, since it has been established that there is a linear relationship between its concentration in the specimen and the area of the peaks due to the decomposition products (see Table in Ref. 31).

Nishi Sueo[32] showed that the method involving pyrolysis can be used for the qualitative and quantitative analysis of carbonyl compounds. The $C_2$–$C_6$ carbonyl compounds are liberated quantitatively from the 2,4-dinitrophenylhydrazones by heating with dicarboxylic acids. A specimen of the dinitrophenylhydrazone being studied is mixed with phthalic acid in the ratio 1 : 10 and introduced into a glass reaction vessel (250 × 0.3 cm) placed directly before the separating column. The dinitrophenylhydrazones of the carbonyl compounds decompose quantitatively at 250° with the liberation of the original compounds, which are then analysed chromatographically.

The use of pyrolysis in reaction gas chromatography is not restricted to the study of the pyrolysis products from polymers and non-volatile compounds. By analysing the pyrolysis products from 2,2- and 2,3-dimethylbutanes, Keulemans and Perry[33] showed that it is possible to identify paraffinic hydrocarbons. The pyrolysis was carried out in an empty quartz tube at 500°. The various possibilities of C–C bond rupture lead us to expect the formation of the following compounds:

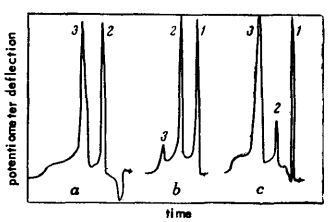

Fig. 4. Chromatogram of pyrolysis products from: *a*) benzyl alcohol; *b*) benzyl benzoate; *c*) benzyl phenylacetate (stationary liquid phase — silicone oil); 1) carbon dioxide; 2) benzene; 3) toluene.

TABLE 2. Chief products of the pyrolysis of 2,2-dimethylbutane (2,2-DMB) and 2,3-dimethylbutane (2,3-DMB).

| Products | Composition, % | |
|---|---|---|
| | 2,2-DMB | 2,3-DMB |
| Propene | 1 | 10 |
| But-1-ene, isobutene | 10 | 3 |
| 3-Methylbut-1-ene | 0 | 0.5 |
| 2-Methylbut-1-ene | 3 | traces |
| 2-Methylbut-2-ene | 11 | 16 |

Data on the composition of the pyrolysis products from the isomeric alkanes 2,2-dimethylbutane and 2,3-dimethylbutane (Table 2) show that the expected products are in fact formed. There is thus a simple relationship between the pyrolysis product and the original compound and this can be used for the identification of the hydrocarbons.

The study of substances by the pyrolysis method is carried out using standard chromatographs fitted with special assemblies for the pyrolysis[34,35] or in specially constructed apparatus[36].

## 3. CRACKING

Hydro-cracking was first used in gas chromatography by Zlatkis and Ridgway[37] to increase the sensitivity and accuracy of quantitative analysis and to simplify analytical calculations. The fractions leaving the separating column undergo cracking to methane and water at 425° in a reaction vessel containing a catalyst (nickel on kieselguhr). The water is absorbed in a special column and the methane is recorded by a thermal-conductivity detector. This method can be used to record various classes of organic compounds: alkanes, alkenes, aldehydes, ketones, alcohols, etc. In particular, the hydro-cracking of chromatographically separated aldehydes to methane has been described[38,39]. It should be noted that when the high-boiling compounds to be analysed are converted into equivalent quantities of methane, it is possible to use simpler and less expensive detector assemblies operating at room temperature.

## 4. HYDROGENATION AND DEHYDROGENATION

It is convenient to use hydrogenation and dehydrogenation reactions for the identification and analysis of compounds which give products whose gas-chromatographic separation has been studied in detail (i.e. for the reduction of an unknown problem to a problem which has already been solved) and also for the determination of impurities. In all cases the resulting hydrogenation and dehydrogenation products have properties which differ sharply from those of the original compounds, and this can be used for the qualitative and quantitative analysis of complex mixtures by comparative calculation based on two chromatograms obtained for the original specimen and the hydrogenated specimen. Thus by carrying out the catalytic hydrogenation of oxygen-containing compounds it is possible to identify ketones, esters, aldehydes, alcohols, and acids in a mixture from the hydrocarbons produced.

Drawert and coworkers[39,40] used hydrogenation to determine small quantities of ethanol in aqueous solutions and in blood. The alcohols were converted into hydrocarbons

by hydrogenation in a short tube filled with catalyst (Raney nickel on kieselguhr in the ratio 1 : 10). The hydrogenation is carried out at 160–200° in a current of hydrogen, which is also used as carrier gas. The above ratio of catalyst and inert carrier is an optimum, since large quantities of nickel above 200° lead to sintering of the catalyst, and when the quantity of nickel is decreased the rate of the hydrogenation also decreases. In the analysis of specimens with a high water content the water is removed from the specimen in a tube which contains $CaH_2$ and is placed after the reaction vessel but before the separating column. This method can be used to determine small quantities of the $C_1$–$C_{10}$ alcohols in aqueous solutions.

In a number of cases, in the analysis of saturated and unsaturated hydrocarbons, hydrogenation is used for the identification of peaks due to alkenes[41], using platinised asbestos as catalyst. The reaction vessel is placed before the column.

Struppe[42] made use of reaction gas chromatography in capillary chromatography. The reaction vessel was an aluminium capillary tube (600.00 × 0.03 cm) whose inner wall was covered with a thin layer of platinum. The catalyst was deposited on the inner walls of the capillary reaction vessel by the usual method for depositing the stationary liquid phase on a capillary column, i.e. the capillary was filled with an ethereal solution of $H_2[PtCl_4]$, the solution was shaken from one end of the tube to the other for 15 min, and the reaction vessel was dried in a current of hydrogen at 150° to reduce the hydrogen chloroplatinate to platinum. The hydrogenation was carried out in a current of hydrogen at 125°. The method was tested by analysing synthetic mixtures of hydrocarbons with boiling points up to 85°. It was shown that mono-, di-, and cyclo-alkenes add on hydrogen rapidly across the double bonds, whereas the carbon structure of aromatic, naphthenic, and cyclic hydrocarbons remains unchanged during hydrogenation under these conditions.

Keulemans and Voge[43] studied the dehydrogenation of naphthenes on a platinum catalyst (platinum–alumina–halogen). It was shown that under the conditions studied, cyclopentanes show different reactivities. In the reaction vessel, placed before the chromatographic column, cyclohexane is converted to benzene, but cyclopentane is unaffected under these conditions. Cyclopentanes undergo aromatisation to a much smaller extent than cyclohexanes and this can be used for the identification of cyclohexane in complex hydrocarbon mixtures.

From these examples, it can be seen that the use of hydrogenation and dehydrogenation provides a useful means of solving a number of analytical problems. The method has a number of disadvantages, however. In particular, the hydrogenation of various alkenes and alkynes containing the same number of carbon atoms in the molecule gives only one alkane, and the dehydrogenation of the *cis–trans*-isomers of cyclohexane derivatives gives only one aromatic hydrocarbon and this makes detailed qualitative analysis and identification of the original compounds difficult. Certain other reactions used in reaction gas chromatography have the same disadvantage.

## 5. DEHYDRATION AND DECARBOXYLATION

Dehydration and decarboxylation have been used successfully to determine alcohols and acids in dilute aqueous solutions. The procedure[2,3] does not require the preliminary separation or concentration of the compounds and solutions. The method can be used to analyse mono- and di-hydric alcohols and acids by separating the hydrocarbons which are formed from the oxygen-containing compounds in a reaction vessel placed directly before the chromatographic column. The reaction vessel consists of a stainless steel tube (10–15 × 0.6–1.0 cm) filled with sterchamol impregnated with phosphoric acid (ratio 2 : 1). The reaction temperature is 250–300°. To remove the water present in the specimen and formed during dehydration, a special drying tube containing calcium hydride is placed between the reaction vessel and the separating column. Monobasic organic acids react with phosphoric acid on heating and are decarboxylated to hydrocarbons; the number of carbon atoms per molecule of the latter is one less than that in the original acid.

Dilute aqueous solutions of glycerol and alcohol have been analysed using a multistage reaction vessel in which, in accordance with the scheme described earlier, the original substances undergo quantitative conversion to propene and ethane, whose gas-chromatographic analysis presents no difficulty.

It should be noted that, in the decarboxylation of each acid, only one product is formed, whereas in the dehydration of secondary alcohols, for example, two alkenes may be formed.

## 6. ESTERIFICATION

Carbonyl compounds, whose determination by ordinary chromatographic methods often presents difficulty, are esterified directly in the column or before the column and are analysed in the form of esters of organic or inorganic acids. Esterification in reaction gas chromatography is also used for the group identification of the individual class of compound in the analysis of complex mixtures.

Drawert and coworkers[1-3,39,40] developed a method for the analysis of alcohols in dilute aqueous solutions in the form of their nitrite esters. The esters are formed in a reaction vessel placed before the chromatographic column in the stream of carrier gas. The water which is present in the specimen and which interferes in the analysis of certain alcohols is absorbed in a drying tube containing calcium hydride. The reaction vessel consists of a stainless steel tube (length 8–12 cm, diameter 10 mm) filled with sterchamol and sodium nitrite (ratio 1 : 1). The nitrite esters are formed at 160–200°. The process of ester formation is improved considerably and takes place quantitatively if the specimen is acidified beforehand with tartaric or oxalic acid. The method was used to determine traces of ethanol (concentration $1 \times 10^{-5}$%) in blood.

Anders and Mannering[9] showed that the introduction of acetic or propionic anhydrides into the chromatographic column several seconds before the introduction of specimens of certain organic compounds, such as primary or secondary amines or compounds containing an alcoholic or phenolic hydroxyl, leads to the direct formation, in the column, of propionates or acetates whose retention times are different from those of the original compounds. Comparison of two chromatograms for the esterified and non-esterified specimens gives the necessary information for the qualitative and quantitative analysis of complex compounds of different classes. The use of this method, which is called[44] "the peak displacement method", makes it possible to determine naphth-1-ol, *p*-phenylphenol, ephedrine,

TABLE 3. The use of esterification in the analysis of some mixtures of compounds*.

| Compound | Column temperature, °C | Volume of 0.5% solution, ml | Without acetic anhydride: retention time, min (area, cm²) | With acetic anhydride: area for esterified compounds, cm² | With acetic anhydride: retention time, min (area of displaced peaks, cm²) |
|---|---|---|---|---|---|
| Amphetamine | 125 | 0.5 | 2.8(70) | 0 | 18.7(4.8) |
| Ephedrine | 125 | 4.0 | 9.2(21.0) | 0 | 63.0(10.8) |
| Naphth-1-ol | 150 | 0.5 | 6.8(6.7) | 3.4 | 9.1(2.0) |
| *p*-Phenylphenol | 150 | 1.0 | 16.3(12.1) | 2.7 | 23.1(6.0) |
| Codeine | 215 | 1.0 | 14.3(18.2) | 16.6 | 20.9(0.3) |
| Morphine | 215 | 6.0 | 16.5(15.8) | 0 | 20.3(22.5) 29.2(11.5) |
| Testosterone | 235 | 1.0 | 12.4(10.4) | 8.6 | 16.8 (0.6) |
| Diosgenin | 250 | 3.0 | 34.7 (68.4) | 11.0 | 47.7 (5.0) |
| Digitoxigenin | 275 | 5.0 | 23.7(21.7) | 6.9 | 28.0 (0.6) |

* 0.5% solutions of each compound were prepared in methanol, ethyl acetate, or tetrahydrofuran.

codeine, and their derivatives at temperatures in the range 125–275°. Table 3 shows that the retention times of the esterified compounds are much higher and this can be used for identification purposes.

## 7. SAPONIFICATION

In the analysis of esters the determination of mixed esters is of interest; this can be carried out by saponification, followed by chromatographic analysis of the alcohols formed.

This method was used successfully by Janak et al.[45] for the identification of esters of malonic acid. The reaction vessel (Fig. 5), placed at the outlet from a laboratory chromatograph with a katharometer, was filled with sterchamol with 40% potassium hydroxide deposited on its surface. Steam from water boiling in flask *D* was passed directly to the reaction vessel. After saponification of the high-boiling ester, a specimen of gas containing the vapour of the corresponding alcohols was collected at the outlet from the reaction vessel. The specimen taken was then introduced into a chromatograph with a flame-ionisation detector, where the alcohols formed on saponification were analysed. As an example, Fig. 6 gives the chromatograms for the products of the saponification of various esters of malonic acid.

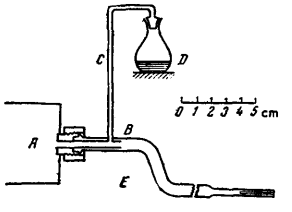

Fig. 5. Assembly for the saponification of ester fractions at the chromatograph outlet: *A*) detector; *B*) reaction vessel; *C*) tube; *D*) flask with boiling water; *E*) reaction vessel thermostat.

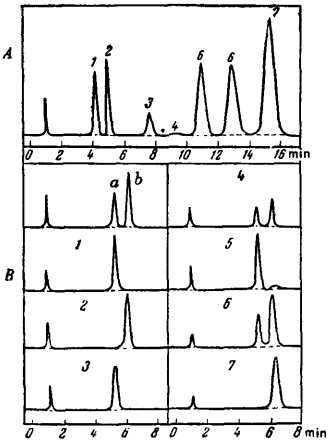

Fig. 6. Identification of esters of malonic acid from the saponification products: *A*) chromatogram of mixture of esters (Apiezon L, 220°); *B*) chromatograms of alcohols in a synthetic mixture [*a*) methanol; *b*) ethanol] and samples of saponified fractions 1–7 (triethanolamine, 60°): 1) methyl phenylacetate; 2) ethyl phenylacetate; 3) dimethyl phenylmalonate; 4) methyl phenylmalonate; 5) dimethyl ethylphenylmalonate + traces of diethyl phenylmalonate; 6) methyl ethyl ethylphenylmalonate; 7) diethyl ethylphenylmalonate.

## 8. FORMATION OF NON-VOLATILE COMPOUNDS

Of considerable importance in the qualitative and quantitative interpretation of the chromatograms of natural hydrocarbon mixtures are the methods of identification in reaction gas chromatography which involve the selective removal of certain classes of compound from the mixture. Thus sulphuric acid forms non-volatile compounds with alkenes. Martin[6] made use of this property of sulphuric acid in a reaction vessel (20.0 × 0.4 cm) filled with silica gel treated with sulphuric acid (2 : 3). The reaction vessel was placed in the gas-chromatographic set-up before the chromatographic column. It was shown that the absorption of monoalkenes, dialkenes, cycloalkenes, and alkynes, up to at least the $C_8$ fraction, takes place quantitatively in a stream of carrier gas in the temperature range 20–50°. The chromatograms given in Fig. 7 characterise fairly clearly the "subtraction method", as described by its author.

Mercury(II) perchlorate can also be used successfully for the selective removal of alkenes from a complex mixture[46]. A reaction vessel (25.0 × 0.8 cm) filled with firebrick moistened with a 1 M solution of mercury(II) perchlorate in 2 M perchloric acid (firebrick : solution ratio = = 1 : 1) is placed before the chromatographic column. Unlike the reaction vessel containing sulphuric acid, the vessel containing mercury(II) perchlorate absorbs only alkenes and does not absorb aromatic hydrocarbons.

The ordinary version of the subtraction method suffers from a number of disadvantages, chief of which are the need to obtain two chromatograms and the low accuracy of the determination for the case of a low concentration of component being removed in a general unresolved chromatographic peak. These disadvantages can be avoided by

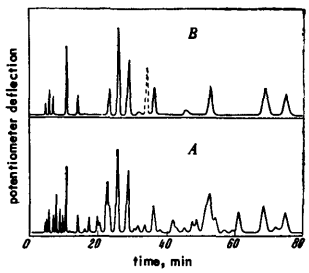

Fig. 7. Chromatograms of petroleum products from catalytic cracking (complex mixture of $C_3$–$C_6$ hydrocarbons); experimental conditions: stationary liquid phase — 10% quinoline on brick; length of column 10.5 m; temperature of column 25°; carrier gas velocity (nitrogen) 60 ml $min^{-1}$; volume of specimen 5 $\mu$l: *A*) without reaction vessel containing $H_2SO_4$; *B*) with reaction vessel containing $H_2SO_4$ (see Table II in Ref. 43 for interpretation of peaks).

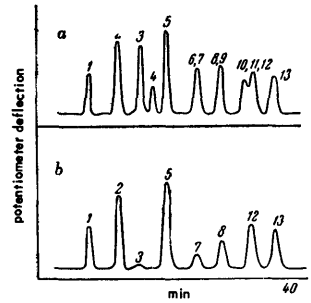

Fig. 8. Chromatograms of mixtures of $C_1$–$C_6$ monobromoalkanes on a column containing Tween 60: *a*) reaction vessel without $AgNO_3$; *b*) reaction vessel containing $AgNO_3$:
1) bromomethane; 2) bromoethane; 3) 2-bromopropane; 4) 2-bromo-2-methylpropane; 5) 1-bromopropane; 6) 2-bromobutane; 7) 1-bromo-2-methylpropane; 8) 1-bromobutane; 9) 2-bromo-2-methylbutane; 10) 2-bromopentane; 11) 3-bromopentane; 12) 1-bromo-3-methylbutane; 13) 1-bromopentane.

using the direct method of determining the individual-group composition of complex mixtures, in which the mixture to be analysed is separated on a chromatographic column, after which only those components of the mixture which are absorbed by the selective absorber of a differential analyser are recorded. This is achieved by placing the selective absorber between the katharometer chambers[47].

Since the analyser should record very low, rapidly-changing concentrations of substances in the chromatographic peaks of different compounds against a background of carrier gas and non-absorbed compounds, and also analyse solid and liquid substances in a gaseous phase, it must satisfy special requirements: (1) the dead space in the absorber should be small, relative to the volume of the carrier gas in which the component being analysed is distributed; (2) it is desirable that the sensitivity of the detector be the same for different compounds; and (3) the absorber should have an appreciable capacity and should absorb rapidly compounds of a definite class.

In addition to group reagents, use is also made of specific reagents reacting with one or a few compounds. For example, water is absorbed using compounds such as Anhydrone, calcium chloride, phosphorus pentoxide, etc.

The method of selective absorption has been used successfully to determine the isomeric bromo-hydrocarbons, 2-bromobutane and 1-bromo-2-methylpropane, which are generally eluted as a single peak in chromatographic analysis. The reaction vessel consisted of a 0.8 cm diameter glass tube filled with various reagents: the first layer (3 cm) consisted of silver nitrate on diatomite (1 : 1), the second (2 cm) consisted of sulphuric acid on diatomite, and the third (1 cm) consisted of disodium phosphate on diatomite. The layers in the reaction vessel were separated from one another by a layer of diatomite brick. The reaction vessel was placed before the separating column. At room temperature, 2-bromobutane is absorbed quantitatively by silver nitrate, whereas 1-bromo-2-methylpropane undergoes almost no reaction with this reagent. By comparing the chromatograms (Fig. 8), it is possible to calculate the concentrations of compounds which are not separated by ordinary gas chromatography.

Gil-Av and Herzberg-Minzly[48] extended the range of the subtraction method by proposing for the identification of peaks due to unknown compounds the use of relatively slow chemical reactions, leading not to complete but merely to partial absorption of the peaks ("the partial subtraction method"). As an example, let us consider the reaction between dienes with conjugated bonds (the components absorbed) and a dienophilic stationary liquid phase — chloromaleic anhydride. The reaction products are non-volatile and remain in the reactor column. The compounds being analysed are identified from the retention volume data and also by quantitative estimation of the rates of the chemical reactions with the stationary liquid phases. For example, the determination of the *cis*- and *trans*-isomers of 1,3-dienes is based on the fact that the *trans*-isomer reacts more rapidly with the dienophilic phase than the *cis*-isomer.

Ray[49] was one of the first to use the method of halogenation, leading to the formation of high-boiling compounds in a gas-chromatographic set-up, for the determination of impurities in ethylene. It was shown that removal of ethylene from the mixture being analysed takes place on a column containing 40% liquid bromine deposited on carbon, as a result of the formation of heavy bromo-derivatives of ethylene. The processes of bromination, adsorption (removal), and subsequent volumetric chromatographic separation of the light impurities were combined in a single instrument. The method made possible the quantitative determination of traces of hydrogen, nitrogen, carbon monoxide, methane, and ethane, present in ethylene in very low concentrations.

In reaction gas chromatography impurities accompanying a given compound are sometimes determined using fillers in the separating columns which "selectively retain" certain compounds. The formation of hydrogen bonds can also be regarded as a chemical reaction. Ackman and Burgher[50] made use of the formation of hydrogen bonds between macromolecular alcohols and the stationary liquid phase in a column to determine these impurities. It was shown that at 180–240° higher aliphatic alcohols are completely absorbed and retained by a separating column containing a polyester phase (diethyleneglycol succinate or

diethyleneglycol succinate containing 2% phosphoric acid) on the carrier. The non-alcoholic impurities in the higher aliphatic alcohols are retained on the polyester phase to an insignificant extent.

It is also of interest to supplement the ordinary method involving the selective absorption of certain compounds by subsequent gas-chromatographic analysis of the resulting non-volatile compounds; for this purpose it is necessary either to alter the temperature conditions of the experiment or to carry out new chemical changes.

## 9. OXIDATION OF ORGANIC COMPOUNDS

The oxidation of organic compounds is used in reaction gas chromatography to increase the sensitivity and accuracy of katharometers, to simplify quantitative calculations on the chromatograms, and also to reduce a complicated analytical problem to a simpler problem which has already been solved. A new method for the analysis of amino--acids was proposed by Zlatkis and Oro[38,51]. The amino--acids are oxidised to volatile aldehydes at 130° in a special reaction vessel placed before the chromatographic column and containing 30% ninhydrin on kieselguhr. The mixture of aldehydes formed was separated on the chromatographic column and passed to a reaction vessel for conversion into methane[37]. This method (where the separating column is placed between two reaction vessels) makes it possible to carry out the quantitative analysis of amino-acids in aqueous solutions at amino-acid concentrations down to $10^{-5}$%. The determination was carried out for a mixture of amino-acids containing alanine, α-amino-n-butyric acid, valine, norvaline, leucine, isoleucine, and norleucine. To improve the sensitivity and accuracy of detection, the fractions leaving the separating column are often oxidised and converted into carbon dioxide and water in a special reaction vessel placed before the detector[52]. Quartz or metallic tubes of different lengths (10–20 cm) and diameters (0.6–1.5 cm), filled with copper oxide wire, are used as reaction vessels. At 700–800° the fractions or individual compounds separated by gas chromatography undergo combustion on copper oxide with the formation of $CO_2$ and $H_2O$. Water is removed, beyond the oxidation reaction vessel, in absorption tubes containing calcium chloride, phosphorus pentoxide, or other effective absorbents.

The increase in sensitivity when the substances are analysed as carbon dioxide is due to the increase in the number of molecules being analysed, since one molecule of original substance gives several molecules of carbon dioxide. For example, the oxidation of one molecule of heptane gives seven molecules of carbon dioxide, so that the sensitivity of detection increases by a factor of 7. A particularly sharp increase in sensitivity (carrier gas nitrogen) is achieved by using a two-stage reaction vessel in which the organic compound fractions are oxidised to $CO_2$ and $H_2O$ and the water is reduced to hydrogen[53]. A tube (30.0 × × 0.4 cm) filled with copper oxide and finely-ground reduced iron is used as reaction vessel. The tube is heated to red heat (700–800°). After leaving the reaction vessel, the gases pass through a short soda lime column to remove carbon dioxide.

The chromatogram given in Fig. 9 shows the increase in sensitivity when various methods of converting the mixture of substances, before the latter reaches the katharometer, are used.

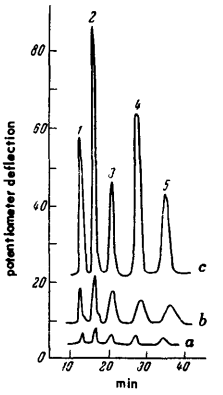

Fig. 9. Change in the sensitivity of the determination of organic compounds when preliminary conversion is used; chromatograms of equal-weight mixtures:
1) cinnamaldehyde; 2) butyl benzoate; 3) coumarin; 4) phenyl propylbutyrate; 5) naphthyl phenyl ketone; experimental conditions: stationary liquid phase — 20% silicone oil on Celite 545; detector — katharometer; carrier gas — nitrogen at 13 ml $min^{-1}$; column temperature 195°; weight of specimen 1 mg;
*a*) without conversion; *b*) conversion into carbon dioxide; *c*) conversion into hydrogen.

TABLE 4. C:H ratio in organic compounds, obtained from the peak areas (standard deviations of values given not greater than 3%; benzene used for calibration).

| Substance | Peak area, $cm^2$ | | Ratio of peak areas ($H_2$:$CO_2$) | C:H ratio | |
|---|---|---|---|---|---|
| | $H_2$ | $CO_2$ | | calculated | observed |
| Benzene | 634 | 140 | 4.53 | 1.00 | 1.00 |
| Cyclohexane | 515 | 55.6 | 9.26 | 2.00 | 2.04 |
| Ethyl ether | 547 | 47.9 | 11.42 | 2.50 | 2.52 |

The oxidation method is used successfully for the elementary analysis of organic compounds[54,55].

A method has been developed[56,57] for the continuous determination of the carbon and hydrogen contents of volatile organic compounds which have previously been separated on a chromatographic column. The conversion is carried out using a two-stage oxidation–reduction reaction vessel (60.0 × 0.6 cm tube) at 725°. After leaving the reaction vessel, the gases were separated on a supplementary column containing acetonylacetone on Celite and detected with a thermal-conductivity detector. The results are shown in Table 4.

In some cases[58,59] quantitative oxidation is used for the continuous radiometric analysis of substances, labelled with $^{14}C$ and $^{3}H$, on leaving the chromatograph. The method involving the detection of the compounds being analysed after their quantitative conversion into $CO_2$ has been used for the analysis of ethane–ethylene and propane–propene fractions[60], phenylchlorosilanes[61], and other purposes[62–64].

## 10. DETERMINATION OF WATER

Water is an important component of many systems to be analysed. In the analysis of specimens containing water, two problems arise: (1) the drying of the specimen, and (2) the quantitative determination of the water, The determination of water by the ordinary chromatographic method presents certain difficulties because of its strongly polar character. In some cases, when the water is present in the specimens in sufficient quantities, it can be determined, for example, on columns containing mono- and poly-ethyleneglycol, but the quantitative estimation of the moisture content of specimens with low water content is extremely difficult. The use of reaction gas chromatography makes it possible to analyse specimens containing down to $2 \times 10^{-4}$% of water[65].

When a reaction vessel containing calcium carbide is placed before the chromatographic column, the water in the mixtures being studied is converted into acetylene, whose determination by gas chromatography presents no difficulty.

If the calcium carbide in the reaction vessel is replaced by calcium hydride, the reaction of $CaH_2$ with water gives hydrogen, which is readily determined by chromatographic analysis. The problem of converting water quantitatively into hydrogen and acetylene in heterogeneous systems is not simple and this operation is a source of experimental error. These sources of experimental error are avoided in a method[66,67] for the determination of traces of water in hydrocarbons, based on the gas-chromatographic determination of the quantity of hydrogen liberated as a result of the reaction between the water dissolved in the liquid specimen under study and a solution of sodium aluminium hydride in the dimethyl ether of diethyleneglycol; the sensitivity of the method is $2 \times 10^{-4}$%.

## 11. QUALITATIVE CHEMICAL REACTIONS

The identification of the components of complex mixtures in gas-chromatographic analysis from retention volume data alone does not always give correct results, since many substances of different classes may have the same retention volumes on the same stationary liquid phase.

Fractions separated chromatographically can be identified by making use of the qualitative chemical reactions of group analysis (Table 5).[68]

The components of the specimen were prepared on an ordinary 1.83 mm analytical column packed with squalene on kieselguhr. Beyond the detector (katharometer) the gas stream was split into five separate streams by means of a special device. Each stream was directed into a tube (diameter 1 cm, height 3.5 cm) filled with a suitable reagent for qualitative functional group analysis. The change in the colour in one of the tubes indicated the class of compound being eluted. For the rapid replacement of the tubes containing the reagents (this is particularly important in the identification of chromatographic peaks with similar retention volumes), the gas stream was directed by means of a three-way tap into one of a series of five tubes. After the compound corresponding to a given chromatographic peak had passed through the tubes containing the five reagents, the gas stream was directed to the next series of tubes.

The composition of the specimens was determined from retention volume data and the results of the qualitative functional group analysis. Each substance was determined by comparing the corrected retention volume with the calibration graph for the corresponding homologous series. Since the plot of log $V$ versus $n$, where $V$ is the retention volume and $n$ the number of carbon atoms in the compound, is linear for two compounds, it is possible to construct this graph when the retention volumes are known.

As an example of the determination of the composition of a complex mixture, let us consider the chromatogram and the results of qualitative analysis given in Fig. 10. Although the chromatogram consists of five peaks, ten compounds were identified. In particular, the first peak corresponds to two compounds — ethanol and propan-2-one.

Thus by using the reagents for qualitative group analysis in chromatography, it is possible to detect substances of a definite class of compound in the fractions leaving the chromatographic column.

---o0o---

The above examples are evidence of the wide scope and the rapid development of reaction gas chromatography as

TABLE 5. Characteristics of reagents for functional group analysis.

| Type of compound | Reagent | Characteristics of positive test; colour of solution or precipitate | Minimum sensitivity, mg | Compounds detected |
|---|---|---|---|---|
| Alcohols | $K_2Cr_2O_7$–$HNO_3$ | pale blue | 20 | $C_1$–$C_8$ |
| | cerium nitrite | amber | 100 | $C_1$–$C_8$ |
| Aldehydes | 2,4-DNPH | yellow precipitate | 20 | $C_1$–$C_6$ |
| | Schiff's reagent | pink | 50 | |
| Ketones | 2,4-DNPH | yellow precipitate | 20 | $C_3$–$C_8$ (methyl-ketones) |
| Esters | Fe hydroxamate | red | 40 | $C_1$–$C_8$ (acetates) |
| Thiols | Na nitroprusside | red | 50 | |
| | isatin | green | 100 | $C_1$–$C_9$ |
| | $Pb(OAc)_2$ | yellow precipitate | 100 | |
| Sulphides | Na nitroprusside | red | 50 | $C_2$–$C_{12}$ |
| Amines | Ginsberg's reagent | orange | 100 | $C_1$–$C_4$ |
| | Na nitroprusside | red, 1° | 50 | $C_1$–$C_4$ |
| | | pale blue, 2° | 50 | $C_1$–$C_4$ diethyl and dipentyl |
| Nitriles | Fe hydroxamate–propyleneglycol | red | 40 | $C_2$–$C_5$ |
| Aromatic | HCHO–$H_2SO_4$ | wine red | 20 | $C_6H_6$–$C_{10}H_{14}$ |
| Aliphatic | HCHO–$H_2SO_4$ | ditto | 40 | $(C_2H_6)$? |
| Halogeno-derivatives | alcoholic $AgNO_3$ solution | white precipitate | 20 | $C_1$–$C_5$ |

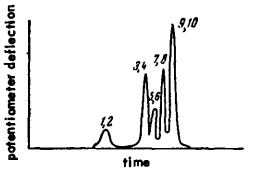

Fig. 10. Identification of compounds in a complex 10-component mixture; experimental conditions: 125°; carrier gas velocity 50 ml $min^{-1}$; volume of specimen 2.0 $\mu$l:
*a*) alcohol and ketone, ROH, RCOR′; *b*) ketone and ester, RCOR′, RCOOR′; *c*) thiol, RSH; *d*) aldehyde, alcohol, aromatic hydrocarbon, RCHO, ROH, ArR; *e*) aldehyde and aromatic hydrocarbon, RCHO, ArR.

an analytical method. The development of analytical reaction gas chromatography is taking place in two directions: (1) the development of new methods which make it possible to extend the methods of gas chromatography to the analysis of compounds which cannot be analysed by the ordinary form of gas chromatography (e.g. the analysis of polymers, salts of organic acids, etc.); (2) the development of simple convenient practical methods for the analysis of specific systems (particularly in biochemical studies) whose analysis requires complex and expensive equipment (capillary chromatography, electron-capture detectors, etc.). These methods are of particular importance for carrying out specific analyses in industry and in the laboratory.

Thus the introduction of a new "variable" (chemical reactions) into gas chromatography has led to the creation of a promising new form of chromatography – reaction gas chromatography. The skilful use of this "variable" will undoubtedly have a positive influence on the development of practical gas-chromatographic methods for the analysis of a wide variety of mixtures.

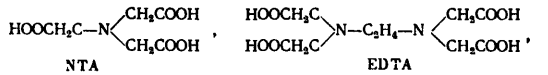
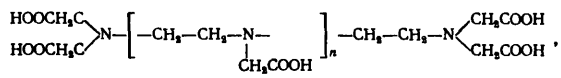
3. The effect of replacing carboxymethyl groups on the nitrogen atom by other groupings 488
4. The effect of increasing denticity when additional iminoacetic acid groups are introduced into the complexone molecule 490
5. The effect of steric factors on the stability of the complexes formed 491

## I. INTRODUCTION



The increasing importance of complex compounds in different fields of theoretical research and, particularly, in practical applications, has led to the rapid developement of the chemistry of multidentate reagents. The complexones form some of the most interesting and promising compounds of this type [1-7].

The term complexone is usually applied to compounds that contain at least one iminodiacetate group $-N(CH_2COOH)_2$, linked to various aliphatic or aromatic substituents by residues of acetic or alkyliminodiacetic acid. At present a series of complexones are also known which are derivatives of iminodipropionic acid, and also aminomethyl--phosphonic and -sulphonic acids [8-17].



The simplest representative of this class of compounds is iminodiacetic acid:

Nitrilotriacetic acid (NTA), ethylenediaminetetraacetic acid (EDTA), and other polyethylenepolyaminepolyacetic acids may be regarded as its structural analogues:

NTA EDTA

where $n = 0, 1, 2\ldots$

These compounds were first mentioned in 1936 when NTA, EDTA, and their salts were patented by I. G. Farbenindustrie and put on the world market under the names Trilon A† and Trilon B‡ as compounds suitable for water

† At present also marketed under the names: Complexone I, Chelaton I, and Titriplex I [these refer to NTA (Ed. of Translation)].

‡ At present also marketed under the names: Complexone III, Chelaton III, Sequestrene, Versene, Irgalon, Titriplex III, Nervanid [most of these refer to the dihydrate of the disodium salt of EDTA, EDTA itself being known as Complexone II, etc. (Ed. of Translation)].

softening. The subsequent work of Schwarzenbach[3,4,18-20] on the determination of the physicochemical constants of the complexones, and on the kinetics and mechanism of their reactions with cations, opened great possibilities for the use of these compounds and provided fruitful ground for the creation of a whole series of new complexones. At the present time there are more than 200 complexones.

These multidentate chelating agents, which created unlimited possibilities for modification of the properties of the central atom and ligands by the formation of highly stable water-soluble complexes, found wide use in many branches of science and technology; this is shown by the tremendous number of publications and patents that have appeared in both Soviet and non-Russian literature.

The introduction of complexones into analytical chemistry opened great possibilities in volumetric[2-7,18-24], gravimetric[2-7,18,19,25-30], colorimetric[2,3,6,7,18,19,31-37], polarographic[2,3,6,7,18,19,38-42], amperometric[6,7,18,19,43,44], and other methods of analysis[6,7,18-20,45-50]. By the use of these compounds the simplest methods of determining cations occurring in difficult combinations without preliminary separation could be developed.

In order to show more clearly the importance of complexones in analysis, it is sufficient to note that at the present time over 60 elements of Mendeleev's Table (practically all the cations and many anions) can be determined by direct or indirect methods with the aid of complexones. These compounds indeed form the nucleus of modern volumetric analysis, which means of analytical chemistry as a whole. The complexones are no less important in the purification and preparation of various elements and compounds. One of the most difficult tasks, the separation of the rare-earth elements, has now been solved by the use of complexones[51-62].

The complexones are of great importance in biology and medicine. These compounds are quite effective in removing toxic metals from the body, including radioactive isotopes and their fission products[63-67]. They are also used for removing radioactive compounds from various contaminated surfaces[68-74]. By the use of complexones and complexonates in some branches of agriculture, the metal content of the soil can be regulated and chlorosis of plants can be prevented[75-78]. Moreover complexones have been widely used in the textile, leather, food, and paper industries, in the production of metals, varnishes, paints, and rubbers, and in the purification of petroleum, wax, fats, etc.[8,9,49]

The number of papers on the use of complexones is very large. Most of them have been summarised and presented as monographs and reviews[2-8].

Problems connected with the study of the effect of the structure of these multidentate chelating agents on their complexing properties, and also on the kinetics and mechanism of their interaction, are dealt with practically only in the original literature. In this connection we consider it expedient to devote the present article to these important questions with a preliminary examination of the fundamental principles of chelate formation.

## II. PROPERTIES OF COMPLEXONES AND PRINCIPLES OF CHELATE FORMATION

Complexones are multidentate chelate-forming reagents. The term "chelate" was proposed by Morgan[79] to denote those cyclic structures that are formed as a result of the union of a cation with two or more donor groups belonging to one molecule of complexing agent. The same is derived from the Greek word "χιλη" which denotes a claw (from which another name for these compounds "clawlike" is derived). This type of ring formation can, of course, only be formed by polyfunctional reagents which can replace more than one position in the coordination sphere of the metal[80-85]. In this connection we distinguish bi-, ter-, quadri-, and multi-dentate complexing agents; these can form one, two, three, and more chelate rings with the metal ion.

Iminodiacetic acid is an example of a terdentate, NTA of a quadridentate, and EDTA of a sexidentate complex-forming agent.

The normal complexes are formed as a result of the interaction of a cation with the completely dissociated anion of the complexone, or in the extreme case, when only betaine hydrogen is present in it. For example, EDTA (denoted below by $H_4Y$) forms a complex by the reaction

$$M_{aq}^{n+} + Y^{4-} \rightleftarrows MY^{n-4} + aq.$$

In an acid medium a weakly basic hydrogen complex may be formed, and in an alkaline medium a hydroxo-complex. In solution the formation of compounds of this kind proceeds in the following manner. When the complexone is introduced into the solution conditions are created for competition between water molecules of the hydration shell of the cation and molecules introduced into the solution by the chelating agent. The necessary conditions for displacing water from the aquo-complex are: a higher donor power of the ligand groups bonding with the metal; a suitable pH value of the solution; and a sufficiently convenient structure of the chelating agent, for otherwise steric hindrance makes coordination impossible.

The competing complexing agent (Y), satisfying these requirements is, under suitable conditions, capable of displacing water from the coordination sphere of the aquo-complex ($M_{aq}$) with the formation of a new complex (MY). The stability of the complexes formed in solution may be denoted by the equilibrium constant (the formation or stability constant):

$$K = \frac{a_{MY}}{a_M a_Y},$$

where $a$ is the activity of compounds taking part in the reaction (the charge is omitted in the formula).

The inverse quantity, the instability constant, is often used[2,3,4,78-85,86]. This quantitative characteristic, indicating the magnitude of the displacement of equilibrium in the direction of complex formation, is derived from the law of mass action, without taking account of successive replacement of the coordination positions in the aquo-complex and the possibility of the formation of several intermediate complexes. At constant ionic strength, concentration ("apparent") stability constants of the complex may be successfully used; these are derived from the equation

$$K_{MY} = \frac{[MY]}{[M][Y]}.$$

These constants show the ratio between the concentrations of ion bound in the complex and the free ion of the metal for every given concentration of the complexing agent.

High thermodynamic stability is an outstanding property of chelate compounds. This is mainly due to the spatially favourable arrangement of complexing groups, leading to the possibility of using in the complex all donor atoms of the ligand, both oxygen and nitrogen, with fairly large polarisability [3,87-90].

EDTA is an ideal example of compounds of this type. This complexone is a universal sexidentate reagent, capable of fully saturating the coordination capacity of most cations, thereby creating the optimal variant of an intra--complex compound with the maximal number of five--membered rings and comparatively little spatial stress.

However, it should be mentioned that there are cases when not all groups of the ligand capable of coordination take part in the formation of rings of a given chelate; as a result less stable compounds are formed. This may be explained by too large a strain on the rings with maximal use of chelate groups capable of coordination, or by the large volume of the coordinating groups, often preventing the achievement of the maximal coordination number of the ions. Phenomena of this kind are undoubtedly connected with the geometrical structure of the internal ligand contour of the chelating agent, and also with the nature of the donor atoms and the central metal ion. Cases are known in which multidentate reagents do not occupy all possible coordination positions in the internal sphere of the complex [3,91-93]. This is mainly observed with small cations and also with some metal ions that form complex compounds with a planar structure. Moreover, the presence in the solution of other donor atoms firmly bound to the cation also leads to a number of cases of incomplete substitution of its coordinating positions by the chelating agent.

The chelate compounds are usually more stable than their non-chelate analogues. In the general case, the equilibrium constant of the substitution reaction

$$ML_n + mY \rightleftarrows MY_m + nL, \qquad (1)$$

where $n$, the number of unidentate ligands replaced by $m$ related multidentate ligands (occupying the same number of coordination positions), is greater than unity. Schwarzenbach called this increased stability that arises through the formation of a ring the "chelate" effect [94,95]. This effect is so general that isolated cases of a negative value of $\log K$ of substitution may be explained either by the complete absence of chelate rings or by a hypothesis about their strain.

Most authors [86,96-100] connect the chelate effect with a greater increase in entropy in reactions in which chelate compounds are formed than in reactions connected with the addition of some simple ligands. Many attempts have been made to determine the entropy change for this effect. Calvin and Bailes proposed that the positive entropy change for the equilibrium substitution, Reaction (1), is mainly due to a gain in translational entropy; however, the effect is observed much less frequently than would be expected from this hypothesis [101]. Martell noted that the value of $\Delta S$ for a number of complexonates increases with increasing number of donor atoms and with decreasing radius of the cation [96]. He also found that the dependence of $\Delta S$ on the number of coordinating acetate groups is linear. Schwarzenbach proposed that the entropy contribution to the chelate effect is related to ring closure and in the main does not depend on the nature of the metal ion or on the bonding atom of the ligand [94]; the greatest chelate effect is observed in the formation of the smallest ring free from strain, which usually consists of five members in a saturated ring and of six members in an unsaturated ring. Adamson [102] considers that the chelate effect is more apparent than real; it is to a large degree a packing effect, which appears as configurational entropy. However, it should be noted that since the chelate effect is expressed by the difference between the logarithms of the stability constants of the chelate complex and the complex with simple ligands of the same type, there is a correlation between factors affecting the stability of the complexes formed and a ring effect. In this connection, the unequal changes of these two constants with a change in the concentration of the complexing agent for a different number of ligands should be taken into account. The value of the stability constant of a simple complex by $n$ ligands (L) given by the equation

$$K_{ML_n} = \frac{[ML_n]}{[M][L]^n},$$

changes with change in concentration of the complexing agent much faster than in the case of chelate formation, expressed by the equation:

$$K_{MY} = \frac{[MY]}{[M][Y]};$$

therefore the standard state of the reacting compounds is usually taken as a 1 M solution of the completely hydrated ions or molecules.

Another important characteristic of the complexing reaction is the kinetics of the process [2,3,85]. Although practically the same quantities (charge, size, and stereochemical configuration, electronegativity, polarisability of the central metal ion and ligands) enter into the factors affecting the rate of reaction and the stability of the complexes formed, it has been stated in the literature [85] that these two quantities are not correlated, that is, the stability of the complexes does not characterise their kinetic behaviour in formation or substitution reactions. A low rate of displacement does not inevitably mean a high stabilisation of the bond. A few studies in the complexone field have shown that the whole process of interaction of the metal with complexones is subject to the same kinetic laws; the exchange proceeds both by a second-order reaction (direct exchange between metal and complex) and by a first-order reaction (dissociation of various protonated complexes) [103-105].

Protonation of the ligand reduces the electron density at the metal bond and increases the rate of dissociation of this bond. For example, HCd(EDTA) dissociates 20 times faster than Cd(EDTA), that is, aquation appears to be catalysed by acids. The formation of complexes of the external shell type Fe(EDTA) is practically instantaneous; the formation of complexes of the internal shell type, in which there is at least one electron on each $d$-shell — for example, Cr(EDTA) and Co(EDTA) — proceeds incomparably slower [103]. Therefore, in compounds of this type the formation and decomposition of the complexes are essential kinetic factors equivalent to the effect of electronic structure. The formation of complexes with cyclohex-1,2-ylenebis(iminodiacetic acid) is somewhat slower [2,3,106], which is probably connected with rigid fixation at a definite distance and the corresponding directional alignment of the complexing groups.

A considerably larger number of investigations have been devoted to the substitution reactions of complexes, in which the central metal ion or a ligand is exchanged. Many complexes enter into exchanges with free metal ions with measurable velocity; very often the exchange proceeds in several stages, sometimes with partial opening of the

chelate ring and the formation of new metal–ligand bonds; in all cases the mechanism of the exchange reaction and the constants for the rate of formation of complexes depend on pH[3,85]. Cation-exchange reactions of most complexonates of NTA and EDTA[103] are practically instantaneous, but the reactions of complexonates of cyclohex-1,2-ylenebis(iminodiacetic acid) are much slower (10 to 100 times). Thus, establishment of the equilibrium

$$FeY^- + Th^{4+} \rightleftarrows ThY + Fe^{3+}$$

takes several days[106] but displacement of nickel from cyclohex-1,2-ylenebis(iminodiacetate) by other cations in general does not reach equilibrium in a measurable time. Of particular interest are the rates of oxidation-reduction processes, and in particular between two oxidation states of the same element in the complex. These reactions are practically instantaneous. Thus, the rate of the exchange reaction $[Co(EDTA)]^{2-}$–$[Co(EDTA)]^-$ is $4 \times 10^{-7}$ mole$^{-1}$ s$^{-1}$ and that for the reaction $[Fe(EDTA)]^{2-}$–$[Fe(EDTA)]^-$ exceeds $1 \times 10^{-3}$ mole$^{-1}$ s$^{-1}$.

Summarising, one should note that this side of the question of complex formation, which is important in practice and interesting from a theoretical standpoint, has been studied insufficiently; it is therefore not always possible to compare results obtained and to give basic interpretations of observed facts.

## III. THE EFFECT OF THE STRUCTURE OF COMPLEXONES ON THEIR COMPLEXING POWER

The question of the relation between the structure of chelating compounds and their reactivity is a very important and topical one from both the practical and the theoretical viewpoints. A knowledge of the fundamental physical constants and the variety of factors that affect complex formation, forms a definite scientific base, which has already made the use of complexones possible not only in a number of problems in analytical chemistry, but also in finding new fields of application for these compounds. This knowledge has been used to solve some most important problems in the national economy and has given rise to promising possibilities of further development.

The theoretical side of the problem is also of undoubted importance; complexones are multidentate reagents[99] that form stable complex compounds with practically all cations and, for this reason, if some degree of selectivity is to be conferred on them, a special structure of the molecule is necessary, account being taken of electronic structure, nature of the coordinating atoms, and the stereochemistry of the complexes. All studies connected with the elucidation of the principles of change in the complexing action of complexones are very valuable contributions to the setting up of a theory of organic reagents. Furthermore, these principles make possible theoretical predictions, which in a number of cases permit the synthesis of new complexones with predetermined properties.

Modifications of the complexone molecule have been carried out in the following main directions:

(1) introduction into the complexone molecule of various substituents not taking part in complex formation but affecting the basicity of the coordinating nitrogen of the iminodiacetate grouping; (2) increasing the denticity of the chelating agent by introducing into the complexone molecule heteroatoms and iminoacetate and characteristic analytical groupings that tend to form complexes with certain elements; (3) changing the geometry of the internal ligand contour.

The following Sections of this review will be devoted to this aspect of the problem.

### 1. The Effect of the Basicity of the Nitrogen of the Iminodiacetate Group

One of the main factors affecting the complexing power of complexones is the basicity of the nitrogen atom of the iminodiacetate groups. This effect has been well studied on derivatives of iminodiacetic acid, which is the simplest structural model of complexones. At the present time a considerable number of compounds with the general formula:

have been synthesised, where R represents various aliphatic, aromatic, or alicyclic substituents containing functional and non-functional groups[107-118]. Data on the complexing properties of these compounds are collected in Table 1.

The first three vertical columns of Table 1 contain values of the acid dissociation constants of the complexones. In accordance with the views of Schwarzenbach, the betaine structure is ascribed to all these acids[18,108-115]:

The betaine structure of these compounds also explains the high value of the negative logarithm of the dissociation constant for the first hydrogen atom, the mobility of which depends on the basicity of the nitrogen atom linked to it. The basicity of the nitrogen atom in turn changes with the inductive effect of substituents R linked to nitrogen. When hydrogen in the iminodiacetic acid group is replaced by the $CH_3$ group, the basic properties of the nitrogen are increased as a result of the positive inductive effect of the $CH_3$ group. If one, or particularly two, phenyl groups are introduced into the methyl group the basicity of the nitrogen decreases somewhat due to the comparatively strong electron-acceptor properties of these groups. In the case of aniline, the electron pair of the nitrogen is displaced towards the benzene nucleus, which leads to a still greater weakening of the basic properties of the nitrogen.

A definite relation between the mobility of the betaine proton and the coordinating power of the nitrogen atom would therefore be expected. In fact, for complexones containing alkyl, alkylaryl, and alicyclic radicals a simple linear relationship is observed between the basicity of the nitrogen, as expressed by the acid dissociation constant of the last proton, and its coordinating power (Fig. 1).

As Fig. 1 shows, the introduction of alkyl and alkylaryl radicals increases the complexing power of the complexones, and, on the contrary, when the phenyl radical is a direct neighbour, the complexing power of the iminodiacetic acid group is lowered.

§ In future the iminodiacetate group $-N\langle^{CH_2COOH}_{CH_2COOH}$ will be denoted by the symbol $-N\langle$.

TABLE 1. Negative logarithms of dissociation constants and stability constants of complexes of iminodiacetic acid and its derivatives.

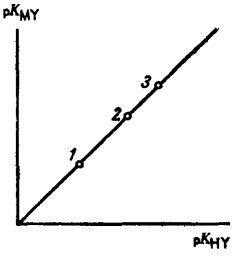

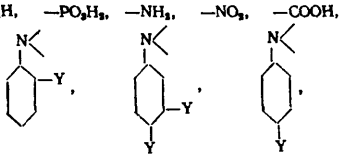

Fig. 1. Dependence of the coordinating power of the nitrogen on its basicity, expressed as an acid dissociation constant of the last betaine proton:
1) benzyliminodiacetic acid; 2) cyclohexyliminodiacetic acid; 3) methyliminodiacetic acid.

More complex relationships are observed when various functional substituents are introduced into the hydrocarbon radical of iminodiacetic acid.

Schwarzenbach [110-114] studied derivatives of iminodiacetic acid and anilinediacetic acid with the general formulae:

X–CH$_2$–N(CH$_2$–N), X–CH$_2$–CH$_2$–N(CH$_2$–N),

where X = –SO$_3$H, –PO$_3$H$_2$, –NH$_2$, –NO$_2$, –COOH, –OH.

and 

where Y = –SO$_3$H, –COOH.

The introduction of similar substituents on iminodiacetic and phenyliminodiacetic acid has a twofold effect on the complexing power of the compounds. On the one hand, the basicity of the imino-nitrogen changes because of the electrostatic effect of the substituents; on the other hand, the complexing power of the compounds changes because of the tendency of some of the substituents introduced to form additional rings. The latter factor mainly affects $\alpha$-derivatives of alkylaminodiacetic acid and *ortho*-derivatives of phenyliminodiacetic acid [109]. For ligands of this kind, containing several types of group capable of coordinating, the linear dependence between the basicity of the nitrogen and coordinating power only holds approximately; the dependence holds only for a number of ligands of similar structure that form the same number of chelate rings of the same size and having the same $\pi$ bonding tendency. If there is no steric hindrance, then the change in free energy (enthalpy) shifts in parallel with the values of p$K$ for $HY^-$ (in water). A greater or lesser deviation from linear dependence between p$K$(MY) and p$K$($HY^-$) is probably due to enthalpy or entropy effects, or to both.

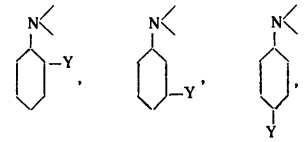
A comparison of various oxygen-containing donors indicates that the stability of the bond practically always increases with increasing basicity of nitrogen, although the relation is not always linear.

## 2. The Effect of Functional-Analytical Groupings and Heteroatoms on the Complexing Power of Complexones

The question of the selectivity of the chelating agent for a given cation is of great interest. One way in which this selectivity can be achieved is by the introduction into the complexing molecule of characteristic functional groupings with a definite specificity; this often leads to the required analytical effect. The presence of these groupings in the complexone, without changing the main reaction mechanism, often promotes a clearer development of the analytical effect, and is favourably reflected in the character of the final product.

The introduction into the complexone molecule of hetero-atoms — sulphur, nitrogen, oxygen — capable of coordinating with a metal to form a new ring, has a similar action. The nature of the donor atom plays the main part in increasing the selectivity.

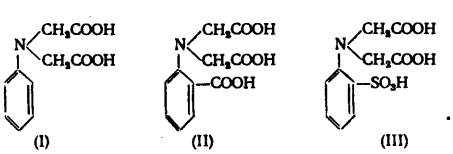
The effect of the introduction of various groupings on the complexing power of the complexone in the aliphatic series has been studied in detail on derivatives of iminodiacetic acid with the general formula $X-CH_2-N<$ [110,114,115,117,118]. Different substituents have different effects on the complexing power.



The nitrogen, oxygen, sulphur, and phosphorus atoms of aliphatically bound groups, $-OH$, $-OCH_3$, $-SH$, $-SCH_3$, $-PO_3H$, $-SO_3H$, $-NH_2$, form a coordinate bond with metals and this considerably increases the stability of the complexes. The maximal effect is observed when the substituent is in the $\alpha$-position to the nitrogen of the iminodiacetate group. In the case of the $\beta$-position the stabilising effect is much weaker. The complexone acquires a definite selectivity depending on the grouping introduced and the nature of the donor atom. Many workers have noted a specificity for iron in complexones containing hydroxyethyl groups [120-126]; this has been utilised in a number of practical problems.

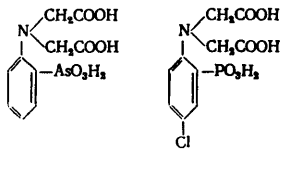
Complexones containing a mercapto-group sulphur atom and an amino-group show a great tendency to form complexes with heavy metals [114]. Sulphur in *NNS*-mercaptoethylaminotriacetic acid shows the same activity [127]. The presence in this compound of an additional complex-forming group makes it more selective than iminodiacetic acid. It has been shown that this complexone is selective with regard to the rare-earth elements; it forms complexes with only four cations out of 14. Moreover, complexes of different stability with the cations of copper and lead, cadmium and zinc, and cobalt, nickel, and zinc may be used for the separation of these metals.

The group of ethyl carbamate, the nitrile group, the positively charged amino-group, and the trimethylammonium group show practically no tendency to coordination; their effect on the stability of complexes is only connected with the change in the basicity of the coordinating nitrogen.

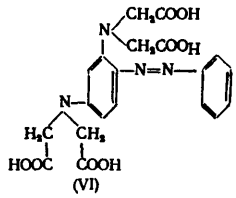


Uramildiacetic acid [perhydro-2,4,6-trioxopyrimidine--5-iminodiacetic acid (Ed. of Translation)], which forms stable complexes, is of considerable interest. The great basicity of the nitrogen atom, and evidently, the presence of a barbituric acid residue greatly increases the stability of complexes formed with uramildiacetic acid [128]. The stability of the complexes increases in the order Ba, Sr, Ca, Mg. The remaining derivatives of the alkyliminodiacetic acids shown in Table 1 are not now widely used and are mainly of theoretical interest.

Schwarzenbach studied the effect of the introduction of substituents into complexones of the aromatic series, using derivatives of anilinediacetic acid [109]:



where Y = $-SO_3H$, $-COOH$. The introduction of carboxylic and sulpho-groups *ortho*, *para*, and *meta* to the iminodiacetate grouping has different effects, on the complexing power of the complexone.



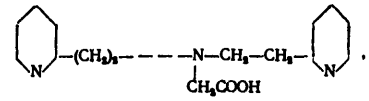
Substituents in the *meta*-, and *para*-positions have no material effect on the basicity of the iminodiacetate group nitrogen and the stability of the complexes formed. Substituents in the *ortho*-position greatly increase the complexing power; the effect of the substituent on the complexing power is in the same order as in the aliphatic series, that is, $-COOH > -SO_3H$. We have continued investigations in this direction, studying the effect of the introduction of arsonic, phosphonic, and azo-groups *ortho* to the iminodiacetate group of the benzene ring, on complexing power; as is well known, these groups comprise the analytical groupings of many valuable reagents. With this object 2-arsonophenyliminodiacetic acid (IV) [129], 4-chloro-2-phosphorophenyliminodiacetic acid (V), and chrysoidinetetraacetic acid [azobenzene-2,4-bis(iminodiacetic acid) (Ed. of Translation)] (VI) [130] have been synthesised and investigated. The complexing properties of these compounds were compared with the properties of phenyliminodiacetic (I), 2-carboxyphenyliminodiacetic (II), and 2-sulphophenyliminodiacetic (III) acids

(I) (II) (III)

(IV) (V)

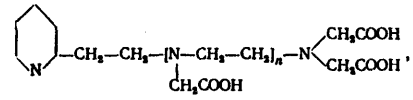
(VI)

The stability of the complexes formed were recorded on the basis of the displacement of the half-wave potential $\Delta E_{1/2}$ = = $E_{1/2}$ (I, II, III, ...) - $E_{1/2}$ (without complexone) (Table 2).



The results obtained showed that the introduction of these groupings increases the complexing properties of phenyliminodiacetic acid, makes the complexone more specific and thus more interesting from a practical point of view. Thus, 2-arsonophenyliminodiacetic acid forms stable complexes with lead and cobalt. This enables lead to be determined polarographically in the presence of copper and bismuth, and cobalt to be determined complexometrically. The presence of the phosphonic acid group enables cations to be determined when present together (Cu, Pb, Cd, As, Zn, Mo) in an acid medium.

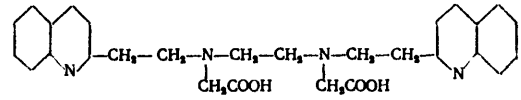
The combination in the chrysoidinetetraacetic acid complexone molecule of azo- and iminodiacetate groupings increases the specificity of this compound compared with *m*-phenylenebis(iminodiacetic acid). The presence of a polarographically active azo-group in this complexone enables arsenic, manganese, and aluminium to be determined polarographically and amperometrically.



The effect of the groupings enumerated above in the *ortho*-position in phenyliminodiacetic acid is determined both by the electrostatic influence of the substituent and by its direct participation in the formation of the complex.

Following the success achieved in the field of analytical reagents, we made other attempts to increase the specificity of complexones by the introduction of special analytical grouping into the skeleton of polyaminecarboxylic acids.

The introduction of pyridine and quinoline nuclei with their marked tendency to bind transition metals (especially Co and Ni) and also some heavy metals (U, V, Pb, Zn, etc.) in stable complexes led to the creation of new complexones selective for heavy metals[9]. Thus, for Co and Ni the complexone



and for Pb, V, Zn, and U the complexone

where $n$ = 1–3, have been proposed.

In a number of compounds the pyridine ring was replaced by the quinoline ring:

These examples, as well as some others, bridge the gap between special reagents for cations and complexones, and to a certain extent enable the theoretical prerequisites developed in the field of organic reagents to be applied to the effect of the structure of the complexones on their specificity.

The complexing power of a complexone is affected to at least an equal degree by the inclusion of the heteroatoms oxygen, sulphur, and nitrogen in the hydrocarbon chain of its molecule.

The part played by the heteroatom in complexones of the aliphatic series has been studied on compounds of the general formula [131]:

where for $n = 2$, X = —O—, —S—, —S'—S—, —N(CH$_3$)—;

for $n = 3$–4, X = —O—.

where X = —O—, —S—, —N(CH$_3$)—.

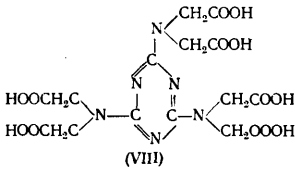
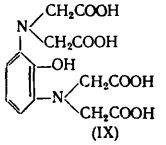
It has been shown that the introduction into the complexone molecule of the heteroatoms N, O, S, which tend to coordinate with metals, leads to an increase in the complexing power of these complexones. Participation in complex formation of the additional N, O, or S atoms confers some specificity on the complexone molecules in relation to certain metal cations [16,132]. Thus, for the alkaline earth cations the relative order of stability is O > N > S; for the transition elements with almost completely filled *d* orbitals the order of stability is N > S > O. With the rare-earth elements the complexing power increases in the order S < N < O.



Van Uitert and Fernelius attempted to explain phenomena of this kind by considering the effective electronegativities of hybrid bonds of the ligand and the metal ion [133].

The studies of Izalt, Fernelius, and Block in this field agree with the ligand field theory [134]. Thus, cations especially sensitive to ligand field stabilisation form the most stable compounds with donor atoms that cause large ligand field splitting and conversely.



The effect of a heteroatom is also shown in cyclic compounds. This was studied on complexones of the triazine series [135,136] and on derivatives of benzthiazole and aminothiazole [137]. The properties of 2-hydroxy-1,3,5-triazin--4,6-diylbis(iminodiacetic acid) (VII), and 1,3,5-triazin--2,4,6-triyltris(iminodiacetic acid) (VIII), containing the 1,3,5-triazine ring are compared in Table 3 with the properties of *m*-phenylenebis(iminodiacetic acid) (IX). The instability constants of the complexes of (VII) and (VIII) are in all cases greater than the constant for compound (IX); moreover (VIII) has a tendency to form more stable complexes than (VII).

(VII)

(VIII)

(IX)

A characteristic of (VII) and (VIII) is the presence of the same grouping

which is capable of forming complexes with metal cations.

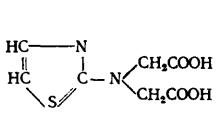


TABLE 3. Logarithms of stability constants of cations with complexones at pH 2.5.

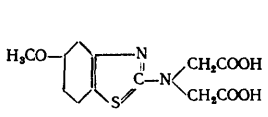
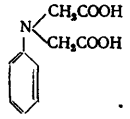
| Cations | (VII) | (VIII) | (IX) |
|---|---|---|---|
| $Pb^{2+}$ | 4.75 | 5.08 | 3.73 |
| $Cu^{2+}$ | 3.78 | 4.07 | 3.36 |
| $As^{3+}$ | 5.08 | 6.10 | 5.01 |
| $Zn^{2+}$ | 6.70 | 7.10 | 3.40 |
| $La^{III}$ | 5.08 | 5.56 | 3.05 |
| $Ti^{IV}$ | 3.89 | 4.22 | — |



It is natural to suppose that the nitrogen of the triazine ring participates in complex formation. It is this that leads to an increase in the complexing power of (VII) and (VIII) compared with (IX).

The increase in the complexing power of (VIII) compared with (VII) may be ascribed to symmetry in the molecule (three iminodiacetic acid groups), leading to easier formation of complexes, sometimes with a large number of rings.



The complexing properties of 1,3-thiazol-2-yliminodiacetic acid (X) and 5-methoxybenzothiazol-2-yliminodiacetic acid (XI), containing two heteroatoms, nitrogen and sulphur, were studied [137] by the polarographic method of displacement of half-wave potentials; these compounds showed a reduction in analytical activity against a series of cations in comparison with a complexone containing an aromatic ring (phenyliminodiacetic acid) (XII):

(X)

(XI)

(XII)

Table 4 shows that (XII) forms weak complexes with nearly all the cations mentioned, while (X) and (XI) behave differently.

In the acid range, pH 2.5–4.4, these complexones form complexes only with Cu, Mo, As, Pb, and Co; in the alkaline range they form complexes with Co, Sb, Pb, Zn, and As, which indicates that they have some specificity. The reduction in analytical activity is probably due to the spatial proximity of the heterocyclic sulphur and nitrogen atoms, which considerably reduces the basic properties of the iminodiacetate nitrogen. The introduction of functional groups and heteroatoms into the complexone molecule is one way of obtaining complexones with a selective action.

### 3. The Effect of Replacing Carboxymethyl Groups on the Nitrogen Atom by Other Groupings

Apart from complexones with a changed composition of radicals on the iminodiacetate group, a number of compounds have been described in which acetic acid residues on the nitrogen atom are replaced by other groups [138-140].

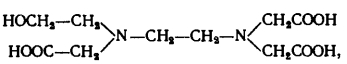
Complexones in which the carboxyl groups are completely or partially replaced by residues of sulphonic, arsonic, or phosphonic acids or by hydroxyalkyl groups are of definite interest. Experimental results in papers by Schwarzenbach [110], Kabachnik [17,141,142], and others on complexones with phosphonic groupings and comparison of their properties with those of the corresponding aminocarboxylic and aminosulphonic acids indicate that the greatest effect is obtained when two types of complexing groups are present on the nitrogen of the complexone. As our investigations showed, with some cations *NN'*-bisphosphonomethylethylenebis(aminoacetic acid) forms more stable complexes than the corresponding analogues containing only carboxymethyl or phosphonomethyl groups [141].



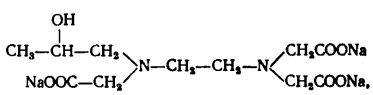
A certain selectivity in compounds of this type should be noted. It was shown by Kabachnik and his coworkers [141,142] that, apart from diethylenetriaminepentaacetic acid, the most powerful complexing agents for rare-earth ions are methylphosphonic acid and *NN'*-bisphosphonomethylethylenebis(aminoacetic acid); these complexing agents are recommended for removing the rare-earth elements from the body. Manecke and Gergs have pointed out the selectivity of ethylenediamine-*NN'*-bisethylarsonic acid for copper [143].

Bruno and coworkers [138] have studied *N*-substituted *NN'N'*-ethylenediaminetriacetic acids of the type:

where R = n-butyl, n-octyl, n-dodecyl, cyclohexyl, or benzyl. Replacement of the carboxymethyl group by these radicals leads to the changes in the properties of EDTA shown in Table 5.

With copper the *N*-benzyl derivative gives a less stable complex than EDTA and a more stable one than the *N*-butyl and *N*-octyl derivatives. *N*-Cyclohexylethylenediaminetriacetic acid forms the weakest complex with copper, and *NN'*-dicyclohexylethylenebis(aminoacetic acid) does not form such complexes at all. With calcium these acids behave as weak complexing agents. However, the *N*-benzyl derivative forms the most stable complexes. Replacement of the $-CH_2COOH$ group in the complexone molecule by hydroxyalkyl groups gave compounds capable of complexing iron in a moderately alkaline medium [9,144]. *N*-(2-Hydroxyethyl)ethylenediaminetriacetic acid:

the trisodium salt of *N*-(2-hydroxypropyl)ethylenediaminetriacetic acid:



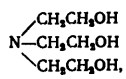


TABLE 5. Complexing power of *N*-substituted ethylenediaminetetraacetic acids.

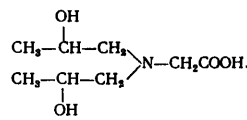
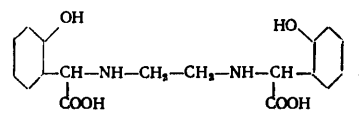
and *NN*-di-(2-hydroxyethyl)aminoacetic acid:



are examples of compounds of this type. The last compound has a characteristic tendency to form a complex with the $Fe^{3+}$ ion, in the same way as the structurally similar triethanolamine:



which, as is well known, is a very powerful complexing agent for the $Fe^{3+}$ ion.

It should be noted that the alkaline earth ions do not form complexes with dihydroxyethylglycine; this compound cannot therefore be used alone for removing the hardness from water and it is generally employed as a mixture with EDTA.

It has been shown that, in contrast to *NN*-di-(2-hydroxyethyl)aminoacetic acid, *NN*-di-(2-hydroxypropyl)aminoacetic acid does not form stable complexes with iron:

This is probably due to steric factors when the hydroxyethyl groups in the complexone molecule are replaced by hydroxypropyl groups. Ethylenebis[amino-(*o*-hydroxyphenyl)acetic acid] is the most specific complexone for tervalent iron; this compound contains the hydroxyphenyl grouping which is characteristic for complex formation with $Fe^{3+}$:

The instability constant of this complex with iron is $10^{-35}$, that is, one of the smallest ever measured for complexes in aqueous solution.

Data on the stability of complexes with some metal ions are given in Table 6.

Thus, the introduction into the complexone molecule skeleton of groupings containing hydroxyalkyl or hydroxyaryl groups led, as would be expected, to the formation of complexones specific for the $Fe^{3+}$ ion [139-145].

4. The Effect of Increasing Denticity When Additional Iminoacetic Acid Groups Are Introduced into the Complexone Molecule

The effect of increasing the denticity without changing the fundamental structure of the complexone has been studied on analogously constructed polyethylenepolyaminepolycarboxylic acids [146-149]: diethylenetriaminepentaacetic acid (DTPA), triethylenetetraaminehexaacetic acid (TTHA), and tetraethylenepentaaminehexaacetic acid (TPHA).

A study of their complexing properties, determination of dissociation and stability constants of their complexes with a number of metals (Table 7) and also comparison of the results obtained with corresponding values for NTA and EDTA have shown that the stability of the complexes for practically all cations increases from nitrilotriacetates to diethylenetriaminepentaacetates (DTPA) and then falls with triethylenetetraaminehexaacetates (TTHA) and tetraethylenepentaaminehexaacetates (TPHA) (Figs. 2, 3, 4).

However, it should be noted that a change in the denticity has a different effect on the instability constants of complexes of different metals.

Potentially, the octo-, deca-, and dodeca-dentate character of these polyethylenepolyaminepolyacetic acids, differing by steric accessibility of the coordinating groups, can ensure full saturation of the coordination capacity of such elements as thorium, aluminium, molybdenum, and the rare-earth elements with a coordination number of 8. The number of rings linked with one metal cation then increases

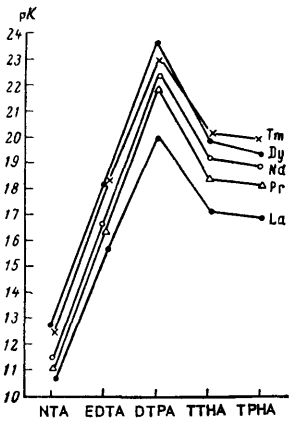

Fig. 2. Dependence of the stability of complexes of the rare-earth elements (p$K$) on the denticity of the complexone.

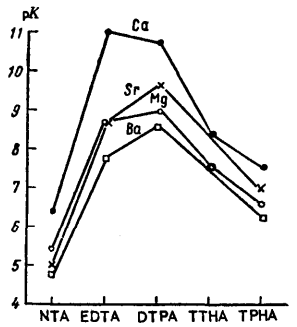

Fig. 3. Dependence of the stability of Ca, Mg, Ba, and Sr complexes on the denticity of the complexone.

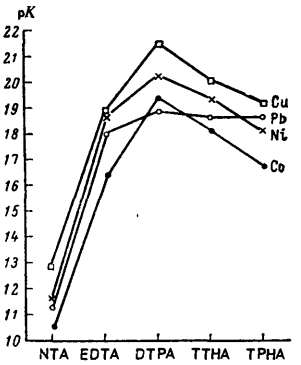

Fig. 4. Dependence of the stability of Ni, Co, Cu, and Pb complexes on the denticity of the complexone.

to 7, and in addition the stability of the complexes formed increases in comparison with that of the ethylenediaminetetraacetates. The comparatively small reduction in the stability of the complexes in the series DTPA, TTHA, and TPHA is probably connected with the change in basicity of the coordinating nitrogen atoms of the iminodiacetate groupings and the possibility of the formation of associated complexes.

For Mg, Ca, Sr, Ba with TTHA and TPHA the formation of complexes of the type $M_2Y$ is characteristic; this accounts for the observed fall in stability and the position of the constants between the corresponding values of

TABLE 7. Logarithms of stability constants of complexes of some metals with polyethylenepolyaminepolyacetic acids [146-149].

nitrilotriacetates and ethylenediaminetetraacetates. For such elements as Co, Ni, Cu, Zn, and Pb, the formation of associated complexes of the 3 : 2 type is also characteristic: this probably gives rise to five rings on each complexing cation. The equality in the stability of these complexes with the corresponding ethylenediaminetetraacetates therefore becomes clear. This kind of increase in denticity of complexing agents without change in structure and without disturbance of the optimal symmetry of chelating groups is thus effective for voluminous cations with high coordination capacity. This may be explained by the possibility of forming additional rings; the optimum variant in the structure of a multidentate complexone is still DTPA. Further increase in the denticity by introducing additional acetate groups into the complexone molecule, does not, as a rule, lead to significant stabilisation of the complexes, but rather to increased selectivity. However, because of the very rapid formation and the high stability of complexes of multivalent cations, these complexones could be successfully used in analytical chemistry to mask interfering impurities and for the determination of a number of cations by physicochemical methods.

## 5. The Effect of Steric Factors on the Stability of the Complexes Formed

Analysis of the structure of chelate rings is of great importance in evaluating the effect of the structure of organic chelating agents on their complexing properties and on increased selectivity in the determination of elements. Alkaline earth and rare-earth elements with constant valency and varying atomic volume are ideal systems for this kind of investigation. The effect on complex formation of such stereochemical factors as ligand isomerism, conformation, distance between the main complexing groups, and the arrangement of the chelate rings may be examined in complexones containing two iminodiacetate groups, such as ethylenediaminetetraacetic acid, cyclohex-1,2-ylenebis(iminodiacetic acid), and cyclopent-1,2-ylenebis(iminodiacetic acid).

The most typical representatives of this group of compounds are EDTA and cyclohex-1,2-ylenebis(iminodiacetic acid) (CHDTA). These compounds with a definite stereochemical configuration differ from one another in the distances between the atoms of nitrogen and their arrangement in relation to the framework of the molecule [150-153]. A study of the chelates of these compounds in the solid state by infrared spectroscopy and thermal analysis permitted elucidation of the nature of the bonds and a precise establishment of coordination numbers for different metals. The ionic bond with carboxyl groups is characteristic of alkaline earth, doubly-charged and some triply-charged cations; the covalent bond is characteristic of transition metals of higher valency and lead.

In most cases these compounds behave as sexi- or quinque-dentate chelating agents, and only in the case of palladium and platinum as bi- and quadri-dentate agents. The presence of two residues of iminodiacetic acid and the close arrangement of the nitrogen atoms ensure a high complexing power in these compounds [11-14,95,143-145].

It follows from Table 8 that *trans*-cyclohex-1,2-ylene- and *trans*-cyclopent-1,2-ylene-bis(iminodiacetic acids) are stronger complexing agents for alkaline earth metals than the corresponding *cis*-analogues and EDTA. However, it should be noted that the stability of the complexes does not increase proportionally with the decrease in the distance between the nitrogen atoms in the ligand molecule. The change in the stability constants of the complexes takes place in the following order: *trans*-CHDTA > *trans*-CPDTA > > *cis*-CHDTA, while the distance between the complexing $-N(CH_2COOH)_2$ groupings decreases in a different order: *cis*-CHDTA ≤ *trans*-CHDTA ≤ *trans*-CPDTA. The reduced stability of alkaline earth metal chelates with *cis*-CHDTA is due to steric hindrance in the chelating reaction:

TABLE 8. Logarithms of the stability constants (p$K$) of complexes of the alkaline earth elements with ethylenediaminetetraacetic acid and cyclohex-1,2-ylene- and cyclopent-1,2-ylene-bis(iminodiacetic acid) [150-153].

| *trans*-Cyclopent-1,2-ylenebis(iminodiacetic acid) | 2.6 | 2.40 | 3.30 | 7.56 | 10.80 | 9.05 | 11.08 | 9.49 | 7.7 |

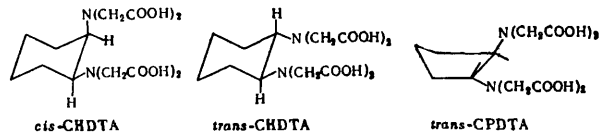

Fig. 5. Models of cyclohex-1,2-ylenebis(iminodiacetic acid) and cyclopent-1,2-ylenebis(iminodiacetic acid).

As the models show (Fig. 5) the *trans*-forms of CHDTA and CPDTA have the maximal number of equatorial substituents. With such an arrangement of ligand groups, the metal–chelate rings are in the same plane as the alicyclic radicals, which leads to a favourable geometrical structure for the molecule. In *cis*-CHDTA the axial hydrogen atoms of the cyclohexane ring prevent free rotation of the carboxymethyl groups, and the plane of the chelate ring is at an acute angle to the plane of the hydrocarbon ring. The steric hindrance produced by this kind of structure of chelating agent in *cis*-compounds and the lack of coplanarity due to it lead to great strain in the complexes formed and to a reduction in their stability.

It is interesting to note that complexes formed by *trans*-CPDTA are more stable than the corresponding compounds with EDTA in spite of the fact that the distance between the iminodiacetate groups in the active form of EDTA is less than the corresponding distance in *trans*-CPDTA. The reduced stability of complexes of EDTA compared with those of CPDTA is connected with the necessity of expending additional energy for converting form (I) into form (II) (Fig. 6), which is capable of forming chelates with metal ions. Moreover, the five condensed chelate rings when EDTA is used as a sexidentate agent form a greatly warped octahedron around the central metal atom with great deformation in the $-N(CH_2)_2N-$ chelate ring plane, in which there are two –N–CO–O– rings at angles deviating greatly

from the normal values [154]. All this produces additional strain in the cyclic structure and also leads to a reduction in the expected stability of the complexes with EDTA. In *trans*-CPDTA the nitrogen atoms are spatially fixed by the cyclopentane ring, which excludes the necessity of expending energy in rotation, and the structure is less strained:

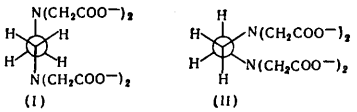

Fig. 6. Models of the two forms of EDTA.

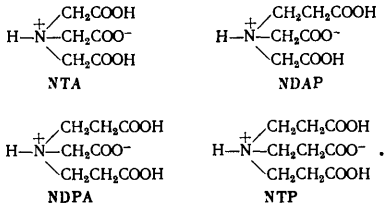
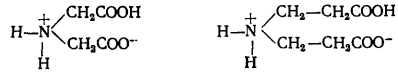
Thus, in these compounds the predominating factor affecting the stability of compounds formed is the mutual arrangement of the ligand groups in the contour of the chelating agent, capable of forming complex structures with more or less strain. However, it should be noted that there are a number of compounds where the decisive part is played by the distance between the complexing groups.



When the distance between the nitrogen atoms is significantly increased, their mutual interaction is weakened and a decrease is observed in the complexing power of the complexone; this is clearly shown by the homologues of EDTA: tri-, tetra-, penta-, etc. polymethylenediaminetetraacetic acids [155-160] (Table 9).

Data on stability constants show that when $n = 2$, with EDTA, the stabilisation produced by the formation of a ring is at a maximum. When the length of the chain of methylene groups (the quantity $n$) increases, the stability due to ring formation disappears and is even replaced by a weak destabilisation effect. This may be explained in the following way: rings with more than seven members are not formed, and when complexones containing four, five, and more hydrocarbon atoms interact with metal ions, the di(carboxymethyl)amino-groups act independently, forming complexes of the composition $M_2Y$. Analogous results were obtained by Schwarzenbach and Ackermann [111] in studying the isomeric cyclohexylenebis(iminodiacetates). The 1,3- and 1,4-derivatives form significantly less stable complexes than 1,2-CHDTA and show a tendency to coordinate with two metal cations and not to form a closed ring. All these results again emphasise the special stability of five-membered rings. However, it should be noted that an increase in the length of the polymethylene bridge in homologues of EDTA ($n = 6$ or 8) promotes the development of specificity in the complex; this specificity is expressed, for example, in increased stability of the complexes with silver and mercury. This is explained by a linear arrangement of valencies in these cations. As the ring increases in size its strain decreases, probably because of bending of the *sp* orbitals of the metal ion.

The distance between the carboxyl group and the nitrogen atom also has a considerable effect on the complexing power of the complexone:



A study of this phenomenon [122] was carried out on a number of derivatives and homologues of iminodiacetic acid and ethylenediaminetetraacetic acid. The following series was investigated: nitrilotriacetic acid (NTA), nitrilodiaceticpropionic acid (NDAP), nitriloaceticdipropionic acid (NDPA), and nitrilotripropionic acid (NTP) (Table 10):

The value of the dissociation constant $pK_3$, and therefore the basicity of the nitrogen, decreases in the order NTA > NDAP = NDPA > NTP.

The stability of the complexes of most metals decreases in the same order as the basicity of the nitrogen atom: NTA > NDAP > NDPA > NTP; the replacement of one or two acetate groups by propionate groups only slightly reduces the stability. A possible explanation is that the propionate group in NDAP and NDPA forms six-membered rings with Cu, Ni, Co, and Zn which are more suitably arranged in space than the five-membered ring in the case of NTA and set up less strain over the whole molecule of complex.

Iminodiacetic acid and iminodipropionic acid:

are similar in structure to the four acids considered [116]. The value of the stability constant of iminodipropionic acid complexes is two orders less than the value of the constant for iminodiacetic acid complexes.

TABLE 9. Logarithms of the stability constants of complexes of the alkaline earth metals with polymethylenediaminetetraacetic acids [109,131,155-160].

| Complexone | pK of dissociation | | | | $pK_{MY}$ | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | $pK_1$ | $pK_2$ | $pK_3$ | $pK_4$ | Mg | Ca | Sr | Ba | Na |
| Ethylenediaminetetraacetic acid | 10.26 | 6.16 | 2.67 | — | 8.69 | 10.59 | 8.63 | 7.76 | 1.66 |
| Trimethylenediaminetetraacetic acid | 10.27 | 7.90 | 2.67 | 2.00 | 6.66 | 7.12 | 5.18 | 4.24 | — |
| Tetramethylenediaminetetraacetic acid | 10.45 | 9.07 | 2.66 | 1.90 | 3.44 | 5.05 | 2.80 | 2.40 | — |
| Pentamethylenediaminetetraacetic acid | 10.48 | 9.50 | 2.7 | 2.2 | 3.63 | 4.62 | 2.72 | 2.38 | — |

TABLE 10. Logarithms of the stability constants of metals with NTA, NDAP, NDPA, and NTP. [108-113,122]

| Complexone | pK of dissociation | | | $pK_{MY}$ | | | | |
|---|---|---|---|---|---|---|---|---|
| | $pK_1$ | $pK_2$ | $pK_3$ | Co | Ni | Cu | Zn | Cd |
| Nitrilotriacetic acid | 1.89 | 2.49 | 9.73 | 10.38 | 11.53 | 12.96 | 11.67 | 9.83 |
| Nitrilodiaceticpropionic acid | 2.10 | 3.69 | 9.66 | 7.9 | 9.0 | 11.6 | 7.9 | 5.6 |
| Nitriloaceticdipropionic acid | 3.25 | 3.98 | 9.67 | 7.9 | 9.1 | 11.9 | 8.0 | 5.6 |
| Nitrilotripropionic acid | 3.67 | 4.24 | 9.30 | 4.8 | 5.8 | 9.1 | 5.3 | 3.4 |

A number of derivatives of ethylenediaminediacetic acid (EDDA) in which the acetate groups were replaced by propionate groups were investigated with the object of studying the effect of the distance of nitrogen from the carboxyl group on the complexing power of the complexone.

Comparison of the complexing power of ethylenediaminepolycarboxylic acids with various doubly-charged cations showed that the replacement of one acetate group of EDTA by a propionate group lowers the $pK_{Me}$ by approximately 3–4 units. This effect is much greater with tetrapropionic acids. Symmetrical replacement of two propionate groups in these compounds by acetate groups increases the $pK_{Me}$ in general by 6–7 units. It is clear from the examples given that acetate groups form more stable chelate structures than propionate groups and therefore in this case increasing the distance of the carboxyl group from the nitrogen atom leads to a decrease in the stability of the complexone complexes with most cations. However, it should be noted that there is some selectivity with regard to copper, which may be explained by the planar structure of the complex formed.

---o0o---

It follows from the foregoing that the synthesis of complexing agents with the maximum possible affinity for metal ions and the development of selective reagents differing as much as possible from one another and having specific complex properties are important problems in coordination chemistry.

After the synthesis and application of such complexes as ethylenediaminetetraacetic acid and cyclohex-1,2-ylenebis-(iminodiacetic acid), the first problem could be considered to be practically solved, but the second is still far from solution.

Ethylenediaminetetraacetic acid appears to be an ideal structural example of a multidentate reagent in its effectiveness in coordinating metal ions. Attempts to make some kind of change in the structure of EDTA which would be expected to increase its complexing power appreciably have, in the main, not given good results; in some cases they showed an effect with only certain groups of elements. Replacement of some acetic acid residues by propionic acid, or of the ethylene bridge joining the two nitrogen atoms by trimethylene, that is, increasing some of the five-membered chelate rings in the EDTA complexes to six-membered rings, reduces the stability of the complexes, although it would seem that this modification of the EDTA molecule should lead to a considerable reduction in the strain which is observed in condensed chelate rings of a complex, particularly in the $-N-(CH_2)_2-N$ plane, and also to stabilisation of the complexes. The behaviour of the oxygen atom of the phosphonic acid group as a ligand atom in ethylenediamine- and 1,2-diaminecyclohexane-tetraacetic acid was also studied. It was found that complexes of completely phosphorylated analogues are more selective, but in many instances less stable than the corresponding carboxyl compounds. This appears to be connected with insufficient use of the complexing atoms of the ligand carrying two negative charges, because of the great expenditure of energy when charged particles approach at the time of coordination. Complexes of beryllium, germanium, and copper, which are highly stable, are exceptions.

Closing of the alicyclic ring in CHDTA, which reduced the free rotation of the amino-group in the ligand and formed an additional ring in the structure, led to an increase in the stability of practically all chelates by 2–3 $pK$ units. Combination in the complexone of two types of grouping on the nitrogen — *NN'*-bisphosphonomethylethylenebis(aminoacetic acid) — increased the stability only of the complexes with certain cations.

In going from EDTA to DTPA, with its greater denticity, there is an increase in affinity for highly charged (3+, 4+) metal ions, while the stability of the complexes with Ca and Mg remains practically unchanged. Further increase in the denticity by introduction of additional iminoacetate groups (TTHA and TPHA) into the molecule leads to stabilisation of complexes formed with cations with the maximal coordination number (rare-earth elements, Th). The special structure of the complex molecule achieved by the introduction of heteroatoms and functional groups, by changing the distance between the iminodiacetate groups, and also between nitrogen and the carboxyl groups, by replacement of the carboxymethyl group by hydroxyethyl and phosphonomethyl groups, or by increasing the electron density of the whole system and destroying the electron density of individual links, as has been shown above, leads to the development of selective complexing agents, but not always to an increase in stability of the complexes formed.

The examples given above thus confirm that in most cases modification of the EDTA molecule leads to some specific activity and only sometimes to a slight increase in the stability of the complexes formed. In this connection, it is desirable that further work on the synthesis and application of complexones should deal with selectivisation linked to both a deeper study of compounds already described in the literature and to the development of complexones and complexing indicators with a specific action.

High selectivity in chelate formation, especially in the case of multidentate reagents is achieved rarely in practice and then only with comparative difficulty. However, the great amount of material in the literature on this subject enables syntheses of complexones with definite properties to be postulated.

According to Schwarzenbach, suitable selectivity of the complex can only be achieved by a special structure of the multidentate ion, account being taken of the maximal geometrical relationship of the internal ligand contour and of the cation. However, such a relationship, besides increasing the stability of chelates with a group of related ions, will hardly increase the selectivity because of the tendency of the ligand to take up a number of conformations and to become deformed to adapt itself to the requirements of other ions. Moreover, the geometric conditions of complex formation for one metal and a given chelate ligand may be close to the conditions for a number of other cations and the same ligand; as a result, the stability of complexes with elements of closely related physical and chemical properties is simply increased. Another way of achieving selectivity is much more promising; this consists in the development of multidentate reagents with the minimum permissible geometric correspondence for a given cation and complete lack of correspondence to the requirements of all other cations [161-163]. This type of variant may be brought about by increasing the rigidity of the system, by limiting free rotation of individual links by steric hindrance, and, finally, by the creation of unusual geometric arrangements of donor atoms with disturbed electron density, achieved by including a weak electron-donor group in the multidentate chelate system. This leads to spatial distortion of the ligand field and to selective action in the reagent. In the creation of model compounds of this type, account must be taken of the

geometric structure of the reagent and chelate molecules, the magnitude of the valency angles and interatomic distances, the change in these parameters under the influence of substituents and other factors, the limits of these changes, the primary coordination of the metal atom, possible distortion of this coordination, the nature of the chemical bond, steric factors, and intramolecular and intermolecular interactions. Besides, in the synthesis of complexones with selectively acting groups, it is desirable to take account of the mobility of the second ligand with regard to the size of the metal ion, so that the distance between the combining atoms corresponds to this volume; this kind of calculation of steric stabilisation increases the selective effect and the stability of the complex. From this point of view complexones would be of great interest if they were capable of reacting with elements of small atomic radius (Be, B, Ti, Ge, Nb, Ta, V, Cr) and high charge, with the rare-earth elements, and also with As, Sb, Sn, Mo, and with anions. Since Be, B, Ti, Ge, and other ions virtually do not coordinate with nitrogen, and the carboxyl groups of the complexones are apparently too voluminous for small cations, complexes of the polyphosphonic or polyarsonic acid type with partial replacement of the acetate groups by amino- and sulpho-groups, and also polyphenols of the pyrocatechol type, or derivatives of 1,8-dihydroxynaphthalene, would be interesting.

For elements that form thio-salts, that is, Sb, As, Sn, Mo, W, and for some platinum metals definite success would be expected from complexones containing mercapto--group sulphur as ligands, which coordinate selectively with these elements. In our opinion, further investigations into the synthesis and detailed study of complexones containing the heteroatoms O, N, S, Se, P, and As appear promising. Investigation of the complexing power of these compounds over a wide pH range, and also in organic solvents, will permit elucidation of the function of these elements in complexones. Moreover, the different nature of the coordinating ligands will increase the stability of these compounds. The preparation of complexones containing arsino- or phosphino-diacetic acids is of undoubted practical and theoretical interest. Since As and P have stronger donor properties than nitrogen, because of the formation of double bonds with metals containing *d* electrons that do not participate in hybrid bond formation, the new complexones will probably form stable complexes with metals of Groups VIII and IB of the Periodic System.

In conclusion, we shall note that the development of complexes capable of binding anions is of great importance. According to Schwarzenbach[4], for this purpose, instead of the nucleophilic atoms, N, O, and S, it would be necessary to introduce electrophilic groups into the molecule; these groups should be capable of coordinating with negatively charged ions. The mercury atom is an electrophilic atom which might be fixed on the framework of the molecule. These compounds would bind halide and other ions.

Studies in the field of the kinetics and mechanism of interaction of complex molecules consisting of different complexing agents and cations would be of undoubted theoretical and practical interest. These complicated systems could potentially form bimetallic and mixed complexes with fundamentally new properties. Moreover, the elucidation of the relative effects of different factors on the kinetics and mechanism of interaction will permit the deliberate direction of reactions and create the necessary conditions for the determination and separation of different cations.

# THE "COAL–METHANE" NATURAL EQUILIBRIUM SYSTEM AND METHODS FOR STUDYING IT

I. L. Ettinger

CONTENTS

1. Methane–coal deposits 496
2. Methods of studying the "coal–gas" natural system 498
3. Coal as a component of the "coal–gas" system 498
4. Gas as a component of the "coal–gas" system 501

## 1. METHANE–COAL DEPOSITS

Deposits of ordinary coal and lignite constitute a gas-producing region of the Earth's crust which is unique and of great practical importance.

The principal components of the gases of coal seams are carbon dioxide, nitrogen, and methane. The appearance of carbon dioxide in coal seams is linked with the oxidation of the coal by oxygen, the metamorphism of the rocks, the migration of the products of the activity of living creatures in the soil layer, and the migration of atmospheric carbon dioxide. The nitrogen has only an atmospheric origin, and the methane is a product of the metamorphism of coal.

The gas phase is not in a quiescent state in the depths of the coalfields: the gases from the metamorphism of coal and rocks move upwards the terrestrial surface, and the gases of atmospheric origin and from biochemical processes move in the opposite direction. The existence of

two steady flows leads to the establishment of dynamic equilibrium between them. Individual gaseous zones will separate out[1] in stable equilibrium in the coal seams and some or others of the components will predominate: a nitrogen–carbon dioxide zone; a zone of nitrogenous gases; a nitrogen–methane zone; and a zone of methane gases.

The present gas-bearing capacity of the coal seams depends on the local geological conditions as well as on the gas-dynamical processes; these conditions include the different coals in the bed and the degree of subsidence of the seams, the presence in them of geological disturbances and outcrops, differences in the gas permeability of the coals and rocks, the action of the infiltrating waters, etc.; all this can assist or impede the migration of coal gases to the day surface.

During the formation of ordinary coal of an average degree of metamorphism, approximately one-quarter of the total organic mass is converted into methane. In the further conversion of the coal into anthracite, another 10% of its total mass is transferred to the gas phase[2].

However, in contemporary coal seams this quantity of methane is not observed. Mining workers find that the methane which is now encountered in coal seams is only about 1 wt.% of the coal mass[2].

The solubility of methane is low; consequently the infiltration water carries very little methane with it. There has been hardly any chemical reaction of the methane with the rocks in the lithosphere, since at the temperatures at which coal formation takes place methane is inert and does not react with either acid or with basic rocks.

For methane, there is only one path for leaving the coal seam — diffusion into the atmosphere; however, if the quantity of methane evolved throughout the whole time of existence of the coal deposits is calculated and the stocks of methane remaining bound with the coal are subtracted, then it appears that 0.02–0.03% of the atmosphere should consist of methane, even without taking into account possible sources of methane other than coal formation (volcanoes, natural gases, petroleum wells, surface decay of plants, etc.). Nevertheless, methane is not detected in the atmosphere in any appreciable amounts.

The most probable hypothesis concerns the oxidation of the methane in those layers of the gaseous envelope of the Earth's crust where there is an appreciable amount of ozone and also in lightning discharges, in which the methane is oxidised to carbon dioxide, by-passing the stages of formaldehyde and carbon monoxide.

However, the quantity of methane which saturates the coal seams in their present condition is so great that the coal deposits can be considered as methane–coal deposits. The methane of the coal seams is often considered only as a hazard in coal mining, but then natural gases should also be considered only as secondary fossil fuel, the exploitation of which is a sideline in petroleum engineering.

The volume of gas liberated from coal in coal mines increases each year; the maximal methane liberation is already approaching 100 $m^3$ (in some instances 300 $m^3$) per tonne of coal mined; the total calorific value of this gas equals 15% or more of that of the coal[3,4]. Therefore in calculating reserves and appraising coal deposits it is necessary to consider them as complex deposits of solid and gaseous fuel and accordingly plan the complex working of both fossil fuels. A coal mine now becomes a producer of not only coal but also the more valuable (in calorific value and convenience of use) fuel — firedamp, the energy of which has until now been lost in flushing it out by a ventilation stream.

TABLE 1. Quantity of methane released from all the mines of a country, $10^6$ $m^3$ $d^{-1}$.

| | | | |
|---|---|---|---|
| USA | 11.0 | Japan | 2.8 |
| Federal Republic of Germany | 8.5 | Belgium | 2.6 |
| | | Czechoslovakia | 1.2 |
| England | 8.0 | Poland | 1.0 |
| USSR | 7.0 | Netherlands | 0.4 |
| France | 3.0 | | |

The reserves of methane in coal seams of industrial importance (on conversion into conventional fuel) occupy the second place (after coal) among fuel sources and are seven times greater than the investigated reserves of natural gas[4].

The firedamp released each year in English coal mines is equivalent to $23 \times 10^8$ kcal, or $13 \times 10^6$ tonnes of good-quality coal[2].

Lidin and Airuni's table (Table 1), which relates to the beginning of 1962, gives an idea of the quantity of methane liberated in the main coal-mining countries in the working of coal deposits.

With the liberation (as subsidiary to coal mining) of such large quantities of methane ($2.5 \times 10^9$ $m^3$ $a^{-1}$ for the USSR) it is impossible to evade the question of the use of this gas in the national economy.

Of course, not all the methane of coal deposits can be used, in view of its low concentration in the ventilation stream, but in the artificial harnessing of the methane, which in ever-increasing degree is being developed here and abroad, firedamp is used as illuminating gas, an industrial and motor fuel, and a chemical raw material.

In the USSR it is planned[3] to increase the recovery of firedamp from $250 \times 10^6$ $m^3$ in 1961 to $1 \times 10^9$ $m^3$ $a^{-1}$ for 1965.

The problem of the recovery of metamorphic methane from coal has, apart from the increase in energy reserves, also another, no less important, side. Because of the explosiveness of oxygen–methane mixtures, firedamp has always threatened the lives of miners, who have considered it their chief enemy and obstacle in work.

In the contemporary development of seams of the most valuable coking coals the depth of mining operations is rapidly increasing and in addition the quantity of gas which is liberated with each tonne of coal mined is also increasing.

In the USSR, up to 1 January 1960 84% of all the coal mined was worked by underground operations and in that over 66% of all pits were gas-bearing, and 30% belonged to the supercategory, that is, to those in which more than 15 $m^3$ gas per tonne of coal mined were liberated in separate regions[5].

Creating safe conditions of work for miners and increasing the profitability of coal deposits are the two sides of the same question, which boils down to how to make coal a competitive source of energy in comparison with natural gas, petroleum, water power, and nuclear energy.

For a scientific and practical solution of these problems, a detailed and thorough study of the natural equilibrium of the "coal–methane" system which exists in most of coal seams being worked is necessary.

## 2. METHODS OF STUDYING THE "COAL–GAS" NATURAL SYSTEM

Study of the structure of coal was started in the 1830's and undertaken by the methods of "classical" chemistry, which achieved much in the study of the chemical nature and composition of the fossil coals and also in establishing the chemistry of the processes in various stages of coal formation. These methods seemed useless when the investigation came to hypotheses about the fine structure and the constitution of the surface of coal, a study of which is necessary for the modern technology of its mining and utilisation.

Over the last 15–20 years a coal science has been formulated[6,7] which united chemico-analytical methods of studying coal with the modern approaches of exact sciences. Both in the USSR and abroad, extensive geological, petrographic, physical, chemical, mechanical, and physicochemical investigations of coal as a source of energy, a metallurgical and chemical raw material, and a medium in which people have to work underground, have been carried out.

An attempt can be made now to present a general picture of the methods for studying fossil coals and to show the utility of each method of investigation. Like every classification of natural phenomena and the sciences of studying them, this scheme has a great element of complexity.

In the geology of coal deposits, by *coal* is meant a solid, combustible, sedimentary rock of plant origin, containing mineral impurities[8].

In the petrology of coal the unit being studied is the coal seam, determinable as a compact stratification, consisting of coal blocks, different in the degree of the chemical modification of the vegetable residues, and also of mineral inclusions and intercalations[9].

In coal petrography, the principal method of investigation of which is optical microscopy, coal is seen as a heterogeneous substance consisting of various petrographic components, which differ from one another in colour, physicomechanical and optical properties, and degree of retention of the plant structure[10].

Physicochemical methods of investigation increase the resolution by three orders of magnitude in comparison with optical microscopy, that is, to $10^{-7}$ cm; they permit the state and area of the surface of fossil coals, their porous structure, and the size distribution of the pores to be studied.

From the viewpoint of the physical chemistry of fossil coals, coal is a highly porous natural sorbent.

Colloidal investigations of coal do not increase the resolution in the study of structure but give a new approach to ideas about coals. In the initial stages of coal formation the coal substance is a heterogeneous, highly disperse system, which consists of the products of conversion of the plant residues, dispersed in water, and possessing aggregate stability.

Such a system can arise by two paths: (1) by dispersion of a coarsely dispersed multi-phase system, or (2) from a single-phase system, by enlargement of the molecules and their aggregates. Both these methods of formation of colloidal systems took place at the time of the peat and lignite stages of coal formation[11].

Ordinary coals are also colloids of the second type, that is, high-molecular-weight systems in which both the disperse phase and the dispersion medium are in the solid state[12].

In the metamorphism of such solid systems there occur the stages of swelling, dispersion, formation of colloidal systems, their aging, and breakdown.

The heterogeneous nature of coal-chemical reactions in which natural coals participate, the non-uniform participation in these reactions of different reactive groups of coals[13] leads to ideas about their macromolecular structure; coal appears to be a three-dimensional polymer in which plane polycyclic networks of atoms of aromatic carbon are linked to one another by side-chains (phenol, hydroxyl, quinone ether, etc. side-chains)[14,15].

Physical methods penetrate deepest of all into the structure of coal. Studies by X-ray diffraction gives information about the dimensions of the polycyclic elements of the macromolecules. Infrared spectroscopy determines the different forms of C–H bonds and the quantitative relation between aromatic and aliphatic compounds.

Thanks to the use of physical methods it has been shown that during metamorphism the coal substance is converted into carboid, in which the plane polycyclic networks of carbon atoms are turned round, tending to be arranged in small piles; some of the electrons of the carbon atoms thereby enter into the space between the atomic layers and bring about an increase in the electrical and thermal conductivities[11].

The eight listed main approaches to coal are different in terminology and methods of investigation, degree of penetration in the structure of coal and possible practical use of their concepts for studying the nature of the "coal–gas" natural system.

The conditions of agglomeration in which the coal deposits were created determine the quantity of gas retained in the seams; the presence of various petrographic micro-components of coals gives the different sorption capacities of coals with the same degree of metamorphism; the mechanical and geological properties of the coal colloids are linked with the different degree of gas-saturation of the coal; the quantitative relation between cyclic condensed nuclei and aliphatic side groups is determined by the degree of natural activity of coals as sorbents; the degree of ordering of the graphite lattice leads to the disappearance of the sorption properties in fossil coals, etc.

The study of the "coal–gas" system is based mainly on physicochemical investigations, but it is unthinkable without geology, petrology, and petrography, colloid science, and coal chemistry and physics.

## 3. COAL AS A COMPONENT OF THE "COAL–GAS" SYSTEM

The properties of coal as a highly porous sorbent are determined by the range of structural sizes, which differ by at least five orders of magnitude (from $10^{-3}$ to $10^{-8}$ cm).

To discriminate between such a large number of structural elements it is necessary to classify coal structures according to their nature and dimensions.

In coal it is possible to distinguish: (1) a molecular structure, determining the chemical nature and reactivity

of the coal, and (2) a disperse (colloidal) structure determining the behaviour of coal in non-chemical processes.

It is possible to discriminate between the rather complex molecular structure of coal only if the classification is continued further and the molecular structure is divided into two, which can be studied by different methods: (a) low-molecular, and (b) polymeric or macromolecular structure.

These three principal structures of coal (molecular, macromolecular, and colloidal) mainly determine its behaviour on reaction with gases.

On the one hand these border on coarser dispersoids (petrographic components and plant residues), and on the other, atomic structures.

(a) Molecular Structure of Coal.

The molecular structure of fossil coals is characterised by the carbon atoms being situated at the vertices of regular hexagons [16]. The carbon skeleton is based on hexagonal systems of cyclic construction, the different orientation of which determines the character of the molecular structure of the coals.

In the metamorphism of mineral coals there is a carbonisation of the substance, that is, an increase in the carbon content relative to the oxygen and hydrogen and also to the "secondary" elements (nitrogen, sulphur, etc.).

However, X-ray investigations of coals destroyed the conception of them as a molecularly homogeneous system in which on moving along the metamorphic series there is only an increase in the number of identical bricks. The coal substance appeared heteromolecular.

The X-ray investigations revealed two types of molecular structures in fossil coals: disordered, which cause general scattering of the X-rays, and more ordered, which cause their diffraction in a definite direction [17].

The more ordered parts of the structure are layers of hexagons; the number of condensed rings in such two--dimensional lattice is from four to ten [6]; with metamorphism, the diameter of these plates of hexagonal-cyclic structure increases from 7 to 16 Å; most of them are orientated at random with respect to one another and do not form a regular graphitic three-dimensional lattice; the maximal number of regularly orientated layers varies from three to ten for coals having an equal stage of metamorphism [18]. The diffraction of X-rays by coals varies for the coals in a metamorphic series (Fig. 1) and differs significantly from the diffraction which is characteristic for graphite [7,19].

Hence there are no graphitic crystals in coals, but only those elements from which the crystals can be formed under appropriate conditions of temperature and pressure. These rudiments of future crystalline structures (crystallites) are the nuclei of the molecular structure of the coal substance.

The framework of graphite-like crystallites is connected together by side groups — unique bridges. These side groups are the most disordered part of the molecular structure, which bring about the general scattering of X-rays. The side radicals of aliphatic structure can contain (in addition to carbon) hydrogen and oxygen, and even sulphur, nitrogen, and other elements. The destructive breakdown of coal when heated in the absence of air leads first to the detachment of unstable side groups; the rest are consolidated into coarse aggregates with an increase in the carbon content and a decrease in the yield of volatile products.

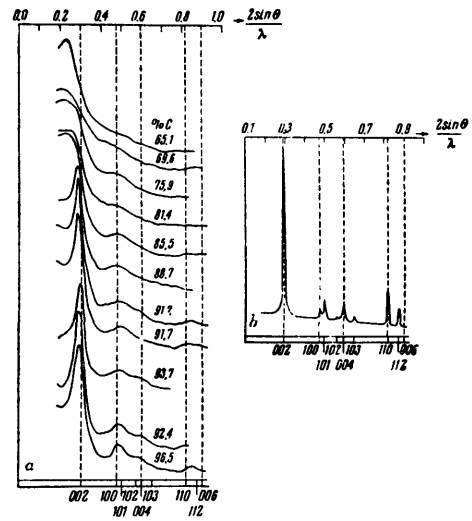

Fig. 1. Photometric trace of X-ray diagrams of: *a*) coal; *b*) graphite.

The nuclei of the polycyclic layers and the side aliphatic groups which connect the nuclei, together form the primary molecular structure of the coal. Hirsch [18] proposed a similar structural model of coal.

The mechanism of the formation of gases from the coal substance, which take place in the bowels of the Earth's crust, is connected with the detachment of the side groups. Gas formation is brought about by homolytic reactions, which proceed in the weakest parts of the molecular structure, that is, at the points of attachment of the side groups to the hexagonal graphite-like layers.

Whereas 82.6 kcal mole$^{-1}$ is required for the rupture of the bond between the carbon atoms in the $C_2H_6$ molecule, only 10–12 kcal mole$^{-1}$ is needed to break a bond between carbon atoms where each is connected with three aromatic rings.

(b) Macromolecular Structure of Coals

In many respects coal is reminiscent of artificial polycondensed resins. The physical and chemical properties of coals are not constant, but change within definite limits; coals are involatile and do not have definite melting or freezing points; the solubility of coals varies with the amount of solvent and the duration of heating, in that coals swell in solvents; vitrification is observed instead of crystallisation in coals; coals are subject to slow plastic deformation and this is highly sensitive to temperature; in the plastic state coals exhibit high viscosity.

In the process of metamorphism fossil coals are subject to polymerisation, which leads to the creation for them of a special amorphous state with a dual nature to the molecular structure, which consists of crystallites and amorphous parts.

Intramolecular reactions (dehydration, decarboxylation, etc.) are characteristic only for the lignite stages of coal

formation; the main processes in the metamorphism of ordinary coals are intermolecular condensations, that is, a growth of the molecule of the coal substance, with an increase in the carbon content from 75 to 95%. For such reactions to take place a definite activation temperature and intermolecular contact are necessary, the latter being achieved in the coal seams owing to the pressure of the overlying rocks.

In the metamorphism of ordinary coals, the polymerisation of their molecular structure proceeds mainly by detachment of side chains; condensed polycyclic layers approach within ~ 3.5 Å in this process; the coal substance acquires the property of a carboid with a characteristic black colour, and electrical and thermal conductivity; starting from the coking coals stage aromatic properties gradually disappear, since the coals are neither nitrated nor sulphonated, that is, they do not give the reactions typical of aromatic compounds [11].

In the detachment of side groups, chemical valencies are left at the place of their removal unsaturated; this facilitates the condensation of the molecular structure.

The primary molecular structure, consisting of nuclei and side groups, forms particles, which serve as elements of a second-order structure [20]. During this, gigantic macromolecules, polymeric in nature, are formed in the coal substance. In the macromolecules of coals, close-range order is observed only within the limits of each crystallite in the form of a two-dimensional lattice. Beyond the limits of the crystallites this order does not exist. The crystallites — small orientated fragments — fasten the coal polymers, like hoops, and make the whole system stable (Fig. 2). Each crystallite is turned somewhat relative to the next, the direction of the rotations being purely random [21].

Natural coals belong to a group of solid polymers whose importance in biology and technology is very great (rubber, cellulose, albumins, plastics, etc.). In solid polymers up to 60% of the material is in an amorphous state, whereas in low-molecular-weight substances the amorphous phase disappears completely during crystallisation [22].

In low-molecular-weight substances crystallisation sharply changes their structure and thermodynamic properties; this is because the whole amorphous mass is reconstructed into crystals with sharp surfaces of separation. In polymers, however, like natural coals, the ordered and disordered parts of the structure are indivisible; the crystallites contain only a small number of atoms, sufficient to diffract X-rays but insufficient to change the thermodynamic properties of the substance.

At the end of the last century, coal chemists made many attempts to devise structural-chemical hypotheses about the macromolecules of ordinary coals and lignites and represent them by formulae [23], but not one of these attempts led to the creation of a generally acceptable model. This is explained by the difficulties of reaching agreement between the concepts of organic chemistry and the results of the physical investigation. Kasatochkin's model [19] gave the most successful representation of the dual nature of the coal macromolecules (Fig. 3).

Van Krevelen's model [7] was devised on the basis of investigations of the optical and mechanical properties and the elemental composition of coals. In this model, which is based on the concepts of organic chemistry, cells of the cyclic parts of the structure are isolated. Such parts are not precisely the same as one another — as is observed in linear polymers with regular repetition of the monomer unit [24]. The value of the model lies in the concept of the existence of "nuclei" and side chains in the macromolecules of the coal substance.

The molecular weight of the macromolecules of the polymers varies within very wide limits — from $10^3$ to $10^6$. Other authors usually give lower values for the macromolecules of the coal substance. On the basis of his statistical structural analysis of coals, van Krevelen considers [24] that as the carbon content rises from 81.5 to 96.0%, the number of rings in the ordered layers increases from four to ten, and the molecular weight rises from $0.5 \times 10^3$ to $1.25 \times 10^3$.

Whitaker [25] in determining the molecular weight by an osmometric method obtained values of $9 \times 10^3$–$12 \times 10^3$ for the products of the thermal dissolution of coals in ethylenediamine.

Probably the most correct ideas [26] are that coal exists as a monolithic aggregate system and has an infinite molecular weight, like a crystal of indefinite size.

### (c) Colloidal Structure of Coal

The colloidal (disperse) structure of the coal substance is coarser than the atomic, molecular, and macromole-

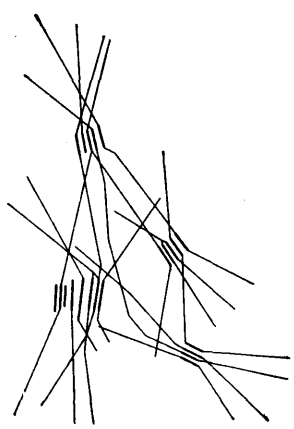

Fig. 2. Macromolecules of a polymeric character (after P. P. Kobeko).

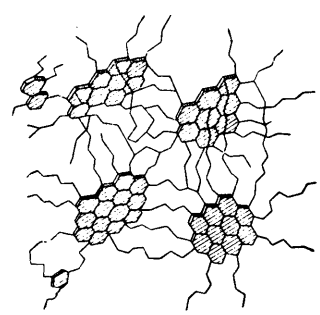

Fig. 3. Macromolecules of coal (after V. I. Kasatochkin).

cular structures. Even at the peat bog stage the aggregates of particles of humus and sapropelite materials acquire such large dimensions that they begin to show colloidal properties.

A complex colloidal structure is superimposed on the molecular structure of the coal substance, distorts its properties, and gives the coal a special quality which determines its behaviour as a component of the "coal–gas" system. The colloidal properties for different coals can differ markedly from one another, even when there is a very great similarity in their molecular composition [20]. The colloidal structure of the coal substance relates to particles with dimensions of $10^{-5}$ to $10^{-7}$ cm, pores and capillaries, with their associated capillary forces, inhomogeneous parts of the surface (where surface forces play the principal part), etc.

Coal colloids occupy a special position, since they can be assigned to both the main types of colloid: disperse heterogeneous systems and high-molecular-weight systems, which are formed by an increase in the size of the macromolecule or the formation of polymers. This explains why during the course of the long process of coal formation the structure and properties of the coal colloids changed sharply.

In the first stage, which can be considered to be mainly biochemical, the plant residues become peat at the bottom of the bog; during this, colloidal hydrosols (that is, disperse heterogeneous systems of the first type) were formed.

Then the hydrosols lost their aggregate stability and conglomeration of the colloidal particles began. The hydrosols were converted into hydrogels — a reticular three-dimensional structure of rigid colloidal particles and capillaries filled with water (peats and earthy lignites). Such gels occupy a position intermediate between liquid colloids and solid polymers.

In the second stage of coal formation (geochemical) the elastic gels were converted into solid polymers owing to the increase in size of the macromolecules of the coal substance (second type of colloidal systems).

In the early stages of coal formation water is the disperse medium; in subsequent stages it was mechanically absorbed by the cells of the hydrogel; in the metamorphic stages of ordinary coals water in the free state almost disappears. The remaining water is held either by close-acting adsorption forces or exists in ordinary coals as a thin film of liquid water, held by adhesion forces. In such a state the water has already lost the properties of a solvent or a dispersion medium.

In further metamorphism, which is accompanied by further loss of water and compaction of the molecular structure, particles of the second order (macromolecules) form still coarser aggregates — elements of a disperse structure of the third order. The coal is converted into a three-dimensional solid polymer. The colloidal properties of such a polymer are already determined not so much by the particle sizes as by the presence of a large boundary with a considerable free surface energy.

The compaction of the molecular structure of coals is accompanied by the detachment of side groups; during this, vacancies are formed in the molecular structure of the coal substance. The forces of molecular attraction tend to compress these vacancies and bring about shrinkage of the coal [20]. However, coals, being three-dimensional polymers with partly ordered packets of a two-dimensional crystalline lattice, are characterised by low elastic limits and rather large moduli of elasticity (up to $15 \times 10^{10}$ dyn $cm^{-2}$). [2] Therefore the coal substance resists compression and the vacancies in it are retained to a considerable degree. This is assisted by the vacancies containing gases formed in the detachment of side groups, conditions being such that migration from the seam is prevented. Ultraporosity appears in the coals, which determines the high sorption activity of the fossil coals and creates a real basis for the prolonged existence in the coal seams of a "coal–gas" system.

Pores in coals are often considered as vacancies, the walls of which serve as the usual phase boundaries, but the surface of the ultrapores, thanks to their small size, is at the limit of disappearance of the phase and does not possess the features of a microscopic surface [20,22]. Calculation of the internal surface of the pores from the sorption by coals of gases which are condensed on phase surfaces is uncertain because of the above reasons.

Usually, in speaking of the colloidal structure of coals the term "micelle" is employed to denote the colloidal particles. The term "micelle of coal substance" has a double meaning.

In a state of colloidal hydrosol a coal micelle, as in the case of all other sols, consists of a central nucleus of a solid substance and, surrounding the nucleus, an electrical double layer of solvated ions; the first layer of stabilising ions is adsorbed on the surface of the central nucleus. The system as a whole is electrically neutral.

A second concept of the micelle of coal is more frequently encountered: this relates to its state in the form of a solid three-dimensional polymer. In this concept the micelle of coal substance should represent a complex of macromolecules, that is, a structural unit of the third order in relation to the molecules and macromolecules. This is colloidal particle ($10^{-5}$–$10^{-7}$ cm) with a phase boundary and a partly ordered structure (crystallites or nuclei of macromolecules). The chain of separate macromolecules forms a more or less spherical micelle, either by the bending of macromolecules and their accumulation in the form of bundles, bound by cross-linking or by radial packing of the macromolecules with later formation of cross-links between them [12].

From determinations of the heats of wetting of coals in methanol, Bangham and coworkers [27] found the internal surface of coals to be 20–200 $m^2 g^{-1}$ and calculated from this the following micelle diameters: 230 Å for gas coals and 2500 Å for coking coals.

The colloidal properties of the solid polymer appear particularly distinctly in what is petrographically the most homogeneous component of coal — vitrain. The parent substance of vitrain is a hydrogel of peat seams, which owing to syneresis has lost part of its water, hardened, and become non-elastic.

## 4. GAS AS A COMPONENT OF THE "COAL–GAS" SYSTEM

The role of the gaseous component of the "coal–gas" system existing in coal seams is determined by its origin, by the qualitative and quantitative composition of the gas mixture saturating the seam and the forces which bind the gas to the coal.

The gases which are formed at the various stages of carbonisation almost completely leave the coal seams,

migrating by various paths to the surface. Coverings packed by subsequent rock beds hinder the migration of gases and create conditions for their accumulation; the comparatively short (from a geological viewpoint) interval of time was insufficient for the coal seams to give off the gases which were formed in the later stages of regional metamorphism and originated in tectonic processes [24,25].

Different geological conditions in the coal seams and geochemical processes accompanying the metamorphism of coals lead to different gas contents in the seams, gas compositions, and zonalities in their vertical distributions. The processes of intraseam migration of gases do not obliterate the non-uniformity in their distribution in the seam, which is associated with the genesis of the gases [28,29]. Coal deposits have a gas zonality (Fig. 4) in which the zone boundaries vary for different deposits and even for different parts of the same deposit.

Ideas about the zonal distribution of the gases in coal allow the main components of the coal seam gases and their proportion in the various zones to be distinguished and show how these ratios vary in different seams and at different depths.

For small deposits, attempts have been made to speak of the mean composition of the gas which saturates the coal seams within the scale of the deposit concerned; with all their tentativeness, such data give some illustration of which gases are held in the seams in their present state and within what concentration limits.

For example, Coppens [30], from analyses of 50 specimens of gas, from 63 Belgian pits, sampled in the zone of methane gases found the compositions of the gases of the Belgian deposits given in Table 2.

Below the zone of gas ventilation the main component of the coal seam gases is methane.

The problem of the origin of carbon dioxide cannot be considered solved. According to Graham [31], gas formation in the carbonisation of plant residues proceeds through the following stages: initially, when the carbon concentration is rising from 65 to 79%, predominantly $CO_2$ is liberated; during the subsequent rise in the carbon concentration from 79 to 85.8%, $CO_2$, $H_2O$, and $CH_4$ are liberated, the volume of the $CO_2$ being twice that of the methane; during the increase in carbon concentration to 88%, the amount of $CH_4$ formed increases; and at 92.3% carbon, methane is already the principal product; above 92.3%, only methane is liberated.

The experiments of Bergius [32] on the artificial carbonisation of peat are indirect confirmation of the predominant

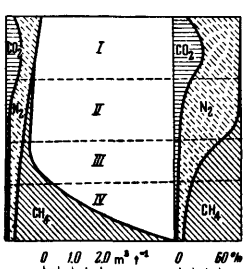

Fig. 4. Gas zonality of coal deposits (after G. D. Lidin).

TABLE 2. Composition of the gases of the Belgian coal seams.

| | $CH_4$ | $C_2H_6$ (+ higher hydrocarbons) | $H_2$ | $CO_2$ | $N_2$(+Ar) | He(+Ne) |
|---|---|---|---|---|---|---|
| Minimal content | 92.9 | 0.02 | 0.000 | 0.03 | 0.0 | 0.001 |
| Maximal content | 99.6 | 2.79 | 0.235 | 3.38 | 6.1 | 0.330 |
| Mean content | 97.3 | 0.47 | 0.044 | 0.74 | 1.5 | 0.044 |

formation of $CO_2$ in the various stages of carbonisation. During the heating of dry peat, Bergius obtained so-called "lignite" containing 75.4% C. In heating 10 g peat, 1110 ml gas containing $CO_2$ 88.1, $CH_4$ 8.4, $H_2$ 2.2%, etc. was evolved. In further experiments on the carbonisation of this "lignite" at pressures up to 6000 atm, Bergius obtained a product with 89% C; the gas liberated contained $CH_4$ 70–80, $CO_2$ 8–11%.

The carbon dioxide formed in the various stages of carbonisation left the coal seams by escaping into the atmosphere, disolving in the seam waters, and reacting with the containing rocks, forming carbonates.

The carbon dioxide which is contained in the coal seams of today has various but different origins: (1) juvenile carbon dioxide (frequently of volcanic origin) penetrates into the coal seams from sources situated below them [24,32]; (2) carbon dioxide which is the final product of deep oxidation of coals, to which lignites are particularly susceptible, which explains, for example, the high concentration of $CO_2$ in the sub-Moscow basin [33].

Hence for contemporary coal seams $CH_4$ is an endogenic gaseous component and $CO_2$ an exogenic.

Ideas about the local penetration of higher hydrocarbons — homologues of methane — into coal seams from petroleum deposits or petroleum-formed substances are still unproved. Other suggestions about the formation of higher hydrocarbons together with methane in the metamorphism of coal and their loss during subsequent natural degassing of the seam are more probable.

The amounts of methane formed throughout the carbonisation process significantly increase the quantities of gas which are now observed in the coal seams. According to Lidin [1], the amount of methane formed during the change from lignite to long-flame coal reaches 30–40 $m^3\ t^{-1}$, that to fat coals 70–80, to lean coals 120–150, and to semi-anthracite up to 200 $m^3\ t^{-1}$. Patteisky [34] considers that these quantities are higher (300–350 $m^3\ t^{-1}$ on conversion into fatty coals) and Vidal [35] gives figures of up to 1300 $m^3\ t^{-1}$ (for anthracites).

In the peat stage of coal formation, when the coal macromolecules originated and the hydrosols were formed, conditions did not yet exist for the creation of an equilibrium system with gaseous components; the gases being liberated in the coal formation reactions escaped.

In subsequent stages, when the hydrosols were converted into hydrogels, which were then subjected to syneresis and lost water, cavities of various dimensions were formed in them. A porous structure was created in the coals; this structure was qualitatively and quantitatively modified both during the conversion of peat into lignite and during the conversion of lignite into ordinary coal.

In the porous structure of fossil coals there appeared forces bonding the coal with the gas which made possible the creation and retention up to the present of the natural equilibrium of the "gas–coal" system. The valence bonds between the carbon atoms in the hexagonal-cyclic parts of the coal macromolecule are characterised by close action and large bonding forces ($\sim 10^2$ kcal mole$^{-1}$); the forces bonding the cyclic part of the molecules with the side chains have an energy an order of magnitude less ($10^1$ kcal mole$^{-1}$); the van der Waals forces which bond the coal substance with the gases have a bond energy again a whole order of magnitude less ($10^0$ kcal mole$^{-1}$), but are characterised by a comparatively large sphere of influence, non-specificivity, and additivity.

The van der Waals forces, which determine the sorption capacity of fossil coals with respect to gases, begin to appear noticeably when water is lost from the coals during metamorphism and side-groups are removed, which screened the sorption surface of the coal.

Hence, as a result of the physical and physicochemical processes taking place throughout the genesis, diagenesis, and metamorphism of coals, there was created in them the specific structure which conferred on the coals the properties of active natural sorbents and was the prerequisite for setting up the "gas–coal" natural system.

A thorough study of such a system has great significance for theoretical and practical problems in not only the mining, but also the utilisation of coals, since in many instances one should now speak not of coal, but of methane–coal deposits.

Study of the "gas–coal" system includes a series of problems, the most important of which are: study of the form of the bond of the coal with the absorbed gases, the sorption and collector properties of coal, the physical and physicochemical conditions of equilibrium of the system at various depths and in different geological circumstances, the conditions of the shift in the equilibrium in the system during changes in pressure, temperature, mechanical influences, etc.

# SYNTHESES INVOLVING REACTIONS OF PEROXIDE COMPOUNDS WITH SALTS OF TRANSITION METALS IN SOLUTION

L. S. Boguslavskaya

CONTENTS

1. The $H_2O_2$–$Fe^{2+}$ system (Fenton's reagent) 504

2. Systems comprising alicyclic hydroperoxides and metal salts 507

3. Systems comprising acyclic peroxides and metal salts 510

4. Ionic reactions of peroxides under the influence of Lewis acids 512

Oxidation–reduction systems comprising peroxides and salts of metals of variable valency are well known as vinylic polymerisation initiators and are widely used in the production of many interesting low-molecular compounds. The free radicals produced in such systems can react with the solvents, or can dimerise, disproportionate or be oxidised or reduced by the metal ions; and under the influence of the metal salts the peroxides themselves can undergo heterolytic rearrangements or catalysed heterolytic reaction with the solvents. These various processes produce various products.

The object of this paper is to provide, without any pretence at complete exhaustiveness, a review of these reactions, intensive study of which has, in recent years, opened new possibilities for organic synthesis and made a substantial contribution towards the chemistry of free radicals in solution.

## 1. THE $H_2O_2$–$Fe^{2+}$ SYSTEM (FENTON'S REAGENT)

This system has been much investigated since its discovery in 1894. Its use as polymerisation initiator in the oxidation of aliphatic compounds and the hydroxylation of aromatic compounds has been reviewed by Semenov [1] and Walling [2].

The accepted mechanism is that proposed by Haber and Weiss, according to which the active particle produced in the system is a free hydroxyl radical:

$$H_2O_2 + Fe^{2+} \rightarrow HO^{\cdot} + HO^- + Fe^{3+}. \quad (1)$$

In the absence of an organic substrate, the latter can undergo the following series of reactions:

$$Fe^{2+} + HO^{\cdot} \rightarrow Fe^{3+} + HO^-, \quad (2)$$

$$HO^{\cdot} + H_2O_2 \rightarrow H_2O + HO_2^{\cdot}, \quad (3)$$

$$HO_2^{\cdot} + H_2O_2 \rightarrow HO^{\cdot} + H_2O + O_2, \quad (4)$$

$$HO_2^{\cdot} + H_2O \rightarrow H_3O^+ + O_2^-, \quad (5)$$

$$O_2^- + H_2O_2 \rightarrow {}^-OH + {}^{\cdot}OH + O_2. \quad (6)$$

In 1958 Coffman and coworkers [3] used Fenton's reagent for the production of bifunctional compounds from unifunctional, according to the reactions†

$$RH + {}^{\cdot}OH \rightarrow R^{\cdot} + H_2O, \quad (7)$$

$$2R^{\cdot} \rightarrow R{-}R. \quad (8)$$

The dilution and pH were selected so as to produce the dimeric compounds as the main reaction products in good yield, the reaction being conducted at room temperature by adding aqueous solutions of equimolar quantities of hydrogen peroxide and iron(II) sulphate to an excess of the aliphatic compound (as an aqueous solution or emulsion). The reaction is not a chain reaction — each mole of reacted aliphatic compound requires one mole of hydroxyl radical. This method was used for the dehydrodimerisation of lower aliphatic carboxylic acids, nitriles, amides, amines, alcohols, and ketones.

The attack of the hydroxyl radicals on the molecule of the aliphatic compound is not specific [3]: the hydroxyl abstracts hydrogen not only from the position $\alpha$ to the functional group, but from more distant positions also; as a result a series of bifunctional isomers is obtained, the yield sometimes reaching 60% (calculated on the hydrogen peroxide).

For example, the reaction of propionitrile with Fenton's reagent gives a mixture of approximately equal amounts of adipodinitrile, $\alpha\alpha'$-dimethylsuccinodinitriles, and $\alpha$-methylglutarodinitrile (total yield 60%). Acetic acid gives a low yield (4%) of succinic acid. Individual dehydrodimers are only obtained when the C–H bonds in the starting material are all equivalent; thus trimethylacetic acid gives $\alpha\alpha\alpha'\alpha'$-tetramethylsuccinic acid (37% yield), and t-butyl alcohol gives $\alpha\alpha\alpha'\alpha'$-tetramethylbutane-1,4-diol (36% yield).

The applicability of the method is limited by the requirements that the starting material should have a suitable solubility in water and should not undergo oxidative decomposition. Best results are obtained at pH 2 and at a dilution of 1 g-mole $H_2O_2$ to 2 litres water.

Comparison of their experimental results with literature data on the activity of chlorine atoms in reaction with propionic and butyric acid [4,5] led Coffman and coworkers to infer that free hydroxyl radicals and atomic chlorine exhibit a similar strength of attack on C–H bonds.

The carbonyl group deactivates the $\alpha$-position in carboxylic acids in respect of attack by the hydroxyl radical; according to their data the C–H bonds in pivalic acid $(CH_3)_3CCOOH$ are nine times as reactive as in acetic acid.

Razuvaev and Boguslavskaya investigated the reaction of methyl esters of aliphatic carboxylic acids and alkyl acetates with Fenton's reagent under the conditions of the Coffman synthesis [6–9], and obtained dimeric and oligomeric esters and oxidation products of the starting esters.

The dehydrodimers of the methyl esters are mixtures of the dimethyl esters of isomeric dicarboxylic acids; those of the alkyl acetates are glycol diacetates. The yields of dimers and oligomers sometimes reach 60% (based on $H_2O_2$) or 70% (based on starting ester). For example, the reaction of methyl isobutyrate with Fenton's reagent gave the following products, the percentage yields, based on $H_2O_2$ and reacted ester respectively, being given in parentheses: dimethyl $\alpha\alpha'$-dimethyladipate (12, 14), dimethyl $\alpha\alpha\alpha'$-trimethylglutarate (14, 17), dimethyl $\alpha\alpha\alpha'\alpha'$-tetramethylsuccinate (2, 2.5), oligomers (trimers and tetramers) of methyl isobutyrate (29, 35), monomethyl esters of $C_8$-dicarboxylic acids (2, 2.5), acetone (-, 2), and isobutyric acid (-, 24) [reactions (9)–(15)]. Similarly, isopropyl acetate gave 1,4-dimethylbutane-1,4-diol (11, 28), oligomers of isopropyl acetate (6, 14), acetone, and acetic acid (-, 58) [reactions (16)–(20)].

In the reaction of esters containing chains of several carbon atoms in the alcohol and acid parts of the molecule, mixed dehydrodimers are formed. These are obtained by dimerisation of radicals formed as a result of attack by hydroxyl on the alcohol and acid parts of the ester molecule. Thus ethyl propionate gives diethyl adipate, diethyl $\alpha\alpha'$-dimethylsuccinate, ethyl 5-propionylhydroxyvalerate and ethyl 2-methyl-4-propionylhydroxybutyrate, with

† Abstraction of hydrogen initially bonded to carbon.

traces of unidentified dimers (total yield 21% on the initial ester).

The processes occurring in the reaction of esters with Fenton's reagent are shown in the following series of reactions:

*Methyl esters (example: methyl isobutyrate)*

$$CH_3CH(CH_3)COOCH_3 + \cdot OH \rightarrow \begin{cases} CH_2C(CH_3)COOCH_3 & (I) \\ CH_2CH(CH_3)COOCH_3 & (II) \\ CH_3CH(CH_3)COOCH_2 & (III), \end{cases} \quad (9)$$

$$2\,(I) \rightarrow (CH_3)_2CCOOCH_3\,|\,(CH_3)_2CCOOCH_3, \quad (10)$$

$$(I) + (II) \rightarrow C(CH_3)_2COOCH_3\,|\,CH_3CH(CH_3)COOCH_3$$

$$2\,(II) \rightarrow CH_3CH(CH_3)COOCH_3\,|\,CH_3CH(CH_3)COOCH_3,$$

$$(CH_3)_2C(OO)COOCH_3 + \cdot OH \xrightarrow[[H_2O_2]]{} (CH_3)_2CCOOCH_3 \rightarrow (CH_3)_2C{=}O, \quad (11)$$

$$CH_3CH(CH_3)COOCH_3 + \cdot OH \xrightarrow[[H_2O_2]]{} CH_2CH(CH_3)COOCH_2OH \rightarrow CH_2CH(CH_3)COOH \quad (12),$$

$$CH_3CH(CH_3)COOCH_3\,|\,CH_3CH(CH_3)COOCH_3 + \cdot OH \rightarrow \begin{cases} \dot{C}HCH(CH_3)COOCH_3\,|\,CH_3CH(CH_3)COOCH_3 & (A) \\ CH_2\dot{C}(CH_3)COOCH_3\,|\,CH_2CH(CH_3)COOCH_3 & (B) \\ CH_2CH(CH_3)COOCH_3\,|\,CH_2{-}CHCOOCH_3\,|\,\dot{C}H_2 & (C) \\ CH_2CH(CH_3)COOCH_3\,|\,CH_2CH(CH_2)COO\dot{C}H_2 & (D), \end{cases} \quad (13)$$

$$(A), (B), (C), (D) + (I), (II), (III) \rightarrow \text{trimers, tetramers, and higher oligomers,} \quad (14)$$

$$(D) + \cdot OH \xrightarrow[[H_2O_2]]{} CH_2CH(CH_3)COOCH_3\,|\,CH_2CH(CH_2)COOCH_2OH \rightarrow CH_2CH(CH_3)COOCH_3\,|\,CH_2CH(CH_2)COOH, \quad (15)$$

*Alkyl acetates (example: isopropyl acetate)*

$$CH_3CH(CH_3)OCOCH_3 + \cdot OH \rightarrow \begin{cases} CH_2\dot{C}(CH_3)OCOCH_3 & (IV), \\ \cdot CH_2CH(CH_3)OCOCH_3 & (V), \end{cases} \quad (16)$$

$$2\,(V) \rightarrow CH_3CH(CH_3)OCOCH_3\,|\,CH_3CH(CH_3)OCOCH_3, \quad (17)$$

$$(IV) + \cdot OH \xrightarrow[[H_2O_2]]{} CH_3C(CH_3)OCOCH_3 \rightarrow (CH_3)_2C{=}O, \quad (18)$$

$$CH_3CH(CH_3)OCOCH_3\,|\,CH_3CH(CH_3)OCOCH_3 + \cdot OH \rightarrow \begin{cases} \dot{C}HCH(CH_3)OCOCH_3\,|\,CH_3CH(CH_3)OCOCH_3 & (E) \\ CH_3CH(CH_3)OCOCH_3\,|\,CHCHOCOCH_3\,|\,\cdot CH_3 & (F) \\ CH_3\dot{C}(CH_3)OCOCH_3\,|\,CH_3CH(CH_3)OCOCH_3 & (G), \end{cases} \quad (19)$$

$$(E), (F), (G) + (V) \rightarrow \text{trimers, tetramers, and higher oligomers} \quad (20)$$

The oligomers are a complex mixture of structural isomers.

Under identical reaction conditions, the maximal yield of dimers and oligomers of methyl esters is obtained with methyl isobutyrate, and that of dimers and oligomers of alkyl acetates with n-propyl acetate (Figs. 1 and 2).

The presence of a large quantity of oligomers makes it difficult to calculate the positions of free-radical attack; however, with methyl isobutyrate an approximate calculation shows that the $\alpha$-position is more reactive than the $\beta$-position.

Complex-forming metal ions ($Fe^{3+}$, $Ni^{2+}$, $Co^{2+}$, $Mn^{2+}$) form complexes with the free alkyl radicals, and so decrease their ability to react and hence favour dimerisation[10]. When $Fe^{3+}$ is used as complex-forming ion, the addition of NaF, which binds $Fe^{3+}$ into a stable complex, produces a considerable decrease in the quantity of dimer formed.

Razuvaev and Boguslavskaya investigated the influence of additions of equimolar amounts of various metal salts on the reaction of aliphatic esters with Fenton's reagent. Addition of Ni, Co, or Mn salts or NaF have no substantial effect on the yield or composition of the products. In the presence of an equimolar amount of NaCl there is practically no dehydrodimerisation of the esters; chlorinated derivatives of the initial esters are produced in small amounts. Chloride ions are known to reduce the rate of oxidation with Fenton's reagent[11,12]:

$$\cdot OH + Cl^- + H^+ \rightarrow Cl\cdot + H_2O. \quad (21)$$

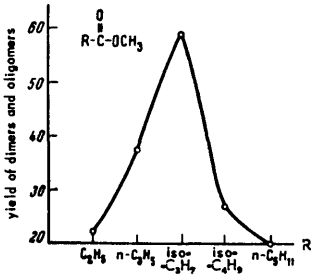

Fig. 1. Yield of dimers and oligomers of esters $RCOOCH_3$ as a function of the size and structure of the radical R.

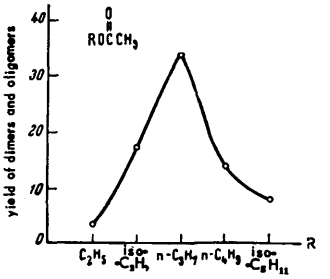

Fig. 2. Yield of dimers and oligomers of esters $ROCOCH_3$ as a function of the size and structure of the radical R.

An equimolar amount of $CuSO_4$ also suppresses the dehydrodimerisation of esters practically completely. It is known that $Cu^{2+}$ can oxidise alkyl radicals [13,14]:

$$R^{\cdot}+M^{+n} \rightarrow \begin{cases} \text{alkene} + M^{+n-1} + H^+ \\ R^+ + M^{+n-1} \end{cases}, \quad (22)$$

$$R^+ + H_2O \rightarrow ROH + H^+, \quad (23)$$

The addition of $CuSO_4$, for example, to the system methyl butyrate–$FeSO_4$–$H_2O_2$ would therefore be expected to produce esters of unsaturated and hydroxy-acids (or their further oxidation products: aldehydo- and keto--acids), but these products have not been observed. Small amounts of unsaturated esters are formed in the absence of $CuSO_4$ as well as in its presence. The considerable decrease in the yield of dimers is probably due to the reduced equilibrium concentration of hydroxyl radicals in the presence of excess of $Cu^{2+}$:

$$Cu^{2+} + H_2O_2 \rightleftarrows Cu^+ + HO_2^{\cdot} + H^+ \text{ (see Semenov[1])}. \quad (24)$$

The reaction of various amines and ethers with Fenton's reagent has been investigated [15]; the corresponding dehydrodimers are produced in very low yields (0.5–10%), *NN'*-diethylbutenediamine is obtained from diethylamine (yield ~ 10%) and *NN'*-diethyl-*NN'*-diphenylbutenediamine from ethylaniline (yield < 10%).

Addition of 1,3-dienes to the $Fe^{2+}$–$H_2O_2$– substrate system produces addition dimers [16,17]:

$$RH + {\cdot}OH \rightarrow R^{\cdot} + H_2O,$$
$$R^{\cdot} + M \rightarrow RM^{\cdot}, \quad (25)$$
$$2RM^{\cdot} \rightarrow RMMR, \quad (26)$$

where M is a molecule of the 1,3-diene. These dimers are straight-chain (H) and branched-chain (J), (K) compounds produced by 1,4- and 1,2-addition to the diene:

$$R(CH_2{-}CH{=}CHCH_2)_2R; \quad RCH_2CH{=}CHCH_2\underset{\displaystyle CH{=}CH_2}{\underset{|}{C}}HCH_2R; \quad RCH_2\underset{\displaystyle CH{=}CH_2}{\underset{|}{C}}HCH_2R.$$
$$\text{(H)} \qquad \text{(J)} \qquad \text{(K)}$$

Addition dimerisation is favoured by adding equivalent amounts of the iron(II) salt, $H_2O_2$, and the diene simultaneously to a large excess of the substrate in water at -5° to 0° at a definite pH.

Substrates used have been carboxylic acids, alcohols, ketones, esters, acetaldehyde, propionitrile, and cyclohexylamine. Butadiene has been the main diene used, but chloroprene, isoprene, cyclopentadiene, acrylonitrile, and maleic acid have also been employed. The yield of addition dimers has reached 70–77% in some cases. The yield of products containing more than two butadiene units in the molecule is less than 10%.

The production of dichlorinated conjugated dienes by addition dimerisation has been patented [18]; thus butadiene reacts with the radicals produced in the $H_2O_2$–$FeCl_2$ system in solution in acetone to give $(ClC_4H_6)_2$. A new method for the addition of two azide groups to alkenes using Fenton's reagent has been developed [19]:

$$H_2O_2 + Fe^{2+} \rightarrow HO^{\cdot} + HO^- + Fe^{3+},$$
$$HO^{\cdot} + (FeN_3)^{2+} \rightarrow (FeOH)^{2+} + N_3^{\cdot}, \quad (27)$$

$$N_3^{\cdot} + \underset{|}{\overset{|}{C}}{=}\underset{|}{\overset{|}{C}} \rightarrow N_3{-}\underset{|}{\overset{|}{C}}{-}\underset{|}{\overset{|}{C}}{\cdot}, \quad (28)$$

$$N_3{-}\underset{|}{\overset{|}{C}}{-}\underset{|}{\overset{|}{C}}{\cdot} + (FeN_3)^{2+} \rightarrow N_3{-}\underset{|}{\overset{|}{C}}{-}\underset{|}{\overset{|}{C}}{-}N_3. \quad (29)$$

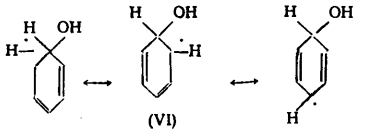
This reaction has been used with styrene, butadiene, hex-1-ene, cyclohexene, etc.

Of interest is the novel synthesis of carboxylic acids by passing carbon monoxide into a $Fe^{2+}$–$H_2O_2$– substrate system [20]:

$$RH + CO + H_2O_2 \xrightarrow{Fe^{2+}} RCOOH + H_2O. \quad (30)$$

The formation of the acids is accompanied by dimerisation of the radicals R· into RR; thus t-butyl alcohol has given the carboxylation product (β-hydroxyisovaleric acid) and the dehydrodimerisation product (ααα'α'-tetramethylbutane-1,4-diol) in yields of 0.23 and 0.33 g-mole per mole $H_2O_2$ respectively.

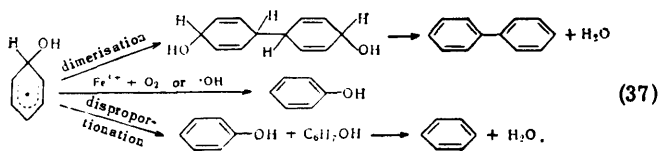
The carboxylation proceeds at room temperature by introducing $H_2O_2$, $FeSO_4$, and CO simultaneously into a vigorously stirred mixture containing an excess of the organic reactant. The optimal $H_2O_2$ : $FeSO_4$ ratio and CO pressure is selected for each organic reactant. In some cases carboxylation takes place at atmospheric pressure. The following mechanism has been suggested:



$$HO{\cdot} + RH \rightarrow R{\cdot} + H_2O,$$
$$R^{\cdot} + CO \rightarrow RC{=}O, \quad (31)$$
$$RC{=}O + Fe^{3+} \rightarrow \overset{+}{R}C{=}O + Fe^{2+}, \quad (32)$$
$$\overset{+}{R}C{=}O + \bar{O}H \rightarrow RCOOH. \quad (33)$$

If the reaction medium contains NaF, which binds $Fe^{3+}$ into a stable complex, the yield of carboxylation products is markedly reduced.

Aromatic compounds are oxidised by Fenton's reagent by a non-chain mechanism [21–23]; hydroxylation occurs, and, with benzene and toluene, dehydrodimerisation also. The total yield of reaction products (based on $H_2O_2$) is always very low (< 5%). Merz and Waters have suggested the following mechanism [22]:



$$ArH + {\cdot}OH \rightarrow Ar^{\cdot} + H_2C, \quad (34)$$
$$2Ar^{\cdot} \rightarrow Ar{-}Ar, \quad (35)$$
$$Ar^{\cdot} + {\cdot}OH \rightarrow ArOH. \quad (36)$$

The oxidation of benzene and toluene by Fenton's reagent has recently been investigated in some detail [24]. The oxidation of benzene produces phenol and biphenyl. The formation of $C_6H_5^{\cdot}$ radicals is excluded, because of the absence of any isotope effect in the analogous oxidation of deuterobenzene. In the suggested mechanism, a hydroxyl radical first adds on to benzene to form the resonance--stabilised adduct (VI):

(VI)

which then dimerises, disproportionates, or is oxidised to produce the final products (phenol, biphenyl, and benzene):

(37)

It is difficult to evaluate the importance of each step in the overall process, but an important characteristic is that the relative amount of phenol produced is decreased by excluding $Fe^{3+}$ (by adding fluoride) and oxygen.

In the oxidation of toluene, which apparently also proceeds by way of the analogous intermediate adduct (as well as by oxidation of the $-CH_3$ group), the following compounds have been obtained, in the indicated relative percentage contents: benzyl alcohol and benzaldehyde (38.3), benzoic acid (18), 1,2-diphenylethane (30.5), phenol (2.9), *o*-cresol (3), *m*-cresol (0.2), *p*-cresol (1), *o*-hydroxybenzaldehyde (3.2), diphenylmethane (1), and bi-*o*-tolyl (2.1).

Brodskii and Vysotskaya[25] used $^{18}O$ to investigate the mechanism of hydroxylation of phenol with Fenton's reagent, and showed that the oxygen in the resulting pyrocatechol comes from the hydrogen peroxide. They conclude that free hydroxyl radicals do not participate in the hydroxylation.

The same conclusion was reached by Hamilton and Friedman[26], who studied the hydroxylation of anisole with Fenton's reagent. They suppose the hydroxylation to proceed by a type of electrophilic substitution.

Cier and Nofre[27] investigated the mechanism of hydroxylation of benzoic acid and *N*-acylanilines in aqueous solution with hydrogen peroxide in the presence of transition metal ions in their lower valency state, and found the activity of the metals to fall in the series $Fe^{2+} > Co^{2+} > Cu^{+} > Mn^{2+}$. Addition of ascorbic acid increases the activity of the systems and changes the order of reactivity: $Cu^{+} > Co^{2+} > Fe^{2+} > Mn^{2+}$. Complexing agents such as ethylenediaminetetraacetic acid activate or inhibit the reaction, depending on their nature and the metal ion. The hydroxylation of benzoic acid gives *o*-, *m*-, and *p*-hydroxybenzoic acids, and is accompanied by partial decarboxylation. The carboxy-group orientates the entering OH group in the ratio $o:m:p = 9:6:5$. For *N*-acylaniline this ratio is 11 : 5 : 4. A free-radical mechanism is accepted for the hydroxylation, and the analogy is pointed out between the reactions studied and biochemical hydroxylation in an organism. The action of a modified Fenton's reagent on purine[28] and pyrimidine bases[29] has been studied, to provide a model for the indirect action of ionising radiations on fundamental biochemical molecules in aqueous media. To increase the catalytic action of the $Fe^{2+}$ ion, it was chelated with sodium pyrophosphate, which allowed the Fenton's reagent to be used at pH 7. The purine bases reacted to the extent of 0.5–1%, and hydroxylation of the pyrimidine bases took place with a yield of approximately 1–6.5%.

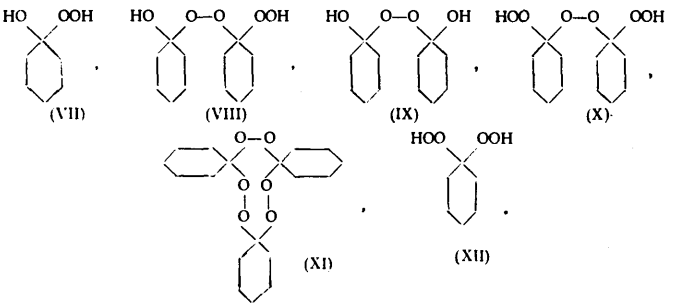
In the presence of iron(III) ethylenediaminetetraacetate and ascorbic acid (a model of a peroxidase system) salicylates are oxidised in aqueous solution by hydrogen peroxide (or oxygen) into 2,3- and 2,5-dihydroxybenzoic acids (yield 50–70% on salicylate)[30].

Phenoxyacetic acid and its halogen-substituted analogues are readily oxidised by Fenton's reagent to form $CO_2$, formaldehyde, phenol, and 1,2-diphenoxyethane[31]; the formation of the last compounds is unexpected, and is explained by the reactions:

$$ArOCH_2COOH + \cdot OH \rightarrow ArOCH_2COO^{\cdot} + H_2O \quad (38)$$

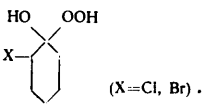
$$ArOCH_2COO^{\cdot} \rightarrow ArO\dot{C}H_2 + CO_2, \quad (39)$$

$$2ArO\dot{C}H_2 \rightarrow ArOCH_2CH_2OAr. \quad (40)$$



The following is also thought to be a probable mechanism:

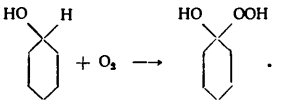
$$ArOCH_2COOH + \cdot OH \rightarrow ArO\dot{C}HCOOH \xrightarrow{\text{migration of H}}$$



$$\xrightarrow{\text{migration of H}} ArOCH_2COO^{\cdot} \rightarrow ArO\dot{C}H_2 + CO_2. \quad (41)$$

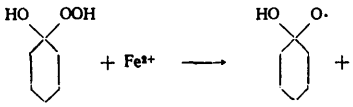
## 2. SYSTEMS COMPRISING ALICYCLIC HYDROPEROXIDES AND METAL SALTS

Cyclohexanone reacts with hydrogen peroxide to give a mixture of the peroxides (VII)–(XII); the structure of these has been much studied[32-36]

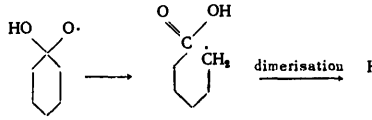


Depending on the method of preparation, one or other of these structures predominates. All the other conversions of the derivative of peroxide cyclohexanone can be considered as reactions of (VII) (1-hydroperoxycyclohexanol); this has not been isolated pure, but Kharasch[36] has prepared the $\alpha$-halogeno-analogues from the $\alpha$-halogenocyclohexanone and hydrogen peroxide:

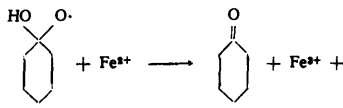
(XIII)



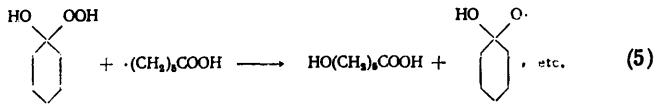
These peroxides (XIII) are individual solid substances and do not form dimeric peroxides of types (VIII)–(XII)[36].



1-Hydroperoxycyclohexanol can be obtained by the autoxidation of cyclohexanol[37]:



Treatment of the derivatives of peroxide cyclohexanone with an equimolar amount of iron(II) sulphate gives a good yield of decane-1,10-dicarboxylic acid, together with caproic acid, $\omega$-hydroxycaproic acid, polymeric acids, and cyclohexanone[37-41]. Low temperature (-10° to 0°) favours formation of the decanedicarboxylic acid, and the



yields of this acid are considerably higher (up to 55%) from "liquid" peroxides of cyclohexanone[41]. These reactions proceed by a free-radical mechanism:

(1)

(2)

(3)

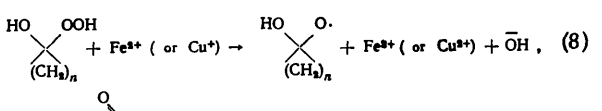
$$HOOC(CH_2)_5\,Fe^{3+} + H_2O \rightarrow HOOC(CH_2)_4CH_2 + Fe^{2+} + OH\,. \quad (4)$$

(5)

Treatment of 2-chloro-1-hydroperoxycyclohexanol with iron(II) sulphate produces a dichlorodecane-1,10-dicarboxylic acid in which the disposition of the halogens has not been established; from subsequent work[14] it may be assumed that this acid is a mixture of isomers with structure (XIV) predominating:

$$HOOC(CH_2)_4CHCl{-}CHCl(CH_2)_4COOH\,.$$
(XIV)

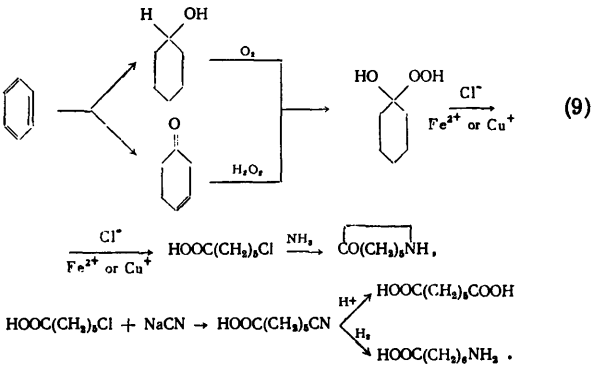
Introduction of butadiene into the peroxide derivative of cyclohexanone $-Fe^{2+}$ system has given[40] $C_{20}$ unsaturated dicarboxylic acids in 65–75% yield:



$$HOOC(CH_2)_5^{\cdot} + C_4H_6 \rightarrow \underset{(A)}{HOOC(CH_2)_5CH_2CH{=}CH{-}\dot{C}H_2} + \quad (6)$$

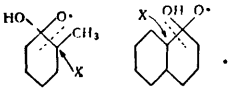
$$+ \underset{(A)}{HOOC(CH_2)_5CH_2\dot{C}HCH{=}CH_2}\,.$$

$$2A \xrightarrow{\text{dimerisation}} C_{20}\text{ unsaturated dicarboxylic acids.} \quad (7)$$



In the presence of an alcohol the corresponding esters are obtained. Similar products are obtained from cyclopentanone, but in lower yield.

Several recent interesting processes are based on the redox reactions of peroxide derivatives of cyclohexanone and other alicyclic peroxides[14,42–49]. Treatment of 1-hydroperoxycycloalkanols with aqueous solutions of equimolar amounts of iron(II) or copper(I) salts in the presence of an excess of hydrogen halides (or their salts), or of alkali metal azides, cyanides, or other salts, at -30° to + 30° gives good yields of the corresponding ω-substituted alkanoic acids[43–48,50,51]:



(8)

where X is Cl,[44] Br,[44] I,[44] $N_3$,[48] SCN,[50] CN,[48] $S_2O_3Na$,[50] or $ROCS_2$,[51] and $n$ is 4 or 5. The ω-substituted acids are the only products of this reaction; the cycloalkanone which is also formed is the initial starting material and is recycled. Thus a peroxide derivative of cyclohexanone gives ε-chlorocaproic acid in a yield of more than 90% (based on ketone), and the product is readily isolated in satisfactorily pure form (> 99%).

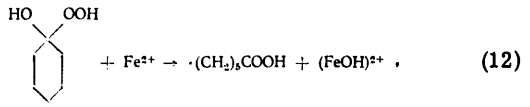
This reaction is the basis of the proposed method for the production of the main starting materials for polyamide resins from benzene[42]:

(9)

Analogous reactions have also been carried out with alkyl-substituted cyclic ketones and perhydrohydroperoxynaphthol[47]. The main product in the decomposition of 1-hydroperoxy-2-methylcyclohexanol by copper(I) or iron(II) salts in the presence of halide anions is the ε-halogenoheptanoic acid, and perhydro-1-hydroperoxynaphth-1-ol gives mainly the γ-(2-halogenocyclohexyl)butyric acid; thus the rupture of the C–C bond when the oxygen radical isomerises occurs mainly on the side which the substituent occupies:

Treatment with alkali of ε-thiocyanocaproic acid produced by (8) gives εε′-dithiodicaproic acid in high yield[50]:

$$2\,HOOC(CH_2)_5SCN \xrightarrow{NaOH} HOOC(CH_2)_5SS(CH_2)_5COOH\,, \quad (10)$$



and the same product is obtained from the ε-substituted caproic acids $HOOC(CH_2)_5X$, where X is $-S-C\overset{S}{\underset{OC_2H_5}{<}}$ or $S_2O_3Na$.[50,51] Similarly δδ′-dithiodivaleric acid is obtained from a peroxide derivative of cyclopentanone[50,51].

The oxidation of the free radicals by metal salts — generally iron(III) or copper(II) halides, of type (8) — has been thought to proceed by ligand transfer[14,49], the reduction of the metal salt occurring with direct transfer of a halogeno-ligand to the free radical in the transition state (XV):

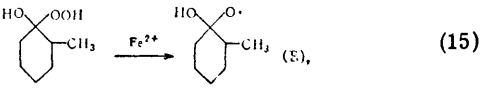
$$R^{\cdot} + M^{n+}X_n \longrightarrow \underset{(XV)}{[R{\cdot}X{-}MX_{n-1} \longleftrightarrow R{-}X\ MX_{n-1}]} \rightarrow RX + M^{+n-1}X_{n-1}\,. \quad (11)$$

In the absence of a suitable ligand the free radicals are oxidised, under analogous conditions, by a competing reaction involving electron transfer. For example, decanedicarboxylic acid is not produced when 1-hydroperoxycyclohexanol is reacted with a mixture of $FeSO_4$ and $CuSO_4$, the main reaction product being hex-5-enoic acid

(in 76% yield based on reacted ketone, or 61% based on $H_2O_2$)[14,49], which is formed by the mechanism:

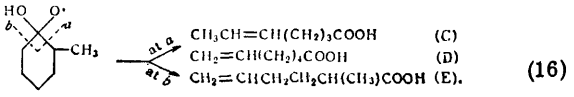
$$+ Fe^{2+} \rightarrow \cdot(CH_2)_5COOH + (FeOH)^{2+}, \quad (12)$$

$$\cdot(CH_2)_5COOH + Cu^{2+} \rightarrow CH_2{=}CH(CH_2)_3COOH + Cu^{+} + H^{+}, \quad (13)$$



$$Cu^{+} + (FeOH)^{2+} \rightarrow Cu^{2+} + (FeOH)^{+}. \quad (14)$$

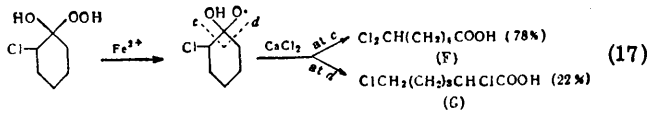
It is not thought that a classical carbonium ion is produced as an intermediate in this reaction, since when it is carried out in an aqueous or alcoholic medium only a very small quantity of substituted hexanoic acids is obtained. The optimal yield of hex-5-enoic acid cannot be obtained if catalytic quantities of the metal salts are used. In practice relatively large amounts of $FeSO_4$ (100–200% based on $H_2O_2$) and slightly smaller amounts of $CuSO_4$ (about 50 mole %) are required.



The used solution of $FeSO_4$ and $CuSO_4$ can be recycled, because of the low conversion of $Fe^{2+}$ ions in the reaction.

In acidified aqueous methanol the reaction produces methyl hex-5-enoate, together with caproic acid formed as the result of abstraction of hydrogen from the solvent.

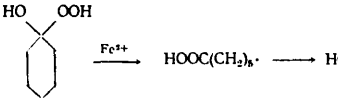
The isomerisation of 2-substituted 1-hydroxycyclohexyloxy-radicals occurring in reactions involving electron or ligand transfer has been investigated; thus a mixture of heptenoic acids is obtained (in 43% yield based on the ketone) in the reaction of 1-hydroperoxy-2-methylcyclohexanol with $FeSO_4$ and $CuSO_4$:



(E), (15)

(C) $CH_3CH{=}CH(CH_2)_3COOH$
(D) $CH_2{=}CH(CH_2)_4COOH$
(E) $CH_2{=}CHCH_2CH_2CH(CH_3)COOH$ (16)

The acid (E) is present in a concentration of 5 mole %, and hence when the radical (B) isomerises the rupture of the C–C bond proceeds almost completely from the side of the methyl group. The acids (C) and (D) are present in the mixture in amounts of about 60% and 40%.

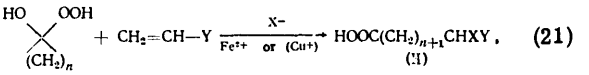


Treatment of 2-chloro-1-hydroperoxycyclohexanol with $FeSO_4$ and $CuSO_4$ gives a low yield of chlorohexenoic acids (~10%). With $FeSO_4$ and $CuCl_2$, dichlorocaprolic acids are produced, in 37% yield based on the ketone:

$Cl_2CH(CH_2)_4COOH$ (78%) (F)
$ClCH_2(CH_2)_3CHClCOOH$ (22%) (G) (17)

The relative amounts of the isomers (F) and (G) show that rupture of the C–C bond occurs about four times as frequently on the side of the chloro-substituent as on the unsubstituted side.

Aliphatic acids and esters are obtained in the decomposition of 1-hydroperoxycyclohexanol with iron(II) salts in the presence of various halogen compounds and thiols[52], and are produced by recombination and transfer of the radicals formed in the system:

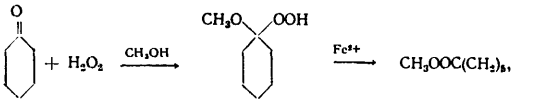


$$\cdot(CH_2)_5COOH + CCl_4 \rightarrow Cl(CH_2)_5COOH + \cdot CCl_3, \quad (18)$$

$$\cdot CCl_3 + \cdot(CH_2)_5COOH \rightarrow CCl_3(CH_2)_5COOH, \quad (19)$$

$$2\cdot CCl_3 \rightarrow C_2Cl_6. \quad (20)$$

In carbon tetrachloride, the reaction produces $\epsilon$-chlorocaprolic, decanedicarboxylic, and $\omega$-trichloroheptanoic acids in yields of 17, 30, and 6% respectively; in methanethiol, the products are caproic acid, decanedicarboxylic acid, and 6-(methylthio)hexanoic acid $CH_3S(CH_2)_5COOH$ in yields of 26, 21, and 12%.



Acrylonitrile (or acrylates) and halogen have been added on to the carboxyalkyl radicals by the reaction[53,54]:

(H) (21)

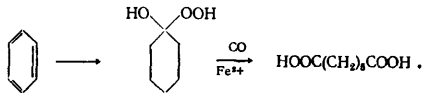
where $n$ is 4 or 5, Y is CN or COOR, and X is Cl or Br. The $\omega$-halogenoalkanoic acids are also formed. Saponification of hydration of the compounds (H) gives the corresponding dicarboxylic acids in yields of 20–30 mole % (based on the initial ketone).

Kochi and Rust[55] have studied the competing processes occurring in the reaction of 1-hydroperoxycyclohexanol in methanol with butadiene (or chloroprene, styrene, or acrylonitrile) in the presence of $FeSO_4$ and $CuSO_4$. Under these conditions the 5-(methoxycarbonyl)pentyl radical adds on butadiene, and the resulting radical is oxidised by the copper(II) salt to give a good yield of methyl methoxydecenoates. The competing reactions are the oxidation of 5-(methoxycarbonyl)pentyl radicals by the copper(II) salt to give methyl hex-5-enoate and 5-methoxyhexanoate, and dimerisation of the radicals:

$$CH_3OOC(CH_2)_5\cdot + C_4H_6 \rightarrow [CH_3OOC(CH_2)_6CH{=}{=}{=}CH{=}{=}{=}CH]\cdot, \quad (22)$$

$$2\,[CH_3OOC(CH_2)_6CH{=}{=}{=}CH{=}{=}{=}CH_2]\cdot \rightarrow \text{three isomeric dimethyl eicosadienedioates}, \quad (23)$$

$$[CH_3OOC(CH_2)_6CH{=}{=}{=}CH{=}{=}{=}CH_2]\cdot + Cu^{2+} \rightarrow [CH_3OOC(CH_2)_6CH{=}{=}{=}CH{=}{=}{=}CH_2]^{+} + Cu^{+}, \quad (24)$$

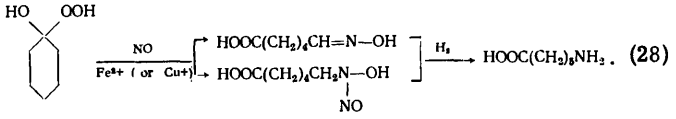


$$[CH_3OOC(CH_2)_6CH{=}{=}{=}CH{=}{=}{=}CH_2]^{+} + CH_3OH \xrightarrow{-H^{+}} \begin{cases} \rightarrow CH_3OOC(CH_2)_6CH{=}CHCH_2OCH_3 \\ \rightarrow CH_3OOC(CH_2)_6CH(OCH_3)CH{=}CH_2, \end{cases} \quad (25)$$

$$CH_3OOC(CH_2)_5\cdot + Cu^{2+} \rightarrow \begin{cases} \rightarrow CH_3OOC(CH_2)_3CH{=}CH_2 \\ \rightarrow CH_3OOC(CH_2)_4CH_2^{+} \xrightarrow[-H^{+}]{CH_3OH} CH_3OOC(CH_2)_6OCH_3. \end{cases} \quad (26)$$

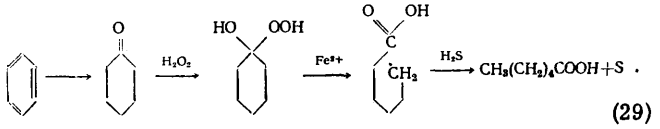
The ability of alkenes to add to the 5-(methoxycarbonyl)-pentyl radical decreases in the series‡: $CH_2{=}CHCH{=}CH_2$, $CH_2{=}C(CH_3)CH{=}CH_2 > CH_2{=}C(CH_3)CH{=}CH_2 > C_6H_5CH{=}CH_2 > > CH_2{=}CHCN > CH_2{=}C(CH_3)CH_2Cl > CH_2{=}CHBr > CH_2{=}CCl_2$.

‡ Presumably one of the isoprenes should be chloroprene (Ed. of Translation).



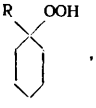
Carbon monoxide has also been added to the carboxyalkyl radicals obtained from 1-hydroperoxycyclohexanol[56,57]. Best results are obtained at pressures above 10 atm. The process may be utilised to prepare $\alpha\omega$-dicarboxylic acids, especially pimelic acid, from benzene:

(27)



The decomposition of hydroperoxides in the presence of sulphur dioxide proceeds analogously, with the formation of sulphonic acids[57]; however, the greater activity of $SO_2$ as compared with CO enforces the use of dilute solutions, so as to avoid reduction of the peroxide to cyclohexanone.

Addition of nitrogen monoxide to the carboxyalkyl radicals followed by hydrogenation of the resulting nitrogen compounds produces amino-acids[58-60].

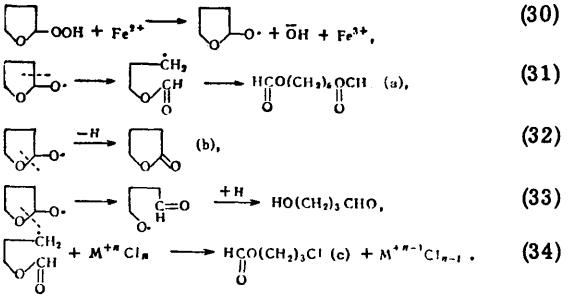


(28)

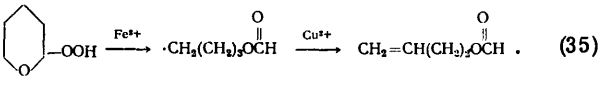
The decomposition of cyclic hydroperoxy alcohols in the presence of an iron(II) salt and hydrogen sulphide is the basis of a new method for the conversion of cyclic ketones into monocarboxylic acids having the same number of carbon atoms[61]. It may be utilised in the production of hexanoic acid from benzene[42]:

(29)

The autoxidation of alicyclic hydrocarbons or ethers[62,63] produces the hydroperoxides:



where R is alkyl or alkoxy.



The reaction of methylcyclopentyl and methylcyclohexyl hydroperoxides with $FeSO_4$ has given[64] dodecan-2,11-dione and tetradecan-2,13-dione respectively, in yields of 40–55%. When 1,3-dienes are introduced into such systems, long-chain unsaturated diketones are obtained[65], of the general formula RMMR, where R is a ketoalkyl group and M is a butadiene or isoprene residue; the yield of such unsaturated ketones may reach 70%.

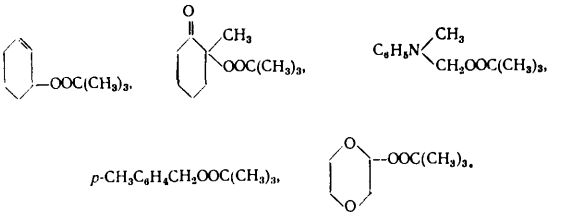
By introducing halide ligands into a system consisting of a cyclic hydroperoxide and $Fe^{2+}$ (or $Cu^{+}$) ions, Minisci and Belvedere[66] have developed efficient methods for the production of $\omega$-halogenated ketones and esters; thus methylcyclopentyl and methylcyclohexyl hydroperoxides give 6-chlorohexan-2-one and 7-chloroheptan-2-one respectively, in yields of ~ 50%. The reaction of methylcyclohexyl hydroperoxide with $FeSO_4$ and $CuSO_4$ produces hept-6-en-2-one in yields of up to 90%.[14] The mechanism of these reactions is identical with that already considered in respect of the hydroperoxyalcohols.

The above reactions have been extended to the hydroperoxides of cyclic ethers, which can be obtained by autoxidation of the ethers. The reaction of a tetrahydrofuryl hydroperoxide with $FeSO_4$ has given[67] hexamethylene diformate, see (a) below, 13.8% yield; $\gamma$-butyrolactone (b), 31.4% yield; and traces of 4-hydroxybutanol. In the presence of metal halides, no dimerisation of the radicals to produce (a) occurs, and 3-chloropropyl formate is obtained (c), 42% yield. The reactions involved are:

The reaction of tetrahydropyran-2-yl hydroperoxide with $FeSO_4$ gives octamethylene diformate in good yield[68]. In the presence of $FeSO_4$ and $CuSO_4$ but-3-enyl formate is obtained in 20% yield[14]:

(35)

If $CuCl_2$ is introduced into this system, 4-chlorobutyl formate is produced in 36% yield[69].



The reductive decomposition of tetrahydro-2,5-dimethylfuranyl hydroperoxide[70,71] gives 1-methylheptamethylene diacetate (46%) and s-butyl acetate (32%); in the presence of $CCl_4$, no s-butyl acetate is obtained, but 4-chlorobut-2-yl acetate (19%) is formed.

## 3. SYSTEMS COMPRISING ACYCLIC PEROXIDES AND METAL SALTS

The addition of catalytic quantities of copper(I) and certain other transition metal salts profoundly affects the course of the reaction between organic peroxides and certain organic compounds in solution[72,73]. In some cases such addition reduces the rate of or inhibits the reactions, and in others the reverse, causing rapid decomposition of the peroxides[75] and catalysing reaction of the peroxides with the solvents to give products which are unusual for normal free-radical reactions[73,74].

These investigations have led to some new and efficient synthetic methods. Thus a new method has been developed[74] for the introduction of peroxide groups into organic molecules by the reaction of t-butyl (or cumyl) hydroperoxide with many types of organic compound in the presence of catalytic amounts of copper, cobalt, or manganese salts at 70–100°. The peroxide group can be introduced in this way, with excellent yields, into compounds such as cyclohexene, 2-methylcyclohexanone,

cyclohexanone, dimethylaniline, xylene, and dioxan, to produce

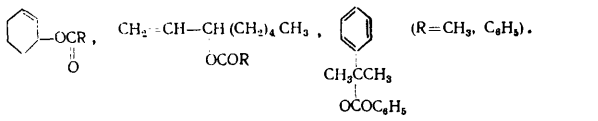
The peroxide group replaces the most labile hydrogen atom.

A mechanism for the reaction has been proposed which involves the formation of intermediate complexes of the free radicals with molecules of the hydroperoxide:

$$ROOH + M^{+} \rightarrow RO\cdot + M^{2+} + \bar{O}H \quad (M=Cu,\ Mn,\ Co), \tag{1}$$

$$RO\cdot + R'H \rightarrow ROH + R', \tag{2}$$

$$R'\cdot + ROOH \rightarrow R'HOOR \ (complex), \tag{3}$$



$$ROOH + M^{2+} \rightarrow ROO\cdot + M^{+} + H^{+}, \tag{4}$$

$$ROO\cdot + R'H \rightarrow R'HOOR \ (complex), \tag{5}$$

$$R'HOOR + oxidant \rightarrow R'OOR + (oxidant + e) + H^{+}. \tag{6}$$

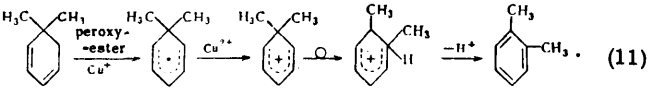
The oxidant may be the $M^{2+}$ ion or the hydroperoxide. The formation of free carbonium ions by the reaction $R^{+}$ + oxidant $\rightarrow R'^{+}$ + (oxidant + $e$) is excluded, since practically no acetates are formed when acetic acid is used as reaction medium, but the yield of peroxide is not reduced.

t-Butyl peroxy-esters react smoothly with alkenes in the presence of catalytic amounts of copper or cobalt salts, producing allyl esters in good or moderate yields[73,76]; thus cyclohexene, oct-1-ene, and cumene have given 3-acyloxycyclohexenes, 3-acyloxyoct-1-enes, and $\alpha\alpha$-dimethylbenzyl benzoate respectively:

While in the absence of catalyst such reactions usually lead to a mixture of isomers, in the presence of copper or cobalt salts the reaction is specific: the acyloxy-group substitutes in the $\alpha$-position to the double bond.

The use of gas–liquid chromatography for the separation and identification of the reaction products has shown[77-79] that the reaction between t-butyl peroxy-esters and alk-1-enes under the influence of catalytic amounts of copper salts produces not only the 3-acyloxyalk-1-enes, but also their isomers, the 1-acyloxyalk-2-enes. This gives grounds for assuming that the reaction involves the formation of relatively free carbonium ions which undergo rearrangement in the course of reaction. The reaction mechanism proposed by Kochi[77,78] and Walling[79] comes down to the multistage process represented by:

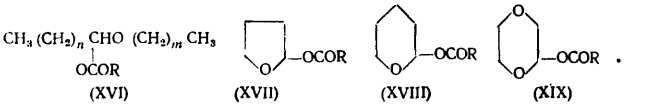
$$CH_3COOOC(CH_3)_3 + Cu^{+} \rightarrow CH_3COO^{-} + Cu^{2+} + (CH_3)_3CO\cdot, \tag{7}$$



$$(CH_3)_3CO\cdot + RH \rightarrow (CH_3)_3COH + R\cdot, \tag{8}$$

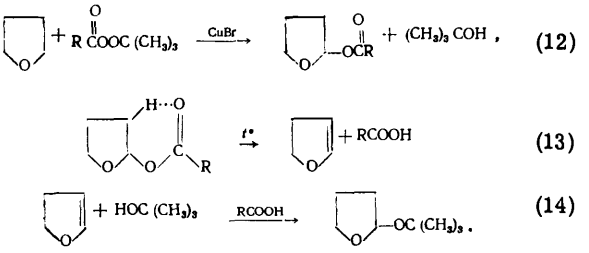
$$R^{\cdot} + Cu^{2+} \rightarrow R^{+} + Cu^{+}, \tag{9}$$

$$R^{+} + CH_3COO^{-} \rightarrow ROCOCH_3. \tag{10}$$



This is a chain reaction maintained by the $Cu^{I}$ and $Cu^{II}$ states of copper.

An interesting rearrangement with 1,2-transition of alkyl groups has been observed by Walling and Lawitsas[79] in the reaction between t-butyl peracetate and 6,6-dimethylcyclohexa-1,3-diene in the presence of copper salts; $o$-xylene was produced in 6% yield, but it is not formed in the absence of the copper or the peroxy-ester. The production of $o$-xylene clearly demonstrates the intermediate formation of a carbonium cation:



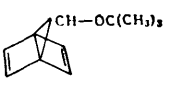
(11)

Aliphatic, aromatic, and cyclic ethers react smoothly with t-butyl peroxy-esters at 67–90° in the presence of CuCl or CuBr[76,80-88]. The primary reaction products are the acyloxy-substituted ethers — for example (XVI)–(XIX) — but these are unstable under the experimental conditions, and partially decompose into the corresponding carboxylic acids and unsaturated ethers[82]:

(XVI) (XVII) (XVIII) (XIX)

2,3-Dihydrofuran (13) is obtained in 66% yield from 2-benzoyloxytetrahydrofuran (XVII). The unsaturated ethers add on the t-butyl alcohol, giving the corresponding acetal (14); this stage is catalysed by the carboxylic acid:

(12)



(13)

(14)

The reaction is general for ethers containing two methylene groups adjacent to the ether oxygen. Diethers such as dioxan give more stable acyloxy-derivatives, which on prolonged heating are slowly converted into the corresponding acetals (in low yield).

The analogous sulphur compounds are obtained in good yields by reaction of thioethers with t-butyl peroxy-esters[83,89,90].

A particular type of substitution occurs[91,92] in the reaction of t-butyl peroxy-esters with norbornadiene under the influence of catalytic amounts of CuBr; this produces 7-t-butoxynorbornadiene in 26% yield:

The mechanism of the catalytic action of copper salts on the reactions of organic peroxides has been considered by Kochi[14,77,78,93-95] and by Walling[79].

In the presence of large quantities of copper salts, the products obtained depend to a considerable extent on the nature of the anion; for instance, $CuCl_2$ and $CuBr_2$ oxidise the alkyl radicals to the corresponding alkyl halides, while under analogous conditions $CuSO_4$ gives unsaturated compounds and solvolysis products. Primary alkyl radicals in the presence of $CuSO_4$ give mainly unsaturated compounds, and tertiary alkyl, benzyl, and allyl radicals give solvolysis products. A desired product can therefore be obtained by suitable choice of reaction conditions. The examples given below illustrate these general statements (see also Section 2).

The reaction between t-butyl hydroperoxide and butadiene in the presence of $FeSO_4$ produces t-butoxy radicals, which readily add on to butadiene, and the resulting t-butoxybutenyl radicals dimerise [96]. When carried out in aqueous methanol in the presence of $FeSO_4$ and $CuSO_4$, [14,94] this reaction gives a good yield (55–60%) of the isomeric methyl ethers of t-butoxybutenols of the composition

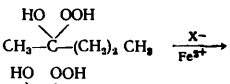
$$(CH_3)_3COCH_2CH(OCH_3)CH{=}CH_2 \quad (\sim 66\%),$$
$$trans\text{-}(CH_3)_3COCH_2CH{=}CHCH_2OCH_3 \quad (\sim 32\%),$$
$$(CH_3)_3COCH_2CHOH.CH{=}CH_2 \quad (\sim 2\%).$$

The mechanism of such reactions has already been discussed in Section 2.

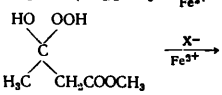
The reaction of t-butyl hydroperoxide with butadiene in the presence of the $Fe^{3+}/Fe^{2+}$ or $Cu^{2+}/Cu^{+}$ system and $Cl^-$, $Br^-$, $SCN^-$, or $N_3^-$ ions gives good yields of compounds $(CH_3)_3CO(C_4H_6)X$, where X is Cl, Br, SCN, or $N_3$. [19,97] For example, the reaction between t-butyl hydroperoxide (0.63 g-mole), butadiene (0.30 g-mole), $FeCl_3.6H_2O$ (0.55 g-mole), $FeSO_4.7H_2O$ (0.32 g-mole), and LiCl (0.56 × × g-mole) at -10° to -15° produces a mixture of 1-chloro--4-t-butoxybut-2-ene and 3-chloro-4-t-butoxybut-1-ene in a yield of 98% on the diene or 47% on the peroxide [97].

Investigation of the reactions of the t-butoxy-radical, which is fairly strongly electrophilic in the presence of chloride, azide, and thiocyanate anions and alkenes, has shown the direction of reaction to depend on the donor–acceptor properties of the substituents in the alkene molecule [19]. With butadiene the reaction is:

$$(CH_3)_3COOH + Fe^{2+} \rightarrow (CH_3)_3CO\cdot + Fe^{3+} + \bar{O}H, \quad (15)$$
$$(CH_3)_3CO\cdot + C_4H_6 \rightarrow (CH_3)_3COC_4H_6\cdot, \quad (16)$$
$$(CH_3)_3COC_4H_6\cdot + (FeX)^{2+} \rightarrow (CH_3)_3COC_4H_6X + Fe^{2+}. \quad (17)$$



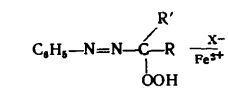
Cyclopentadiene behaves analogously to butadiene. Under the same conditions, styrene forms 1-chloro-1-phenylethyl t-butyl ether in the presence of chloride ions, and a mixture of $C_6H_5CHN_3CH_2OC(CH_3)_3$ and $C_6H_5CHN_3CH_2N_3$ in the presence of sodium azide. Clearly, in the latter case two parallel processes take place:



$$(CH_3)_3CO\cdot + C_6H_5CH{=}CH_2 \rightarrow C_6H_5\dot{C}HCH_2OC(CH_3)_3 \xrightarrow{(FeN_3)^{2+}} \xrightarrow{(FeN_3)^{2+}} C_6H_5CHN_3CH_2OC(CH_3)_3, \quad (18)$$
$$(CH_3)_3CO\cdot + (FeN_3)^{2+} \rightarrow N_3\cdot + Fe^{3+} + (CH_3)_3CO^-, \quad (19)$$
$$N_3\cdot + C_6H_5CH{=}CH_2 \rightarrow C_6H_5\dot{C}HCH_2N_3 \xrightarrow{(FeN_3)^{2+}} C_6H_5CHN_3CH_2N_3. \quad (20)$$

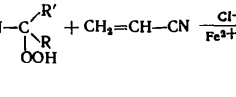
A t-butoxy-radical of reduced reactivity is observed in the decomposition of t-butyl hydroperoxide in the presence of the $Fe^{3+}/Fe^{2+}$ system, chloride ions, and acrylonitrile, when $\alpha$-chlorobutyronitrile is obtained as main reaction product. This is because the strongly electrophilic t-butoxy-radical cannot react with the ethylenic bond of the acrylonitrile, which is electron-deficient in nature, and it therefore decomposes to give a methyl radical, which has nucleophilic properties:

$$(CH_3)_3CO\cdot \rightarrow CH_3COCH_3 + CH_3\cdot, \quad (21)$$
$$CH_3\cdot + CH_2{=}CH{-}CN \rightarrow CH_3CH_2\dot{C}HCN \xrightarrow{(FeCl)^{2+}} CH_3CH_2CHClCN + Fe^{3+}. \quad (22)$$



The decomposition of peroxides of acyclic ketones with iron(II) or copper(I) salts in the presence of $Cl^-$, $SCN^-$, or $N_3^-$ ions gives the corresponding substituted alkanes [56]:

$$\xrightarrow[Fe^{3+}]{X^-} CH_3CH_2CH_2X + CH_3COOH, \quad (23)$$



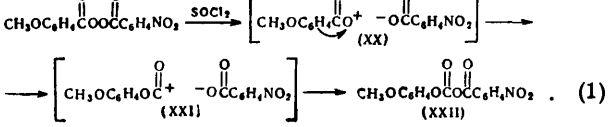
$$\xrightarrow[Fe^{3+}]{X^-} CH_3OCOCH_2X + CH_3COOH. \quad (24)$$

The reaction of peroxides of acyclic diketones or keto--esters with iron(II) sulphate in the presence of butadiene produces diketones and esters of long-chain dicarboxylic acids [98,99].

The reaction of hydroperoxides of ketone phenylhydrazones with iron(II) or copper(I) salts in the presence of $Cl^-$, $Br^-$, $SCN^-$, or $N_3^-$ follows the course of the Sandmeyer reaction, with the formation of the correspondingly substituted aryl compounds [100]:

$$\xrightarrow[Fe^{3+}]{X^-} C_6H_5X + R'COR + N_2. \quad (25)$$

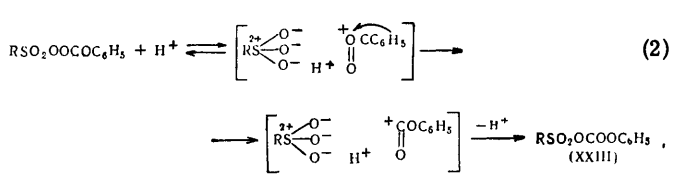
The reaction of these hydroperoxides with acrylonitrile or acrylates under analogous conditions (the Meerwein reaction) [101] gives good yields of the $\alpha$-substituted $\beta$-phenylpropionitriles or $\beta$-phenylpropionate esters respectively:



$$+ CH_2{=}CH{-}CN \xrightarrow[Fe^{3+}]{Cl^-} C_6H_5CH_2CHClCN + R'COR + N_2. \quad (26)$$

## 4. IONIC REACTIONS OF PEROXIDES UNDER THE INFLUENCE OF LEWIS ACIDS

Recent years have seen the accumulation of much experimental material which shows that certain peroxides can decompose in solution by an ionic, as well as a radical, mechanism [102–107].



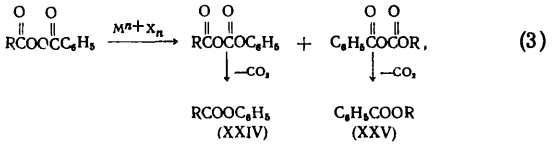
The ionic reactions of peroxides are catalysed by polar solvents [102,103], strong acids [102–107] and Lewis acids ($AlCl_3$, $SbCl_5$, $FeCl_3$, $BF_3$, etc.) [104,106,108–114].

Heterolytic decomposition of peroxides leads most frequently to intramolecular rearrangement [102–105,110,113], and hence to loss of the ability to initiate radical polymerisation [102,103]. For example, *p*-methoxybenzoyl--*p*-nitrobenzoyl peroxide decomposes by a radical mechanism in benzene, but by an ionic mechanism in the strongly polar thionyl chloride, producing a mixed anhydride of *p*-nitrobenzoic acid and mono-(methoxyphenyl) carbonate (XXII) [102]:

$$\xrightarrow{SOCl_2} \left[CH_3OC_6H_4\overset{+}{C}O \quad {}^-OCC_6H_4NO_2\right] \longrightarrow \quad (XX)$$
$$\longrightarrow \left[CH_3OC_6H_4O\overset{+}{C} \quad {}^-OCC_6H_4NO_2\right] \longrightarrow CH_3OC_6H_4OCOCC_6H_4NO_2. \quad (1)$$
(XXI) (XXII)

The *p*-methoxyphenyl radical in the cation (XX) migrates to the peroxidic oxygen to form the carbonium cation (XXI); recombination of the ions then gives the mixed anhydride (XXII).

Alkanesulphonyl peroxides decompose in organic solvents (irrespective of their polarity) by an ionic mechanism[111], with the formation of the mixed anhydrides (XXIII); this reaction is catalysed by the alkanesulphonic acid which is produced by the initial homolytic decomposition of the peroxide[104,105]:

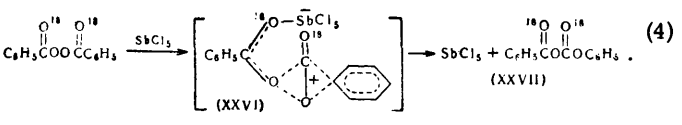


(2)

(XXIII)

where R is $CH_3$, $C_2H_5$, n-$C_3H_7$, or iso-$C_3H_7$. If the sulphonic acid is bound (for example, by means of dry powdered potassium carbonate[104,105]), the peroxides decompose predominantly by a radical mechanism; on the other hand, addition of a sulphonic acid or of aprotonic acids ($AlCl_3$, $SnCl_4$, or $SbCl_5$) directs the reaction towards the heterolytic isomerisation (2), the mixed anhydrides of alkanesulphonic acid and monophenyl carbonate (XXIII) being obtained in more than 85% yield.

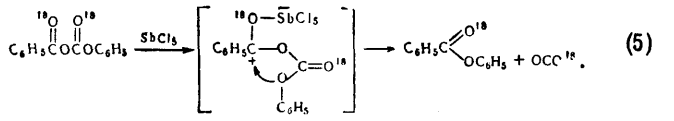
Analogous rearrangements are undergone by benzoyl peroxide[102,108,109,115,116] under the influence of $AlCl_3$ or $SbCl_5$, and by unsymmetrically substituted analogues of benzoyl peroxide and other non-symmetric acyl peroxides under the influence of $BF_3$.[113] The acyl phenyl carbonates produced by the heterolytic rearrangement are unstable, and decompose in the presence of aprotonic acids to form the corresponding esters (in 70–95%) and $CO_2$:



(3)

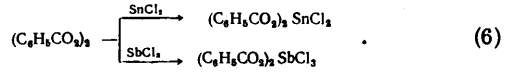
(XXIV) (XXV)

where $M^{n+}X_n$ is $AlCl_3$, $SbCl_5$, or $BF_3$, and R is $C_6H_5$, *p*-$CH_3OC_6H_4$, *p*-$CH_3C_6H_4$, *p*-$ClC_6H_4$, *p*-$BrC_6H_4$, *p*-$NO_2C_6H_4$, *o*-$CH_3C_6H_4$, *o*-$ClC_6H_4$, $CH_3$, $ClCH_2$, $C_2H_5$, etc. Depending on R, either (XXIV) or (XXV) may predominate; thus the reaction produces 100% (XXIV) when R is *p*-$NO_2C_6H_4$, and 100% (XXV) when R is *p*-$CH_3OC_6H_4$.



Denney and coworkers have investigated the heterolytic rearrangement, under the influence of $SbCl_5$, of benzoyl peroxide[115,116] and of some other peroxides[117–118], labelled with $^{18}O$ in the carbonyl group; the resulting ester — (XXIV) or (XXV), R = $C_6H_5$ — still contains $^{18}O$ in the carbonyl group, but the phenolic oxygen does not contain the remaining $^{18}O$. It is therefore concluded that the heterolysis of the peroxide does not produce free carbonium cations, but that the rearrangement proceeds in the transitional complex (XXVI):

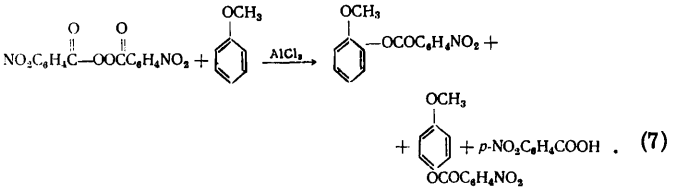
(4)



(XXVI) (XXVII)

Under the influence of the $SbCl_5$ the mixed carbonate (XXVII) rapidly decomposes as follows:

(5)

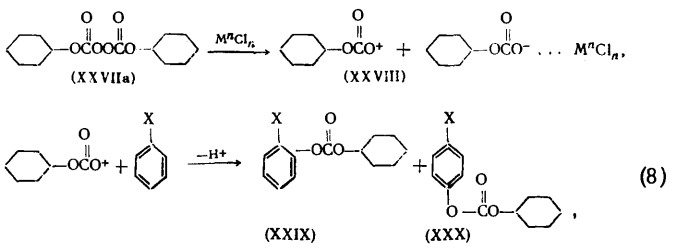


Benzoyl peroxide reacts quantitatively with $SnCl_2$ and $SbCl_3$ at room temperature as follows[119]:

(6)

Apparently, in these reactions the benzoyl peroxide splits homolytically at the O–O bond, and the resulting benzoyloxy-radicals react with the salt present, the $Sn^{2+}$ and $Sb^{3+}$ being converted into $Sn^{4+}$ and $Sb^{5+}$ respectively.

Edward and coworkers have recently shown[114] that under the influence of an equimolar amount of $AlCl_3$ *pp'*-dinitrobenzoyl peroxide can react with strongly nucleophilic solvents (anisole, mesitylene, 1,3-dimethoxybenzene) at 0–25° by a Friedel–Crafts type reaction, giving moderate yields of the corresponding *p*-nitrobenzoates:

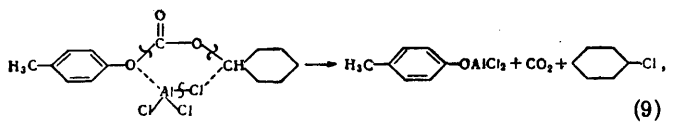


(7)

The peroxide apparently splits heterolytically at the O–O bond, and the resulting *p*-nitrobenzoyloxy-cation attacks the aromatic ring. This electrophilic attack is facilitated by electron-donating substituents, and does not occur with benzene or toluene.

The reaction between dicyclohexyl peroxodicarbonate (XXVIIa) and aromatic compounds under the influence of $FeCl_3$,[112] $SbCl_5$, $SbCl_3$, and $AlCl_3$ has been investigated. In the absence of the aprotonic acids, the peroxodicarbonate decomposes homolytically in toluene at 50–65° to form $CO_2$ and cyclohexyloxy-radicals, which partially disproportionate in a "cage" of solvent, and partially react with the toluene, the resulting benzyl radicals dimerising to produce 1,2-diphenylethane[120].

Catalytic amounts of aprotonic acids ($SbCl_5$, $FeCl_3$) do not affect the decomposition of the peroxodicarbonate, since they are removed from the sphere of reaction as solid complexes[120]. If the aprotonic acids are added in amounts of 10–50 mole %, the homolytic reaction with the solvents is suppressed, and the peroxodicarbonate enters into a Friedel–Crafts reaction with aromatic compounds, forming the corresponding mixed carbonates (XXIX, XXX):



(8)

(XXVIIa) (XXVIII) (XXIX) (XXX)

where X is H, $CH_3$, $OCH_3$, or Cl.

The cyclohexyloxycarboxy-cation (XXVIII) is fairly reactive and does not require activation of the aromatic ring by electron-donating substituents; under the influence of $FeCl_3$ it reacts with benzene to give a 17% yield of cyclohexyl phenyl carbonate, and with toluene to give cyclohexyl *o*-tolyl and cyclohexyl *p*-tolyl carbonates in yields of 34% and 7% respectively. Electron-donating substituents favour the electrophilic attack; thus even in the absence of Lewis acids anisole reacts to give cyclohexyl *o*-methoxyphenyl and cyclohexyl *p*-methoxyphenyl carbonates in good yield.

Strong Lewis acids, such as $AlCl_3$, can decompose the mixed carbonates. The main product of the decomposition of the peroxodicarbonate in toluene at 40–60° in the presence of 50 mole % $AlCl_3$ is *p*-tolylcyclohexane (40% yield), which is obtained as the result of decomposition of the initial cyclohexyl tolyl carbonates (XXIX) and (XXX):

(9)

(10)

When carried out in chlorobenzene the reaction produces *p*-chlorophenylcyclohexane. The reaction mechanism is confirmed by the quantitative liberation of hydrogen chloride.

The ionic reactions of peroxides with solvents are almost restricted to the examples given[112,114]. However, the growing interest in such processes suggest that in the near future the ionic reactions of peroxides will form the basis of new methods of synthesis.

# ADVANCES IN THE CHEMISTRY OF POLYETHYLENEIMINE (POLYAZIRIDINE)†

D. S. Zhuk, P. A. Gembitskii, and V. A. Kargin

## CONTENTS

1. Methods of synthesising polyethyleneimine 516
2. Polymerisation of aziridine 516
3. Thermal decomposition of 2-oxooxazolidine 520
4. Properties of polyethyleneimine 522

† Since polyethyleneimine is an industrial product, and really a straight-chain compound, it has seemed advisable to retain this name in the translation, while the more systematic *aziridine* is used for the monomer (Ed. of Translation).

5. Reactions of polyethyleneimine 523

6. Copolymers of aziridine 525

Polyethyleneimine has been produced on the industrial scale since 1938, in Germany by the Badische Anilin- und Soda-Fabrik AG. at Ludwigshafen and in the USA by the Chemirad Corporation. It is used mainly for the water--repellent finishing of paper and textiles[1-4], for conferring dyeability on them[5], in the manufacture of reactive dyes[6], for the production of anion-exchange resins, films, and membranes[7-9], in the foundry industry[10], and as an additive to motor fuels[11].

## 1. METHODS OF SYNTHESISING POLYETHYLENEIMINE

Polyethyleneimine is obtained mainly by the polymerisation of aziridine. Another simple and convenient method for obtaining it is the thermal decomposition of 2-oxooxazolidine. Polyethyleneimine of low molecular weight (in the form of a mixture mainly of triethylenetetramine and tetraethylenepentamine) — the so-called polyethylenepolyamine — is manufactured in large quantities by the condensation of dichloroethane in ammonia or ethylenediamine[12], and is used as a hardening agent for epoxide resins.

## 2. POLYMERISATION OF AZIRIDINE

The polymerisation of strained three-membered rings constitutes a special aspect of the more general question of the conversion of rings into linear polymers. Unlike other methods of synthesising compounds of high molecular weight, the polymerisation of rings generally involves no change in electronic structure (provided that the peculiarities of the type of bond in strained three-membered rings are disregarded) or in the number of chemical bonds in the system: only the way in which the bonds are arranged is changed. Although a C–N bond in the ring is cleaved on the polymerisation of aziridine, a similar bond is formed in the linear polyethyleneimine molecule:

Thermodynamically, the possibility of polymerisation of ring monomers is determined by the accompanying change in free energy. The strain in three-membered rings results in the polymer being more stable thermodynamically than the monomer, and their heat of polymerisation (~23 kcal mole$^{-1}$ for aziridine)[13] provides a measure of this strain. Thus, in their tendency to polymerise, three-membered rings are close to a double bond in olefins (heat of polymerisation ~22.5 kcal mole$^{-1}$).

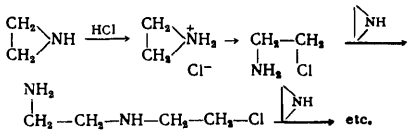
An aspect, requiring separate consideration, is the kinetic possibility of polymerisation, i.e. the mobility of the relevant bonds under the reaction conditions, since thermodynamically unstable compounds may be quite stable kinetically, and will not polymerise if they contain no labile bond. As example we can cite cycloalkanes, for which, in spite of their fairly considerable thermodynamic instability (e.g. ~25 kcal mole$^{-1}$ for cyclopropane), conditions of polymerisation have not yet been found‡. In this case the complete equivalence of all the bonds in the ring is responsible for the thermodynamic instability of strained alicyclic rings at high temperatures manifesting itself specifically[15] in their homolytic thermal isomerisation into ethylene derivatives.

Three-membered heterocycles (aziridine, oxiran, thiiran) are completely stable kinetically when absolutely pure, owing to the similarity in the energy characteristics of all the cyclic bonds. However, they polymerise in the presence of certain activators (polymerisation catalysts), which act selectively on the carbon–heteroatom bond. In fact it has been shown[16] that absolute dry§ and pure aziridine does not polymerise even at 150°. The most usual polymerising agents are acids[17-24] (including carbon dioxide[25,26], acid salts[18-20], and phenol[27]), alkylating agents[18,28-30], boron trifluoride[18,31-33], anhydrous iron(III) chloride[33], silver nitrate or perchlorate[34], surface-active substances (kieselguhr, activated carbon[20], aluminium oxide, silica gel, etc.[32]), ammonia under pressure[35], and water¶. Any reagent which can convert the ring nitrogen atom into the quadrivalent state (by salt formation, oxidation, or coordination) can act as a polymerisation catalyst for aziridine.

Bases, which are known to catalyse the anionoid polymerisation of oxides, do not cause the polymerisation of aziridine[32]. Peroxides and ultraviolet radiation†, which induce the free-radical polymerisation of vinyl compounds, are also ineffective in this respect[32]. Inhibitors of free--radical polymerisation do not exhibit the polymerisation of aziridine. Sodium, potassium, sodamide, and strontium carbonate exert an inhibiting action[18,32].

### Mechanism

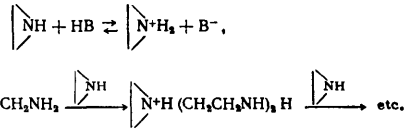
There is no consensus of opinion concerning the mechanism of the polymerisation of aziridine. German authors[24,32,39] regard it as a case of polycondensation, which presupposes intermediate formation of an addition product with the catalyst, involving cleavage of the aziridine ring (in the case of hydrochloric acid, for example, 2-chloroethylamine hydrochloride is formed), and its occurrence in two stages



‡ One paper has been published[14], describing the preparation of a polymeric product from phenylcyclopropane under high pressures (up to 2000 atm).

§ A special technique has been worked out[16] for preparing absolutely dry aziridine. The dry product (dried by standing over sodium) is distilled under vacuum and condensed over sodium which has been freshly cut and warmed in a vacuum. On cooling with solid carbon dioxide, the sodium dissolves to form a bright blue solution. The aziridine is distilled off from the resulting solution into a carefully evacuated flask. A solution of sodium is not formed if the aziridine has not undergone preliminary drying.

¶ Water is a peculiar polymerisation catalyst for aziridine. In the presence of water alone[36,37] polymerisation is extraordinarily slow (even at elevated temperatures) and usually ceases at the tetramer stage. Water has been proposed[37] as a specific catalyst for the dimerisation, trimerisation, and tetramerisation of aziridine.

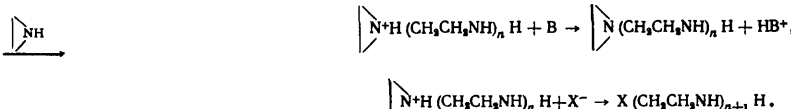


† Results reported by Japanese workers[38], showing the polymerisation of aziridine when irradiated on poly(vinyl chloride), do not contradict the above statement. Careful investigation has established that, in contrast to the radical mechanism of vinyl polymerisation, the polymer is formed in this case by the usual acid polymerisation of aziridine catalyst by OH or COOH groups produced on exposure of the substrate polymer.

– intramolecular version (rate-determining stage) and anionoid fission:

This mechanism is inconsistent with the more thorough and rigorous kinetic investigations of British[16,40] and American[18] workers. No explanation is provided of the fact that the reaction of 2-chloroethylamine hydrochloride with the feebly anionoid aziridine is of the second order, whereas the reaction of this compound with the strongly anionoid caustic potash obeys a different kinetic law. 2-Chloroethylamine hydrochloride was not isolated from reaction mixtures undergoing polymerisation, although it itself was shown to polymerise slowly at room temperature[18].

These workers suggested a mechanism of cationoid additive polymerisation of polar type, involving stepwise reaction of the aziridinium ion with uncharged rings:

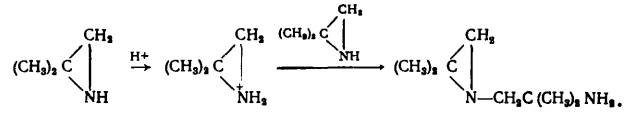


The first of these reactions is reversible, and since the rate of growth of the polymer chain is slower than transfer of a proton, all the protons will be distributed in a definite fashion among the various basic centres in the polymerising mixture. The distribution is a function of the relative concentration and basic strength of these centres. In the early stages most of the protons are combined with monomeric molecules, and the main product of polymerisation is the dimer. When the concentration of the dimer has become considerable relative to that of the monomer, formation of the trimer, tetramer, and higher polymers begins: i.e. as in chain transfer by a radical or by an ion in vinyl (radical or ionic) polymerisation, we have here a protonation transfer equilibrium.

During the progress of the reaction, the degree of polymerisation will increase, and products of low molecular weight will gradually disappear. This is confirmed[16] by the successive chromatography (on paper) of the polymerisation products of aziridine. On the first chromatogram up to seven different spots or bands (up to the octamer) are distinguished, with an unresolvable band due to higher polymers. Two faint spots were also observed, more mobile than the dimeric spots, which were shown to be caused by traces of aminoethanol and 2-2′-aminoethylaminoethanol (a hydrolysis product of the dimer).

It is also possible that two polymeric molecules may combine through their terminal aziridine groups. This is supported by the increase in the degree of polymerisation in mixtures containing no monomeric aziridine[16], and also by the spontaneous polymerisation of the specially synthesised dimer of aziridine[41].

Chain termination (in this case deactivation of the quaternary ion) can occur on abstraction of a proton by a base B (e.g. by a monomer molecule, an amino-group or an aziridinyl group of a polymer, an anion, water, etc.) or when the ring is opened by an anion:



If in the latter reaction $X^-$ represents an aziridinyl group of a polymer, the polymer chain becomes branched.

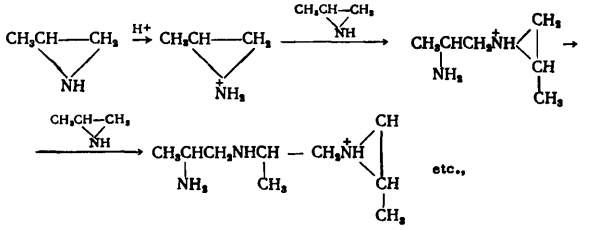
Thus although aziridine undergoes additive polymerisation, and only a few reactive aziridinium ions are present at any given instant, the general character of the process resembles stepwise polycondensation, in which all molecules contain reactive groups because of the very rapid redistribution of hydrogen ions among the various substances present.

In order to settle the question of the mechanism of this polymerisation, it is of interest to study the behaviour of unsymmetrically substituted derivatives of aziridine, since differences in reaction mechanism, which for unsubstituted aziridine can be revealed only by the kinetic form, lead in this case to structural differences.

It has been shown[42] for the polymerisation of 2,2-dimethylaziridine that the reaction involves fission of the bond between nitrogen and the cyclic methylene group (the dimer was isolated, and its structure established by a separate synthesis):

This direction of ring cleavage corresponds‡ to the bimolecular inversion mechanism $S_N2$ of interaction between charged and uncharged 2,2-dimethylaziridine rings.

The conclusion that other alkylated aziridines polymerise by an $S_N2$ type of mechanism is confirmed indirectly by a rough comparison of their rates of polymerisation§. Alkylated aziridines containing a cyclic primary carbon atom (2-methylaziridine, 2-ethylaziridine, 2,2-dimethylaziridine) are found to polymerise as readily as does aziridine itself. In contast, the polymerisation of the



‡ As noted above, preferential rupture of a cyclic bond at a primary rather than a secondary or a tertiary carbon atom indicates an inversion mechanism, whereas preference to a tertiary in relation to a primary atom would indicate an ionisation mechanism [$S_N1$].

It has been shown[43] that change to a more nucleophilic ion or a donor molecule can produce a bimolecular inversion with structures which are subject to an ionisation mechanism in the presence of less powerful nucleophiles. It must be noted in this connection that the aziridinium nitrogen should exert a considerable effect (through carbon attached to the nitrogen) favouring inversion.

§ Kinetic investigation of the polymerisation of alkylated aziridines is complicated by the solubility characteristics of the polymers. Thus the polymer of 2,2-dimethylaziridine, in contrast to polyethyleneimine, is insoluble in water and soluble in ether. This makes it difficult to use viscometric methods in studying the kinetics of polymerisation. To determine reaction rates the authors distilled unchanged monomer from an alkaline solution of the reaction mixture.

alkylated rings containing no primary carbon atom (*trans*--2,3-dimethylaziridine, 2,2-dimethyl-3-propylaziridine) is extraordinarily difficult.

Polymerisation of the optically active (+)- and (-)-2-methylaziridines (with the ether-$BF_3$ complex or with HCl) yields[33] solid polymers which soften at ~60–80° and show strong optical rotation (up to ±100°) opposite in sign to that of the monomer. The high degree of optical activity and the considerable rise in softening point compared with polymeric (±)-2-methylaziridine suggest a high degree of preservation of asymmetry during polymerisation. This is compatible only with an $S_N2$ type of ring cleavage at a primary carbon atom:

since the latter is accompanied neither by the formation nor by the rupture of bonds attached to the asymmetric carbon atom.

## Kinetics

Let us discuss briefly the kinetics of the acid polymerisation of aziridine. If the catalyst concentration is assumed to remain substantially unchanged during the reaction, the polymerisation of aziridine, which according to the above mechanism is a second-order reaction (with respect to the aziridine rings), can be represented by the equation

$$\frac{1}{1-p} - 1 = \frac{p}{1-p} = Kt,$$

where $p$ is the fraction of the monomeric aziridine which has reacted. On the further assumption that the molecular-weight distribution resembles that calculated for polycondensation[44] and is independent of temperature, reaction velocity, etc., we obtain $X^{-0.5} - 1 = Kt$,¶ where $X$ is the fraction of the monomer unchanged.

If the time variation of polymerisation with various acids is plotted as $p/(1-p)$ against $t$ (Fig. 1), the progressively diminishing slope of the curves indicates a gradual decrease in rate during the reaction, which is most clearly shown in the early stages. Two types of explanation are possible for this phenomenon: (1) the aziridine nitrogen atom in monomer or polymer is more strongly basic than an amino--nitrogen atom, and as a result competes more vigorously for possession of a proton; and (2) the catalyst is consumed in the course of the reaction.

Careful dilatometric kinetic investigations have shown[16] that the molecular-weight distribution is independent of the nature or concentration of the catalyst. This implies that the relative distribution of protons among the various basic centres (aziridine nitrogen in monomer and polymer, primary and secondary amino-nitrogen in the polymer) is identical. In this case the reaction velocity at any stage

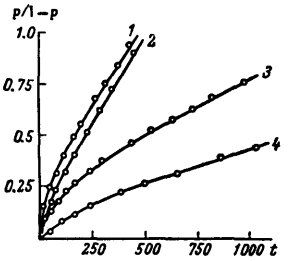


Fig. 1. Polymerisation of aziridine in the presence of various acidic catalysts (dependence of degree of conversion on time): 1) 0.025 M chloroacetic acid; 2) 0.054 M toluene-*p*-sulphonic acid; 3) 1.00 M benzoic acid; 4) 0.88 M dichlorophenol.

in the conversion will be proportional to the concentration of protons, and can be expressed mathematically as

$$-\frac{d[M]}{dt} = \sum^{x,y} K_{xy}[M_x][M_yH^+], \qquad (1)$$

where $M_x$ represents an uncharged terminal aziridine ring in a polymer having a degree of polymerisation of $x - 1$, and $M_yH^+$ is a charged aziridinium ring in a polymer having a degree of polymerisation of $y - 1$, while [M] is the total concentration of aziridine rings.

Thus the hypothesis that the catalyst concentration remains constant during polymerisation is incorrect (at least for the acids investigated), and the slowing down in the early stages of the reaction is caused not by formation of a strongly basic dimer but by diminution in the catalyst concentration†. The consumption of catalyst during polymerisation in the presence of hydrochloric, hydrobromic, and sulphuric acids, whose anions are able to compete with an aziridine molecule in opening a protonated aziridine ring, is not unexpected, since all three acids are capable of reacting with aziridine to form open-chain products.

The polymerisation of aziridine in the presence of perchloric, picric, and other acids having very feebly nucleophilic anions occupies a special position. In this case the original hypothesis, that the catalyst concentration is constant during polymerisation, proves to be correct, and Eqn. (1) remains valid. The only side-reaction in this case can be solvolytic opening of the aziridine rings (by hydrolysis, alcoholysis), which, however, makes no effective difference to the kinetic interpretation.

With the first group of acids considered here, in contrast, the reaction velocity is greatly dependent[16] on the acid used, since the kinetics of the breakdown of catalyst in a side-reaction with the aziridine varies with the different acids. In this case the kinetic interpretation must take into account the differences in the partial consumptions of monomer in the side-reaction. These differences

¶ This equation is of the same form as for a reaction of order 1.5 with respect to the monomer.

† The first hypothesis can also be rejected on the basis of the following simple experiment. Rates of polymerisation in the presence of 10–15% of added strong bases (dimer of aziridine, n-butylamine, piperidine) were compared[16] with the course of reaction in the absence of these additions. The slight retarding effect can be attributed to dilution of the aziridine.

are most definite in form with strong acids (sulphuric, hydrochloric, toluene-*p*-sulphonic) and with weak acids. (acetic and benzoic acids, 2,4-dichlorophenol). Whereas with strong acids the kinetics of catalyst destruction are consistent with their complete ionisation in aziridine solution, the kinetic treatment for weak acids is based on the hypothetical formation of ion-pairs. The kinetic regularities for both cases will be examined in detail below.

Thus, although the polymerisation of aziridine is additive, it differs from vinyl additive polymerisation (radical or ionic) in two main features. Firstly, as a result of the presence of a transfer equilibrium, all monomeric and polymeric molecules are capable of being activated (and deactivated). This produces definite kinetic characteristics resembling those observed in condensation polymerisation. Secondly, the partial consumption of catalyst usually exceeds that of the monomer, whereas the opposite is the case in other types of polymerisation.

## Strong Acids

Changing the initial concentration of the strong toluene-*p*-sulphonic acid has no effect[16] on the course of polymerisation (which in all experiments is represented by a single curve relating extent of conversion with time — Fig. 2). Thus although the catalyst is consumed during the reaction, the rate of polymerisation at any instant is proportional to the catalyst concentration:

$$-\frac{d[M]}{dt} \propto [HA]_0. \qquad (2)$$

The similarity in the catalytic activity of all strong acids (for the polymerisation of aziridine) shows that they are practically completely ionised in aziridine. Consequently $\Sigma[BH^+] = [HA]$ at time $t$. If $[M_yH^+]/[BH^+]$ is independent of the acid concentration, so that $[M_yH^+] \propto [HA]$, substitution of this expression in Eqn. (1) yields

$$-\frac{d[M]}{dt} \propto [HA], \qquad (3)$$

i.e. the rate of polymerisation at time $t$ is proportional to the instantaneous acid concentrations, and consequently the ratio of the fractional decrease in concentration of the monomer to the fractional decrease in concentration of the acid should be constant:

$$\frac{[HA]\,d[M]/dt}{[M]\,d[HA]/dt} = K. \qquad (4)$$

On substituting here the relation (3), we obtain $-d[HA]/dt \propto \propto [HA]^2$ (a relationship of the second order with respect to the acid concentration). It is consistent with the consumption of acid by the reaction

$$\overset{+}{\text{N}}\text{HR} + A^- \rightarrow ACH_2CH_2NHR, \qquad (a)$$

where R = H or a polymer chain of any length.

For this latter reaction, too, we can write

$$-\frac{d[HA]}{dt} = \sum^{y} K_{yA^-}[A^-][M_yH],$$

and if we substitute, in view of the above, $[A^-] = [HA]$ and $[M_yH^+] \propto [HA]$, we obtain the general expression for the rate of polymerisation of aziridine given previously (p. 518). Thus the kinetics of polymerisation catalysed by a strong acid which is able to cause only one side-reaction of type (a) can be regarded as completely elucidated by the case discussed here of toluene-*p*-sulphonic acid. Polymerisation in the presence of hydrochloric and sulphuric acids is also of this type.

## Weak Acids

The above kinetic regularities do not occur with weak acids. In the case of benzoic acid the overall rate is greater than would be expected for the first order with respect to the initial acid concentration. The discrepancy is especially clearly marked (see Fig. 3) in the later stages of the reaction, at which with a low concentration of benzoic acid reaction has practically ceased, although the greater part of the aziridine still remains unchanged.

It has already been noted that the catalytic action of weak acids is far weaker than that of strong acids even in the initial stages of the reaction. Strong acids are assumed to undergo complete dissociation in aziridine solution. In order to explain the low catalytic activity of weak acids, we must either assume that they undergo equilibrium dissociation (with considerable quantities of the undissociated form present) or suppose, by analogy with ionic vinyl polymerisation[45], that they form not free ions but ion-pairs of the type $\overset{+}{\text{N}}\text{H}_2A^-$, whose catalytic activity (their tendency to ring-opening) is presumably less than that of the free aziridinium ion.

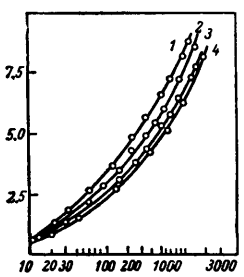

Fig. 2. Dependence of rate of polymerisation of aziridine at 40° on initial concentration (wt.%) of a strong acid (toluene-*p*-sulphonic):
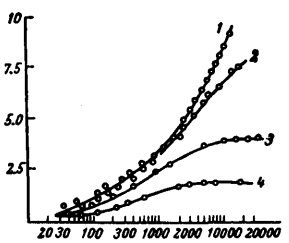
1) 6.1; 2) 3.85; 3) 2.30; 4) 1.30.



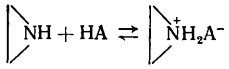


Fig. 3. Dependence of rate of polymerisation of aziridine at 40° on initial concentration (wt.%) of a weak acid (benzoic):
1) 12.25; 2) 5.72; 3) 3.47; 4) 1.53.

If we now accept that the equilibrium in the reaction

is displaced completely to the side of the ion-pair, the kinetic treatment for the case of weak acids will be entirely analogous to that given above for strong acids (with toluene-*p*-sulphonic acid as example) except that the concentration of the free aziridinium ion has been replaced by that of the ion-pairs. The relationship (3) remains valid. However, destruction of the catalyst, which was a second-order reaction with strong acids, becomes a first-order reaction with ion-pairs. Consequently $-d[HA]/dt \propto [HA]$, and Eqn. (4) for strong acids is replaced in the case of weak acids by the equation

$$\frac{[HA]\, d\,[M]/dt}{[M]\, d\,[HA]/dt} = K\,[HA],$$

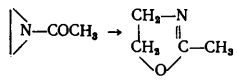
according to which the fractional decrease in catalyst concentration (and hence the rate of polymerisation), corresponding to the fractional decrease in monomer concentration, will exceed the decrease in the acid concentration. In other words, the initial rates will fall more rapidly for the most dilute solutions of the acids, as actually occurs when benzoic acid is used.

Thus the hypothesis of the existence of ion-pairs provides a good explanation of the difference in kinetic behaviour between strong and weak acids. There may also be intermediate cases.

## 3. THERMAL DECOMPOSITION OF 2-OXOOXAZOLIDINE

Another important method of obtaining polyethyleneimine is provided by thermal decomposition of the cyclic urethane 2-oxooxazolidine. Thermolysis of this compound in a strongly alkaline solvent (trishydroxyethylamine) yields monomeric aziridine[46]; thermolysis which is uncatalysed or is catalysed by weakly basic catalysts results in polyethyleneimine[47,48]. The simplicity of the synthesis of 2-oxooxazolidine and of its pyrolysis, the absence of complicated catalysts, solvents, or special apparatus, and also the avoidance of the use of the highly toxic[49-51] and mutagenic aziridine have led to the appearance of many theoretical and practical papers on this line of research within a short period[46-48,52-55].

The possibility of obtaining polyethyleneimine while avoiding the use of aziridine was first reported in the patent literature[47], without any data on the properties or composition of the pyrolysis products, only the information being given that the maximum nitrogen content reached in the polymer was 23.7%. A more detailed account[48] showed that polyethyleneimine is not the only product of thermal decomposition, for three substances of low molecular weight (one solid and two liquid) were isolated together with the polymer. One of the liquid products was aminoethanol, which was regarded as produced by the hydrolysis of aziridine formed as an intermediate. The other two substances were considered to be substituted ureas. Infrared-spectroscopic investigation of the polymer showed that it also contained carbonyl groups. Japanese workers have recently described in a series of papers[52-54] a careful investigation of the composition of the thermolysis products of various substituted 2-oxooxazolidines (as well as of 2-oxooxazolidine itself), and the kinetics and mechanism of this reaction.



### Thermolysis Products

The pyrolysis of 2-oxooxazolidine at 230° and atmospheric pressure in a stream of dry nitrogen is accompanied by the evolution of only ~61% of the theoretical quantity of carbon dioxide[53], and hence ~39% of the 2-oxooxazolidine is converted into other thermally stable carbonyl compounds. Disappearance of the carbonyl band of 2-oxooxazolidine in the infrared spectrum (at 1760 $cm^{-1}$) of the pyrolysate is accompanied by the appearance of a new carbonyl band (at 1686 $cm^{-1}$).

The pyrolysate was separated into four components (Table 1) by careful fractionation. In agreement with the above observations by Jones and his coworkers[48], the first fraction consists of aminoethanol. The structure of 1-2′-hydroxyethyl-2-oxoimidazolidine (second fraction) and of 1-2′-aziridinylethyl-2-oxoimidazolidine (third fraction) was proved by analysis, infrared examination, and comparison with synthetic preparations. The large quantity of products of low molecular weight (~62%) is probably explained by the solubility of 2-oxooxazolidine at temperatures above 80° in the pyrolysis products, which increases the likelihood of side-reactions.

The infrared spectrum of the fourth, polymeric fraction contains three amide absorption bands, at 1695, 1495, and 1275 $cm^{-1}$, which are analogous to bands in the spectra of the second and third fractions. Thus these results suggest that the polymeric products of the pyrolysis of 2-oxooxazolidine consist of a mixture of polyethyleneimine fractions of low molecule weight‡, some of them containing terminal 2-oxoimidazolin-1-yl rings.

The pyrolytic decarboxylation of 3-acetyl-2-oxooxazolidine gives, together with the corresponding polymer, a considerable quantity of 2-methyl-$\Delta^2$-oxazoline[53], probably formed by a rearrangement of *N*-acetylaziridine

resembling the rearrangement of *N*-benzoylaziridine into 2-phenyl-$\Delta^2$-oxazoline[58].

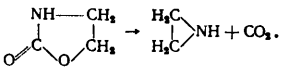


TABLE 1. Composition of pyrolysate of 2-oxooxazolidine.

| Fraction | B.p., °C | M.p., °C | Compound | Content, % |

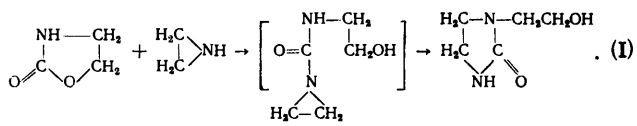
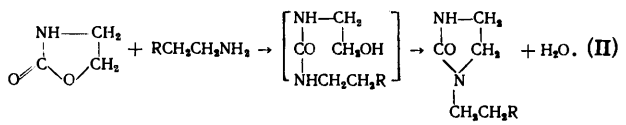
‡ The relatively low molecular weight of polymers obtained by the thermolysis of 2-oxooxazolidine is consistent with investigations of the depolymerisation of polyethyleneimine and its *N*-substituted derivatives. The latter are usually depolymerised at lower temperatures than is polyethyleneimine itself[41]. Thus poly-*N*-phenethylethyleneimine and poly-*N*-n-butylethyleneimine are completely depolymerised to the corresponding piperazines at 150° and 200° respectively. Although polyethyleneimine itself depolymerises to piperazine only at 280°,[56,57] branched-chain polyethyleneimine molecules can be regarded as representing a particular case of *N*-substituted derivatives of polyethyleneimine, so that the temperature of pyrolysis is linked with the structure of the polymer.

## Mechanism

According to Jones[48] the mechanism of the thermal decomposition of 2-oxooxazolidines is best explained by the formation of aziridine in the first stage of the reaction



In fact, aziridine, while being extremely stable in strongly alkaline medium, readily polymerises in the presence of acids, forming polyethyleneimine by a stepwise mechanism (p. 517) promoted by aziridinium cations. Initiation of the polymerisation of aziridine by carbon dioxide can be written



This route and also pyrolytic polymerisation initiated by certain acidic impurities or traces of water probably lead to the formation of polyethyleneimine instead of aziridine in the thermolysis of 2-oxooxazolidine.

The formation of secondary products in pyrolysis can also be explained by the intermediate formation of aziridine. For example, 1-2′-hydroxyethyl-2-oxoimidazolidine results from nucleophilic attack on the 2-oxooxazolidine molecule by aziridine followed by cyclisation of the adduct:

(I)

Similar attack on 2-oxooxazolidine by the terminal group of a polymer with subsequent elimination of water from the adduct leads to the formation of various 1-2′-aminoethyl--substituted derivatives of 2-oxoimidazolidine:

(II)

Actually, the compound in which R =  , i.e. 1-2′-aziridinylethyl-2-oxoimidazolidine, and a polymer having the structure (II) represents two other products of the pyrolysis of 2-oxooxazolidine. The water evolved according to Eqn. (II) is probably used up in opening the aziridine rings (to form aminoethanol) and also end-groups in the polymer.

However, the above mechanism of the formation of 1-substituted 2-oxoimidazolidines of low molecular weight and terminal 2-oxoimidazolidinyl groups on polymer chains necessarily presupposes the absence of substituents in position 3 of 2-oxooxazolidine, and consequently in position 1 of aziridine. Thermal decomposition of 3-substituted cyclic urethanes results[53] in the complete evolution of carbon dioxide, and the infrared spectrum of the pyrolysate contains no frequencies due to carbonyl groups. The pyrolysate of 3-*p*-chlorophenyl-2-oxooxazolidine consists entirely of poly-*N*-*p*-chlorophenylethyleneimine of low molecular weight. Even when decomposition of this oxooxazolidine was stopped after the evolution of half the theoretical quantity of carbon dioxide, the band at 1767 $cm^{-1}$ (due to carbonyl in the original oxooxazolidine) could be detected in the pyrolysate at half the intensity observed with the original compound; no new carbonyl absorption bands were observed.

Thus, in contrast to the usual decarboxylative polymerisation, in which decarboxylation and polymerisation occur simultaneously, in the thermolysis of oxooxazolidines these two processes are completely independent reactions.

## Kinetics

Study of the rate of the uncatalysed decarboxylation of 2-oxooxazolidine has shown[54] that in this case the decomposition is autocatalytic. It is seen from the graph in Fig. 4 that the rate of conversion $dx/dt$ first increases as reaction proceeds, reaches a maximum, and then decreases. Such a dependence of rate on $x$ represents the characteristic rate curve for autocatalytic reactions. Here it is the principal reaction products — aziridine and its polymer — which develop the autocatalytic properties.

A comparative study of the rates of decarboxylation of various 3-substituted 2-oxooxazolidines has established[54] that the ring is cleaved at the C–N bond, not at C–O (Table 2). In fact the reactivity of a 3-aryl-2-oxooxazolidine is greatly dependent on the electronic character of the substituent in the benzene ring: electron-acceptor groups accelerate decarboxylation, whereas electron-donor groups slow it down.

Thus the cleavage of the C–N bond in oxooxazolidine is the rate-determining stage in the process of decarboxylation.

A kinetic study of the catalytic decarboxylation of 2-oxooxazolidines in the presence of aromatic amines has shown that the resulting pyrolysate exerts a stronger catalytic effect than does the aromatic amine added as catalyst, the rate of conversion being represented by a curve having a maximum, which is characteristic of autocatalytic reactions.

In the presence of high-boiling aliphatic amines, however, the reaction velocity has its highest value at the

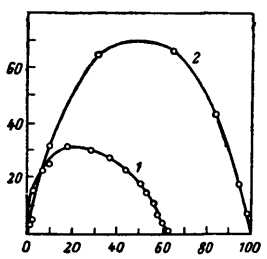


Fig. 4. Variation in rate of uncatalysed decarboxylation of 2-oxooxazolidines during reaction:
1) 2-oxooxazolidine (200°); 2) 3-*o*-nitrophenyl-2-oxooxazolidine (230°).

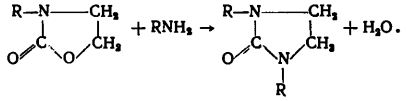

TABLE 2. Relative rates of decarboxylation of 3-substituted 2-oxooxazolidines.

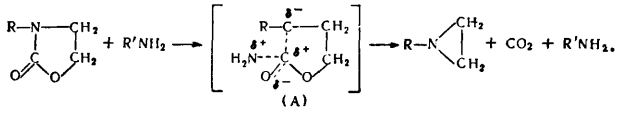
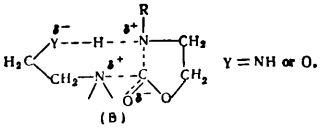
| Oxooxazolidine (R–Ox) | Relative rate |
|---|---|
| $C_6H_5Ox$ | 1 |
| $p$-$CH_3$—$C_6H_4$—Ox | 0.7 |
| $p$-Cl—$C_6H_4$—Ox | 1.9 |
| $p$-$O_2N$—$C_6H_4$—Ox | 130.0 |

beginning. The descending curve in Fig. 5 (in contrast to the expected linear dependence of $dx/dt$ on $X$ for this pseudo-first-order reaction) is explained by consumption of the added amine in the side-reactions of ammonolysis of the intermediate aziridine



and condensation with the initial 2-oxooxazolidine



Polyamines and amino-alcohols are still more active decarboxylation catalysts[54]. Since the catalytic effect of the former exceeds the value calculated from the number of amino-groups, while it is generally absent from alcohols, a "push-pull" type of mechanism is suggested. As applied to the decarboxylation of 2-oxooxazolidines, this may consist in simultaneous nucleophilic attack by the amino-group on the positively charged carbonyl carbon atom in the oxooxazolidine and electrophilic attack by hydrogen in another amino-group (or more probably in a hydroxy--group) at the nitrogen in the urethane group of the oxooxazolidine.

Thus whereas the uncatalysed decarboxylation of oxooxazolidines and the reaction in the presence of aromatic amines are autocatalytic, the reactions catalysed by aliphatic amines, polyamines, and amino-alcohols progess in two different ways depending on the structure of the catalyst. If a simple amine is used as catalyst, reaction goes mainly through the transition state (A):

In the reaction catalysed by an amine containing a $\beta$-$NH_2$ or $\beta$-OH group, on the other hand, the active transition complex probably approximates to structure (B)

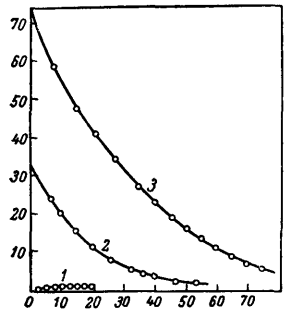


Fig. 5. Type of variation in rate of decarboxylation of 2-oxooxazolidines during reaction at 230° (1 M $p$-nitrophenyl-2-oxooxazolidine catalysed by different concentrations of n-dodecylamine in dibenzyl ether):
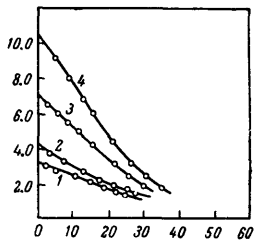
1) no catalyst; 2) 0.5 M; 3) 1 M.



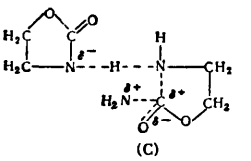


Fig. 6. Nature of variation in rate of decarboxylation at 230° of different concentrations of 2-oxooxazolidine catalysed by different concentrations of n-dodecylamine in dibenzyl ether:
1) 0.5 M + 0.75 M; 2) 0.5 M + 0.5 M;
3) 1 M + 0.75 M; 4) 1 M + 0.5 M.

In the presence of simple aliphatic amines, the decarboxylation of 2-oxooxazolidine follows a peculiar course[54] (see Fig. 6). All curves for rates of conversion with different initial concentrations of 2-oxooxazolidine are seen to converge to a single point (at about 60% conversion). The corresponding kinetic calculations show that in this case the initial rate of decarboxylation is of the second order with respect to the oxooxazolidine and of the first order with respect to the amine. These features can be explained by a peculiar, coordinated mechanism, in which the amine attacks the oxooxazolidine as a nucleophile, while another oxooxazolidine molecule attacks it as an electrophile. The transition state can be represented by the structure (C)

## 4. PROPERTIES OF POLYETHYLENEIMINE

### Molecular Weight

Oligomeric polyethyleneimine, obtained by the acid polymerisation of aziridine, is a viscous, almost colourless resin, which can be freed from fractions of low molecular weight by electrodialysis through cellulose acetate membranes[32]. The molecular weight of polyethyleneimine oligomers has been determined by cryoscopy[18] in diphenylamine, determination of the maximum quantity of dibromoethane necessary for the complete cross-linking of all the aziridine (and amino-) groups in the polymer[59], and viscosity measurements on aqueous solutions[18]. The corresponding Staudinger viscosity constant for a 1% solution of polyethyleneimine in water $K_{\bar{m}} = 2.8 \times 10^{-4}$ was obtained by extrapolation of the relative viscosity curve for purified polyethylenepolyamines. Polyethyleneimine was found to be an oligomer of comparatively low molecular weight.

The degree of polymerisation of polyethyleneimine can be calculated[24] theoretically from the molecular proportions of aziridine and of the catalyst, but the practical values

are always lower owing to the presence in the polymer of fractions of low molecular weight. Polymerisation of aziridine in the presence of the usual acidic catalysts may yield polymers of molecular weight not exceeding[24,32,60] 1000–2200, § the mean-molecular-weight of the polyethyleneimine depending on the conditions of polymerisation[24]: it is increased by increasing the initial concentration of aziridine at constant temperature, and lowered by increasing the catalyst concentration. If polyethyleneimine of as high molecular weight as possible is desired, the initial solutions of aziridine must be as concentrated as possible and a minimum amount of catalyst must be used. In practice this minimum amount is 1 mole % based on the aziridine (because of the consumption of acid in side-reactions[16]).

Theoretically this corresponds[24] to a polymer of molecular weight 4300 (if pure aziridine is used in the absence of solvent). In practice, however, this is impracticable, since increasing the aziridine concentration above 50% greatly increases the rate of polymerisation, which then is often explosive in character[32,63,64]. The explosiveness is due to inadequate removal of the heat of polymerisation at high reaction velocities.

Raising the temperature also increases the rate of polymerisation[24]. The effect of temperature depends substantially on the initial concentration of aziridine: it is considerably greater at high concentrations than with dilute initial solutions.

The comparatively low molecular weight of polyethyleneimine obtained by the acid polymerisation of aziridine in aqueous and alcoholic solutions is probably established when polymerisation ceases owing to the gradual cleavage of the aziridinyl groups at the ends of the growing polymer chains (as a result of solvolysis or side-reaction with the catalyst, see above). Polymerisation of aziridine with catalysts which do not cause ring-opening as a side-reaction (in non-aqueous media), and in the absence of contamination by compounds of low molecular weight, can probably lead to the synthesis of polyethyleneimine of higher molecular weight. Special attentian is being paid to the polymerisation of aziridine in the presence of catalysts of high molecular weight, e.g. surface-active substances or cation-exchange resins.

### Degree of Branching

Polyethyleneimine can contain up to 38% of nitrogen in the form of primary amino-groups[65-67]: i.e. it is a strongly branched polymer. The formation of such polymers is observed mostly when polymerisation is continued until the monomer has been almost completely converted. Infrared examination[67] of polyethyleneimine shows it to contain primary, secondary, and tertiary nitrogen atoms (bands at 2.9, 6.3, 9.0, and 9.6 μm). In the polymerisation of aziridine in the presence of 1 mole % of HCl the degree of branching increased with rise in temperature and increase in the acid concentration[66]. It is interesting that at low temperatures (20°) the degree of branching diminishes with fall in the acid concentration (from 38% to 12%);

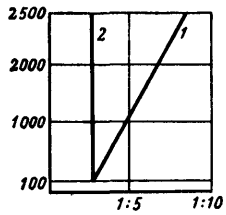

Fig. 7. Dependence of degree of branching of polyethyleneimine on catalyst (HCl) concentration for polymerisation of $C$ = 50% of aziridine at:
1) 20°; 2) 80°. The molar ratio of aziridine to catalyst is plotted as ordinate.

at high temperatures (80°) it is independent of concentration and has the value 38% (see Fig. 7). The complete polymerisation of polyethyleneimine at high temperatures results in the degree of branching again increasing to 38%.

Unbranched polymers can be obtained by the polymerisation of an $N$-substituted aziridine. Thus the preparation has been described[13] of a straight-chain polyethyleneimine (up to a molecular weight of 2000) by the polymerisation of $N$-benzenesulphonylaziridine (by heating or in the presence of traces of boron trifluoride).

## 5. REACTIONS OF POLYETHYLENEIMINE

### Ionisation Equilibrium

Three papers have been published[59,67,68] on the use of potentiometric titration to study the ionisation of polyethyleneimine. Although different specimens of the polymer were employed, the results show quite good agreement. The titration curve for polyethyleneimine in aqueous potassium chloride (Fig. 8) resembles that for monoacid bases, except that the pH values fall more sharply than with amines of low molecular weight. This indicates that the NH groups in the polymer have a far smaller ability to combine with acid than have the simpler amines. The basic strength of the NH groups in polyethyleneimine is increased by the presence of a neutral salt (KCl). Thus a 0.01 M solution of the polymer in 1 $N$ KCl has pH 9.89, while the equivalence point is at pH 4.4. The equivalence point is reached at 66% neutralisation: in other words, only two-thirds of the basic groups in polyethyleneimine can be titrated. A similar phenomenon is observed with proteins[68] and with poly-$N$-vinylimidazole[69].

Similar results have been obtained[67] by the back titration of polyethyleneimine hydrochloride with alkali. Exact neutralisation is achieved after 34% of the hydrochloride HCl has been titrated. The curve representing titration of the hydrochloride with alkali is inverted with respect to the titration curve for the basic polymer.

The acid dissociation constant of polyethyleneimine $K_a \simeq 10^{-9}$ has been calculated[67] by means of the modified Henderson–Hasselbalch equation for polyelectrolytes. This equation is valid only up to a degree of dissociation of $\alpha = 0.5$. Over this range polyethyleneimine conforms to Katchalsky's theory of polyelectrolytes[70]; above $\alpha = 0.5$ it behaves as a monomeric acid.

§ Although the molecular weight of industrial specimens of polyethyleneimine produced by the BASF firm probably lies within or near the above limits, with American specimens[61] $M$ = 30 000–40 000 and even[62] 100 000.

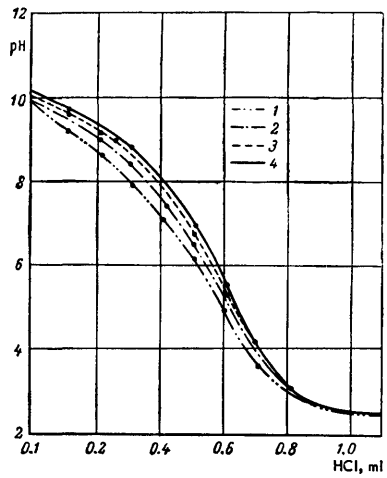

Fig. 8. Curves representing potentiometric titration of a 0.01 M solution of polyethyleneimine with 0.5 *N* HCl in the presence of various concentrations of neutral salt (*N* KCl): 1) 0.1; 2) 0.5; 3) 1.0; 4) 2.0.

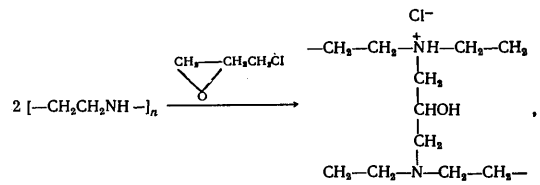
British workers succeeded[59] in titrating amino- and aziridinyl groups in the polymer separately, obtaining $pK_a$ values of 9.0 and 10 respectively. Calculation of the constants was based on Katchalsky's equation for chain polyelectrolytes[71].

Very similar results were obtained in a study of the ionisation of polyethyleneimine which had been cross-linked with dibromoethane[72]. Although the titration curves were similar in form to those for the oligomer, a difference was caused by the appearance of new nitrogen atoms which could not be titrated even at pH 1–2, i.e. extremely feebly basic (tertiary) atoms. Their number corresponds exactly with the number of dibromoethane molecules which have reacted. The results of the titration of oligomeric polyethyleneimine become clear when it is remembered that specimens of the polymer usually contain up to 38% of tertiary nitrogen atoms owing to branching.

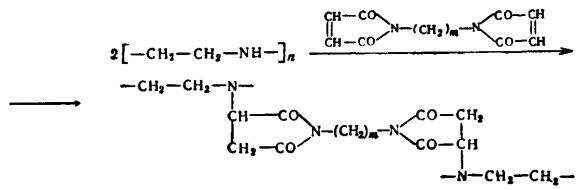
## Salts of Polyethyleneimine, Complex Formation

Viscosity measurements on partly neutralised aqueous solutions of polyethyleneimine[67] show that maximum viscosity occurs at 80% neutralisation. Further addition of electrolyte merely screens the charges on the long-chain polymer molecule. This weakens the electrostatic repulsion between ionised groups, as a result of which the extended filaments of ionised polyethyleneimine pass more and more into random tangles, as with uncharged fibrous molecules.



It has also been found that polyethyleneimine salts are strongly hydrolysed in solution (up to 30%). Titration of cross-linked polyethyleneimine with different acids gives the sequence – acetate < chloride < toluene-*p*-sulphonate – for the affinity of the resin for anions. The degree of swelling of the corresponding salts of the cross-linked oligomer in water falls in the same sequence, which indicates increasing association of the ions owing to van der Waals forces of adhesion between the anions and the polymer chains.

Polyethyleneimine has been found[67,72] to absorb copper (and also cobalt and nickel) to form ammines. Complex formation is accompanied by a decrease in the basic strength of the polymer and in the viscosity of aqueous solutions, owing to the weakened hydrophilic character produced by screening of the ionic groups by the complexing copper ions. The ammines of polyethyleneimine with copper and nickel can be completely dried, and the resulting powders, unlike polyethyleneimine itself, are not hygroscopic.



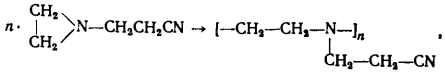
Study of the salts of polyethyleneimine is of interest for the fundamental theory of polyelectrolytes in view of the exceptionally high charge density of the ionic groups.

## Cross-Linking of Polyethyleneimine Chains (Hardening Reactions)

The preparation of purely aliphatic anion-exchange resins of extraordinarily high capacity, based on polyethyleneimine networks, has attracted special attention to the study of the cross-linking of this polymer by various substances. Among cross-linking agents which have been used are 2,3-epoxypropyl chloride[73,75]

dichloroethane and dibromoethane[74], formaldehyde[72], and maleimide[75]

(cross-linking by addition to an activated double bond).



The reaction with dibromoethane has been studied the most thoroughly. The minimum quantity of the latter required to form a gel with polyethyleneimine is[72] 0.028 mole g-equiv.$^{-1}$. To obtain a mechanically stable resin, however, this quantity must be increased fivefold (to 0.16 mole g-equiv.$^{-1}$). Only a small proportion of the dibromoethane was actually found to form cross-links between the polyethyleneimine chains, most of it reacting with nitrogen atoms in the same chain to form small closed loops. Drying the resin at 100° produces further cross-linking (the degree of swelling is diminished). Cross-linked polymers obtained by this method are stable to acids and alkalis for 2–3 months.

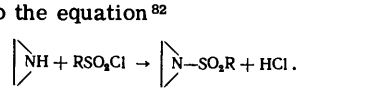
## *N*-Substituted Polyethyleneimines

Acetylation of polyethyleneimine with acetic anhydride yields a water-soluble *N*-acetyl derivative, which has been proposed[76] as a blood-plasma substitute. Acylation (acetylation and benzoylation) of polyethyleneimine has been suggested as a method for determining its degree of branching, but the results obtained are not very reliable.

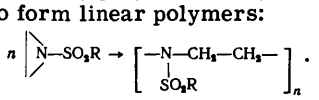
A probably more reliable method is reaction of the terminal amino-groups of polyethyleneimine with nitrous acid by Van Slyke's procedure[65], and also conductimetric titration.

Poly-*N*-cyanoethylethyleneimine has been obtained[77] by the polymerisation of β-aziridinylpropionitrile:

which in turn is readily obtained by the cyanoethylation of aziridine:



Benzoylation. The Schotten–Baumann benzoylation of polyethyleneimine gives[18] a viscous white product soluble in chloroform, which after reprecipitation in ligroin is obtained as a white powder having a softening point of 110°.



Poly-*N*-nitrosoethyleneimine. This compound has been obtained[18,78] as an insoluble precipitate by the addition of hydrochloric acid to polyethyleneimine in aqueous sodium nitrite solution. The nitrogen content of the resulting polymer differs markedly from the calculated value.

Poly-*N*-sulphonylethyleneimines. These polymers have been obtained both by the reaction of polyethyleneimine with sulphonyl chlorides[79] and by the direct polymerisation[80,81] of *N*-sulphonylaziridines (the methanesulphonyl, benzenesulphonyl, toluene-*p*-sulphonyl, naphthalene-1-sulphonyl, etc. derivatives).

Liquid or low-melting solid *N*-sulphonylaziridines are obtained by the reaction of sulphonyl chlorides with aziridine according to the equation[82]

Polymerisation of the initial aziridine by the hydrogen chloride formed is prevented by carrying out the reaction in the presence of alkali. The monomeric *N*-sulphonylaziridines thus obtained are readily polymerised by heating or by the action of alkali to form linear polymers:

The most effective polymerisation catalysts are organic bases, including aziridine. Polymerisation is inhibited by acids (e.g. arenesulphonic acids and acetic acid).

Poly-*N*-sulphonylethyleneimines are chemically stable solids of high melting point, insoluble in the usual organic solvents and extremely resistant to hydrolysis (by alkalis and acids). Their physical properties can be modified by carrying out polymerisation in the presence of alkaline catalysts. The degree of polymerisation can be controlled to a certain extent by varying the temperature and duration of polymerisation.

*N*-Sulphonylaziridines are readily polymerised on substrates — textiles, paper, etc.

Methylation. The methylation of polyethyleneimine has been accomplished[83] by the action of dimethyl sulphate on an aqueous solution of the polymer, with subsequent neutralisation with sodium carbonate. The product of exhaustive methylation obtained is a readily water-soluble polymer, which is used for pretreating cellulosic fibres before the application of direct dyes.

A large amount of specialised work has been done on the industrial exploitation of the reaction of polyethyleneimine with cellulose[84,85], and this has been reviewed by Machida[86].

## 6. COPOLYMERS OF AZIRIDINE

### Copolymers with Carbon Monoxide and Carbon Disulphide

Rubberlike solid products are obtained by the copolymerisation of aziridine with carbon monoxide[87] and with carbon disulphide[88,89]. Reaction with the former is carried out at high temperatures (150°) and high pressures of carbon monoxide (~2000 atm). Results of elementary analysis on the product of m.p. 211° correspond to the formula $[(C_2H_5N)_2CO]_n$.

### Copolymers with Cyclic Oxides

Depending on the relative proportions of the components, copolymers of aziridine with oxiran and methyloxiran can be obtained as viscous oils of various consistencies[90]. The products have not been investigated in greater detail. They have been used for the processing of textiles. A patent[91] has proposed the use as ion-exchange membranes of copolymers of aziridine with 2,3-epoxypropyl chloride obtained by heating the components (in the proportions 12 : 1) without a catalyst.

A detailed study of the copolymerisation of aziridine with oxides in the presence of various Lewis acids has been made by Overberger and his coworkers[92]. They have shown that even the most active of the catalysts examined (the ether complex of boron trifluoride) gives a product which is not a true copolymer, but consists of a polyamine main chain which has been β-hydroxylalkylated by the epoxides. Actually, the reaction with 1-ethylaziridine, which cannot form side-chains with the oxides, gave a copolymer containing 86 mole % of aziridine residues, while epoxide residues were present only as end-groups (resulting from chain termination). Complex formation between the catalyst and basic polymeric and monomeric aziridine derivatives evidently makes it incapable of catalysing the growth of epoxide chains.

### Copolymers with Diisocyanates and Isothiocyanates

Many synthetic resins, from viscous oils to solids, have been obtained[93-99] by the condensation (effected by heating or by the action of acids, alkalis, etc.) of aziridine with aliphatic or aromatic diisocyanates and isothiocyanates, e.g. with 4-methyl-1,3-phenylene diisocyanate.

### Copolymers with αβ-Unsaturated Acids, Aldehydes, and Ketones and with Acrylonitrile

The products described in the patent literature[77,98,100,101] are probably polymers of *N*-substituted aziridines, obtained by the addition of aziridine to the vinyl components.

Copolymers with *N*-Sulphonylaziridines

The copolymerisation of mixtures of a sulphonylaziridine and aziridine occurs spontaneously[81], the resulting polymer containing both components. The properties of the copolymers obtained differ from those of polyethyleneimine and of polysulphonylethyleneimines. They depend on the relative proportions of the components. With small amounts of aziridine, resins are obtained which are insoluble in water and in acids. Copolymers containing not less than 5 moles of aziridine per mole of *N*-sulphonylaziridine dissolve in acids, alkalis, and organic solvents. Depending on the contents of the components, the state of aggregation of these copolymers varies from viscous oils to solid resins.

---o0o---

The growing interest in the chemistry of polyethyleneimine is due not only to the developing fields for its industrial application. The intrinsic interest of this branch of the chemistry of macromolecular compounds is connected both with the peculiar character of the reactivity of functional groups in a polymer chain and with the problem of the special features of multifunctional polymers.

The polyethyleneimine system — the simplest heterochain polymer and polybase — is most convenient for investigations on these lines. This system is formed by replacing one-third of the carbon atoms in polyethylene with nitrogen atoms. While preserving several of the properties of polyethylene (including thermal stability), it is nevertheless highly reactive.

7. Method of calculating the angle of rotation of optically active 2-mercurated alcohols 534

V. Hydroxymercuration of alkenes when there is preliminary coordination of a mercury ion with functional groups 534

## I. INTRODUCTION

In 1892 Kucherov discovered that mercury(II) salts are capable of addition to a C–C double bond[1]. Eight years later — in 1900 — Hofman and Sand[2] developed this reaction, and in subsequent investigations it was shown that the reaction of alkenes with mercury(II) salts leads to the formation of hydroxyalkylmercury compounds and their derivatives:

Since then, hydroxymercuration has remained a subject widely studied from various viewpoints. Hydroxyalkylmercury compounds, being readily available, find application as pesticides, antiseptics, diuretics, preservatives, seed dressings, etc.

The alkoxyalkylmercury halide derivatives obtained in this way were used to solve several important theoretical problems. Thus the example of electrophilic substitution

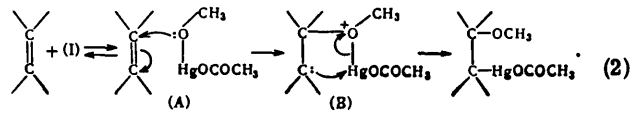
by mercuric chloride on *cis*-2-methoxycyclohexylneophylmercury showed that the configuration is retained during bimolecular electrophilic substitution at a saturated carbon atom[3].

Hydroxymercuration can be applied to alkenes of various structures; it is simple to perform and usually takes place with high yields. Chatt[4] has reviewed the extensive literature on this reaction.

However, despite intensive study, the stereochemistry of hydroxymercuration has not yet been strictly established. On the one hand, the difficulty of determining the configuration of mercurated alcohols was due to the impossibility of using chemical methods, since in chemical reactions the C–Hg bond is affected and the reactions proceed with substitution at the asymmetric carbon atom, whereas the stereochemistry of electrophilic substitution at a saturated carbon atom has become known only in the last few years. On the other hand, the use of physical methods of investigation, for example, X-ray diffraction or the measurement of dipole moments, also did not allow the configuration of mercurated alcohols to be determined unambiguously and conclusively and in some instances led to incorrect conclusions. Thus in 1951 Brook and Wright[5] made an X-ray diffraction analysis of 2-methoxycyclohexylmercury chloride, obtained by the methoxymercuration of cyclohexene, and found that it has the *trans*-configuration. Because of this, in Chatt's review[4] the information on the hydroxymercuration was interpreted from the standpoint of *trans*--addition. However, in later studies[6-8] (see also Kreevoy and Kowitt[9]) Wright assumed error in the X-ray data and even expressed the opinion that this method is generally not very dependable when applied to the products of hydroxymercuration. [Now, however, the X-ray diffraction method is considered reliable (see IV, 2) (Ed. of Translation)].

The present review considers the stereochemistry of the hydroxymercuration of alkenes, which only recently has been established reliably, using various methods. It will be necessary to consider also some earlier work, already reviewed by Chatt[4]. Note that there is also a review by Wright[6] dealing with the hydroxymercuration of alkenes, but all its stereochemical conclusions are wrong.

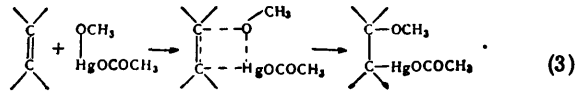
## II. MECHANISM OF THE REACTIONS OF HYDROXYMERCURATION AND DEHYDROXYMERCURATION



Because of the above-mentioned difficulties in establishing the configuration of mercurated alcohols attempts were made to determine it starting from the stereochemical requirements of the reaction mechanism.

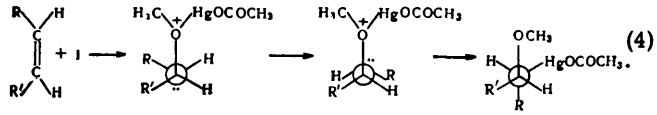
The addition of mercury salts is electrophilic and the presence of electron-acceptor substituents hinders the reaction. Hydroxymercuration proceeds stereospecifically: from the *cis*- and *trans*-isomers of alkenes different diastereomers are obtained free from the second isomer as impurity; the reaction is not accompanied by *cis–trans* isomerisation of the alkene. The hydroxymercuration product of the *cis*-alkene is usually called the $\alpha$-diastereomer; the $\beta$-diastereomer is formed from the *trans*-alkene, and also on isomerisation of the $\alpha$-isomer. The dipole moment of the $\alpha$-diastereomer is usually less than the $\beta$-diastereomer. The rate of hydroxymercuration of the *cis*-alkene is greater than that of the *trans*--alkene, which allows this reaction to be used to determine the configuration of the alkenes. Kinetic investigations showed that the reaction is second-order[6-8].

The mercurated alcohols are readily dehydroxymercurated, and because of this Nesmeyanov[10] called them "quasicomplex compounds". Dehydroxymercuration also proceeds stereospecifically and leads to the alkene of the original configuration, and many examples[11] have shown that the diastereomer with the lesser dipole moment is dehydroxymercurated more readily.



Two alternative mechanisms have been proposed for the hydroxymercuration. Wright[6,12,13] proposed a non-ionic mechanism in which there is first alcoholysis (hydrolysis) of the mercury(II) acetate with formation of a hydroxoacetatomercury(II) or an acetatoalkoxymercury(II) complex, which then reacts with the alkene in the slow stage of the reaction:

$$CH_3OH + Hg(CH_3COO)_2 \rightleftharpoons \underset{(I)}{CH_3OHgOCOCH_3} + CH_3COOH, \qquad (1)$$



(2)

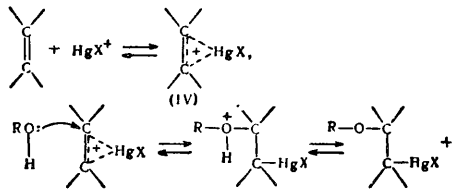
It is assumed that acetatomethoxymercury(II), (I), is in rapid equilibrium with mercury(II) acetate in methanol solution. Note that in the case when stages A and B are distinct this mechanism is inadmissible, since it presumes nucleophilic attack on the double bond by the methoxy oxygen. This difficulty is easily overcome by assuming that the slow stage of the reaction proceeds through a four-centred transition state:

(3)

In accordance with this reaction mechanism, hydroxymercuration should proceed as a *cis*-addition. Therefore in all of Wright's studies[6,7] the $\alpha$-diastereomer is given the *cis*-configuration. The most substantial argument in support of the molecular mechanism is thought by Wright to be the fact that the rate of hydroxymercuration is greater in methanol than in water[7,14]. To explain possible instances of *trans*-addition, Wright introduced the "coordinative dipole" mechanism[14], according to which during the stage of the A → B change in scheme (2) there is rotation around the C–C bond:

(4)

This mechanism is undoubtedly incorrect, since the hydroxymercuration reaction is considered in essence again as a nucleophilic addition.



Winstein and coworkers[15] proposed an ionic mechanism on the basis of a study of the distribution of cyclohexene between carbon tetrachloride and water or an aqueous solution of mercury(II) nitrate; it was found that cyclohexene forms two types of complexes with the mercury ions, by schemes (5) and (6):

$$C_6H_{10} + Hg^{2+} \overset{K_1}{\rightleftarrows} \underset{(II)}{C_6H_{10}Hg^{2+}}, \qquad (5)$$

$$C_6H_{10} + Hg^{2+} + H_2O \overset{K_2}{\rightleftarrows} \underset{(III)}{C_6H_{10}\overset{+}{H}gOH} + H^+, \qquad (6)$$

where $K_1 = 2.2 \times 10^4$ and $K_2 = 5.0 \times 10^4$.

The authors formulated the structure of these complexes by analogy with the "bromonium" cation[16] and expressed the opinion that similar complexes, especially singly-charged complexes of type (III), are intermediates in hydroxymercuration, which proceeds in this way by schemes (7)–(8):

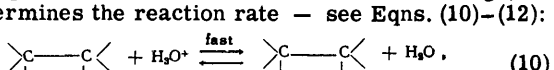
(7)

(8)

In accordance with this mechanism — by analogy with the discovery of other bridged ions which may be formulated as $\pi$ complexes — hydroxymercuration should take place as a *trans*-addition.

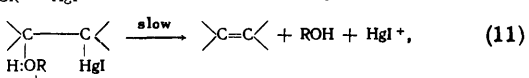
Although subsequently Brook and Wright[17] found that under these conditions cyclohexene is converted into formylcyclopentane, this, however, does not disprove the results of Winstein and coworkers[15], since the rate of such a conversion is far less than the rate of reaching equilibrium in the distribution of cyclohexene between two phases (the measurements were made after 0.5, 1, and 1.5 h and were extrapolated to zero time).

One of the arguments put forward by Wright against an ionic mechanism[14] is the absence from the outer electron cloud of the mercury ion of free electron pairs by which a cyclic "onium" ion could be formed, analogous to that originally proposed, for example, for the bromine cation[16]. However, the cyclic ion proposed by Winstein and coworkers[15] must be considered essentially as a $\pi$ complex[21] The electronic structure of the complex of the mercury ion with an alkene was considered by Dewar[18] (see also Kreevoy and Kowitt[9]), who proposed that in the alkenemercury(II) ion (IV) the $6sp$ hybrid orbital of the mercury atom overlaps with the two $2p$ orbitals of the carbon atoms, forming a pseudoaromatic structure. Here additional stabilisation is also possible with participation of the $5d$ electrons of the mercury and the antibonding $\pi$ orbital of the alkene[9].

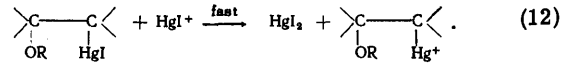


However, not one of the mechanisms of hydroxymercuration presented above explains certain features of this reaction; for example, catalysis by peroxides and by oxygen[11].

It seemed possible to draw reliable stereochemical conclusions only by studying the mechanism of dehydroxymercuration. Kreevoy showed[9,19-22] in 1959 that dehydroxymercuration by perchloric acid proceeds by the following stoichiometric equation:

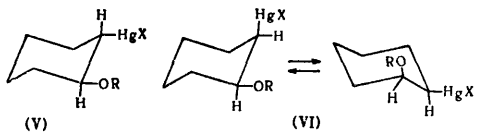


(9)



Detailed study of the mechanism of this reaction showed[9,19-22] that in the first stage there is a rapid and reversible addition of a proton to the alkoxy oxygen atom, with subsequent formation of alkene in the second stage, which determines the reaction rate — see Eqns. (10)–(12):

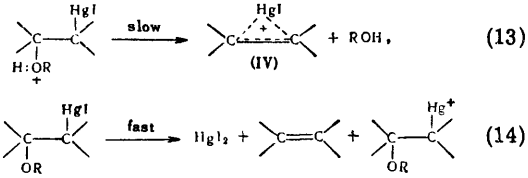
(10)



(11)

(12)

The reaction takes place very readily; for example, the rate of dehydroxymercuration of 2-hydroxypropylmercury(II) iodide is $10^{11}$ times as great as the acid-catalysed dehydration of propan-2-ol[9].



From the results of kinetic studies of the dehydroxymercuration of $\alpha$- and $\beta$-2-methoxycyclohexylmercury(II) chloride, (Va) and (VIa) respectively, Kreevoy[9,21] drew convincing conclusions about the structure of the transition state at the stage which determines the rate of the reaction, Eqn. (11).

(a) R=CH$_3$; (b) R=H.

The $\alpha$-diastereomer (Va) is dehydroxymercurated approximately $10^6$ times faster than the $\beta$-diastereomer (VIa); for the $\alpha$-diastereomer $\Delta H^{+} = 17.75 \pm 0.19$ kcal × × mole$^{-1}$ and $\Delta S^{+} = 4.6 \pm 0.6$ cal mole$^{-1}$ deg$^{-1}$, whereas for the $\beta$-diastereomer $\Delta H^{+} = 26.2 \pm 0.7$ kcal mole$^{-1}$ and $\Delta S^{+} = 4.5 \pm 2.0$ cal mole$^{-1}$ deg$^{-1}$.

Starting from these results for the rate-determining stage a structure was adopted for the mercurinium ion (IV) analogous to that proposed earlier[15]. Reactions (11) and (12) can be more strictly represented by Eqns. (13) and (14):

(13)

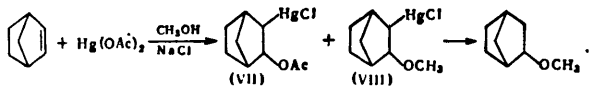
(14)

If the mercury and oxygen are in the *trans*-position, there will be a synchronous withdrawal of the ROH group and formation of the mercurinium ion, which proceeds without appreciable steric hindrance[9,21]. The required coplanarity of the groups being detached can be attained with little distortion of the bond angles only for the *trans*-isomer (in the diaxial conformation). Hence the dehydroxymercuration of the *trans*-isomer requires a lower activation enthalpy than the *cis*-isomer, and the $\alpha$-diastereomer (Va) can be ascribed the *trans*-configuration. It is noteworthy that the activation entropies for the two diastereomers are similar. This shows that the solvation in the two transitional states is about the same.

The mechanism proposed by Wright can also be considered in its application to dehydroxymercuration where the rate-determining stage for the reaction is represented by the equation:

(15)

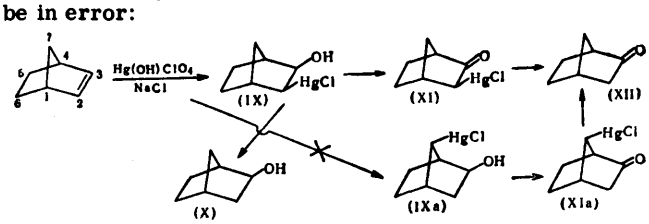
When, in accordance with Wright's results, the *cis*-configuration is taken for the $\alpha$-diastereomer, then its higher rate of dehydroxymercuration should be due to the solvation of the mercury ion being detached by the methanol being better than that by water, which is generally improbable. Furthermore, the difference in the rates of dehydroxy-



mercuration of two isomers should be due normally to differences in the entropies of activation rather than to the activation enthalpies[9].

Hence the information about dehydroxymercuration allows the *trans*-configuration to be fairly reliably ascribed to the α-diastereomer obtained by the hydroxymercuration of cyclohexene.

## III. HYDROXYMERCURATION OF BICYCLOALKENES (IN THE ABSENCE OF PRELIMINARY COORDINATION OF THE MERCURY ION WITH THE SUBSTITUENTS)

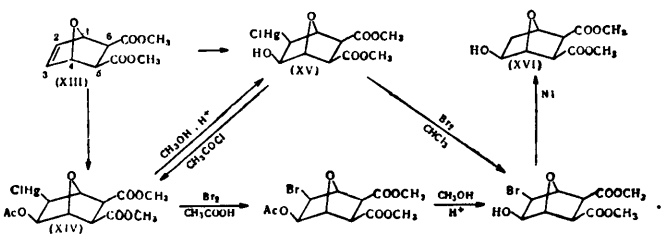


Of great interest in establishing the stereochemistry of hydroxymercuration is the study of this reaction in the case of bicyclo-bridged systems of the norbornene type. The geometry of these alkenes predetermines *exo*-attack of the reagent being added on, as was confirmed by an extremely large number of varied reactions[23-25]. On this basis the HgX group can be ascribed *exo*-configuration and then the problem of determining the stereochemistry of hydroxymercuration leads to the determination of the configuration of the hydroxy- or alkoxy-groups respectively.

In 1959 there appeared work by Wright and coworkers[7] and a brief communication by Traylor and Baker[26] devoted to the hydroxymercuration of norbornene. However, the stereochemistry of hydroxymercuration was interpreted differently in these papers. Wright and coworkers[7] found that under the action of mercury(II) acetate norbornene forms 3-acetoxynorborn-2-ylmercury(II) chloride (VII) or 3-methoxynorborn-2-ylmercury(II) chloride (VIII):

Unexpectedly, this reaction is essentially different in its stereochemical result from the hydroxymercuration of ordinary alkenes and undoubtedly takes place heterolytically, since it is catalysed by acids. The α-diastereomer formed is relatively stable to the action of acids whereas the β-diastereomer very easily undergoes dehydroxymercuration in acid; the dipole moment of the α-diastereomer is greater than that of the β-diastereomer. In the reduction of the α-diastereomer (VIII) methyl *endo*-norbornyl ether was obtained, and from this it was concluded that the α-diastereomer is the *trans*-isomer, additional confirmation of which was given by consideration of dipole moments. Since the stereochemistry of this reaction is the antithesis of what is observed for alkenes of the cyclohexene type, Wright considers that the hydroxymercuration of the latter should proceed as a *cis*-addition, that is, in accordance with the non-ionic mechanism.

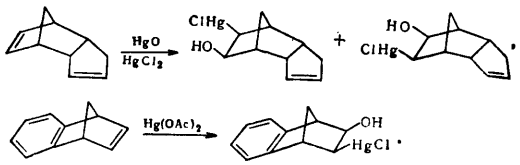
Traylor and Baker[26] also concluded that the stereochemistry of the hydroxymercuration of norbornene is different from that observed for ordinary alkenes, but on reducing the α-diastereomer (IX) they obtained *exo*-norborneol (X) and therefore the alleged preparation of methyl *endo*-norbornyl ether in the above work[7] is considered to be in error:



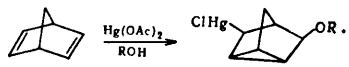
Hence the hydroxymercuration of norbornene proceeds as a *cis-exo*-addition, while the hydroxymercuration of ordinary alkenes takes place as a *trans*-addition through the intermediate mercurinium ion.

As is well known, ionic addition to norbornene can be accompanied by a Wagner–Meerwein rearrangement. This possibility was not considered by Wright and coworkers[7], whereas Traylor and Baker specially confirmed the absence of the rearrangement by oxidising the α-diastereomer (IX) to the ketone (XI) and reducing the latter with sodium stannite to norcamphor (XII), which is characteristic for the α-ketomercury chloride derivatives. However, this series of reactions is not a strict demonstration of the absence of rearrangement. The double bond of norbornene can participate in the stabilisation of the carbonium formed during the solvolysis of the 7-substituted derivatives[27,28]. Therefore the preparation of norcamphor can be explained starting from the structure of the *syn*-3-hydroxynorborn-*exo*-7-ylmercury(II) chloride for the α-diastereomer (IXa), assuming the interaction of the 2-keto- and 7-chloromercury-groups in the ketone (XIa) on reduction.

The stereochemical data on the hydroxymercuration of norbornene were supplemented by Yur'ev and coworkers[29-31] in a study of the hydroxymercuration of a similarly constructed bicyclo-system — 7-oxanorbornane, having an oxygen bridge atom, for which the correctness of the *exo*-addition rule had been shown earlier[32]. In order to avoid the Wagner–Meerwein rearrangement, the model selected for studying the stereochemistry of hydroxymercuration was the dimethyl ester of *exo-cis*-7-oxanorborn-2-en-5,6-dicarboxylic acid (XIII). The presence of electron-acceptor groups in this type of bicyclo-compound greatly reduces the rate of solvolysis of halides[33], stabilises the α-oxide ring[34] and results in most of the additions at the double bond proceeding without the Wagner–Meerwein rearrangement[35,36], although in principle all courses of the reaction with rearrangement are possible also in the presence of electron-acceptor groups[35,36].



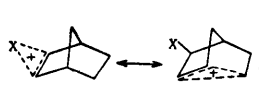
Hydroxymercuration of the diester (XIII) leads to the acetoxy- (XIV) or hydroxy-derivative (XV), depending on the conditions[31]:



The compounds obtained, like *exo-cis*-3-hydroxynorborn-2-ylmercury chloride (IX), seemed relatively stable in acid. The *exo*-hydroxydiester (XVI) was obtained by a series of successive conversions from (XIV) and (XV), the configuration of which had been established earlier[31,32]. Hence the hydroxymercuration of the diester (XIII) proceeds by an *exo-cis*-addition (additional proofs are given below).

In 1963 Traylor and Baker showed that the hydroxymercuration of bicyclopentadiene and benznorbornene takes

place as an *exo-cis*-addition without the Wagner–Meerwein rearrangement[37]:



It is interesting that norbornadiene reacts with mercury(II) salts as a homoallyl system with participation of the two double bonds and formation of a 6-acetoxy- or 6-alkoxy-tricyclo[2,2,1,$0^{3,5}$]hept-2-ylmercury(II) chloride[38,39]:

From the above information on the study of hydroxymercuration there is no doubt that stereochemically the course of this reaction depends on the type of alkene taking part: in unsaturated bicyclo-systems having sterically hindered *endo*-attack, hydroxymercuration proceeds as a *cis*-addition, whereas the hydroxymercuration of ordinary alkenes of the stilbene or cyclohexene type takes place as *trans*-addition.

It must be emphasised, however, that the problem of the reason for *cis*-addition in hydroxymercuration is not completely clear. The opinion has already been expressed in the literature that strongly solvated bridged onium ions or $\pi$ complexes can, in the case of hindrance to *trans*-attack by a nucleophilic agent, undergo *cis*-opening of the ring as revealed by the products[26,31,37]. This finds confirmation in the stereochemistry of additions or rearrangements taking place through an intermediate $\pi$ complex of a proton with the alkene, or a bridged "protonium" ion. The disclosure of such an undoubtedly strongly solvated ion proceeds anomalously stereochemically in comparison with the usual *trans*-opening of intermediate cyclic onium ions (or $\pi$ complexes), as has been shown by several examples[40,41]. Similar behaviour can occur during hydroxymercuration. Confirmation of this is obviously provided by the fact that the action of mercury(II) acetate in methanol on norbornene gives a mixture of 3-acetoxynorborn-2-ylmercury chloride (VII) and 2-methoxynorborn-2-ylmercury chloride (VIII).[7] In the case of *trans*-addition the methanol concentration is immeasurably greater than that of the acetate anion, and the reaction leads almost solely to the formation of the methoxy-derivative. In the case of *cis*-addition, the anion which attacks the intermediate mercurinium ion is taken from the solvate sheath of the mercury ion.

However, the hindrance to *trans*-opening of the mercurinium ion obviously cannot be explained solely by the steric shielding of the double bond from the *endo*-side. It was noted[37] that in bicyclo-systems it is difficult to attain a planar transition state for *trans*-addition. However, examples of *trans*-opening of an $\alpha$-oxide ring[32,32] or of *trans*-addition at the double bond[36] nevertheless show the possibility in principle of such a transition state. Yet another factor is probably required in explaining the cases of *cis*-hydroxymercuration in bicyclo-systems, namely, the contribution in the transition state of a structure with partial delocalisation of the electrons of the 1,6- and 4,5-bonds:

An analogous explanation was postulated for instances of radical *cis*-bromination[43], but it can probably be applied also to heterolytic processes. The contribution of this type of structure was also introduced to explain some instances of *endo-exo*-isomerisation[44].

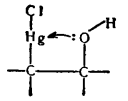
It has also been suggested that *cis*-hydroxymercuration is due to the directional effect of the double bond in the bicyclo-systems studied[37]. If this is really so, then the hydroxymercuration of strained monocyclic alkenes of the cyclobutene and cyclooctene type should also proceed as a *cis*-addition.

## IV. METHODS OF FINDING THE CONFIGURATION OF 2-MERCURATED ALCOHOLS

### 1. Nuclear Magnetic Resonance

In 1961 Anderson and Henry[45] used nuclear magnetic resonance to find the configuration of the $\alpha$-diastereomers obtained by hydroxymercuration of norbornene (IX) and cyclohexene (Vb). In the nuclear magnetic resonance spectrum for (IX) the coupling constant between protons 2 and 3, $J_{23}$, is 6.8 Hz, which agrees closely with the constant found for the *endo-cis*-hydrogen atoms (7.7 Hz) and is greatly different from that found for *trans*-hydrogen atoms (2.2 Hz). Hence (IX) has an *exo-cis*-configuration.

It was found for (Vb) that the hydrogen atom at the carbon attached to the mercury has two coupling constants, equal to 10 Hz and characteristic for axial–axial coupling, and also one constant, equal to 3.5 Hz, characteristic for axial–equatorial coupling. Hence the mercury atom and the hydroxyl group should be in the equatorial position and (Vb) should have *trans*-configuration.



### 2. X-Ray Diffraction

As mentioned above, Brook and Wright ascribed the *trans*-configuration to $\alpha$-2-methoxycyclohexylmercury(II) chloride (Va) and the *cis*-configuration to the $\beta$-isomer (VIa) on the basis of X-ray diffraction studies. Later, Wright suggested that these results are questionable and unreliable[6–8] (see also Kreevoy and Kowitt[9]). However, as has now been established, the configurations deduced from the X-ray diffraction studies are correct. Obviously doubt about the possibilities of applying this method to organomercury compounds are greatly exaggerated and Brook and Wright's original data[5] are reliable.

### 3. Infrared Spectroscopy

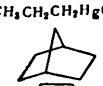
Traylor and Baker[37] developed a method of determining configuration by comparison of the infrared spectra of hydroxymercuration products and the corresponding hydroxy-compounds in the region of the stretching vibrations of the hydroxyl group. In this region in the infrared spectrum of 2-mercurated alcohols there is only one absorption band, which shows the absence of a hydrogen bond between the hydroxyl group and the mercury atom. In the *cis*-compounds there is a single additional interaction,

absent from *trans*-compounds, namely the interaction of the oxygen of the hydroxyl group with the mercury atom:

Owing to this, displacement of the absorption band of the hydroxyl group into the long-wave region should be greater in the case of *cis*-compounds. Experimental investigation showed that the displacement of the hydroxyl group band in *trans*-hydroxymercury(II) chloride derivatives, as compared with the corresponding hydroxy-derivatives is 6–10 $cm^{-1}$, whereas that for the *cis*-hydroxymercury(II) chloride derivatives is 18–22 $cm^{-1}$. However, this method should obviously be used with caution for compounds exhibiting free rotation of a C–C bond or conformational mobility of the ring.

## 4. Dipole Moments

Dipole moments were measured for several pairs of diastereomeric 2-mercurated alcohols[7,11]. Although the measurement of dipole moments is one of the principal methods for establishing the configuration, this method has led to incorrect conclusions in a series of hydroxymercurated alcohols[7]. Only a qualitative correlation has been noted between the rate of dehydroxymercuration and the magnitude of the dipole moment: the diastereomer with the lower dipole moment is more readily dehydroxymercurated in acid[11].



The main difficulty in using dipole moments is, according to Wright[7], the uncertainty in the C–Hg–X angle. On considering the vector scheme of the moments of the C–Hg–Cl group, Wright found that the angle between the moments of the C–Hg and Hg–Cl bonds is acute and amounts to 80°. Hence assuming free rotation, it turns out that the resultant vector moment of the C–Hg–Cl group (3.66 D) precesses 59° relative to the C–Hg bond and in the opposite direction. In this context, the calculations are very difficult, since there are two non-regular functional groups in the molecules of the 2-mercurated alcohols. Therefore, depending on the conformation, the dipole moment can change strongly and the choice of preferential conformations for the given compounds is arbitrary.

We have calculated the dipole moments of some 2-mercurated alcohols and found that dipole moments can be used to determine configuration but the angle C–Hg–X should be taken as 180°. Actually, investigation of the vibrational spectra and electron diffraction studies showed[46] that $HgCl_2$, $HgBr_2$, $HgI_2$, HgBrCl, HgICl, and HgIBr molecules are linear, while in the X-ray diffraction studies[5] mentioned above it was found that the angle C–Hg–X is 180° and 178° for (Va) and (VIa) respectively. Hence the C–Hg–X group can be considered linear, which greatly facilitates the calculation, since it is not necessary to consider the moment of the Hg–X bond separately and the whole moment of the HgX group can be considered directed along the C–Hg bond. The value of the moment along the C–HgCl bond can be taken as approximately equal to the dipole moment of propylmercury(II) chloride (3.70 D in dioxan).

The moment of the methoxy-group was taken as 1.30 D, with 55° as the angle of precession relative to the bond direction[47]. We made the calculation on the assumption that there is free rotation of the methoxy-group; the total moment was calculated as the mean of four moments: from the maximal and minimal values of coordinate $z$ and two extreme values with coordinate $z = \frac{1}{2}(z_{max} + z_{min})$ for the vector of the methoxy-group. The vectorial scheme of the norbornane molecule was taken from Wilcox[48]. The Table gives the dipole moments which we have calculated on this basis and shows that the agreement between the experimental and calculated values is good (except for compound 7) despite several assumptions having been made in the calculation: the interaction between the oxygen atom and the mercury atom in *cis*-compounds has been neglected, and the mean moment of the C–Hg–Cl bonds is unknown and can only approximately be taken as equal to the moment of propylmercury(II) chloride. An unfavourable circumstance is that the dipole moments were measured in dioxan, which can be coordinated differently with the mercury atoms in different isomers. The discrepancy between the found and calculated dipole moments for compound 7 is to be expected, since in the *endo*-derivatives of norbornane there is considerable steric interaction, leading to distorted geometry of the molecule.

Qualitatively, the similarity between the experimental and calculated values is completely adequate for unambiguously establishing the configuration. In rigid cyclic systems in the absence of other groups which exhibit their own substantial dipole moment and in the presence of rotation of the methoxy-group the moment of the *cis*-isomer will be greater than that of the *trans*-isomer, since the moments of the methoxy and chloromercury(II) groups in the *cis*-compound are directed to one side, and in the *trans*-compound the moments of these groups are directed at an obtuse angle. Hence it is also understandable that if in accordance with Wright's results it is assumed that the moment of the –HgCl group is directed to the opposite side with respect to the C–Hg bond at an angle of 59°, then we obtain on calculating in the reverse order of the calculated quantities the value of the dipole moments for the *cis*- and *trans*-isomers.

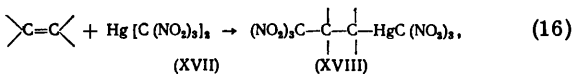


TABLE. Dipole moments of the derivatives of 2-mercurated alcohols.

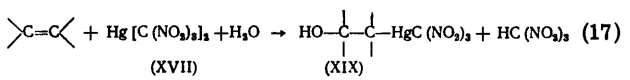
| Compound No. | Formula | Dipole moment, D | | Δμ | Reference |
|---|---|---|---|---|---|
| | | found | calculated | | |
| 1 | $CH_3CH_2CH_2HgCl$ | 3.70 | | | 7 |
| 2 |  | 0.45 | | | 7 |
| 3 |  | 4.1 | 4.38 | −0.28 | 11 |
| 4 |  | 2.9 | 3.38 | −0.48 | 11 |
| 5 |  | 4.22 | 4.24 | −0.02 | 7 |
| 6 |  | | 3.22 | | |
| 7 |  | 2.77 | 3.80 | −1.03 | 7 |

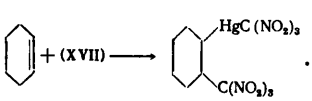


5. Methods Based on Difference in Dehydroxymercuration Rates

As already indicated above, the rate of dehydroxymercuration for the *trans*-isomer is much greater than that for the *cis*-isomer. Therefore on the basis of the measurement of the kinetics of dehydroxymercuration, configurations can be ascribed to pairs of diastereomeric 2-mercurated alcohols and this has been done [9,20,21]. Manolopoulos and coworkers [49] developed a relatively simple semiquantitative method for comparing dehydroxymercuration rates. The inconvenience of this method is that for a strict proof it is necessary to have the $\beta$-diastereomer, which is not always available.

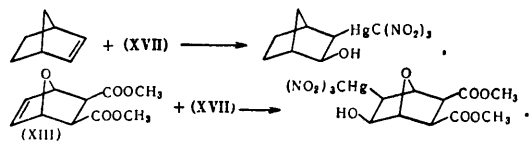
A method of determining the stereochemistry of the addition of mercury salts with the aid of bis(trinitromethyl)mercury(II) (XVII), based essentially on the same principle, was developed by Zefirov and coworkers [50]. This compound is able to add on to alkenes to form derivatives of trinitromethyl-3,3,3-trinitropropylmercury(II) (XVIII) [51-53]:

(16)



(17)

On carrying out the reactions in water it could be expected that Eqn. (17) would hold, with the formation of derivatives of 2-hydroxyethyltrinitromethylmercury(II) (XIX). However, the formation under such conditions of compounds of type (XIX) is possible only in the case of their stability in acid, since the trinitromethane liberated is itself a relatively strong acid ($K = 6.8 \times 10^{-1}$) [54]. Derivatives of type (XVIII) obtained by Eqn. (16), are extremely stable in acid [53], since their demercuration must be accompanied by rupture of a C–C bond. The stereochemical course of the reaction of hydroxymercuration according to Eqn. (17) should be the same for any mercury salts, especially if the possibility of the intermediate formation of a doubly-charged mercuronium ion of type (II) is taken into account — Eqn. (5).

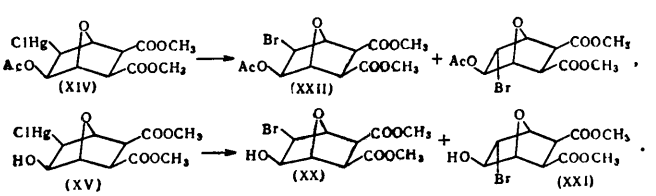


Hence, to determine the stereochemistry of the addition of mercury salts to an alkene the reaction must be carried out with an aqueous solution of bis(trinitromethyl)mercury(II), so that the formation of an addition product of type (XVIII) will show that the hydroxymercuration of this alkene proceeds as a *trans*-addition, whereas the formation of a product of type (XIX) will show *cis*-addition. Compounds of types (XVIII) and (XIX) are easily distinguished in the product analyses.

Actually, the addition of (XVII) to cyclohexene always proceeds with formation of trinitromethyl-2-trinitromethylcyclohexylmercury(II), whatever the solvent [52]:

The configuration of derivatives of type (XVIII) which are obtained has not been established experimentally, but probably *trans*-addition takes place here.

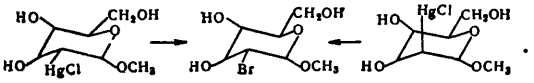
However, norbornene and the dimethyl ester (XIII) react with an aqueous solution of bis(trinitromethyl)mercury(II) according to Eqn. (17), [50] that is, *cis*-addition occurs here:



These methods are inapplicable when the stability of the 2-mercurated alcohol is due to some other structural factor. One of such factors is intramolecular closing of lactone rings, and also of tetrahydrofuran or tetrahydropyran rings [52-53].

6. Method of Replacement of HgX Groups

In connection with progress in investigations of the mechanism and stereochemistry of electrophilic substitution at a saturated carbon atom [55,56] it became possible to use chemical methods to determine the configuration of 2-mercurated alcohols. The replacement of halogenomercury-groups by halogen is the most convenient for this purpose, since the configuration of the halogenoalcohols obtained is usually known already or is relatively easily established by the usual methods. The stereochemistry of electrophilic replacement of chloromercury-groups by bromine was first studied by Jensen and Gale [57] who found that in non-polar solvents bromination takes place by a homolytic mechanism with racemisation or partial retention of configuration; bromination in polar solvents, for example, acetic acid, proceeds mainly with retention of the configuration. During bromination in pyridine there is complete retention of the configuration ($S_E2$ reaction), but the yield of the corresponding halogeno-derivative is only 50–65%, due to resinification taking place. Later, these conclusions were refined and supplemented (see Uglova [58]).



It must be emphasised that there has been no systematic study of the stereochemistry of electrophilic replacement of the HgCl group by halogen in the presence of neighbouring substituents.

Yur'ev and coworkers [31] used the halogenation of 2-mercurated alcohols with replacement of the HgX group as a method of finding configuration; they took as examples *exo*-3-acetoxy-5,6-dimethoxycarbonyl-*endo*-7-oxanorborn-2-ylmercury chloride (XIV) and *exo*-3-hydroxy-5,6-dimethoxycarbonyl-*endo*-7-oxanorborn-2-ylmercury chloride (XV).

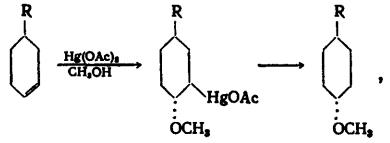
It was found that bromination of the hydroxyester (XV) in chloroform leads to the *cis*-bromo-alcohol (XX) mixed with a little of the *trans*-bromo-alcohol (XXI), whereas bromination in pyridine leads only to the *cis*-bromo-alcohol (XX). The bromination of the acetoxyester (XIV) is analogous.

However, Jensen's rule about the retention of the configuration during bromination of organomercury compounds in polar solvents must be applied with caution to 2-mercurated alcohols, since it is possible that the presence of neighbouring substituents can alter the stereochemical result of the reaction. Inversion of the configuration during halogenation in several 2-mercurated alcohols was shown by the example of the bromination of the hydroxymercurated product of D-glucal[49], where both diastereomers gave identical bromomethoxy-derivatives:

Unfortunately, in this work the stereochemistry of bromination was investigated only in methanol and in carbon tetrachloride. Apparently, in the latter solvent reactions can also proceed by a radical, instead of $S_E2$ mechanism and in view of the considerable importance of the question, a study of the stereochemistry of bromination of these compounds in acetic acid and especially in pyridine would be welcome. Furthermore, a paper by Inglis and Schwarz appeared simultaneously[59] in which the hydroxymercuration of D-glucal and its triacetate is considered as *trans*-addition, and hence the results of these two studies are incompatible.

It should also be noted that in finding the configuration of 2-mercurated alcohols by other methods they can act as a convenient model for studying the stereochemistry of electrophilic replacement at a saturated carbon atom.

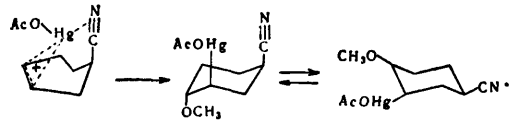
### 7. Method of Calculating the Angle of Rotation of Optically Active 2-Mercurated Alcohols



In 1963 Sokolov and Reutov[60] calculated the molecular rotation for certain optically acitive organomercury compounds by Brewster's method and showed that this type of calculation can be used to show the stereochemistry of the addition of mercury salts to alkenes. In 1947 Romeyn and Wright[61] obtained optically active $\alpha$- and $\beta$-2-methoxycyclohexylmercury chloride (Va) and (VIa), with $[M]_D$ = = -139° and +45° respectively, by an asymmetric synthesis. The molecular rotation calculated[60] for the *trans*-isomer (Va) is -130° and hence the $\alpha$-diastereomer should have the *trans*-configuration.

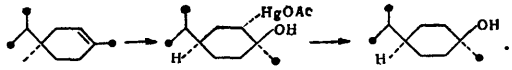
The use of this method is restricted by the difficulty of obtaining optically 2-mercurated alcohols of high purity. Naturally, calculation of the molecular rotation of organomercury compounds is restricted to those models for which Brewster's method is generally applicable[62].

## V. HYDROXYMERCURATION OF ALKENES WHEN THERE IS PRELIMINARY COORDINATION OF A MERCURY ION WITH FUNCTIONAL GROUPS

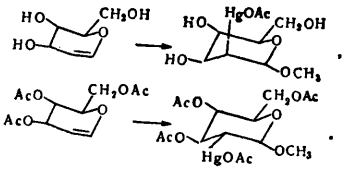


Due to the strong tendency of mercury to form coordination bonds, its preliminary reaction with functional groups attached to the alkene is possible in principle. Depending on the position of the functional group in relation to the reaction centre, such coordination can determine the direction of the initial attack of the mercury ion on the double bond, and consequently can lead to stereochemically anomalous reaction products.

In 1959 Henbest and Nicholls[63] hydroxymercurated 4-substituted cyclohexenes and in subsequent reduction obtained the corresponding *trans*-derivatives:

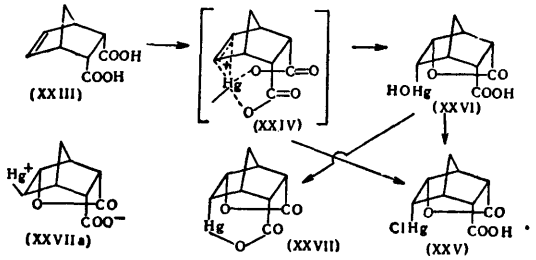


where R = OH, $OCH_3$, $CH_2OCH_3$, $COOCH_3$, CN.

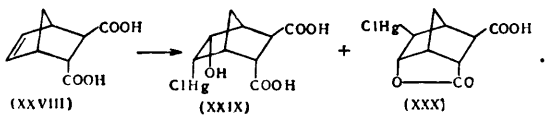


Hence assuming that the hydroxymercuration takes place as a *trans*-addition it follows that the atom of mercury atom is initially coordinated with the substituent and this determines the stereochemical course of the addition in a given case:

In the absence of preliminary coordination the *cis*-derivative is obtained after reduction, as the example of carvomenthene showed[64]:

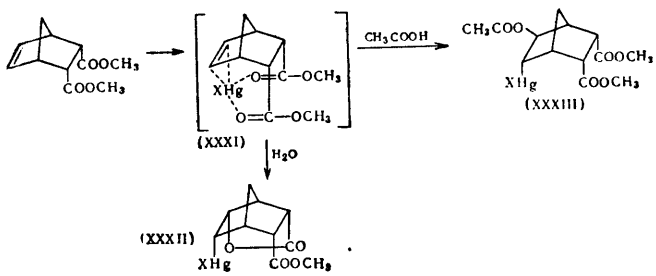


Manolopoulos and coworkers[49] found further that hydroxymercuration of D-glucal takes place as a *cis*-addition, whereas its triacetate is hydroxymercurate with formation of a *trans*-addition product:



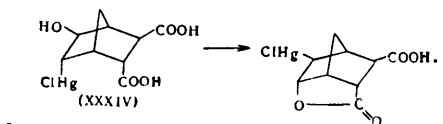
Such a difference in the stereochemical course of hydroxymercuration was explained by the preliminary coordination of the mercury ion with the hydroxyl groups in D-glucal. We must remember, however, that according to the results of Inglis and Schwarz[59] hydroxymercuration of glucal is a *trans*-addition[59], and therefore these studies need experimental verification.

The problems of the stereochemistry of hydroxymercuration when there is preliminary coordination were studied in considerable detail by Wright and coworkers[7,65], using norbornene derivatives with *endo*-functional groups. Thus the hydroxymercuration of the *endo*-norbornene-dicarboxylic acid (XXIII) proceeds as an *endo-cis*-addition to form the lactone (XXV)[7,65]:



This stereochemical course of the reaction is thought by the authors to be brought about by the preliminary formation of the complex (XXIV). The *endo*-configuration of the HgCl group was demonstrated by obtaining the anhydrolactone (XXVII) by the action of acetic anhydride on the lactonemercury hydroxide (XXVI).

Hydroxymercuration of the *trans*-acid (XXVIII) proceeds less stereospecifically and leads to a mixture of the products of *endo-cis*- (XXIX) and *trans*-addition (XXX)[7]:

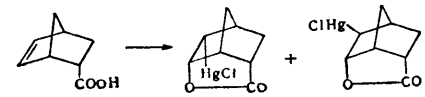


(XXVIII) (XXIX) (XXX)

Preliminary coordination of the mercury ion can also be effected with the methoxycarbonyl groups. Hydroxymercuration of dimethyl *endo-cis*-norbornenedicarboxylate proceeds in different directions with different solvents[7]. The coordination complex formed in the first stage (XXXI) gives the *endo*-lactonemercury chloride (XXXII) in water. In acetic acid, there is *trans*-opening with formation of the diestermercury chloride (XXXIII):

(XXXI) (XXXII) (XXXIII)

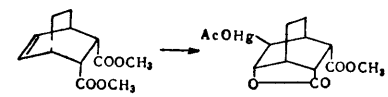
However, this paper[7] describes a series of conversions which raise doubts about the correctness of the allotted configurations. Thus, the thermal conversion of the *exo*-hydroxy-acid (XXXIV) into the lactone (XXX) remains uncertain:



(XXXIV) (XXX)

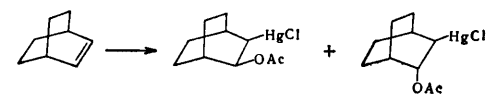
[Carried out in sodium amalgan (Ed. of Translation)].

The dipole moments measured for many of these substances[7] are not reliable criteria for finding the configurations of such polyfunctional compounds. Essentially *endo-cis*-addition was only shown by the formation of the anhydrolactone (XXVII). The reliability of such a method is subject to doubt[9] and it was suggested that this compound exists in the form of a "zwitter-ion" (XXVIIa) with the mercury atom in the *exo*-position. Compounds existing in the form of "zwitter-ions" were obtained earlier in the hydroxymercuration of certain unsaturated acids[66]. Unfortunately Abercrombie and coworkers[7] did not measure the dipole moment of the anhydrolactone (XXVII).



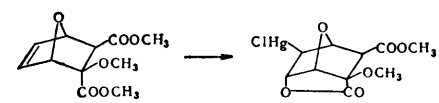
If the anhydro-compounds actually exist as "zwitter-ions" then all the data on the stereochemistry of the hydroxymercuration of norbornene derivatives having *endo*-functional groups, and for which initial *endo*-attack of the double bond by the mercury ion is assumed, due to preliminary coordination of the latter with the *endo*-substituent, must be reconsidered, and the question of the possibility of an anomalous stereochemical course of reaction remains open.

Malaiyandi and Wright[67], in studying the hydroxymercuration of *endo*-norbornenecarboxylic acid, separated two compounds which were given the following configurations:



However, in this work the proof of the configuration is not strict — it is based on the analogy between the dipole moments with those of the already available products of the hydroxymercuration of norbornenedicarboxylic acids.

An ester of a bicyclooctenedicarboxylic acid was also first assumed to undergo *endo-cis*-addition[65] but it was found subsequently that *trans*-addition takes place[68]:



However, according to Traylor's later results[69] hydroxymercuration of bicyclooctene proceeds with formation of a mixture of the products of *cis*- and *trans*-addition:

It is therefore possible that the products of *cis*-addition to the dimethyl bicyclooctenedicarboxylate could not be separated because of experimental difficulties.

Yur'ev and coworkers[70] have shown that the hydroxymercuration of dimethyl 5-methoxy-7-oxanorborn-2-en-*trans*-5,6-dicarboxylate also proceeds by *trans*-addition:

---o0o---

The most general features of the principal stereochemical rules for the addition of mercury(II) salts to alkenes have now been explained. It has been found that unlike other reactions of electrophilic addition at multiple bonds the stereochemical course of this reaction depends strongly on the alkene: the hydroxymercuration of ordinary acyclic and monocyclic alkenes is a *trans*-addition, whereas the hydroxymercuration of unsaturated, strained bridge bicyclo-compounds, having spatial hindrance against *trans*-attack, is a *cis*-addition.

However, there are many problems still awaiting solution. Thus the details of the mechanism of this reaction are still not clear, and the question of the possibility of anomalous stereochemical course of reaction due to preliminary coordination with functional groups has still not been decided unambiguously.

Undoubtedly, further investigation will lead to progress in understanding the fine stereochemical aspects of this reaction and may allow the rules found to be applied to a wider range of other additions.

# THE REACTIONS OF ANTI-TUMOUR ALKYLATING COMPOUNDS

A. Ya. Berlin and L. S. Yaguzhinskii

CONTENTS

I. Introduction 537

II. Reactivity of alkylating compounds 537

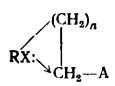
III. Bifunctionality 540

1. Mutual effect of electrophilic centres in bifunctional alkylating groupings 540

2. A special feature in the structure of bifunctional alkylating compounds 542

## I. INTRODUCTION

Of the tremendous number of substances that have been tested for anti-tumour activity, a large group of compounds with alkylating properties is outstanding; these compounds attack tumour cells to a somewhat greater degree than normal cells.



At present these preparations are widely used in the chemotherapy of some types of malignant tumours[1]. There are a number of reviews and monographs dealing with the biological properties of alkylating agents and also with the dependence of biological activity on chemical structure[2-7].

Since the selectivity of anti-tumour activity in these compounds is closely connected with the chemical properties of their electrophilic centres, it is of interest to examine in one review the most important features of the reactivity of those types of alkylating agent which have shown anti-tumour activity clinically or in animal experiments.

## II. REACTIVITY OF ALKYLATING COMPOUNDS

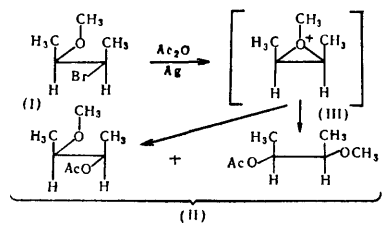


Table 1 gives a list of various types of compounds that have yielded preparations with anti-tumour activity.

In about half the compounds in Table 1 (the first ten) a heteroatom with a free pair of electrons is situated in position 2 or 4 to the electrophilic centre. This structure makes possible interaction between the electron pair and the electrophilic centre of the molecule, which facilitates the intramolecular removal of the substituent A on the carbon atom:

where X is N, O, or S and $n$ = 1 or 3.

When the substituent A is eliminated by an intramolecular reaction, a cyclic cation is usually formed[24,25]. For example, in acetolysis of *D*-2-bromo-3-methoxybutane (I) with acetic anhydride in the presence of silver ions, the racemate of 2-acetoxy-3-methoxybutane (II) is formed; this can only be explained by the formation of an intermediate oxonium cation (III):

There are also direct proofs of the formation of cyclic products in the reactions of some alkyl halides. Thus when aliphatic 2- or 4-chloroalkylamines are dissolved in water, at first rapid separation of chloride ions without material change in the pH of the solution is observed[8,26,27]:

Moreover, stable salts of aziridinium have been separated from 2-chloroethylamines[28]. The rate of formation of the aziridinium ion is directly related to the basicity of the nitrogen atom[29-31] (see Table 2).

The question of the cyclisation of the 2-chloroethylamines is considered in detail in reviews[2,5,33]. According to polarographic results[34], a cyclic cation is also first formed in the hydrolysis of 2-mesylethylamines. Opening

TABLE 1.

| Type of compounds | Formula | References |
|---|---|---|
| 2-Halogenoalkylamines* | $R_2NCH_2CH_2X$ | 1, 5, 8, 9 |
| 2-Aminoethyl methanesulphonates* | $R_2NCH_2CH_2OSO_2CH_3$ | 10, 11 |
| 2-Aminoethyl toluene-*p*-sulphonates | $R_2NCH_2CH_2OSO_2C_6H_4CH_3$-*p* | 12 |
| Polyalcohol derivatives | | |
| a. halogeno-derivatives* | $R(CHOH)_nCH_2X$ | 13 |
| b. esters of methanesulphonic acids | $R(CHOH)_nCH_2OSO_2CH_3$ | 13 |
| c. alkyl sulphates | $R(CHOH)_nCH_2OSO_2OR$ | 11 |
| 2-Halogeno-thioethers* | $RSCH_2CH_2X$ | 14 |
| 4-Halogenoethers | $RO(CH_2)_4X$ | 15, 16 |
| $\alpha$-Halogenocarbonyl compounds* | $RCOCHXR'$ | 17 |
| *N*-Alkylaziridines* | $RN(CH_2)_2$ | 5 |
| 1,2-Epoxides* | $RCHCH_2O$ | 18, 19 |
| Esters of methanesulphonic acid* | $ROSO_2CH_3$ | 1 |
| Esters of *N*-arylsulphamic acids | $ArNRSO_2OR'$ | 20, 21 |
| Diazo-compounds(aliphatic)* | $RN_2$ | 22 |
| *N*-Nitrosoalkylurea derivatives | $RN(NO)CONR'_2$ | 23 |
| Allyl alcohol derivatives* | $CH_2=CHCHROH$ | 24 |

* The anti-tumour activity of representatives of this type has been clinically studied.

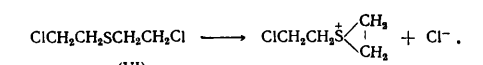
TABLE 2. Basicity constants and rate of cyclisation of 2-chloroethylamines[5,32].

| Amine | $pK_a$ | $K$, min$^{-1}$ at 15° |
|---|---|---|
| $(C_2H_5)_2NCH_2CH_2Cl$ | 8.82 | 0.145 |
| $C_2H_5N(CH_2CH_2Cl)_2$ | 6.57 | 0.128 |
| $N(CH_2CH_2Cl)_3$ | 4.39 | 0.073 |
| $C_6H_5N(CH_2CH_2Cl)_2$ | 2.2 | 0 |

of the aziridinium cation proceeds comparatively slowly in the main by a bimolecular mechanism ($S_N2$),[35] and in agreement with this, stronger nucleophilic agents react more rapidly with the aliphatic chloroethylamines[26,36].

Aromatic 2-chloroethylamines differ somewhat from their aliphatic analogues. Hydrolysis of these compounds proceeds by an $S_N1$-mechanism[37-40]. An intramolecular mechanism is also indicated by the fact that the hydrolysis of nuclear-substituted 2-chloroethylamines of type (IV):

$$p\text{-}RC_6H_4N(CH_2CH_2Cl)_2 \qquad (R = OCH_3,\ CH_3,\ H,\ Cl,\ COOC_2H_5)$$
(IV)



increases with increasing electron-donor properties of R [5] and falls sharply when the chloride ion is added to the solution[41].

The formation of the aziridinium ring in reactions of these compounds has not been proved[2,5,10], since the stability of rings of type (V)

(V)

must be greatly reduced because of the electron-attracting properties of the phenyl nucleus. Aromatic 2-chloroethylamines react faster with acid anions the greater the nucleophilic properties of the anion[37,42]. In this case, in contrast to hydrolysis, the reaction apparently proceeds by an $S_N2$-mechanism.

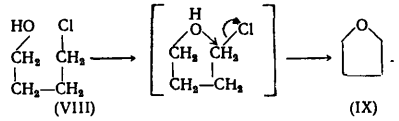
2-Halogeno-thioethers are very similar in properties to chloroethylamines. A study of the kinetics of hydrolysis of Yperite [mustard gas, bis-(2-chloroethyl) sulphide (Ed. of Translation)] (VI) showed that the intramolecular elimination of chlorine is also the rate-determining step[43,44]:

(VI)

As in the case of the aromatic chloroethylamines, the relative rate of reaction of bis-(2-chloroethyl) sulphide with acid anions increases with the nucleophilic properties of the anion; this probably also explains the change in substitution mechanism[45-47].

The dependence of the reaction mechanism on the nucleophilic properties of the attacking agent is particularly clearly shown in aromatic 2-chloroethyl sulphides[48]. Thus, in the hydrolysis of type (VII) compounds:

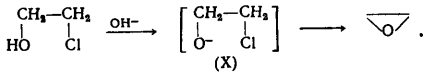
$$p\text{-}RC_6H_4SCH_2CH_2Cl \qquad (R = CH_3O,\ CH_3,\ H,\ I,\ Br,\ Cl,\ NO_2),$$
(VII)



the rate of reaction increases with increasing electron-donor properties of R ($S_N1$-mechanism), but in the reaction with the iodide anion, which is a stronger nucleophilic agent than water, the reaction rate decreases with increasing electron-donor properties of nuclear substituents ($S_N2$-mechanism).

2-Halogenoalcohols, $HOCH_2CH_2X$, behave differently from most of the foregoing compounds in neutral and acid aqueous solutions.

The rate of hydrolysis of these compounds is ten or a hundred times less than the rate of hydrolysis of alkyl halides, which are similar in structure[49]. Reduction in the mobility of the chlorine by the introduction of a hydroxy-group in position 2 is observed both for the primary alkyl halides[50,51], reacting with water mainly by an $S_N2$-mechanism, and for the tertiary alkyl halides[52,53], decomposing under these conditions by an $S_N1$-mechanism.



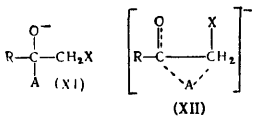
At present it is difficult to give an acceptable explanation of this effect. In any case, the reduction in the rate of the intramolecular reaction under the influence of an atom of oxygen in the $\beta$-position indicates the absence of interaction of the latter with the electrophilic centre of the molecule.

However, in 4-halogenoalcohols such an interaction exists between the oxygen and the $\delta$-carbon atom. Streitwieser[33] explains this by the fact that a five-membered ring is formed more easily than a three-membered one. Hydrolysis of 4-chlorobutanol (VIII) gives tetrahydrofuran(IX):

(VIII) (IX)

In this reaction the rate of elimination of the halide ion is 1000 times greater than in the hydrolysis of 2-chloroethanol[59].

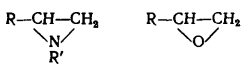
Kinetic data indicate[60,61], that in strongly alkaline solutions of 2-halogenoalcohols the alkoxide ion (X) is formed, and as a result, rapid intramolecular cyclisation takes place:



(X)

The rate of elimination of halide from the halogenoalcohols is substantially higher than the rate of elimination from the alkyl halides[62,63].

4-Halogenoethers, $RO(CH_2)_4X$,[15,16] appear to be similar to the corresponding alcohols in their behaviour on acid hydrolysis.



$\alpha$-Halogenoketones, $O{=}C(R)CH_2X$, are close in structure to the types of compounds described above (Table 1), but steric considerations make the interaction of the lone pair of oxygen electrons with the $\alpha$-carbon atom ($\beta$-position to the oxygen) impossible.

$\alpha$-Halogenoketones react with nucleophilic agents by a bimolecular mechanism[64-66]. At first it was assumed that replacement of the halogen proceeds through a polar transition complex (XI).[67] However, such a scheme does not explain the significant difference

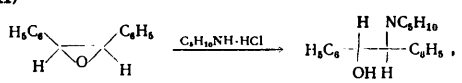
(XI) (XII)

in the rates of reaction of $\alpha$-bromo- and $\alpha$-chloro-ketones with the same reagent[68]. It was therefore postulated that the slow stage of the reaction is the formation of the intermediate (XII).[70,71]

Derivatives of aziridine and ethylene oxide [oxiran]:

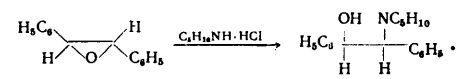
are closely related genetically to 2-halogenoalkylamines and 2-halogenoalcohols and are formed by treating the latter two compounds with alkalis[60,72,73]. On the other hand, 2-halogenoalkylamines and 2-halogenoalcohols may be prepared by treating the corresponding cyclic compounds with hydrohalogen acids[42,74,75]:

Aziridine itself is a weak alkylating agent, but it readily adds on a proton to give the reactive aziridinium ion (XIII):



(XIV) (XIII)

The nitrogen atom of the aziridine ring (XIV) having a substituent with electron-acceptor properties should be considered separately. The equilibrium of the protonation reaction will here be strongly displaced to the left in contrast to aziridines not substituted on the nitrogen; however, the cation formed (XIII) must be more reactive because of the greater positive charge on the nitrogen atom.



According to Ross[2], these compounds can react by a bimolecular mechanism without the participation of protons as catalyst.

The reactions of oxiran and the reactions of aziridine are catalysed by acids, but oxiran, in contrast to aziridine readily reacts with nucleophilic agents also in neutral and alkaline solutions. The mechanisms of these reactions change according to the conditions. Data on the rate of hydrolysis of substituted 1,2-epoxides in neutral and acid media (Table 3) show that replacement of an electron-donor substituent ($CH_3$–) by an electron acceptor ($ClCH_2$–) in neutral medium leads to an increased rate of reaction, but in an acid medium the opposite effect is observed[5,76]. This shows that in a neutral medium the reaction proceeds by an $S_N2$-mechanism and in acid medium by an $S_N1$-mechanism. This view is supported by a large number of papers[77,83].

A deeper study of some reactions of 1,2-epoxides catalysed by acids showed that the reactions are stereospecific. For example, when *cis*-$\alpha\alpha'$-epoxybibenzyl (XV) is opened by hydrogen halides[84], or by piperidine in the presence of piperidinium chloride[85], the *threo*-isomer is formed (XVI), but *trans*-$\alpha\alpha'$-epoxybibenzyl (XVII) gives the *erythro*-isomer (XVIII)

(XV) (XVI)

(XVII) (XVIII)

TABLE 3. Rate constants for the hydrolysis of 1,2-epoxides in neutral and acid solutions.

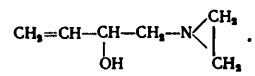
| 1,2-Epoxides | $k_{H_2O}$, $s^{-1}$ ($S_N2$) | $k_{H^+}$, $s^{-1}$ ($S_N1$) |
|---|---|---|
| $CH_3$– | $2.2\cdot10^{-6}$ | $123\cdot10^{-3}$ |
| $ClCH_2$– | $5.1\cdot10^{-6}$ | $1.9\cdot10^{-3}$ |

These facts contradict interpretations according to which a free carbonium ion is formed in these reactions ($S_N1$-mechanism).

An explanation of these contradictions has been given on the basis of the "push–pull" mechanism proposed by Swain[86]. According to this scheme, the reaction is regarded as a synchronous approach of the new substituent and removal of the old one; the rate of reaction is determined, on the one hand, by the strength of the interaction of the attacking substituent with the electrophilic centre of the molecular ("push component" of the reaction) and, on the other hand, by the ease of elimination of the old substituent ("pull component"). This mechanism explains[64,87,88] both the stereospecificity of the 1,2-epoxide (a consequence of the synchronism of the substitution), and the characteristics of a unimolecular mechanism shown by these reactions; these are particularly marked in acid solutions since protonation favours the rupture of the C–O bond of the oxide ring.

Aminomethanols, $R_2NCH_2OH$, form a characteristic type of alkylating agent. In the presence of acids they form the so-called carbimmonium cation[89]

which is the real alkylating agent[90–92]. Thanks to high activity, this cation can enter into an electrophilic substitution reaction at the carbon atom, for example, in the Mannich reaction[93]:



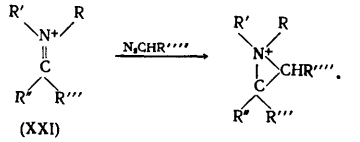
Derivatives of allyl alcohol, $CH_2$=CHCHROH, apparently cannot be regarded as typical alkylating compounds; however, in the presence of acids these compounds can sometimes form a carbonium ion (XIX)[94] which may behave as an alkylating agent:

(XIX)

The allyl alcohol residue forms part of the molecule of the anti-tumour compound "Etoksen" ("Tetramin")[95]

Derivatives of esters of methanesulphonic acid, $ROSO_2CH_3$, not containing atoms with a lone pair of electrons are typical alkylating compounds. They react with nucleophilic reagents by a bimolecular mechanism[96–98].

Esters of sulphuric acid, $ROSO_2OR'$, are well known as compounds with pronounced alkylating properties[99]. It has been shown by experiments with labelled water ($^{18}O$) that the hydrolysis of these compounds proceeds simultaneously by $S_N1$- and $S_N2$-mechanisms[100]. There are indications that the mannitol derivative (XX) has anti-tumour activity[11,101]:

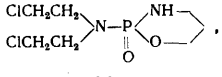


(XX)

Esters of *N*-arylsulphamic acids, $ArNRSO_2$.$OR'$, are hydrolysed in alkaline medium at the same rate as 2-chloroethylamines[102]. The mechanism of this reaction has not been studied.

Diazo-compounds (aliphatic), $RN_2$, as alkylating agents have the important characteristic that they alkylate by a radical mechanism[103].

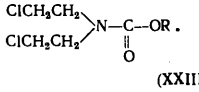
Reactions of diazo-compounds with the carbimmonium cation (XXI) leading to the formation of aziridine derivatives are interesting[104]:



(XXI)

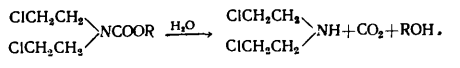
As can be seen from the scheme shown, this reaction *in vivo* might lead to the formation of new alkylating compounds[89,92].

Derivatives of nitrosoalkylurea, $R_2NCON.(NO)R'$, serve as starting materials for the preparation of diazo-compounds[105]. It has been shown in direct experiments that, under biological conditions in the organism, they behave as alkylating agents[23,106], reacting with purine basis of nucleic acids[107].



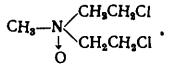
An important property of anti-tumour alkylating agents, which should be pointed out, is their ability to react with nucleophilic centres under relatively mild conditions. The high reactivity of a number of alkylating agents is shown by data on the hydrolysis of chloroethylamines[6,108-110], aziridines[76,111,112] and esters of methanesulphonic acid[2,98]; by data on the reaction of chloroethylamines[8,26] and 1,2-epoxides with the thiosulphate ion[76]; and also by the relative rates of reaction of bis-(2-chloroethyl sulphide and chloroethylamines with different anions[36,42,45,46].

In addition to these, there is a large group of anti-tumour compounds with very low alkylating activity[113]. However, partial decomposition of the molecule of such compounds, which may occur in the body, gives products with relatively high alkylating power. Because of this property, these compounds have been called alkylating compounds with latent activity[114,115]. They include such an effective preparation as the cyclophosphamide "Tsikolfosfan" ("Endoxan")(XXII)[114]:



(XXII)

and also a large number of derivatives of carbamic acid of type (XXIII)[115-120]:



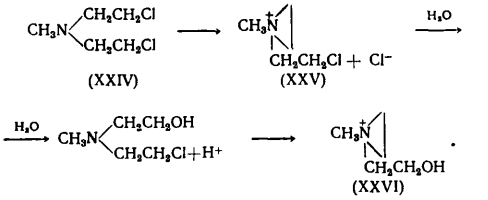
(XXIII)

In compounds of type (XXII) or (XXIII) the electron-acceptor substituent sharply reduces the basicity of the nitrogen, and, as a result, participation of the nitrogen in activating the substitution reaction at the β-carbon atom becomes impossible (see above). Hydrolytic or enzymic decomposition of these compounds under conditions in the body gives bis-(2-chloroethyl)amine[119]:

Bis-(2-chloroethyl)methylamine *N*-oxide ("Nitromin") obviously belongs to the type mentioned above[121]:

The relatively low alkylating properties of this compound should increase when it is reduced under biological conditions in the body to give bis-(2-chloroethyl)methylamine ("Embichin"†).

## III. BIFUNCTIONALITY



Highly effective anti-tumour alkylating compounds have an important structural feature: as a rule, their molecules contain two electrophilic groups. Compounds with one electrophilic centre have only one-tenth of the anti-tumour activity or they are entirely inactive‡.

This principle was first observed in aromatic[122] and aliphatic[123] chloroethylamines. Later the bifunctional rule was also noted in 1,2-epoxides[124,125], aziridines[124], and methanesulphonic acid esters[126]. Table 4 shows that not one unifunctional compound among the many classes of alkylating compounds has found practical application as a pharmaceutical preparation.

### 1. Mutual Effect of Electrophilic Centres in Bifunctional Alkylating Groupings

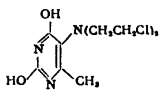
The cause of the higher biological activity of multifunctional compounds may lie, in principle, in the change in reactivity of the electrophilic centres as a result of the mutual influence of alkylating residues. It is therefore of interest to examine special features in the behaviour of this type of compound in comparison with the corresponding unifunctional compounds.

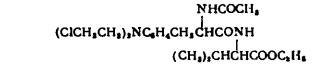
Aliphatic bis-(2-chloroethyl)amines, for example (XXIV) when dissolved in water form an aziridinium cation (XXV) at a slower rate then monochloroethylamines[32] (see Table 2)

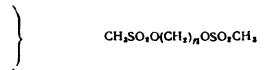
(XXIV) (XXV) (XXVI)

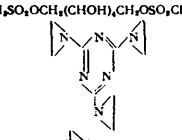
It is also significant that the second electrophilic centre in such compounds can only enter into reaction after opening of the aziridinium ion (XXV).

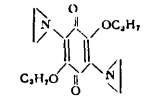
The aziridinium ion

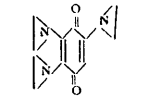












may be regarded as a symmetrical structure with four alkyl substituents on the nitrogen atom; it may therefore

† This is the hydrochloride, also known as Mechlorethamine hydrochloride, etc. (Ed. of Translation).

‡ This rule has a number of exceptions[5]. The main exceptions are compounds which contain, in addition to one alkylating centre, one residue without alkylating properties but nevertheless capable of interacting with some cell components (see p.542).

TABLE 4. Anti-tumour preparations used in practice* (from the Report of Committee of Experts on the Chemotherapy of Cancer [1]).

| Compound | Structural formula |
|---|---|
| Bis-(2-chloroethyl)methylamine | $CH_3N(CH_2CH_2Cl)_2$ |
| Bis-(2-chloroethyl)-2-chloropropylamine | $CH_3CHClCH_2N(CH_2CH_2Cl)_2$ |
| γ-*p*-Bis-(2-chloroethyl)aminophenyl-butyric acid | $HOOC(CH_2)_3C_6H_4N(CH_2CH_2Cl)_2$ |
| β-*p*-Bis-(2-chloroethyl)aminophenyl-α--alanine | $HOOCCH(NH_2)CH_2C_6H_4N(CH_2CH_2Cl)_2$ |
| 4-Methyl-5-[bis-(2-chloroethyl)amino]-uracil |  |
| Ethyl ester of *N*-acetyl-β-*p*-[bis-(2--chloroethyl)amino]phenyl-α--alanylvaline |  |
| 1,6-Bis-(2-chloroethylamino)-1,6-dideoxy-*D*-mannitol | $ClCH_2CH_2NHCH_2(CHOH)_4CH_2NHCH_2CH_2Cl$ |
| Bis-(2-chloroethyl)methylamine *N*-oxide |  |
| 2-[Bis-(2-chloroethyl)amino]perhydro--2-oxo-1,3,2-oxazaphosphorine |  |
| Tetramethylene bismethanesulphonate ($n = 4$) |  |
| Nonamethylene bismethanesulphonate ($n = 9$) | |
| Mannitol 1,6-bismethanesulphonate | $CH_3SO_2OCH_2(CHOH)_4CH_2OSO_2CH_3$ |
| 2,4,6-Triaziridinyl-*sym*-triazine |  |
| Triaziridinylphosphine sulphide |  |
| 3,6-Diaziridinyl-2,5-di-propoxy-*p*--benzoquinone |  |
| 2,3,5-Triaziridinyl-*p*-benzoquinone |  |
| 1,2 : 3,4-Diepoxybutane |  |
| 1,1′-Bis-(2,3-epoxypropyl)-4,4′--bipiperidyl |  |

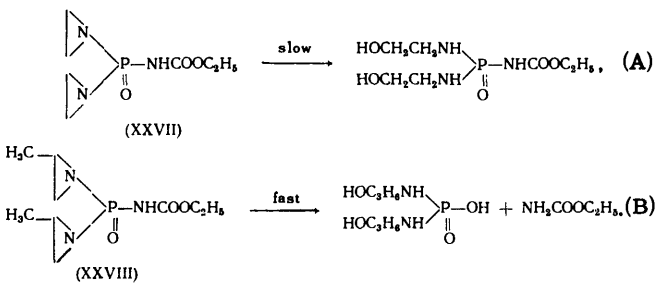
* The table contains only the preparations that have been most studied clinically.

be supposed that in reactions of this compound there will be rupture not only of the three-membered ring, but in some measure also rupture of one of the bonds of the nitrogen atom with the substituent R or R′.

When two β-chloroethyl residues are present on the nitrogen atom, as for example in compound (XXIV), the probability of elimination of a $CH_3$ group must greatly increase because an aziridinium cation (XXV), (XXVI) is formed twice in the course of the reaction.

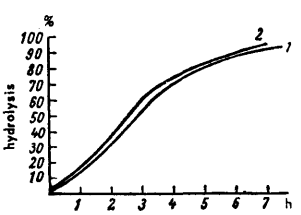
Thus, the amine (XXIV) when introduced into the animal body is almost completely destroyed with elimination of a methyl group[127]. According to Warwick, under the same conditions aromatic bis-(2-chloroethyl)amines do not eliminate a phenyl nucleus[128,129].

Bifunctional aromatic 2-chloroethylamines also show some special features connected with the presence of two 2-chloroethyl residues on one nitrogen atom. Because of the lower basicity of the nitrogen atom (Table 2), the rate of hydrolysis of chlorine in these compounds is appreciably less than in the corresponding monochloroethylamines. According to Ross, *N*-2-chloroethyl-*N*-ethylaniline ($pK_a = 3.5$) is hydrolysed under standard conditions to the extent of 58%, but *NN*-di-(2-chloroethyl)-aniline ($pK_a = 2.2$) is hydrolysed only to the extent of 20%.[5] The basicity of some 2,2′-iminodiethanols is nearly 1000 times greater than the basicity of the corresponding bis-(2-chloroethyl)amines[108]. It follows from these facts that after the first chlorine atom in dichlorodiethylamine is replaced by a hydroxyl group, the basicity of the nitrogen atom increases sharply, and this, in turn, should lead to hydrolysis of the second chlorine atom at a faster rate. In fact, with some examples[109] an inflection is observed on the curves of the concentration of chloride ion (Figure); this unambiguously indicates that the hydrolysis is accelerated at a definite stage.



A similar effect should occur in the reactions of bis--(2-chloroethyl)amines with primary and secondary amines. Thus, the bifunctional aromatic chloroethylamines, in contrast to the unifunctional compounds, have a latent reactivity in some reactions; after the first alkylating residue enters into reaction the reactivity of the second increases.

When di-(2-chloroethyl)amines react with tertiary amines the quaternary ammonium salts,

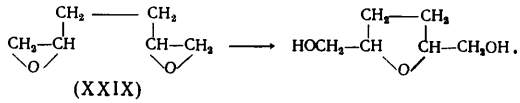


$$ClCH_2CH_2NRCH_2CH_2\overset{+}{N}R'R''R'''$$

are formed; the central nitrogen atom hardly changes its basicity and therefore in such reactions there should be no increase in the reactivity of the second electrophilic centre.

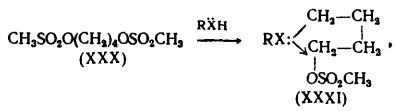
The mutual influence of aziridine residues in different di- and tri-aziridines has not been specially studied. However, it is interesting to note the work of Bardos, in which it was shown that (XXVII) is hydrolysed by Scheme (A), but (XXVIII) is hydrolysed by Scheme (B).[130]

The mutual influence of two oxide rings in bifunctional compounds has also been little studied. Their mutual arrangement in the molecule is of great importance.



Curves showing the concentration of chloride ion in the hydrolysis of aromatic bis-(2-chloroethyl)amines:
1) *p*-bis-(2-chloroethyl)aminophenylalanine;
2) bis-(2-chloroethyl)aniline.

Ross has noted the fall in the rate of hydrolysis constant of diepoxybutane with time[76]. This may be connected with the formation of a less active intermediate product:



If the oxide rings are separated by two methylene groups (XXIX) a stable tetrahydrofuran ring is formed[131,132]:

(XXIX)

Compound (XXIX) reacts with only one molecule of water; it behaves as a unifunctional compound.

Esters of methanesulphonic acids, for example "Mialosan" ("Mileran") (XXX), containing two alkylating centres, react with strong nucleophilic reagents to form compounds of type (XXXI) in the first stage:

(XXX) (XXXI)

X = NR, O, S)

in which the character of the reactivity of the alkylating residue is materially changed by interaction of the electrophilic centre with the lone pair of electrons of the atom X.

There is indirect information to show that the 2-chloroethyl ester of methanesulphonic acid reacts *in vivo* with cysteine with the formation of 2-chloroethylcysteine, which has high alkylating power[2]:

Among derivatives of nitrosoalkylureas the most active are derivatives of 2-chloroethylurea[106]. When such compounds react *in vivo*, biologically active compounds of type (XXXII) may also be formed:

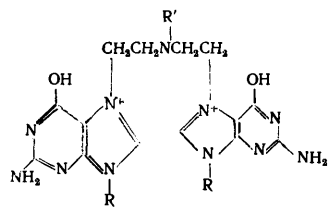
(X = NR, O, S) (XXXII)

Anti-tumour compounds with unsymmetrical bifunctional groupings, in particular the halogenoalkylamines have the interesting property that one of their alkylating centres is very weakly reactive[8,133]. Table 5 shows that the replacement of an alkylating residue with weak reactivity by a residue having no alkylating properties at all leads to disappearances of activity. Compounds in which both electrophilic centres are slightly reactive are devoid of anti-tumour activity.

TABLE 5. Unsymmetrical dihalogenoalkylamines.

| Preparations having anti-tumour activity | Preparations having no anti-tumour activity |
|---|---|
| $CH_3N(CH_2CH_2Cl)(CH_2CH_2CH_2Cl)$ | $CH_3N(CH_2CH_3)(CH_2CH_2CH_2Cl)$ |
| $CH_3N(CH_2CH_2Cl)(CH_2CH_2CH_2CH_2CH_2CH_2Cl)$ | $CH_3N(CH_2CH_2OH)(CH_2CH_2Cl)$ |
| $C_6H_5N(CH_2CH_2Cl)(CH_2CH_2CH_2Cl)$ | $C_6H_5N(CH_2CH_2CH_2Cl)(CH_2CH_2CH_2Cl)$ |

Alkylating compounds containing one alkylating centre and a metabolite residue, for example, serine diazoacetate or diazooxonorleucine,

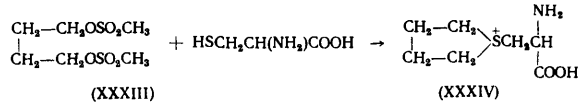


may also be regarded as unsymmetrical bifunctional compounds.

According to Baker[134-137], the natural parts of such molecules are capable of being adsorbed on the active centre of an enzyme, while the alkylating residue, reacting with a neighbouring nucleophilic group, may fix the whole molecule in this position.

## 2. A Special Feature in the Structure of Bifunctional Alkylating Compounds

The overwhelming majority of bifunctional alkylating compounds with pronounced anti-tumour activity are characterised by an important structural feature; the electrophilic centres of the bifunctional compounds are connected together by a chain of atoms which is preserved in the alkylating reaction. Because of this property, such compounds are capable of "stitching" DNA molecules, or cell nucleoproteins, forming so-called cross-linked bonds (cross-linking effect), which, in the opinion of some workers should lead to a sharp dislocation of the mitotic process[138-140].

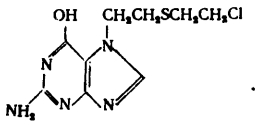


Several experimental results confirming this view have been obtained. Price and coworkers[141] proved indirectly that cross-linked bonds are formed between the DNA chains when DNA is treated with a derivative of bis-(2-chloroethyl)amine; cross-linked bonds are formed between the DNA chains because of the formation of $N_7$ derivatives of guanine:

Lowley and Brookes hydrolysed DNA that had been treated with bis-(2-chloroethyl) sulphide or Embichin, and they separated and identified cross-linked pairs of the bases guanine–guanine and guanine–cytosine[142]. Similar products are formed by the action of bis-(2-chloroethyl) sulphide on nucleic acids *in vivo*.[143]

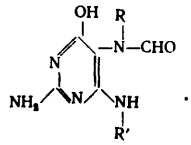
Earlier work of Alexander[144] indicates the possibility of cross-linking chains of DNA by the reaction of bifunctional compounds with phosphate residues.

The property of non-interaction between the two electrophilic centres in bifunctional compounds also favours the reaction of both centres with the same atom to form specific cyclic products. At present it may be considered proved that when "Mileran" (XXXIII) is introduced into the blood of animals, it reacts with cysteine to form a cyclic compound (XXXIV)[4,151-153]

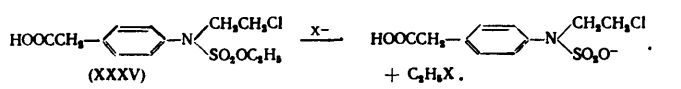


(XXXIII) (XXXIV)

There are also indications that, under biological conditions, the chloroethylamines are capable of forming unstable cyclic products of the thiazan type [128]:



When only one of the two alkylating centres reacts with a molecule of metabolite, compounds termed alkylating metabolites are formed. Timmis showed that an alkylating derivative of guanine is formed in tissue treated with bis-(2-chloroethyl) sulphide [154,155]:



The formation under biological conditions in the body of (2-chloroethyl)cysteine [2] with alkylating properties has been mentioned above.

However, some workers cast doubt on the biological significance of the effect of cross-linking DNA chains [145,146]. Alkylation of DNA is accompanied by degradation of the molecule. Thus alkylation of guanine on the $N_7$-position may lead to the depurinisation of DNA, [141,147] or it is accompanied by the oxidative cleavage of the imidazole ring with the formation of the formyl derivative of an aminopyrimidine [148]:

In the reactions mentioned above, the system of hydrogen bonds in the doubly stranded DNA molecule is destroyed and this facilitates rupture of the DNA; the viscosity of the DNA gradually falls [149]. Brookes and Lowley consider that the high biological activity of bifunctional alkylating agents is due to their ability to destroy simultaneously the structure of both strands of DNA. [150]

Recently, in animal experiments, the anti-tumour activity of a compound containing a new unsymmetrical bifunctional alkylating group has been observed; this is the ester of an *N*-(2-chloroethyl)arylsulphamic acid (XXXV): [20,21]

(XXXV)

The electrophilic centres of compound (XXXV) are separated in the alkylation reaction. The result of this work is a direct proof that non-interaction of the electrophilic centres of bifunctional alkylating agents is not a necessary condition for anti-tumour activity.

---o0o---

The property of alkylating compounds of attacking tumerous tissues cannot be connected with any definite alkylation mechanism. Different types of alkylating compounds with anti-tumour activity differ materially in reactivity. They include compounds capable of reacting with nucleophilic agents by both $S_N1$- and $S_N2$-mechanisms and also compounds that react by a mixed mechanism. Diazo-compounds and derivatives of nitrosoalkylurea react with nucleophilic centres through a stage in which free radicals are formed.

It is interesting to note that the reaction of acylation products does not lead to selective attack on tumour cells (there is not a single anti-tumour "acylating" agent), although acylating compounds (for example, anhydrides, acid chlorides, etc.), like alkylating compounds, contain strong electrophilic centres and are capable of reacting with nucleophilic centres in the living cell.

Examination of the structure and chemical properties of intermediate products of the conversion of alkylating agents under living conditions in the body shows that many of these may be active biologically. This shows that the anti-tumour activity of alkylating compounds is not necessarily the result of their direct action on the cell, but may be connected, at least in some instances [156], with subsequent reactions of the primary interaction products of these compounds with metabolites of the living organism.

It is important to note that the anti-tumour activity of alkylating compounds is connected with their ability to act selectively precisely on those cell processes which determine the difference between tumour cells and healthy cells, and this property must be directly related to the specific chemical behaviour of alkylating agents. The elucidation of this specificity will open the way to further progress in the development of anti-tumour preparations.

# COMPLEX COMPOUNDS OF GERMANIUM AND ITS STATE IN SOLUTION

V. A. Nazarenko and A. M. Andrianov

In connection with the increasing interest taken in germanium in the last two decades, many of its complex compounds have been described, particularly in the literature on analytical chemistry, but the available information is extremely limited. In many cases, only the fact of complex formation has been established, and even the composition of the complexes has not been determined. There are very few quantitative data on the stability and other properties of germanium complexes. The incomplete nature of the experimental material makes it difficult to use for the solution of various theoretical and practical problems in technology, analytical chemistry, geochemistry, etc.

No reviews have been published on the chemistry of germanium complexes. Grinberg's monograph [1] characterises the ability of germanium to form complexes, in relation to its position in the Periodic System. Reviews of the chemistry of germanium [2,3] and textbooks of general chemistry give only fragmentary information.

In the present review we have tried to summarise data on the present state of the chemistry of germanium complexes. Since complex formation is closely related to the state of an element in solution and since this question has been insufficiently studied for the case of germanium, we shall examine this problem at the same time.

The chemistry of germanium complexes has certain characteristic features. In accordance with its position in the Periodic System, germanium, which is an analogue of silicon and tin, shows in its complex compounds the dual nature characteristic of an element intermediate between metal and non-metal. As in the case of silicon, complexes with oxygen-containing ligands are more characteristic of germanium, but in the formation of these complexes in aqueous medium, germanium in many cases behaves as a cation, like tin. Like silicon, germanium readily forms heteropoly-acids with molybdenum and tungsten. On the other hand, germanium, like tin, belongs to the hydrogen sulphide analytical group, and forms thio-complexes, although these are less stable than those of tin. Complexes with nitrogen-containing ligands, in the form of addition compounds of the tetrahalides, are known both for germanium and for silicon and tin, but only germanium and tin, unlike silicon, form complexonates.

The characteristic coordination number of quadrivalent germanium is 6, and that of bivalent germanium 4.

## State of Germanium in Aqueous Solution

Bivalent germanium is formed by the reduction of $GeO_2$ with hypophosphorus acid in hydrochloric-acid solution [4,5]. According to Pugh [6], the acidic properties of bivalent germanium hydroxide are similar to those of tervalent arsenic hydroxide. According to the data of Everest and Terrey [7], however, bivalent germanium hydroxide exhibits no acidic properties. These authors concluded that the acidic properties attributed to $Ge(OH)_2$ were due to the presence of quadrivalent germanium. The suggestion of Hantzsch and Carlsohn [8] that equilibrium exists between bivalent germanium hydroxide and germanic acid is not now taken into consideration.

As a result of the ease of hydrolysis and the tendency to form complexes, $Ge^{2+}$ cations do not exist in aqueous solution, although they have been found in crystalline germanium diiodide [9].

Aqueous solutions of $GeO_2$ contain the ions of metagermanic acid $H_2GeO_3$ and pentagermanic acid $H_2Ge_5O_{11}$. The ratio between them is determined by the pH of the solution and the total germanium concentration [10,11]. At a $GeO_2$

concentration less than 0.01 M, only the ions of metagermanic acid are present; the ions of pentagermanic acid are present in more concentrated solutions [12,13] at definite pH values. Everest and Salmon [14,15] showed by the ion-exchange method that in the pH range 6.9–9.4 the only germanium ion is the singly charged ion of pentagermanic acid $HGe_5O_{11}^-$. Above and below these pH values, depolymerisation of the pentagermanate ions takes place with the formation of metagermanic acid. It has been suggested [16,17] that germanium forms not pentagermanate ions but complex heptagermanate ions $HGe_7O_{16}^{3-}$ and $H_2Ge_7O_{16}^{2-}$. Brintzinger [18] showed that in strongly alkaline solutions (2.5 M KOH) quadrivalent germanium is present in the form of $[Ge(OH)_6]^{2-}$ ions. On the basis of all these data, Dhar [19] established the following ranges of existence of various ions of germanic acids in solution —

$$HGeO_3^- \rightleftarrows HGe_5O_{11}^- \rightleftarrows HGeO_3^- \rightleftarrows [Ge(OH)_6]^{2-},$$
$$pH\ 6 \leftrightarrow pH\ 9.4 \leftrightarrow pH\ 11 \leftrightarrow pH > 13.$$

It has not been possible to isolate germanic acids in the solid state from solution. The isolation of pentagermanic acid, reported by Carpeni and Tchakirian [10,20], was not confirmed by later work [21].

The following values are accepted [22] for the ionisation constants of metagermanic acid: $K_1 = 2.6 \times 10^{-9}$ and $K_2 = 1.9 \times 10^{-13}$ at 20°, in accordance with Pugh's measurements [23]. Later, other workers obtained for the first ionisation constant of metagermanic acid values close to that given above: Gulezian and Müller [24] between $1.0 \times 10^{-9}$ and $3.0 \times 10^{-9}$ at 25°, Carpeni [25] $0.79 \times 10^{-9}$ at 12°, and Lourijsen-Teyssèdre [12] $0.89 \times 10^{-9}$. The thermodynamic value of the first ionisation constant of $H_2GeO_3$ according to Antikainen [26] is $1.86 \times 10^{-9}$ at 25°. The values of $K_1$ for metagermanic acid, obtained by Roth and Schwarz [27] ($1.2 \times 10^{-7}$ at 18°) and by Schwarz and Huf [28] ($0.5 \times 10^{-7}$ at 20°) are too high, owing to the inadequate purity of the germanium dioxide used. The value obtained by Carpeni [25] for the second ionisation constant of metagermanic acid ($2 \times 10^{-13}$ at 12°) agrees with the value given by Pugh.

Antikainen [26] established that temperature has an unexpectedly marked influence on the ionisation of metagermanic acid. Thus with increase in temperature from 10° to 45°, the first ionisation constant of $H_2GeO_3$ increases by a factor of almost 20. This marked effect of temperature is not observed with weak acids [29]. Increase in temperature apparently leads to the polymerisation of metagermanic acid and the formation of a certain quantity of the stronger polygermanic acids.

Antikainen [30] also observed the formation of polygermanic acids in the preparation of concentrated (0.23 M) solutions of germanium dioxide by means of a cation-exchange resin. According to him, these solutions contain singly charged di- and tri-nuclear oxoanions of germanium. The polynuclear peroxo-complex of germanium $[Ge_n(H_2O_2)_4]^-$, where $n = 2–3$, is formed by the action of hydrogen peroxide on 0.01–0.02 M solutions of metagermanic acid [31]. The equilibrium constant for the formation of the mononuclear peroxo-complex is $K = [Ge(H_2O_2)_2^-]/[HGeO_3^-][H_2O_2]^2 = 48$. The stability of certain polyoxoanions has been examined by Yatsimirskii [32].

Tchakirian suggested that metagermanic acid, like boric, phosphoric, and arsenious acids, reacts under certain conditions with the sulphates, chlorides, or nitrates of alkali and alkaline earth metals to form complex acids [33].

Hardly any work has been done on quadrivalent germanium cations. De Carvalho and Lederer [34] merely point out the possibility that cationic forms of germanium may exist in acidic solutions. On the basis of a comparison of the solubilities of germanium dioxide and arsenic sesquioxide, Pugh [35] suggested that the basic dissociation constant of $GeO_2$ should be less than that of $As_2O_3$, which is close to $10^{-14}$. Everest and Salmon [14], on the basis of experiments with cation-exchange resins, concluded that no germanium cations are present in solution in the pH range 7–1. The statement [36] that the $Ge^{4+}$ cation is formed at pH 3.36–3.31, according to the equilibrium $GeO_3^{2-} + 6H^+ \rightleftharpoons Ge^{4+} + 3H_2O$, is without foundation and has been criticised [37,38]. $Ge^{4+}$ cations probably appear as one of the equilibrium forms only in strongly acid solutions.

The existence of germanium cations in weakly acidic solutions is confirmed by observation and by everyday analytical practice. Germanium lies in the same group of the Periodic System as tin, titanium, zirconium, and hafnium, for which $MO^{2+}$, $M(OH)_2^{2+}$, and $M^{4+}$ ions are known. Like tin and zirconium, germanium reacts with phenylarsonic acid and its derivatives [39]. In its reactions with sulphides and *o*-hydroxyquinones, the behaviour of germanium is analogous to that of tin. The existence of the germanyl ion $Ge(OH)_2^{2+}$ or $GeO^{2+}$ is confirmed by the formation of germanyl cyanoferrate(II) $[Ge(OH)_2]_2[Fe(CN)_6]$ or $(GeO)_2[Fe(CN)_6].2H_2O$ when potassium cyanoferrate(II) is added to an acidic solution of sodium germanate [40].

Migration experiments have made it possible to detect germanium cations in weakly acidic solutions and to establish the approximate ranges of their existence [41]. The germanium dioxide concentration chosen for these experiments excluded the possibility of formation of colloidal particles of $GeO_2$. The results show that germanium cations are produced at pH ~ 7 and exist together with anions of germanic acids. The relative quantity of germanium cations increases with decrease in pH. These data have been subsequently confirmed by experiments on the sorption of germanium by cation-exchange resins (KU-1, KU-2, and Wofatit No. 4) and anion-exchange resins (AV-16, AV-17, AV-27) on columns [42] and under static conditions [43].

## State of Germanium in Inorganic Acid Solutions

Everest [44] suggests that bivalent germanium exists in acidic solutions only in the form of complex compounds. Hydrohalic acids contain acido-complexes $HGeX_3$, whose salts $MGeX_3$ (where M is an alkali metal and X chlorine, bromine, or iodine) have been isolated [45,46]. The complex phosphate $Ge_3(PO_4)_2.2GeHPO_4$ [44] and complex halogenohypophosphites of germanium $Ge(H_2PO_2)_2.GeCl_2$, $Ge(H_2PO_2)_2.GeBr_2$, and $3Ge(H_2PO_2)_2.GeI_2$ [44,46] have been prepared.

The state of quadrivalent germanium in solutions of inorganic acids has been studied considerably more fully. In hydrofluoric acid, quadrivalent germanium readily forms six-coordinated complexes. Tananaev and Avduevskaya [47] established in the $GeO_2$–HF–$H_2O$ system the existence of complex acids having the compositions $H_2[GeOF_4].2H_2O$ and $H_2[GeF_6].2H_2O$, which were isolated in the solid state. These acids are stronger than hydrofluoric acid; hydrogen hexafluorogermanate $H_2GeF_6$, which is formed at higher HF concentrations, is the strongest acid. No complexes of higher fluorine content are formed. Fluorogermanate complexes are more stable than fluorosilicate complexes. Thus alkali-metal hexafluorogermanates dissolve in

100% HF without decomposition[48], unlike the hexafluorosilicates, which decompose under these conditions with the liberation of silicon tetrafluoride[49]. Comparison of the relationship between the stability of the fluoro-complexes and the position of the element in the Periodic System[50] shows that the stability in general increases with decrease in the radius of the central ion, but this relationship is complicated by the competing influence of the bond between the complex-forming ion and oxygen. The competing influence of the bond with oxygen is clearly shown for the fluoro-complexes of the Ge–Si pair.

Cryoscopic studies[52] in 0.01–0.2 M solutions of K, Rb, and Cs hexafluorogermanates show that a molecule of the salt forms three ions. The solubilities of $K_2GeF_6$, $Rb_2GeF_6$, and $Cs_2GeF_6$ in water at 25° are 0.0221 M, 0.0167 M, and 0.0471 M respectively.

Hexafluorogermanates are decomposed completely by alkalis. The hydrolysis of hexafluorogermanates in water is autocatalytic and takes place by a solvolytic dissociation mechanism[51]:

$$GeF_6^{2-} + H_2O \rightleftarrows Ge(OH)F_5^{2-} + HF.$$

This reaction is followed by rapid hydrolysis of the $Ge(OH)F_5^{2-}$ ion to $GeO_2$.

According to the data of Benoit and Place[53], the hexafluorogermanate complex is not formed in acid solutions. Depending on the HF concentration, mononuclear hydroxofluorogermanate complexes $Ge(OH)_jF_i$ are formed, where the maximum value of $i$ is 5. The overall stability constants of the complexes $Ge(OH)_jF_5^{(j+1)-}$ and $Ge(OH)_jF_4^{j-}$, determined in 0.5 M $HClO_4$, are $\beta_5' = (8.8 \pm 0.2) \times 10^8$ and $\beta_4' = (2.0 \pm 0.3) \times 10^7$ respectively. The fluoro-complexes of germanium, like the tin complexes, are not decomposed by hydrogen sulphide, and this is used in analysis to separate germanium from arsenic[54]. The sorption of hydrogen fluorogermanate on an anion-exchange resin is also used for this separation[55].

The fluorination of metallic germanium by the action of $ClF_3$ in liquid hydrogen fluoride leads to the formation of hydrogen hexafluorogermanate, which can then be isolated as the silver salt[56]. As in the case of aqueous solution, the fluorogermanate complex in liquid hydrogen fluoride is more stable than the fluorosilicate complex, and is readily formed.

The ease of formation of the fluoro-complexes also extends to the fluoro-organometallic compounds of germanium and the fluorogermanes. Thus the addition of KF to trifluoromethyltrifluorogermane $CF_3GeF_3$ in aqueous solution gives a sparingly soluble precipitate of $K_2[CF_3GeF_5]$. Clark and Willis[57] studied this reaction and suggest that in aqueous solution $CF_3GeF_3$ forms ionised molecules of the type $CF_3Ge(OH)_2F_3^{2-}$ and $CF_3Ge(OH)_3F_2^{2-}$ as a result of hydrolysis. The hydrolysis is readily reversible, and the addition of KF to the solutions precipitates $K_2[CF_3GeF_5]$. Monofluorogermane $GeH_3F$ reacts with ammonia at -78° to give[58] the addition product $GeH_3F.2NH_3$, which decomposes at 25° to $NH_3$ and $[GeH_3.NH_3]F$. The latter compound decomposes only at 180°.

The hexachlorogermanate complex is formed much less readily than the hexafluorogermanate complex. The hexachlorogermanates of caesium[59–61] and rubidium[60,61] are formed under special conditions. After unsuccessful attempts[62] tetramethylammonium hexachlorogermanate $[N(CH_3)_4]_2GeCl_6$ was also prepared[60]. Attempts to isolate free hydrogen hexachlorogermanate $H_2GeCl_6$ were unsuccessful[59,61,63]. Nevertheless, the maximum on the solubility curve for germanium dioxide in hydrochloric acid[64] and the mechanism of the extraction of germanium from hydrochloric-acid solutions[65,66] are attributed to the existence of this acid as one of the equilibrium forms. It is claimed that the decrease in the solubility of $GeO_2$ after the maximum[64], and the decrease in the partition coefficient for germanium[65,66], are due to the decomposition of $H_2GeCl_6$ and the separation of $GeCl_4$ as a separate phase with increase in the concentration of hydrochloric acid.

A study of solutions of germanium dioxide and tetrachloride in hydrochloric acid using ion exchange led Everest and Harrison[61] to the conclusion that in 6–9 M HCl an equilibrium exists between metagermanic acid or germanium dioxide and the chlorogermanate anions $GeCl_5^-$ or $GeCl_6^{2-}$. Intermediate acido-complexes of the type $[Ge(OH)_xCl_{5-x}]^-$ and $[Ge(OH)_xCl_{6-x}]^{2-}$, where $x$ = 3 or 4, take part in the equilibrium. It is suggested that the singly charged acido-complex is more likely to be formed. The intermediate acido-complex is the chief form of germanium compound in 6.5–9 M HCl. At HCl concentrations lower than 6.5 M, hydrolysis of the intermediate complex takes place with the precipitation of germanium dioxide. Increase in the hydrochloric acid concentration above 9 M leads to chlorination of the intermediate acido-complex with the separation of germanium tetrachloride as a separate phase. The quantity of $GeCl_6^{2-}$ ions taking part in the equilibrium could not be determined by the ion-exchange method. By measuring the ultraviolet absorption of hydrochloric-acid solutions of germanium tetrachloride, Angerstein and Davidson[67] found that photometrically measurable quantities of $GeCl_6^{2-}$ ions appear in 6–7 M HCl and reach a concentration of 80% in 12 M HCl; with increase in the HCl concentration above 12 M, the concentration of hexachlorogermanate ions increases, but does not reach 100%. This last fact agrees with the data of Benoit and Clerc[68], who consider, moreover, that formation of the $GeCl_6^{2-}$ ion in anhydrous HCl is unlikely. In this, germanium differs from tin, since the $SnCl_6^{2-}$ ion is formed under these conditions[62].

Using the ion-exchange method, Nelson and Kraus[69] obtained results which indicated that the formation of anionic complexes of germanium is negligible at HCl concentrations in the range 0.1–4 M. This was confirmed by later work in the same laboratory[70]. With increase in the HCl concentration, the degree of complex formation increases, giving no maximum up to the highest HCl concentrations and passing through the range of formation of the uncharged $GeCl_4$ species without the separation of germanium tetrachloride as a separate phase. The lack of agreement in this respect with other data[61,64–66,67–69] is most probably due to differences in the germanium concentrations in the solutions. Thus in the experiments of Nelson and Kraus[69] at low germanium concentrations, $GeCl_4$ could not separate as an individual phase because of its dissolution, so that all the germanium remained in solution; increase in the HCl concentration produced hexachlorogermanate ions, which were more strongly absorbed by the resin. The solubility of $GeCl_4$ in hydrochloric acid has been discussed by Knyazev[71].

Brauer and Müller[64] assume that hydrobromic acid solutions contain uncharged complex species of the type $Ge(OH)_{4-x}Br_x$, where $x$ may have values of 1–3, depending on the acid concentration. The existence of a small quantity of species of this type in hydriodic acid is also possible.

The solubility curve for germanium dioxide in sulphuric acid shows a slight maximum at an $H_2SO_4$ concentration of 15 $N$, but this is not explained by Brauer and Müller. The formation of a more soluble sulphato-complex of germanium may be assumed in this case. In general, however, the tendency of germanium to form complexes with sulphate ions is slight. This can be seen from the fact that the solubility curve for $GeO_2$ in sulphuric acid differs little from the corresponding curves for perchloric and nitric acids, in which germanium is thought to form no anionic complexes. Other workers also observed no formation of complexes by germanium in nitric-acid solutions [72,73].

On the basis of the results of a study of ion exchange in germanium dioxide solutions containing sulphate and phosphate ions, Everest and Salmon [15] suggest the existence of complex ions $[GeO_2(SO_4)]^{2-}$ and $[HGeO_2(PO_4)]^{2-}$ in the pH range 7–9. In a study of the reaction of soluble germanium dioxide with orthophosphoric acid, Everest [44] established that in 35–50% $H_3PO_4$ a compound is formed corresponding to the formula $Ge(HPO_4)_2$; this compound is readily hydrolysed and dissolves in concentrated $H_3PO_4$. Avduevskaya and Tananaev [74] consider that the dissolution of germanium dioxide in concentrated orthophosphoric acid is due chiefly to complex formation. They therefore regard the new phase with composition $GeO_2.P_2O_5.2H_2O$, which they isolated, as hydrogen diphosphatogermanate, having the formula $H[Ge(OH)(HPO_4)_2]$ or $H_2[GeO(HPO_4)_2]$.

## Germanium Heteropoly-Acids

On the basis of the work of Pfeiffer [77], who supplemented the theories of Miolati and Rosenheim, the first workers to study germanium heteropoly-acids [68,75,76] ascribed to these compounds the formulae $H_8[Ge(Mo_2O_7)_6]$ and $H_8[Ge(W_2O_7)_6]$. Subsequent work on the preparation, structure, and properties [80,83–92] of germanium heteropoly-acids was related to their extensive use in analysis [93]. The compounds prepared included molybdovanadogermanic [78–83] and tungstovanadogermanic [83–92] heteropoly-acids, in which isomorphous replacement of molybdenum or tungsten in the heteropoly-anion by vanadium takes place. This is confirmed by electron-diffraction studies of molybdovanadogermanic heteropoly-acids [88].

Heteropoly-acids of germanium, like those of other elements, are formed in acid medium. The optimum acidity for molybdogermanic acid is 0.2–0.5 $N$ $H_2SO_4$. Once formed, the germanium complexes are stable in more acidic solution; thus molybdogermanic acid does not decompose [94] even in 3.3 $N$ $H_2SO_4$. The ternary heteropoly-complexes of germanium are less stable than the binary complexes. The acidity of stable solutions of molybdovanadogermanic acid [95] corresponds to 0.20–0.28 $N$.

Germanium heteropoly-acids also decompose with increase in the pH of the solution.

Tchakirian and Souchay [86] found that at pH 3.2 dodecatungstogermanates begin to undergo conversion to undecatungstogermanates. The conversion is almost complete at pH 4.2. At pH > 7.3, undecatungstogermanates decompose completely to germanates and tungstates. The molybdenum heteropoly-complexes are less stable than the corresponding tungsten compounds. The undecamolybdogermanate anion exists in the pH range 3.5–4.2; at pH > 4.2, this compound begins to decompose to germanate and molybdate [96], the reaction being complete at pH 5.4. Unlike molybdosilicic acid, molybdogermanic acid [97] resembles molybdophosphoric acid [98] in its ready decomposition by hydroxy-carboxylic acids, e.g. citric acid.

Spectrophotometric and electron-diffraction study of the blue products of the reduction of germanium heteropoly-acids showed that the heteropolyanions and the blue compounds formed from them have the same structure [87,88]. In the blue anion, part (approximately one-quarter) of the molybdenum or tungsten is present in the quinquevalent state but occupies the same position in the complex as in the original heteropoly-acid. The blue colour is produced as a result of the intensification of the polarisation effect, due to the presence, in the molecule of the compound, of ions of the element with different valencies. In contrast to the previously accepted view [99,100] that the molybdenum or tungsten coordinated in heteropoly-acids exhibits an increased oxidising power, it was shown [87,88] that the redox potentials of the $Mo^{VI}/Mo^{V}$ and $W^{VI}/W^{V}$ systems in heteropoly-compounds are not higher but lower than the potentials of uncomplexed molybdenum and tungsten, and that the increased redox potential is shown by the whole complex heteropolyanion. The introduction of vanadium into the heteropolyanion considerably raises the redox potential of the latter [87].

A large amount of practical information, which has been obtained and used chiefly in analytical chemistry [76,78,85,90,101,112], shows that the germanic heteropoly-acids form no more than tetra-substituted salts with simple and complex inorganic and organic bases. This contradicts the views of Miolati, Rosenheim, and Pfeiffer, according to whom germanium heteropoly-acids should be octabasic. The low basicity of molybdenum and tungsten heteropoly-acids was explained successfully by Keggin and his followers [85,113–115] on the basis of X-ray structural measurements. Physicochemical studies established that dodecatungstophosphoric acid is tribasic [116] and that dodecatungstogermanic [91] and dodecatungstosilicic [117] heteropoly-acids are tetrabasic. On the other hand, there are experimental data confirming the high basicity of certain other heteropoly-acids and these data cannot be explained by Keggin's treatment. Thus it has been shown that dodecamolybdoceric [118–120], dodecamolybdothoric [121], and dodecamolybdostannic [122] heteropoly-acids are octabasic.

Babko and Shkaravskii [123] explain the contradiction between the views of Miolati, Rosenheim, and Pfeiffer on the one hand and Keggin on the other in terms of the ratios of the radii of oxygen and the central ions in the heteropoly-complex. With small central ions (radius 0.30–0.56 Å) — $Bi^{III}$, $Si^{IV}$, $Ge^{IV}$, $P^{V}$, and $As^{V}$ — the compounds should show a coordination number of 4 with tetrahedral configuration of the oxygen environment and a corresponding basicity for the heteropoly-acids of 8 - $n$, where $n$ is the valency of the central ion. With large central ions having a radius of 0.56–0.99 Å — $Sn^{IV}$, $Ce^{IV}$, and $Th^{IV}$ — the octahedron is the more stable, and the basicity of the corresponding heteropoly-acids should be 12 - $n$. Not all of the facts, however, fit into this scheme: dodecamolybdozirconic [124,126] and dodecamolybdotitanic [125,126] heteropoly-acids are tetrabasic, although the radii of the $Ti^{4+}$ and $Zr^{4+}$ ions are greater than 0.56 Å (0.64 Å and 0.87 Å respectively).

The experimental data and theoretical considerations indicate nevertheless that germanium heteropoly-acids are tetrabasic.

## Addition Compounds Formed by Germanium Tetrahalides

The complex-forming properties of germanium tetrahalides are due to the ability of the central atom to fill the *d* level of its outer electronic shell by using the free electron pairs of attached ligands. In the addition products formed by germanium tetrahalides, these ligands are chiefly ammonia [127] and nitrogen-containing bases — hydrazine, piperidine, pyrrolidine [127], ethylenediamine [127,128], 2,2′-bipyridyl [129], 1,10-phenanthroline [130], pyridine [128-130], trimethylamine, *NNN′N′*-tetramethylethylenediamine [131], triethylamine [132,133], and *o*-hydroxyquinoline [128,134]. These addition products are usually readily hydrolysed by water. On the other hand, amines of high molecular weight, e.g. an *N*-dodecyltrialkylmethylamine [135], form stable addition complexes with germanium tetrachloride, and these can be extracted from hydrochloric-acid solutions with non-aqueous solvents.

Addition products are particularly numerous with germanium tetrafluoride, which forms complexes $GeF_4.2L$ and $GeF_4.L$ (here and subsequently L represents a ligand) with compounds containing nitrogen, phosphorus, oxygen, or sulphur [127]. Besides the complexes with the nitrogen-containing compounds listed above, complexes have been prepared with phosphine and trimethylphosphine, with acetone, ethylene oxide, methanol, tetrahydrofuran, and dioxan, with hydrogen sulphide, dimethyl sulphide, methanethiol, and tetrahydrothiophen. These complexes are relatively unstable. It is suggested that the 1:2 complexes have an octahedral structure with *cis*- and *trans*-arrangement of the ligands, and that the 1:1 complexes are polymeric fluorine-bridged structures [127].

Udovenko and Fialkov measured the viscosity [136] and dielectric constant [137] of systems formed by germanium tetrachloride with ethers and esters, and established that in these systems $GeCl_4$, unlike the tetrachlorides of titanium and tin, does not form addition compounds. The lower complex-forming power of germanium tetrachloride compared with $SnCl_4$ and $TiCl_4$ was attributed [136] to the smaller ionic radius of germanium compared with the ionic radii of tin and titanium, and the consequent greater screening of the germanium ion by chloride ions. The greater screening of the germanium ion by chloride ions, compared with the screening by fluoride ions, may also explain the fact that the complex-forming power of $GeCl_4$ is less than that of $GeF_4$.

## Complex Compounds of Germanium with Polyhydroxy-Compounds.

The addition of a polyhydric alcohol or a monosaccharide to a neutral aqueous solution of germanium dioxide leads to a decrease in the pH of the solution as a result of the formation of complex acids which are stronger than simple germanic acids. Tchakirian [33,138], who was the first to describe this phenomenon, assumed that in the case of mannitol a dinuclear complex with a germanium:ligand ratio of 1:1 and the properties of a dibasic acid is formed. Saito [139] found by high-frequency titration and pH and polarographic measurements that in the complex fructosatogermanic acid the germanium:ligand ratio is 1:4, but this was not confirmed by other authors. In addition, a 1:1 complex which is reduced at a mercury electrode is also formed. Contradictory data on the composition of the complexes of germanium with ethylene glycol, glycerol, and mannitol were obtained by Everest and Harrison [140,141] by an ion-exchange method. Antikainen [142,143] established by a differential potentiometric method that germanium forms 1:2 complexes with mannitol, glucose, galactose, mannose, and fructose, and also 1:1 complexes with glycerol and glycols. Antikainen's data were confirmed by pH measurements [144]. It was established that in the presence of excess of glycerol, mannitol, glucose, galactose, and fructose, complex monobasic acids with a germanium:ligand ratio of 1:2 are formed; the thermodynamic ionisation constants of these acids at 25° are $5.05 \times 10^{-6}$, $1.21 \times 10^{-5}$, $8.35 \times 10^{-6}$, $2.39 \times 10^{-5}$, and $1.04 \times 10^{-4}$ respectively. Mannitol [33,138,145-148], fructose [149], and invert sugar [150], consisting of fructose and glucose, are used in analytical chemistry for the alkalimetric determination of germanium.

According to Antikainen [143,151], the ability of polyhydroxy-compounds to form complexes increases in the sequence — ethylene glycol, propylene glycol, butylene glycol, 3-methoxypropane-1,2-diol, glycerol, D-galactose, D-glucose, D-mannose, D-mannitol, and D-fructose. This agrees with the results obtained by other authors [140,152,153]. Antikainen and his coworkers [142,143,151,154,155] determined the formation consists of a large number of complexes of germanium with polyhydroxy-compounds, in order to characterise their relative stability. In the calculations these workers used the apparent ionisation constants of metagermanic acid in the presence of the polyhydroxy-compound and neglected the changes in the activity coefficients of the ions present in the solution with change in the concentration of the polyol, assuming that the latter concentration and the ionic strength of the solution had no influence on the formation constants of the complexes. In fact, however, it has been shown [153] that both the concentration of polyhydroxy-compound and the ionic strength have a marked influence on the formation of polyol complexes of germanium. The thermodynamic constants for dissociation of the diglycerolato-, diglucosato-, digalactosato-, dimannitolato-, and difructosato-germanate complexes, according to the equation $GeL_2^- + m H_2O \rightleftharpoons HGeO_3^- + 2L$, determined with allowance for this influence, have the values $7.85 \times 10^{-2}$, $3.54 \times 10^{-2}$, $7.64 \times 10^{-3}$, $4.04 \times 10^{-4}$, and $4.24 \times 10^{-5}$ respectively at 25°.

Some of the factors influencing the formation of complexes by germanium with polyhydroxy-compounds have been studied [139,151,154,155]. Increase in the number of carbon atoms and hydroxy-groups in the ligand leads to the formation of more stable complexes. Ketoses give more stable complexes than do aldoses. Complexes having the ratio 1:2 are characteristic of polyhydroxy-compounds containing a large number of hydroxy-groups, and the spatial arrangement of the latter is also important. The formation of lactol forms in solution by saccharides decreases their tendency to form complexes. Mutarotation, which changes the spatial arrangement of the hydroxy-groups and depends on the pH of the solution, also influences the formation of complexes. When the saccharide ligand is present in the lactol form, the influence of the number of carbon atoms and hydroxy-groups in less marked than that for an open chain.

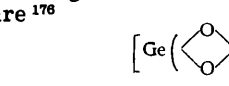
## Complexes of Germanium with Carboxylic Acids.

Complexes of germanium with tartaric [156-161], tartronic [159], quinic, 1-hydroxycyclopentanecarboxylic [160], malic [157,158,160], mucic [160,161], phenyllactic, bromomandelic, benzilic, 2-hydroxyoctanoic [162], lactic [161,162], gluconic [160,161,163], mandelic [158-160,162,164,165], and oxalic [33,166-168] acids have been described. Acids such as tropic, diglycollic, glyceric,

ascorbic, and γ-hydroxybutyric acids do not form complexes with germanium [160].

Data on the composition of the complexes of germanium with carboxylic acids are often contradictory. Thus the values of the germanium : ligand ratio given by different authors are 1 : 1 and 1 : 2 for tartaric acid, 1 : 1, 1 : 2, and 1 : 3 for lactic acid, 1 : 1 and 1 : 2 for mucic acid, and 1 : 2 and 1 : 3 for mandelic acid. These discrepancies are due to the fact that the compounds formed and the ranges of their existence in solution have been inadequately studied. The tartrato- and oxalato-complexes of germanium have been studied in more detail, because of their use in analysis [169-172].

Everest and Harrison [161] established by an ion-exchange method that a 1 : 1 tartrato-complex of germanium is formed in the pH range 0.78–9; the complex is decomposed completely at pH > 11. With increase in the germanium concentration in a large excess of tartaric acid, a complex having a germanium : ligand ratio of 2 : 3 is formed; an excess of germanium leads to the formation of a 5 : 4 polynuclear complex. Everest and Harrison did not establish the existence of the 1 : 2 tartrato-complex, but the isolation [169] of barium tartratogermanate $Ba_2GeC_8H_8O_{14}.2H_2O$ indicates its existence.



The oxalato-complex of germanium is a dibasic acid; salts of this acid with the organic bases quinine, strychnine, and benzoquinoline have been isolated [33,172-174]. The hexahydrate $H_2[Ge(C_2O_4)_3].6H_2O$ has been obtained in crystalline form [168]. Study of the infrared spectra of solutions of germanium dioxide in oxalic acid confirms that the compound formed is complex [175]. It was found by an ion-exchange method [167] that oxalato-complexes of germanium are not formed in alkaline medium; at pH < 3, complex ions $[Ge(C_2O_4)_3]^{2-}$ are sorbed, together with a small quantity of $[HGe(C_2O_4)_3]^-$ and $[HGeO(C_2O_4)_2]^-$ ions; in the pH range 3–6, and also when the solution contains insufficient oxalate ions, the complexes $[GeO(C_2O_4)_2]^{2-}$ and $[GeO_2(C_2O_4)]^{2-}$ are formed. Solubility studies and measurement of the pH and electrical conductivity [168] in the $GeO_2$–$H_2C_2O_4$–$H_2O$ system also established the existence, in addition to hydrogen trioxalatogermanate, of an intermediate complex acid having a Ge : ligand ratio of 1 : 2; the ammonium and potassium salts of this acid were isolated.

The stability of the complexes of germanium with carboxylic acid has been little studied. According to Vartapetian [158] the stability increases in the order — lactic, malic, mandelic, and tartaric acids.

## Complexes of Germanium with Dihydric Phenols

Germanium dioxide reacts in aqueous solution with simple o-dihydroxy-derivatives (catechol, pyrogallol, benzene-1,2,4-triol, naphthalene-2,3-diol, etc.) to form two types of compound — sparingly soluble neutral complexes $GeL_2.2H_2O$, the so-called germanium–diphenols [176], and the soluble complexes $H_2GeL_3$, termed phenolgermanic acids [177-179] or hydrogen trisdiphenolatogermanates.

Bisarenediolatogermanium complexes are formed in concentrated solutions of germanium dioxide and the dihydric phenol, and are insoluble in organic solvents. The dicatecholatogermanium complex has been assigned the structure [176]

and this has been confirmed by chemical and thermogravimetric analysis [176], by determination of the infrared spectra [180], and by X-ray diffraction studies [181]. The composition $GeL_2.2.5H_2O$ ascribed to this complex [180] does not agree with the above structure.

Bisarenediolatogermanium complexes do not exist in solution but dissociate according to the scheme [176]

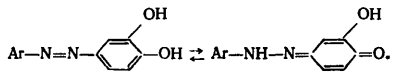
$$3\,GeL_2 \cdot 2\,H_2O \rightleftarrows 2\,GeL_3^{2-} + 4\,H^+ + GeO_2.$$

Polarographic, spectrophotometric, and pH measurements have in fact established [182-186] that the only complexes present in germanium dioxide solutions containing dihydric phenols are the corresponding hydrogen trisarenediolatogermanates, which are very strong acids. The thermodynamic second ionisation constants [186] for hydrogen tricatecholatogermanate and tripyrogallolatogermanate at 25° are $(1.85 \pm 0.06) \times 10^{-2}$ and $(2.21 \pm 0.07) \times 10^{-2}$ respectively.

Hydrogen trisarenediolatogermanates are more stable than bisarenediolatogermanium complexes. The formal constants for the formation of the tricatecholato- [185,187], tripyrogallolato- [187], and trithyroninato-complexes [187] were determined without allowance for the ionisation of germanic acid and the corresponding complex acids, and the values do not characterise their true stability. The thermodynamic constants for dissociation of the tricatecholato- and tripyrogallolato-complexes at 25° according to the scheme [188]

$$HGeL_3^- + 3H_2O \rightleftarrows HGeO_3^- + 3H_2L$$

are $(2.16 \pm 0.12) \times 10^{-9}$ and $(0.88 \pm 0.09) \times 10^{-9}$ respectively.



Numerous disubstituted salts of hydrogen trisarenediolatogermanates have been prepared with ammonia, organic bases (pyridine, quinoline, and triphenylmethane dyes), and the complex phenanthrolineiron(II) cation [179]. The formation of phenanthrolinecadmium tricatecholatogermanate $[Cd\,phen_2][Ge(O_2C_6H_4)_3]$ is used for the gravimetric determination of germanium [189], and that of 2,3′-bipyridylium tricatecholatogermanate for the extraction-photometric determination of germanium [190]. The formation of hydrogen tricatecholatogermanate itself is also used in analysis for the volumetric [176,191-193], polarographic [194,195], and amperometric [196] determination of germanium.

Noteworthy complexes are formed by germanium with tannin and humic acids, whose structures are characterised by the presence of one or more aromatic nuclei with two or more phenolic hydroxy-groups. Tannin is of importance in the technology [197] and the analytical chemistry [93,103,198,199] of germanium. In the geochemistry of germanium, the accumulation of the element in coals has been attributed to humic acids. It is suggested that the accumulation is due to the sorption of germanium by humic acids from circulating solutions at the stage when the coal is formed [200-202]. Only preliminary data [203,204] have been given on complex formation by germanium with humic acids, and there are no published data on its complex formation with tannin. This is due to the fact that the individual chemical compounds covered by the general names "tannin" and "humic acids" have been insufficiently studied.

## Complexes of Germanium with Hydroxy-Carbonyl Compounds

Coloured or fluorescent complexes with aromatic hydroxyl-containing ligands play an important part in the analytical chemistry of germanium [93] by providing a basis

for photometric methods for its determination. A characteristic feature of these ligands is the presence of a phenolic hydroxyl in the *ortho*- or, less frequently, the *peri*-position relative to a carbonyl (quinonoid) group, or of two phenolic hydroxy-groups *ortho* to one another, together with a group, *para* or *ortho* to one of these, permitting tautomeric conversion of the compound into an *o*-hydroxyquinone, e.g. for derivatives of 3,4-dihydroxyazobenzene:

All compounds of this class can be divided into two types.

A. Compounds already containing an *ortho*- or a *peri*-hydroxy-carbonyl grouping in the molecule.

(1) Triphenylmethane dyes — pyrogallolaurin, pyrogallolsuccinein, catecholphthalein [205-208], Catechol Violet [209], etc.

(2) Xanthen dyes — gallein [205], coerulein [208], and derivatives of 2,3,7-trihydroxy-6-oxoxanthen with aromatic or aliphatic radicals as substituents on the $C_{(9)}$ carbon atom [210-214], including the familiar photometric reagent for germanium 2,3,7-trihydroxy-6-oxo-9-phenylxanthen or phenylfluorone [215-217].

(3) Flavone dyes — 3-hydroxyflavone [3-hydroxy-4-oxo-2-phenylchromen] [218] and its hydroxy-derivatives: 2',3,4',5,7-pentahydroxyflavone (morin) [218,219], 3,3',4',5,7-pentahydroxyflavone (quercetin), and 3,3',4',5,7-pentahydroxyflavone-6-sulphonic acid (quercetinsulphonic acid) [220,221].

(4) Derivatives of 4*H*-pyran, quinoid dyes of vegetable origin (brazilein [205,207] and haematein [205,207,222]).

(5) The tropolone dye purpurogallin [205-208], and also tropolone itself, 3-hydroxytropolone, and 3-aminotropolone [223]. The latter form colourless complexes with germanium.

(6) Hydroxyanthraquinones, containing a hydroxy-group in the *peri*-position to a carbonyl group and reacting with germanium in concentrated sulphuric acid, e.g. quinalizarin, purpurin, 1,2,4,5,6,8-hexahydroxyanthraquinone [39,224,225], the structurally similar monohydroxynaphthacenequinonesulphonic acid [226], and also acetylquinalizarin [227], which, unlike quinalizarin, reacts with germanium in weakly acidic medium.

(7) Colourless compounds reacting with germanium to form complexes which are luminescent under ultraviolet radiation. These compounds contain a hydroxy-group *ortho* to a nuclear carbon atom attached to a side-chain containing a carbonyl group — 2,4-dihydroxyacetophenone [228], 2,4,6-trihydroxyacetophenone, 2,4-dihydroxy-ω-methoxyacetophenone, 2-hydroxy-4-methoxybenzaldehyde, 2,4-dihydroxybenzaldehyde, and salicylaldehyde [229]. A fluorescent compound with germanium is formed also by benzoin [229], which contains a keto–enol group between two phenyl radicals.

(8) Dihydroxy-derivatives of naphthaquinone [230] — spinazarin, spinochromes B1 and M1, etc.

B. Compounds with an arene-*o*-diol structure, capable of tautomeric conversion into *o*-hydroxyquinones.

(1) *o*-Dihydroxyazo-compounds [205-208] — azobenzene-3,4-diol, 3',4'-dihydroxyazobenzene-4-sulphonic acid, 1-phenylazonaphthalene-2,3-diol, etc.

(2) *o*-Dihydroxy-derivatives of triarylmethanols [205-208] — 3,4-dihydroxytriphenylmethanol, 3,4-dihydroxynaphthyldiphenylmethanol, 4,4'-bisdimethylamino-3",4"-dihydroxytriphenylmethanol, etc.

(3) Schiff bases from dihydroxy-aldehydes and oximes and phenylhydrazones of the latter [205,207] — 3',4'-dihydroxybenzylideneaniline, the phenylhydrazone and oxime of protocatechualdehyde, etc.

(4) 3,5-Dinitrocatechol [205,207].

(5) Anthocyanidins containing hydroxy-groups on the $C_{(3')}$ and $C_{(4')}$ atoms — delphinidin and cyanidin [208] — and also the *o*-dihydroxychromenols with similar structures [231].

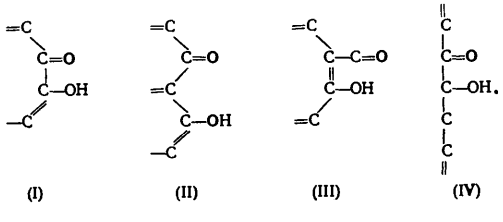
(6) Dihydroxy-derivatives of 2-oxochromen — 6,7-dihydroxy-4-methyl-2-oxochromen (methylaesculetin) [230] and 7,8-dihydroxy-4-methyl-2-oxochromen [232].

(7) Dihydroxy-derivatives of benzofuran [208] — 6,7-dihydroxy-3-oxobenzofuran, gallorubin, and 3-*p*-dimethylaminobenzylidene-6,7-dihydroxybenzofuran.

(8) Oxazine dyes — gallocyanine and Modern Violet [205-208].

All these compounds react with germanium in acid medium, forming soluble or insoluble coloured or, less frequently, colourless or fluorescent complexes. These complexes have been insufficiently studied and for many of them even the composition has not been determined. Tchakirian and Bévillard [205-207,233,234] suggested that the reaction of *o*-hydroxyquinone compounds of type A with germanium is due to the presence of the *o*-hydroxyquinone group in the molecule, whereas the reactivity of arene-*o*-diol compounds of type B results from preliminary tautomeric conversion to the *o*-hydroxyquinone form. Later, Bévillard [208,235] abandoned this viewpoint and concluded that these compounds react with germanium in the arene-*o*-diol form to give complexes of the hydrogen phenolatogermanate type [179] having the composition $H_2GeL_3$, and that the quinonoid structures, even if present in the ligand molecule, do not take part in the interaction with germanium.

Kimura et al. [230], who could not establish that reaction takes place between germanium and partly and completely methylated phenylfluorone and 2-hydroxy-1,4-naphthaquinone, came to the same conclusion. Kimura's proof, however, is not convincing, since methylated phenylfluorone in general is unable to form cyclic complexes with metal ions, and for the hydroxynaphthaquinone an equivalent structure is that of 4-hydroxy-1,2-naphthaquinone in which this compound is also unable to form cyclic complexes.



Subsequent studies have established that the complexes of germanium with compounds of type A have a composition different from that of hydrogen phenolatogermanates. Thus for trihydroxyxanthones a Ge : L ratio of 1 : 2 was found [214,236,237]. It was shown that the trihydroxyxanthones containing both groups — *o*-diol and *o*-hydroxyquinonoid — react with germanium [238] and also with zirconium [238], antimony [238], scandium [238], and molybdenum [239] as *o*-hydroxy-carbonyl compounds. Similar proof was obtained for the complexes of germanium with Catechol Violet [240] and purpurogallin [241]. Chloranilic acid, 2,5-dichloro-3,6-dihydroxy-1,4-benzoquinone, which is capable of undergoing tautomeric conversion into 3,6-dichloro-4,5-dihydroxy-1,2-benzoquinone, reacts with germanium in the *o*-hydroxy-

quinonoid form [242], forming three coloured complexes with Ge : L ratios of 1 : 1, 1 : 2, and 1 : 3. Kanno [218,243] established that only those hydroxyflavones which have an unsubstituted hydroxy-group on the $C_{(3)}$ carbon atom are capable of reacting with germanium in acid medium: i.e. the reactive group is the $C_{(3)}-C_{(4)}$ *o*-hydroxy-carbonyl group. Analogous results had been previously obtained in a study of the reaction of hydroxyflavones with zirconium [244-246].

The reactivity of *o*-dihydroxychromenols towards germanium and other metals is attributed to tautomeric conversion of the dyes into anhydro-bases having the structure of *o*-hydroxyquinones [231]. It was finally shown [247] that the *o*-diols 3′,4′-dihydroxyazobenzene-4-sulphonic acid and 3,4-dihydroxynaphthyldiphenylmethanol react with germanium in dilute solutions of strong acids only after conversion into the *o*-hydroxyquinonoid forms, to give complexes GeL and $GeL_2$ (in the case of the first compound) or only GeL (with the second compound).

The composition GeL has been established for the complexes of germanium with hydroxyanthraquinones, formed in sulphuric acid medium [39].

The groups of atoms which, in the molecules of hydroxy--carbonyl compounds, react with germanium in acid medium can be represented by the fragments: (I) — compounds of type A (1)–(5) and (8), and all compounds of type B in the tautomeric form; (II) — A (6); (III) — A′ (7), *o*-hydroxy--phenones and *o*-hydroxy-aldehydes; and (IV) — A (7), benzoin.

(I) (II) (III) (IV)

The groups (I)–(III) are parts of the conjugated bond systems of aromatic nuclei, and in the coloured compounds they are also parts of the chromophoric conjugation systems. The group (IV) of benzoin is not part of an aromatic ring, but the influence of the conjugation systems of the two phenyl radicals on either side of the group gives it an "aromatic" character. In the reaction with the ions of germanium or other multivalent metal, five-membered [groups (I) and (IV)] or six-membered [groups (II) and (III)] cyclic complexes are formed, in which the metal atom is joined to the oxygen atoms of the ligand by non-equivalent bonds — by an ionic bond or almost ionic covalency to the phenolic oxygen, and by a donor–acceptor bond to the carbonyl oxygen. The complexes in which the metal ion replaces only one hydrogen atom in the ligand molecule during ring formation are more stable than the cyclic complexes formed by the dihydric phenols, whose formation involves the replacement of two hydrogen atoms. According to the law of mass action, the influence of hydrogen ions on the equilibrium for the formation of the complex is proportional to the first power of the concentration in the first case and to the square of the concentration in the second case. The nature of the complex-forming bond in the phenylfluoronates of germanium and other metals was examined by Sano [248].

In the colourless addition compounds formed by germanium tetrahalides with acetylacetone and other β-diketones [249], the ligand is present in the keto–enol form; this is to some extent analogous to the case of the complexes formed by germanium with aromatic *o*-hydroxy-carbonyl ligands.

## Nitrogen- and Sulphur-Containing Complexes of Germanium

Apart from the addition products formed by germanium tetrahalides, complexes of germanium with compounds containing nitrogen and sulphur are few in number. It is generally considered that the formation of complexes containing a Ge–N bond is not characteristic of germanium. It has been established, however, that germanium forms a complex with 1,1′-bianthrimide in sulphuric acid [250], analogous to the complex formed by boron with the same reagent, and a complex with ethylenediaminetetraacetic acid ($H_4Y$) in weakly acidic solutions [251], suitable for quantitative analysis. A complex with $H_4Y$ of composition $GeY.2H_2O$ has been isolated in crystalling form by the action of $GeCl_4$ on hot $Na_2H_2Y$ solution [258].

The naturally occurring sulphides of germanium — argyrodite, germanite, and renierite — and also double sulphides [252] of the type $CuS.GeS_2$ are undoubtedly complex compounds. The potassium and sodium thiogermanates $M_6[Ge_2S_7].9H_2O$ isolated by Schwarz and Giese [253] have the structure of dinuclear complexes. Formation of the dinuclear complex thiogermanate $K_2Ge_2S_5$ is used for the iodometric determination of germanium [172]. Among organic thio-compounds, toluene-3,4-dithiol (dithiol), which forms a complex dithiolate, has been described as a reagent for germanium [254]. Germanium reacts with the thiol analogues of hydroxy-carboxylic acids — mercaptoacetic, mercaptosuccinic, and mercaptopropionic — to form di- and tri--basic complex acids [259], whose ionisation constants have been determined.

Potassium and sodium selenogermanates $M_6[Ge_2Se_7].9H_2O$, analogous to the corresponding thiogermanates, have been prepared [255].

## Complex-Forming Germanium Ions.

It is evident that for complexes of bivalent germanium, the complex-forming ion is $Ge^{2+}$, even if it exists in insignificant quantities only as one of the equilibrium forms. It is much more difficult to reach conclusions regarding the nature of the complex-forming ions of quadrivalent germanium, since our knowledge of the state of quadrivalent germanium in solution is inadequate.

It may be taken as established that in the reactions with polyhydroxy-compounds and dihydric phenols, the complex--forming ion is the metagermanate ion $HGeO_3^-$, since complex formation takes place at germanium concentrations which exclude the formation of polymeric forms either in acidic medium or in alkaline medium, where no germanium cations are formed. This agrees with the situation for the analogous complexes formed by boron and arsenic with polyhydroxy-compounds, where the complex-forming ions are assumed to be the singly charged ions of boric and arsenious acids [256]. It may be assumed that, in the reactions with hydroxyanthraquinones in concentrated sulphuric

acid, the complex-forming ion is a germanium cation, since it has been shown for the analogous reactions of boron [257] that the complex-forming ion is a boron cation. In the same way, it may also be assumed by analogy that germanium cations take part in the reactions with *o*-hydroxy-carbonyl compounds and ethylenediaminetetraacetic acid in acidic medium. It is probable that in all complex-formation reactions in acid medium the complex-forming ions are germanium cations, but there are as yet no data for characterising these cations.

It is evident that a successful quantitative study of the chemistry of germanium complexes is possible only if the forms of the components of the complex-formation equilibrium are known. Thus determination of the basic dissociation constants of $GeO_2$ and of the ranges of existence of the individual cations is of primary importance in the chemistry of germanium.

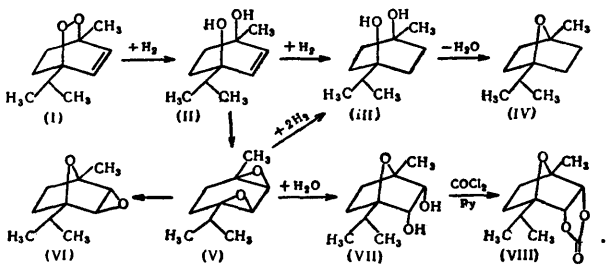
## I. INTRODUCTION

The present review surveys the reactions of conjugated dienes with molecular oxygen to form peroxides.

It has been established that transannular epidioxides are produced by the photosensitised oxidation of alicyclic, aromatic, and heterocyclic homoannular 1,3-dienes. Such dienes undergo the Diels–Alder reaction with maleic anhydride and other dienophiles. Therefore the photooxidation of homoannular 1,3-dienes to transannular epidioxides can be regarded as a photochemical Diels–Alder reaction in which oxygen acts as dienophile.

It has recently been found that homoannular 1,3-dienes are oxidised to transannular epidioxides by molecular oxygen in an excited singlet state. This must be regarded as a diene synthesis with singlet oxygen. It is probable that excited singlet oxygen is the active intermediate also in photosensitised oxidations with molecular oxygen.

The ability of homoannular 1,3-dienes to form transannular epidioxides at low temperatures, and also the ease with which some of the latter rearrange into more stable oxygen compounds or break down again with the liberation of oxygen, suggest that some biological oxidation processes may involve the intermediate formation of transannular epidioxides. This hypothesis has recently been confirmed experimentally.



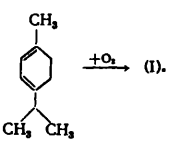
The paper covers the literature published up to 1st March 1965.

## II. REACTION OF MOLECULAR OXYGEN WITH ACYCLIC AND ALICYCLIC 1,3-DIENES

### 1. Ascaridole

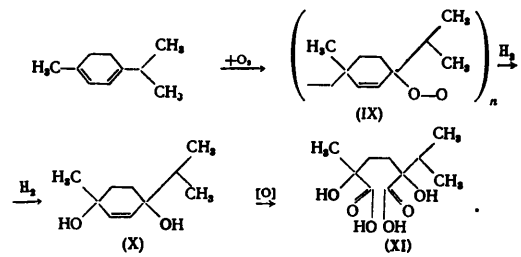
In 1908 Gütig[1] isolated an oily substance, having the composition $C_{10}H_{16}O_2$ and boiling at 80–84° (4–5 mm), from chenopodium oil (the essential oil of a species of wormwood, *Chenopodium ambrosioides* var. *anthelminticum*), which possesses an anthelmintic (vermifugal) action. This substance, which is the active principle of chenopodium oil, was termed *ascaridole*. In 1912 Wallach[2,3] established that ascaridole was 1,4-epidioxy-*p*-menth-2-ene (I): catalytic hydrogenation with colloidal palladium gave the previously unknown *p*-menthane-*cis*-1,4-diol (III), dehydration of which with oxalic acid yielded the known 1,4-epoxy-*p*-menthane (IV).

It must be noted that at that time ascaridole was the only known organic compound having a transannular epidioxide structure.



Study of the chemical properties of ascaridole gave interesting results. Catalytic hydrogenation with platinum

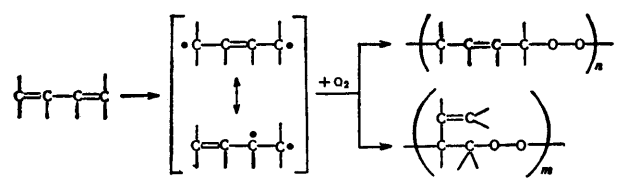
oxide[4] or with Raney nickel[5] yielded the diol (III). Reduction with lithium tetrahydroaluminate[6] or with a potassium–sodium alloy in ether[5] produced *p*-menth-2-ene-1,4-diol (II). This unsaturated glycol (II) was also obtained by the catalytic reduction of ascaridole with relatively inactive palladium[4] or nickel[5] catalysts. When heated to 130–150° ascaridole decomposes explosively[2,3]. Nelson[7] found that when heated in *p*-cymene at 150°, ascaridole isomerises to a diepoxy-*p*-menthane. It was found later[6,8] that the thermal isomerisation of ascaridole is more conveniently carried out in boiling xylene, and Schenck[5] showed that ascaridole is converted into this diepoxide by the action of ultraviolet radiation. Nelson[7] assumed that, on being heated, ascaridole is first converted into an unstable isomer, 1,2:3,4-diepoxy-*p*-menthane (V), which then rearranges to the stable isomer, 1,4:2,3-diepoxy-*p*-menthane (VI). In the presence of dilute sulphuric acid, the diepoxide adds on a molecule of water to form 1,4-epoxy-*p*-menthane-2,3-diol (VII). The cyclic carbonate (VIII) has been obtained[9] by the action of carbonyl chloride and pyridine on (VII). Matic and Sutton[6] determined the structure of the thermal isomerisation product of ascaridole by reducing it with lithium tetrahydroaluminate, and isolated the compound (III) and a triol $C_{10}H_{20}O_3$ from the reaction products. The formation of (III) proved the presence of the 1,2:3,4-diepoxide (V) in the product of isomerisation. The triol $C_{10}H_{20}O_3$ could have been formed by reduction of the 1,4:2,3-diepoxide (VI) to 1,4-epoxy-*p*-menthan-2(or 3)-ol, followed by hydration of the latter to *p*-menthane-1,2(or 3),4-triol. It follows from these results that the product of the thermal isomerisation of ascaridole is probably a mixture of the diepoxides (V) and (VI)†. It must be noted that the configuration of 1,4-epoxy-*p*-menthane-2,3-diol (VII) has not been rigorously proved.



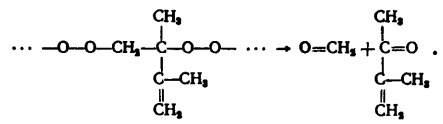
Ascaridole is used in medicine for the treatment of intestinal helminthiases in both adults and children. Chemists use ascaridole as an initiator for radical reactions.

## 2. Autoxidation of Acyclic and Alicyclic 1,3-Dienes

Ascaridole (I) can be regarded as an internal peroxide of *p*-mentha-1,3-diene. In 1933 Bodendorf[4] put forward the hypothesis that autoxidation of the latter compound involves the addition of oxygen to the conjugated system of double bonds at the 1,4 positions to form ascaridole:



However, experiments undertaken to test this hypothesis showed that molecular oxygen reacts with *p*-mentha-2,3-diene to form, not ascaridole, but an unsaturated polymeric peroxide of low molecular weight. Bodendorf reduced the polyperoxide catalytically, and oxidised the reduction product with potassium permanganate. From the oxidation products he isolated 2,5-dihydroxy-2-isopropyl-5-methyladipic acid (XI). Hence it followed that in the autoxidation of *p*-mentha-1,3-diene the oxygen added on at the 1,4 positions to form the unsaturated polymeric peroxide (IX), catalytic reduction of which yielded the unsaturated glycol (X), and this was oxidised to the dicarboxylic acid (XI):

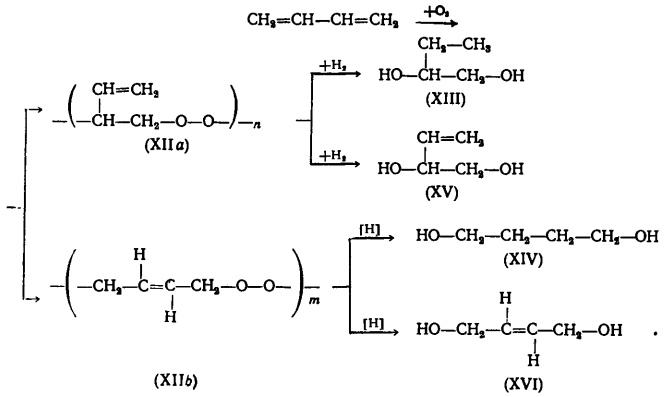


Bodendorf also found that only polymeric peroxides were formed in the oxidation of other diene hydrocarbons (*p*-mentha-1,5-diene, cyclohexa-1,3-diene, isoprene, and 2,3-dimethylbuta-1,3-diene).

Subsequently other investigators have established that polymeric peroxides of low molecular weight are formed in the autoxidation of buta-1,3-diene[13,14], isoprene[15], 2-chlorobuta-1,3-diene[16,17], 2,3-dimethylbuta-1,3-diene[15,16-20], 2,4-dimethylpenta-1,3-diene[21], 2,5-dimethylhexa-2,4-diene[22,23], 2,6-dimethylocta-2,4,6-triene[24-28], cyclopentadiene[15,29], cyclohexa-1,3-diene[15,29,30], *p*-mentha-1,3-diene[31], 1,1′-bicyclohexenyl[32], and methyl octadeca-9,11-dienoate[33].

Study of the structure of copolymers of 1,3-dienes with oxygen has shown that oxygen can add on to dienes in both the 1,2 and the 1,4 positions:

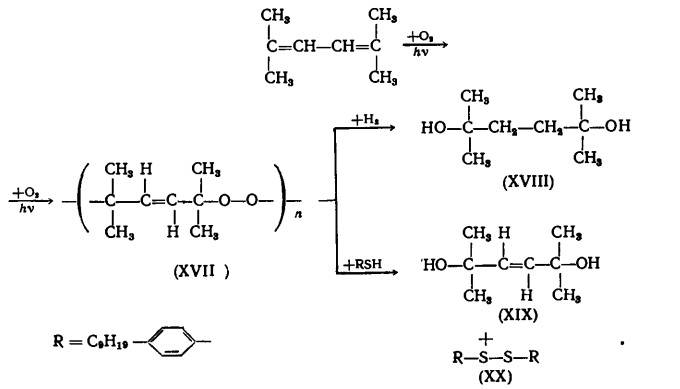
Bodendorf[4] and Kern[15,18] found that thermal decomposition of the polyperoxide of 2,3-dimethylbuta-1,3-diene yields formaldehyde and 3-methylbut-3-en-2-one:



Later Kawahara[20] isolated formaldehyde, the above methylbutenone, αβ-dimethylenebutyraldehyde, and butane-2,3-dione from the decomposition products of this copolymer. Formation of the last two compounds from the copolymer is perhaps explained by the presence in it of 1,4 links as well as the 1,2 links.

Handy and Rothrock[14] established that both 1,2 and 1,4 addition of oxygen takes place in its copolymerisation with buta-1,3-diene, the latter predominating. Catalytic reduction of the polymeric peroxide — (XII*a*) and (XII*b*) — gave

† Other experimental results have been published[10-12] indicating the possible presence of (V) and (VI) in the product of the thermal isomerisation of ascaridole.



butane-1,2-diol (XIII) and a larger quantity of butane-1,4--diol (XIV), while its reduction with lithium tetrahydroaluminate yielded but-3-ene-1,2-diol (XV) and *trans*-but--2-ene-1,4-diol (XVI).

(XII*a*) (XII*b*) (XIII) (XIV) (XV) (XVI)

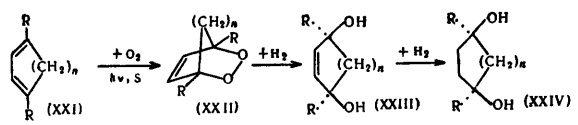
Analysis of the infrared spectrum of the copolymer (XII*a*) and (XII*b*) confirmed the chemical evidence of its structure.

Griesbaum et al.[23] have shown that the autoxidation of 2,5-dimethylhexa-2,4-diene is rigorously selective with the formation of a *trans*-1,4-polyperoxide (XVII). The structure and the configuration of this copolymer were proved by an analysis of the nuclear magnetic resonance and infrared spectra. The proton resonance spectrum revealed signals only from vinyl and methyl protons at relative intensities of 1 : 6. Hence it followed that the polyperoxide had the 1,4 structure. Analysis of the infrared spectrum showed that the double bond in the polyperoxide had the *trans* configuration. The *trans*-1,4 structure of the copolymer was confirmed also by a chemical method. Catalytic hydrogenation of the polyperoxide (XVII) produced 2,5-dimethylhexane-2,5-diol (XVIII), whereas reduction of the polyperoxide with *p*-nonylbenzenethiol gave *trans*-2,5-dimethylhex-3-ene-2,5-diol (XIX) and di-*p*--nonylphenyl disulphide (XX)‡:

(XVII) (XVIII) (XIX) (XX)

## 3. Synthesis of Ascaridole

Schenck and Ziegler[5,34-36] suggested that ascaridole is formed in plants by the diene condensation of *p*-mentha--1,3-diene with molecular oxygen under the photosensitising influence of chlorophyll. This hypothesis was verified by shaking a dilute alcoholic solution of *p*-mentha-1,3-diene in the presence of Eosin in an atmosphere of oxygen while exposed to a 300 W lamp. After completion of the photooxidation the solution was reduced in the presence of a palladium catalyst. *p*-Menthane-*cis*-1,4-diol (III) was isolated from the products. In a parallel experiment Schenck distilled off the solvent, and was able to obtain from the residue a preparation melting at 2.5°, a mixture of which with natural ascaridole showed no melting-point depression.



In further experiments Schenck carried out the photochemical diene synthesis of ascaridole in ethanol, propan-2-ol, acetone, and toluene in the presence of various photosensitisers (chlorophyll, Eosin, Erythrosin, Methylene Blue, Fluorescein, Pinacyanol, etc.). The photooxidation of *p*-mentha-1,3-diene in isopropyl alcohol in the presence of Methylene Blue gave a 25% yield of ascaridole. Pure synthetic ascaridole had m.p. 4.2°.

The catalytic hydrogenation of synthetic ascaridole over Raney nickel produced a 96% yield of *p*-menthane--*cis*-1,4-diol (III), whereas the reduction of ascaridole with a potassium–sodium alloy in ether gave a 57% yield of *p*-menth-2-ene-1,4-diol (II).

## 4. Epidioxides of Cyclopentadiene, Cyclohexa-1,3-diene, Cycloheptа-1,3-diene, and Their Derivatives

The photosensitised oxidation of cycloalka-1,3-dienes having five-, six-, and seven-membered rings and their derivatives has been studied by Schenck and other workers.

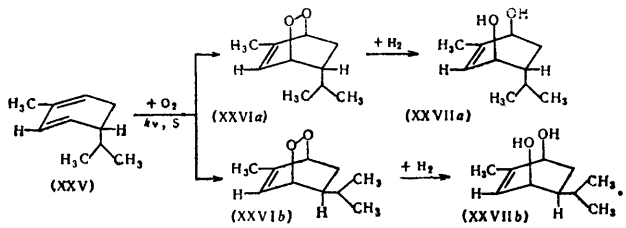
In 1952 Schenck[35,37,38] obtained a very unstable epidioxide of cyclopentadiene (XXII*a*) (5,6-dioxabicyclo[2,2,1]hept-2--ene) by the photosensitised oxidation of cyclopentadiene (XXI*a*) at -80°. On warming to 0° cyclopentadiene epidioxide decomposes explosively. Catalytic reduction of the epidioxide (XXII*a*) yielded cyclopentane-*cis*-1,3-diol (XXIV*a*), whereas reduction with thiourea at -20° gave cyclopent-4--ene-*cis*-1,3-diol (XXIII*a*).

(XXI) (XXII) (XXIII) (XXIV)

where S is the sensitiser; and for XXI–XXIV:

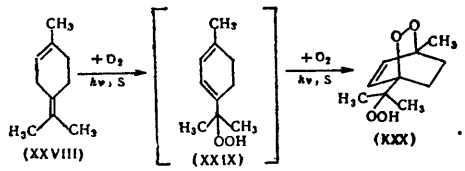
(*a*) $n = 1$; R = H,
(*b*) $n = 1$; R = $C_6H_5$,
(*c*) $n = 2$; R = H,
(*d*) $n = 3$; R = H,
(*e*) $n = 3$; R = $C_6H_5$.

Schenck[39,40] obtained the epidioxide (XXII*b*) by the photosensitised oxidation of 1,4-diphenylcyclopentadiene (XXI*b*), and reduced the product catalytically to the *cis*-1,3-diol (XXIII*b*). It was found that 1,4-diphenylcyclopentadiene (XXI*b*) can act as a photosensitiser both for its reaction with oxygen and for other diene syntheses of transannular epidioxides (e.g. the synthesis of ascaridole from *p*-mentha--1,3-diene). On heating, the epidioxide (XXII*b*) of 1,4-diphenylcyclopentadiene breaks down into oxygen and the original hydrocarbon (XXI*b*).



‡ See also Ref. 211 for the structure of the polymeric peroxide of 2,5-dimethylhexa-2,4-diene.

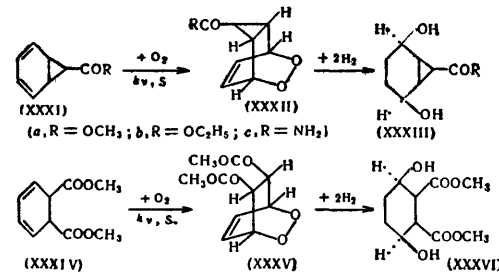
The photosensitised oxidation of cyclopentadienyltriphenyltin at -20° also gave an epidioxide, reduction of which at -20° with thiourea, with sodium tetrahydroborate, or catalytically resulted in an unsaturated *cis*-1,3-diol.[41]



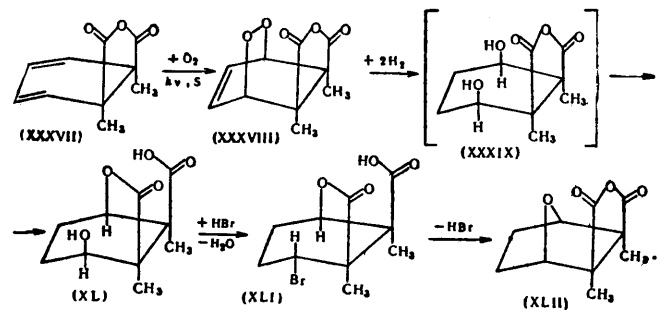
Schenck also found[5,35,37,38,42] that the photosensitised oxidation of cyclohexa-1,3-diene (XXI*c*) forms a crystalline epidioxide of cyclohexa-1,3-diene (XXII*c*) (5,6-dioxabicyclo[2,2,2]oct-2-ene)§.

In 1957 Cope[43] showed that the photosensitised oxidation of cyclohepta-1,3-diene (XXI*d*) involves formation of the crystalline epidioxide (XXII*d*), catalytic reduction of which produced the *cis*-1,4-diol (XXIV*d*). Later Courtot[44,45] established that a crystalline transannular epidioxide (XXII*e*) is formed by the photosensitised oxidation of 1,4-diphenylcyclohepta-1,3-diene (XXI*e*). The product was reduced catalytically to the *cis*-1,4-diol (XXIV*e*).

By the photosensitised oxidation of *p*-mentha-1,5-diene (XXV) Schenck[5,35,38,42] obtained two crystalline stereoisomeric epidioxides (XXVI*a*) and (XXVI*b*), which were reduced to the stereoisomeric unsaturated *cis*-1,4-diols (XXVII*a*) and (XXVII*b*):

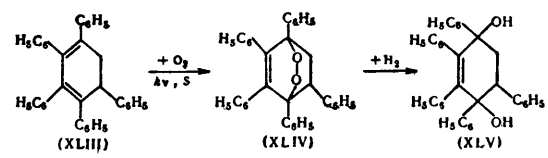


Schenck[38] also showed that the photosensitised oxidation of *p*-mentha-1,4(8)-diene (XXVIII) initially involves migration of the double bond with formation of *p*-mentha-1,3-diene 8-hydroperoxide (XXIX), when then condenses with a second molecule of oxygen by a mechanism of diene synthesis to form the extremely unstable ascaridole 8-hydroperoxide (XXX):

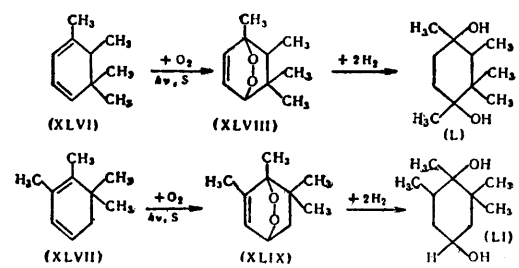


Schenck[35,38,46] studied the photosensitised oxidation of methyl and ethyl norcaradienecarboxylates (XXXI*a*) and (XXXI*b*) and dimethyl 1,2-dihydrophthalate (XXXIV). Oxidation of the first two esters gave the epidioxides (XXXII*a*) and (XXXII*b*), which on catalytic reduction were converted into the saturated 1,4-diols (XXXIII*a*) and (XXXIII*b*). These epidioxides were transformed into the amide (XXXII*c*) by the action of ammonia, the same amide being obtained by the photooxidation of norcaradienecarboxyamide (XXXI*c*).

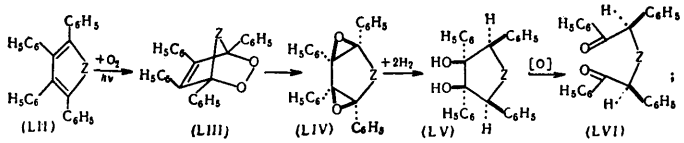
§ In 1951 Hock established[29,30] that a very small yield of the epidioxide of cyclohexa-1,3-diene (XXII*c*) is formed by the autoxidation of cyclohexa-1,3-diene.



Photooxidation of the ester (XXXIV) enables Schenck to obtain the epidioxide (XXXV), catalytic reduction of which resulted in the saturated 1,4-diol (XXXVI):

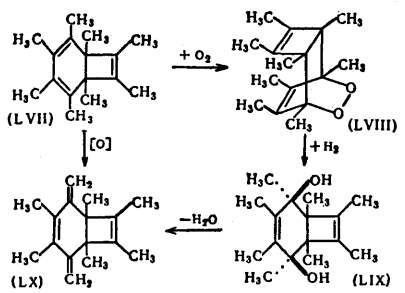


In 1953 Schenck[38,47] accomplished the stereospecific synthesis of cantharidin. The photochemical diene condensation of synthetic dehydrocantharidin (XXXVII) with oxygen gave dehydrocantharidin epidioxide (XXXVIII), in which the peroxide bridge occupies the same spatial position as the ether bridge in natural cantharidin. Catalytic hydrogenation of the epidioxide (XXXVIII) formed the diol (XXXIX), which under the experimental conditions underwent lactonisation to hydrohydroxycantharic acid (XL). The action of hydrogen bromide on the product yielded hydrobromocantharic acid (XLI), thermal decomposition of which gave cantharidin (XLII):

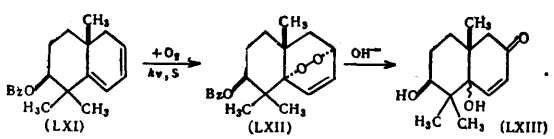


Bergmann[48] studied the photosensitised oxidation of 1,2,3,4,5-pentaphenylcyclohexadiene (XLIII), obtaining the epidioxide (XLIV), catalytic reduction of which gave the unsaturated 1,4-diol (XLV):

Schenck[35,42] investigated the photosensitised oxidation of 1,5,5,6- and 1,2,6,6-tetramethylcyclohexa-1,3-diene (XLVI) and (XLVII). He obtained the corresponding transannular epidioxides (XLVIII) and (XLIX), catalytic hydrogenation of which gave the saturated 1,4-diols (L) and (LI):



Dufraisse[49] showed that the photochemical oxidation of 2,3,4,5-tetraphenylcyclopentadiene (LII*a*) forms the epidioxide (LIII*a*), which on heating isomerises into the diepoxide (LIV*a*). The structure of the latter was proved by its reduction to the *cis*-1,2-diol (LV*a*), oxidation of which with iodic acid or lead tetraacetate gave 1,2,4,5-tetraphenylpentane-1,5-dione (LVI*a*).

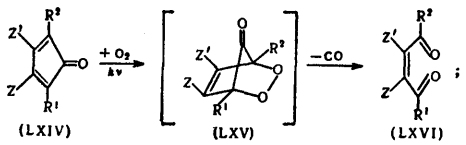


(*a*) Z = >$CH_2$; (*b*) Z = >C = $CH_2$.

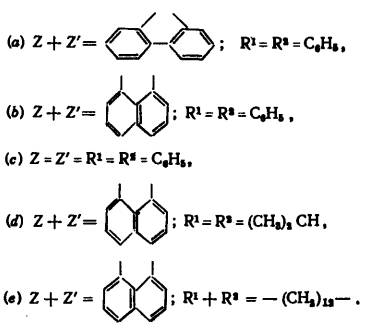
Dufraisse[50] also found that the photooxidation of 2,3,4,5-tetraphenylfulvene (LII*b*) gave the epidioxide (LIII*b*), which under the experimental conditions isomerised into the diepoxide (LIV*b*). The latter was reduced with lithium tetrahydroaluminate to the *cis*-1,2-diol (LV*b*), which was oxidised with lead tetraacetate to 3-methylene-1,2,4,5-tetraphenylpentane-1,5-dione (LVI*b*).

In 1962 Criegee[51,52] reported that the 1,2,3,4,5,6,7,8-octamethylbicyclo[4,2,0]octa-2,4,7-triene (LVII) which he had synthesised was oxidised so readily that it could be prepared only when oxygen was completely excluded. In air this hydrocarbon oxidises quantitatively to a crystalline peroxide after a few hours. Examination of the infrared, ultraviolet, and nuclear magnetic resonance spectra of the product showed it to be a transannular epidioxide (LVIII). When a methanolic solution of the hydrocarbon (LVII) was shaken with oxygen for 20 min, exactly one molecule of oxygen was absorbed, the peroxide being formed at the same rate in the light and in the dark. This represents the first case of the formation of an epidioxide in a dark reaction. Nor did addition of inhibitors affect the rate of oxidation of the hydrocarbon (LVII)¶. The epidioxide (LVIII) was reduced to the diol (LIX), dehydration of which yielded the hydrocarbon (LX). The same hydrocarbon was obtained by the oxidation of (LVII) with silver nitrate, chloranil, or benzoquinone. Criegee found that the octamethylbicyclooctatriene (LVII) forms diene adducts with tetracyanoethylene and azoformic ester, but does not react with maleic anhydride or acetylenedicarboxylic ester even at 140°.

Halsall[53,54] established that exposure of a dilute alcoholic solution of 1,2,3,4,5,10-hexahydro-1,1,10β-trimethyl-2β-naphthyl benzoate (LXI) to the light from a 500 W lamp in the presence of Eosin and oxygen results in the formation of the 6α,9α-epidioxide (LXII), which in alkaline medium is converted into an αβ-unsaturated ketone (LXIII). The oxygen bridge in the epidioxide (LXII) must be assumed to have the α configuration, since the 1- and 10-methyl groups prevent attack on the diene (LXI) from the β side.



## 5. Photooxidation of Arylated Cyclopentadienones (Cyclones) and Arylated Cyclopentadienols

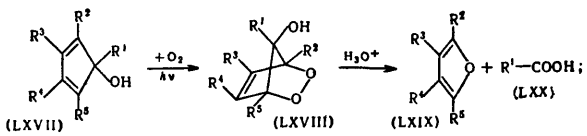


In 1938 Dilthey[55] discovered that, when solutions of phencyclone (LXIV*a*) in pyridine or toluene are exposed to sunlight in the presence of air, 9,10-dibenzoylphenanthrene (LXVI*a*) is formed. In the photochemical oxidation of acecyclone (LXIV*b*) in chlorobenzene medium in air, 1,2-dibenzoylacenaphthylene (LXVI*b*) is obtained[55].

Schenck[56], Dufraisse[57,58], Becker[59], and Wilcox[60] have established the formation of 1,2,3,4,-tetraphenylbut-*cis*-2-ene-1,4-dione (LXVI*c*) and carbon monoxide in the photooxidation of tetracyclone (LXIV*c*).

In 1953 Allen[61] reported that photooxidation of the cyclones (LXIV*d*) and (LXIV*e*) yields the 1,4-diketones (LXVI*d*) and (LXVI*e*).

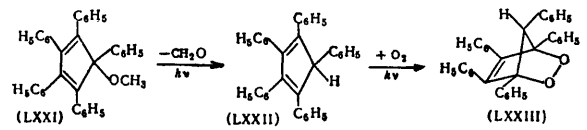
It must be assumed that the photooxidation of cyclones (LXIV*a–e*) involves the initial formation of unstable diene adducts having an *endo*-carbonyl bridge (LXV*a–e*), which under the experimental conditions break down into carbon monoxide and 1,4-dicarbonyl compounds (LXVI*a–e*)†.



Dufraisse[57,58] and Rio[63] established that in the photooxidation of pentaarylcyclopentadienols (LXVII*a–f*) the corresponding photoperoxides (LXVIII*a–f*) are formed, and these on being heated with acetic acid undergo fission

¶ 1,2,3,4,5,6-Hexamethylcyclohexa-1,3-diene, which was synthesised for comparison, did not oxidise in the dark.

† The mechanism of the photooxidation of cyclones has been discussed by Syrkin and Moiseev[62].

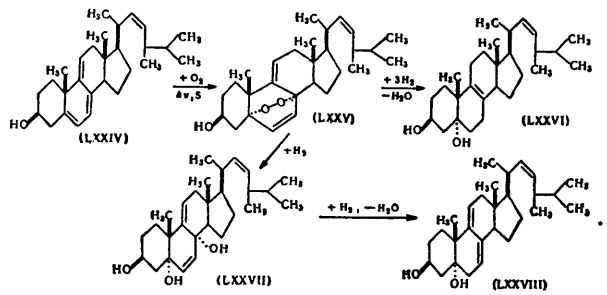


with the formation of tetraarylfurahs (LXIX*a–f*) and aromatic acids (LXX*a–f*):

(LXVII) (LXVIII) (LXIX) (LXX)

(*a*) $R^1 = R^2 = R^3 = R^4 = R^5 = C_6H_5$,
(*b*) $R^2 = R^3 = R^4 = R^5 = C_6H_5$; $R^1 = p\text{-}(CH_3)_2NC_6H_4$,
(*c*) $R^1 = R^2 = R^4 = R^5 = C_6H_5$; $R^3 = p\text{-}(CH_3)_2NC_6H_4$,
(*d*) $R^2 = R^3 = R^4 = R^5 = C_6H_5$; $R^1 = p\text{-}CH_3C_6H_4$,
(*e*) $R^1 = R^3 = R^4 = R^5 = C_6H_5$; $R^2 = p\text{-}CH_3C_6H_4$,
(*f*) $R^1 = R^2 = R^4 = R^5 = C_6H_5$; $R^3 = p\text{-}CH_3C_6H_4$.

The photooxidation of 1-methoxypentaphenylcyclopentadiene (LXXI) at first involves photolysis with production of formaldehyde and pentaphenylcyclopentadiene (LXXII), which undergoes photooxidation to form an epidioxide (LXXIII):[57]

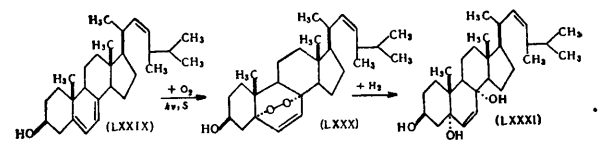


(LXXI) (LXXII) (LXXIII)

## 6. Steroid Epidioxides

In 1928 Windaus[64], while studying the conversion of ergosterol [24-methylcholesta-5,7,22-trien-3β-ol] into vitamin $D_2$ [ergocalciferol], found that irradiation of dilute alcoholic solutions of the former with a 200 W lamp in the presence of a photosensitiser (Eosin, Erythrosin) and air led to the addition of a molecule of oxygen to a molecule of ergosterol, the product possessing the properties of a peroxide and being termed ergosterol peroxide. The photosensitised oxidation of 24-methylcholesta-5,7,9(11),22--tetraen-3β-ol under the same conditions[65–67], produced "9(11)-dehydroergosterol peroxide".

It was subsequently found that other homoannular steroid 1,3-dienes are readily converted into peroxides. Peroxides were prepared from 24-methylcholesta-5,7-dien-3β-ol[68], 3β-acetoxy-24-methylcholesta-6,8(14),9(11),22-tetraene,[69–72] 3-acetoxy-2-methylcholesta-3,5,7,22-tetraene[73], 3-acetoxy-24-methylcholesta-3,5,7,9(11),22-pentaene[73], 3-acetoxy-5α-pregna-6,8(14),9(11)-trien-20-one[71,72], 3β,21-diacetoxy-5α-pregna-6,8(14),9(11)-trien-20-one[71], lumisteryl acetate [3-acetoxy-24-methyl-10α-cholesta--5,7,22-triene][74], [3-acetoxy-24-methyl-10α-cholesta--5,7,9(11),22-tetraene[74], cholesta-5,7-dien-3β-ol[75,77], 3β-acetoxycholesta-5,7-diene[76], cholesta-5,7,24-trien--3β-ol[77], cholesta-2,4-diene[78–80], cholesta-1,3,5-trien--7-one[81], and androsta-5,7-diene-3,17-diol[82].

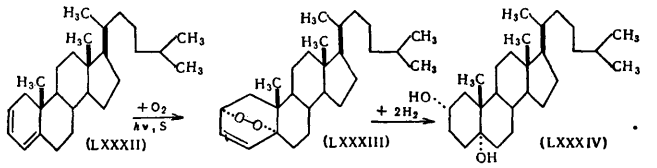


Examination of the ultraviolet spectrum of the peroxide obtained from 24-methylcholesta-5,7,9(11),22-tetraen-3β--ol (LXXIV) showed that it did not contain a conjugated system of double bonds, and on catalytic reduction formed a 24-methylcholestadienediol, for which the structure (LXXVI) was established[67]. From these results it was concluded that the dehydroergosterol peroxide had the structure (LXXV)[67]. The formation of the diol (LXXVI) on catalytic hydrogenation of the transannular epidioxide (LXXV) is explained by initial formation of the 3,5,8-triol, which is dehydrated with formation of a double bond between $C_{(8)}$ and $C_{(9)}$.

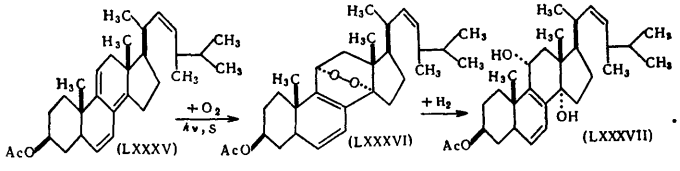
(LXXIV) (LXXV) (LXXVI) (LXXVII) (LXXVIII)

When the epidioxide (LXXV) was reduced with zinc and alcoholic alkali, a trienediol was obtained[67,83], whose ultraviolet spectrum showed it to contain two conjugated cyclic double bonds. The trienediol gave no diene adduct with maleic anhydride, so that its conjugated double bonds were present in different rings. On the basis of these results the structure (LXXVIII) was assigned to the trienediol. Its formation probably involved reduction of the epidioxide (LXXV) to the trienetriol (LXXVII) followed by elimination of the 8-hydroxyl and migration of a cyclic double bond to a conjugated position.

In 1950 Fieser[84,85] adduced weighty arguments in support of the α configuration for the oxygen bridge in steroid epidioxides. During 1952–1954 Bladon et al.[86–89] established the α configuration for the oxygen bridge in 24-methylcholesta-5,7,9(11),22-tetraen-3-ol epidioxide (LXXV), and described a method for preparing cortisone from it.

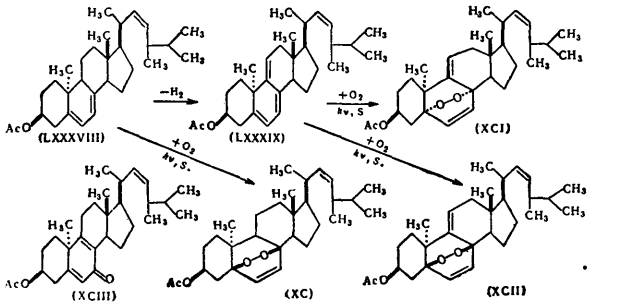


(LXXIX) (LXXX) (LXXXI)

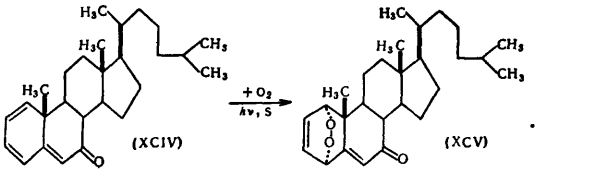


By the photosensitised oxidation of ergosterol (LXXIX) Windaus[64–66] obtained its peroxide, which was reduced with zinc and alcoholic alkali to a dienetriol. Study of the chemical reactions of the latter led Achtermann[90], Müller[67], and Heilbron[91] to conclude that the epidioxide bridge had been attached to $C_{(5)}$ and $C_{(6)}$. However, in 1936 Fieser[92] cited convincing evidence (see also Ref. 85, p. 96) indicating that the reduction product was a 3,5,8-triol (LXXXI), which could be formed only from a transannular epidioxide (LXXX). In 1939 Bergmann[93] agreed with Fieser's view, that the epidioxide of ergosterol had the structure (LXXX). Fieser[84] in 1950 and Henbest and Jones[94] in 1953 showed that the oxygen bridge in the epidioxide had the α configuration.

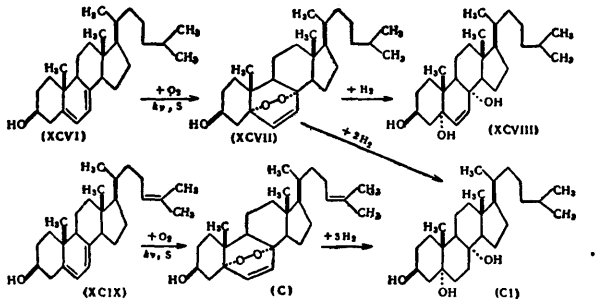
In 1947 Wieland and Prelog[95] isolated the epidioxide (LXXX) from the mycelia of the mould *Aspergillus fumigatus*, and in 1964 Bauslaugh et al.[96] isolated it from the mycelia of *Trichophyton schönleini*. The epidioxide (LXXX) was identified by the method of mixed melting points with a synthetic specimen[95,96]. The identity of the two samples was confirmed by examination of the infrared, nuclear magnetic resonance, and mass spectra[96].



By catalytic reduction of the epidioxide of cholesta-2,4--diene Bergmann[79,80,93] obtained a saturated diol, for which he established the structure (LXXXIV). Hence the product of the photosensitised oxidation of cholesta-2,4--diene (LXXXII) was the epidioxide (LXXXIII). In 1953 he showed[97] that the oxygen bridge in the epidioxide (LXXXIII) had an $\alpha$ configuration.



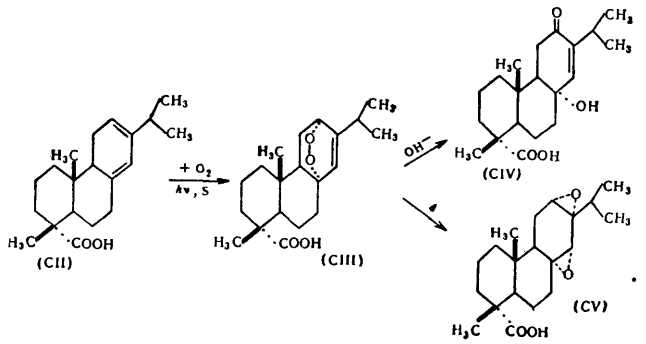
During 1953–1956 Laubach[69,70] established that the photosensitised oxidation of 3$\beta$-acetoxy-24-methylcholesta--6,8(14),9(11),22-tetraene (LXXXV) gives the 11$\alpha$,14$\alpha$-epidioxide (LXXXVI), hydrogenation of which in the presence of Lindlar's catalyst yielded 3$\beta$-acetoxy-24-methylcholesta-6,8,22-triene-11$\alpha$,14$\alpha$-diol (LXXXVII). He developed[98,70] a method for preparing from the epidioxide (LXXXVI) the compound 3-acetoxy-24-methylcholesta--8,22-dien-11-one, from which cortisone can be obtained.



In 1955 Bladon[74] found that the photosensitised oxidation of 3$\beta$-acetoxy-24-methyl-10$\alpha$-cholesta-5,7-22-triene (LXXXVIII) yields 3$\beta$-acetoxy-24-methyl-10$\alpha$-cholesta--5,7,9(11),22-tetraene (LXXXIX), the $\beta$-epidioxide (XC) of (LXXXVIII), the $\alpha$-epidioxide (XCI) of (LXXXIX), the $\beta$-epidioxide (XCII) of (LXXXIX), and 3$\beta$-acetoxy-24--methyl-10$\alpha$-cholesta-5,8,22-trien-7-one (XCIII). Photooxidation of (LXXXIX) gave the $\alpha$-epidioxide (XCI) and the $\beta$-epidioxide (XCII).

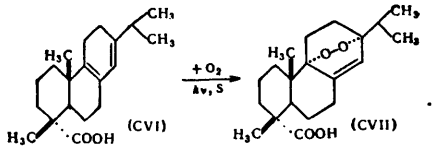
In 1956 Henbest[81] reported that the photosensitised oxidation of cholesta-1,3,5-trien-7-one (XCIV) produces the $\alpha$-epidioxide (XCV):

In 1936 Schenck[75] found that the photosensitised oxidation of cholesta-5,7-dien-3$\beta$-ol (XCVI) involves formation of its epidioxide. Reduction of the latter with zinc and alcoholic alkali gave a cholestenetriol. From the results of a study of the structure and chemical reactions of epidioxides of other steroids, the compound formed from (XCVI) was to be regarded as the 5$\alpha$,8$\alpha$-epidioxide (XCVII), and its reduction product as having the structure cholest-6--ene-3$\beta$,5$\alpha$,8$\alpha$-triol (XCVIII). During 1963–1964 Dvornik and Kraml[77,99] prepared epidioxides from cholesta-5,7--dien-3$\beta$-ol (XCVI) and from cholesta-5,7,24-trien-3$\beta$-ol (XCIX), and reduced them catalytically.



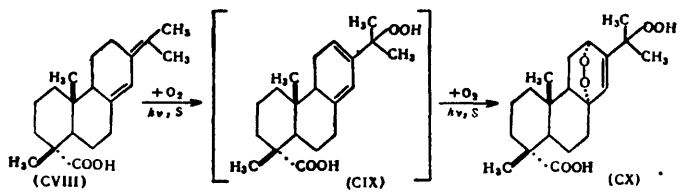
Dvornik and Kraml studied the mechanism of the conversion of lanosterol [4,4,14-trimethylcholesta-8,24-dien-3$\beta$-ol] into cholesterol [cholest-5-en-3$\beta$-ol] during the biochemical synthesis of the latter in cholesterologenic tissues. The method used in this investigation was to inhibit enzymes responsible for individual stages in the biosynthesis of cholesterol. These workers were able to detect in rat blood serum a steroid, examination of whose ultraviolet spectrum showed it to be a homoannular conjugated diene. They isolated from rat's liver a steroid which they identified as a transannular epidioxide (XCVII) of cholesta-5,7--dien-3$\beta$-ol (XCVI). Pig's liver was found to contain a steroid having an ultraviolet spectrum typical of homoannular conjugated diene steroids. The compound was identified by conversion into a transannular epidioxide, which was isolated in an analytically pure form and identified as 5$\alpha$,8$\alpha$-epidioxycholesta-6,24-dien-3$\beta$-ol (C). The structure of the latter was established by catalytic reduction with platinum oxide to cholestane-3$\beta$,5$\alpha$,8$\alpha$-triol (CI), which proved to be identical with a known specimen of this triol, prepared by the photosensitised transannular addition of oxygen to cholesta-5,7-dien-3$\beta$-ol (XCVI) followed by catalytic reduction of the resulting epidioxide (XCVII) to the triol (CI). Examination of the nuclear magnetic resonance spectrum of the epidioxide (C) supported the chemical evidence of its structure.

Dvornik and Kraml's investigation has shown that cholesta-5,7-dien-3$\beta$-ol (XCVI) is an intermediate in the biosynthesis of cholesterol, and that cholesta-5,7,24--trien-3$\beta$-ol (XCIX) is probably a precursor of (XCVI) in this process.



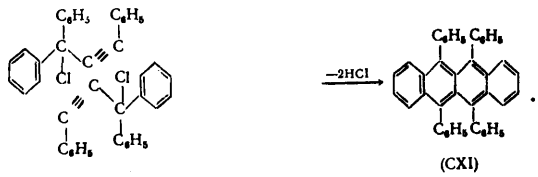
In 1964 Blondin et al.[100] reported that [4-$^{14}$C]cholesta--5,7-dien-3$\beta$-ol is converted into radioactive cholecalciferol in a homogenate of bass liver incubated in the dark. They suggested that 5$\alpha$,8$\alpha$-epidioxycholest-6-en-3$\beta$-ol (XCVII) may be an intermediate in this non-photochemical reaction. An experiment undertaken to verify this hypothesis showed that cholesta-5,7-dien-3$\beta$-ol (XCVI) is converted into the 5$\alpha$, 8$\alpha$-epidioxide (XCVII) in a homogenate of fish liver incubated in the dark.

### 7. Epidioxides of Resin Acids

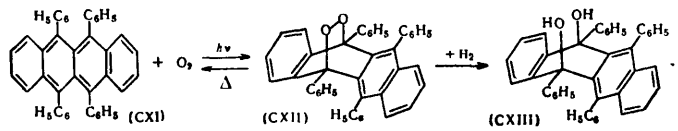


In 1958 Moore and Lawrence[101-104] discovered that the photosensitised oxidation of laevopimaric acid (CII) involves the formation of a crystalline transannular epidioxide — 6α,14α-epidioxy-Δ⁷-dodecahydro-7-isopropyl--1β,12β-dimethylphenanthrene-1α-carboxylic acid (CIII)‡ — which in alkaline medium is converted into Δ⁷-dodecahydro-14α-hydroxy-7-isopropyl-1β,12β-dimethyl-6-oxophenanthrene-1α-carboxylic acid (CIV). When a xylene solution of the epidioxide is boiled, the latter rearranges into 6,7α : 8,14α-diepoxytetradecahydro-7-isopropyl-1β,12β--dimethylphenanthrene -1α-carboxylic acid (CV):[104]

In 1960 Schuller, Moore, and Lawrence[103,104,107] reported that the photosensitised oxidation of palustric acid (CVI) gives a crystalline epidioxide — 7α,13α-epidioxy-Δ⁸-dodecahydro-7-isopropyl-1β,12β-dimethylphenanthrene-1α-carboxylic acid (CVII):

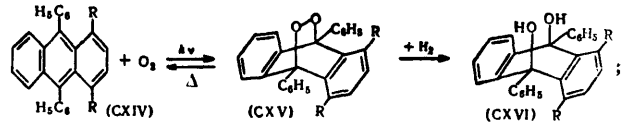


Schuller and Lawrence[104-106] also established that the photosensitised oxidation of neoabietic acid (CVIII) first involves a monoene addition and migration of a double bond to form the 18-hydroperoxy-derivative (CIX) of laevopimaric acid, which reacts further with a second molecule of oxygen by a diene addition mechanism to form a diperoxide — 6α,14α-epidioxy-Δ⁷-dodecahydro-7-(2--hydroperoxyprop-2-yl)-1β,12β-dimethylphenanthrene-1α--carboxylic acid (CX):



‡ Lawrence[106] attributes an α configuration to the oxygen bridge in the epidioxides of resin acids, since the β-methyl groups prevent attack from the β region on the 1,3-diene system of the resin acids, as in the case of steroids.

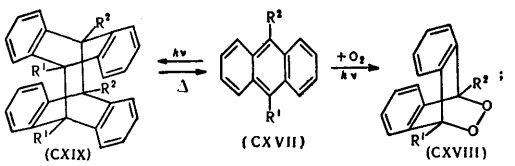
## III. REACTION OF MOLECULAR OXYGEN WITH AROMATIC DIENES



In 1926 Moureu and Dufraisse[108] observed that, when 3-chloro-1,3,3-triphenylprop-1-yne is heated in a vacuum to 100–120°, hydrogen chloride is evolved, and a red hydrocarbon having the composition $C_{42}H_{28}$ is formed. The name of this hydrocarbon is rubrene. These workers established[108] that dilute solutions of rubrene in benzene, carbon disulphide, chloroform, and other solvents rapidly lose their colour on exposure to sunlight or artificial light in the presence of air. A compound possessing the properties of a peroxide and having the composition $C_{42}H_{28}O_2$ was isolated from the decolorised solutions. When rubrene peroxide was heated in a vacuum to 140–150°, it broke down into the original hydrocarbon and oxygen. This decomposition was accompanied by luminescence. It was established[109,110] in 1936 that rubrene was 5,6,11,12-tetraphenylnaphthacene (CXI)§.

In 1937 Dufraisse[112] observed that catalytic reduction of rubrene peroxide gave the 5,12-diol (CXIII), which had been obtained previously by the action of phenyllithium on 6,11-diphenylnaphthacene-5,12-quinone[110] and by the action of potassium permanganate on rubrene[113]. Since rubrene peroxide gave the 5,12-diol (CXIII) on reduction, it must have been a transannular epidioxide (CXII):

By irradiating solutions of 9,10-diphenylanthracene (CXIV*a*) in the presence of air, Dufraisse[114,115] obtained a peroxide of this compound, reduction of which gave the 9,10-diol (CXVI*a*). Consequently the peroxide of 9,10-diphenylanthracene had the transannular structure (CXV*a*). When heated in a vacuum to 180°, the epidioxide of 9,10-diphenylanthracene (CXV*a*) decomposes into oxygen and the original hydrocarbon (CXIV*a*).



(*a*) R = H; (*b*) R = $OCH_3$.

By the photooxidation of 1,4-dimethoxy-9,10-diphenylanthracene (CXIV*b*) Dufraisse[116,117] obtained the transannular epidioxide (CXV*b*), which slowly dissociated into the original components even at room temperature.

§ For the mechanism of the formation of rubrene from 3-chloro--1,3,3-triphenylprop-1-yne, see Ref.111.

It was also found[118-121] that irradiation in the presence of air of dilute carbon-disulphide solutions of anthracene (CXVII*a*), 9-methylanthracene (CXVII*b*), 9-ethylanthracene (CXVII*c*), 9,10-dimethylanthracene (CXVII*d*), and 9-ethyl-10-methylanthracene (CXVII*e*) yields the transannular epidioxides (CXVIII*a–e*), which when heated in a vacuum decompose violently without the evolution of free oxygen:

(CXIX) (CXVII) (CXVIII)

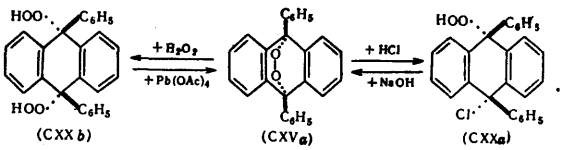
(*a*) $R^1 = R^2 = H$,
(*b*) $R^1 = H$; $R^2 = CH_3$,
(*c*) $R^1 = H$; $R^2 = C_2H_5$,
(*d*) $R^1 = R^2 = CH_3$,
(*e*) $R^1 = CH_3$; $R^2 = C_2H_5$.

When solutions of anthracene (CXVII*a*), 9-methylanthracene (CXVII*b*), and 9,10-dimethylanthracene (CXVII*d*) in benzene, xylene, glacial acetic acid, and other solvents are exposed at room temperature in the absence of air, photodimers (CXIX*a*), (CXIX*b*), and (CXIX*d*) are formed. This reaction is reversible: the anthracenes are regenerated when the temperature is raised in the dark. Other anthracene derivatives also form photodimers. However, neither 9,10-diphenylanthracene (CXIV*a*) nor rubrene (CXI) undergoes photochemical dimerisation. This may be due to steric hindrance, or else to thermal instability of the photodimers under the experimental conditions[122].

Dufraisse, Clar, Étienne, and other investigators have established that transannular epidioxides are formed by various linear and angular fusion products of anthracene with benzene rings, several of their derivatives, and nitrogen analogues[123-126]. All attempts to prepare photoperoxides of naphthalene, phenanthrene, or acridine were unsuccessful[127,128].

Hence it follows that transannular photoepidioxides are formed only from polycyclic aromatic compounds which contain an anthracene ring system (acenes). These compounds contain a reactive aromatic diene system (an *o*-quinoid grouping), and are capable of undergoing diene synthesis with maleic anhydride, *p*-benzoquinone, azoformic ester, and other dienophiles. The photooxidation of acenes can therefore be regarded as a photochemical diene synthesis with molecular oxygen.

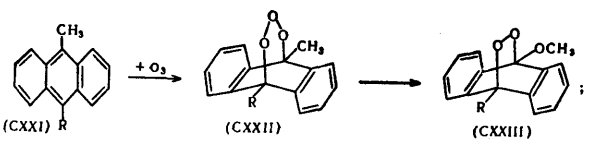
Anthracene, 9,10-diphenylanthracene, rubrene, and other acenes act as sensitisers, and therefore do not require the addition of other photosensitisers for their photooxidation. Acenes can be used also as photosensitisers in the oxidation of other organic compounds. In the presence of rubrene, for examples, *p*-mentha-1,3--diene is oxidised to ascaridole[39,40].



The rate of formation of acene epidioxides is greatly dependent on the nature of the solvent. Thus Dufraisse[129] found the relative rates of photooxidation of rubrene in various solvents to be as indicated in the accompanying Table.

Study of the chemical reactions of the photoperoxides of acenes has given interesting results. For example, Pinazzi[130] established that 9,10-diphenylanthracene photoepidioxide (CXV*a*) reacts with hydrogen chloride to form

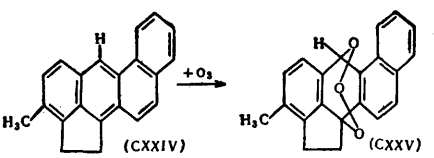
TABLE.



| Solvent | Relative rate of photo-oxidation of rubrene (benzene = 1) |
|---|---|
| Carbon disulphide | 9 |
| Chloroform | 3 |
| Ethyl iodide | 1 |
| Benzene | 1 |
| Acetone | 1 |
| Ether | 0.5 |
| Anisole | 0.4 |
| Pyridine | 0.25 |
| Nitrobenzene | 0.10 |

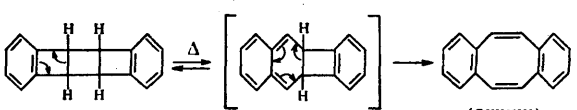
a chloro-hydroperoxide (CXX*a*), which yields the original peroxide (CXV*a*) on treatment with alkali. He also observed[131] that the epidioxide (CXV*a*) reacts with hydrogen peroxide to form a dihydroperoxide (CXX*b*). Criegee[132] obtained the original 9,10-diphenylanthracene epidioxide (CXV*a*) from the latter by treatment with lead tetraacetate.

(CXX*b*) (CXV*a*) (CXX*a*)



It has recently been found[133,134] that 9,10-dimethylanthracene (CXXI*a*) and 9-methoxy-10-methylanthracene (CXXI*b*) in dichloromethane react at -78° with ozone to form monoozonides. The nuclear magnetic resonance spectra of the latter show them to be transannular-9,10-adducts (CXXII*a*) and (CXXII*b*). In solution these adducts are rapidly converted even at room temperature into the transannular 9,10-epidioxides (CXXIII*a*) and (CXXIII*b*).

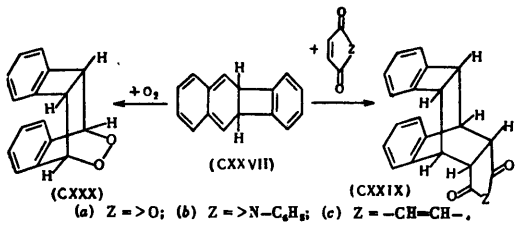
(CXXI) (CXXII) (CXXIII)



(*a*) R = $CH_3$; (*b*) R = $OCH_3$.

The ozonisation of 3-methylcholanthrene (CXXIV) in dichloromethane at -78° gave a mixture of peroxides, which probably contained the transannular 6,12b-ozonide (CXXV).[135]

(CXXIV) (CXXV)

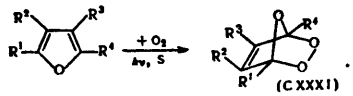


Nenitzescu has shown[136-138] that the linear dimer (CXXVI) of benzocyclobutadiene rearranges on heating to form 1,2 : 5,6-dibenzocyclooctatetraene (CXXVIII). He[137,138] as well as Cava[139] put forward the hypothesis that this change involves two consecutive reactions — (1) reversible isomerisation of (CXXVI) into an unstable hydrocarbon of *o*-quinoid structure (CXXVII), and (2) rearrangement of the latter to (CXXVIII):

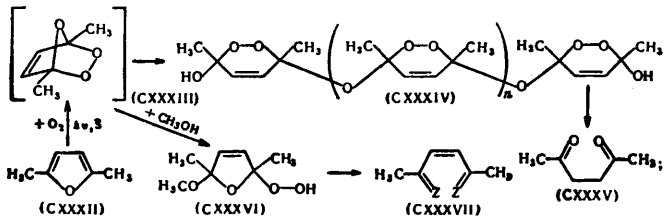
(CXXVI) (CXXVII) (CXXVIII)

This mechanism for the rearrangement was confirmed by trapping the intermediate *o*-quinoid compound (CXXVII) with

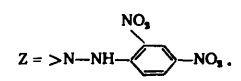
various dienophiles: heating the hydrocarbon (CXXVI) with maleic anhydride, *N*-phenylmaleimide, and *p*-benzoquinone gave the corresponding diene adducts (CXXIX*a–c*) [137–139].



(*a*) Z = >O; (*b*) Z = >N–$C_6H_5$; (*c*) Z = –CH=CH–.

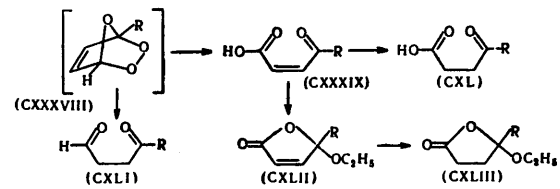


Nenitzescu [137,138] also found that, when a stream of oxygen is passed through an ethereal solution of dibenzotricyclooctadiene (CXXVI), a crystalline peroxide is formed, to which he attributed the transannular structure (CXXX). This peroxide is sparingly soluble in the usual solvents, and Nenitzescu does not exclude the possibility that it may be a polymeric compound. Catalytic reduction of the peroxide yields, instead of the expected diol, a hydrocarbon having the composition $C_{16}H_{16}$.



## IV. REACTION OF MOLECULAR OXYGEN WITH 1,3-DIENES CONTAINING HETEROATOMS

In 1952 Schenck [35,38,140–142] reported that furan and its derivatives on exposure to light in the presence of a photosensitiser, react with molecular oxygen by a mechanism of diene synthesis to form extremely unstable adducts of ozonide structure (CXXXI), which cannot be isolated¶:

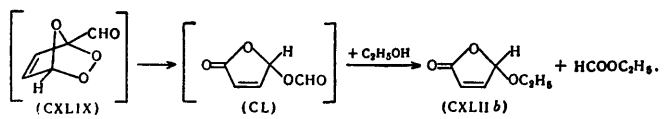


The first attempt at photosensitised oxidation was undertaken with 2,5-dimethylfuran (CXXXII). A dilute alcoholic solution of this compound containing Eosin was shaken in an atmosphere of oxygen while exposed to a 300 W lamp for 10 days. The photooxidation product possessed peroxide properties, and from it was isolated a crystalline polymeric peroxide, catalytic hydrogenation of which gave a quantitative yield of hexane-2,5-dione (CXXXV). Hence, in the photosensitised oxidation of 2,5-dimethylfuran, the oxygen had added on at the 2,5 positions to form a readily polymerisable diene adduct of ozonide structure (CXXXIII). Schenck assumes that the polymeric peroxide which he isolated had the structure (CXXXIV).

In 1964 Foote [147] established that the photosensitised oxidation of 2,5-dimethylfuran (CXXXII) in methanol gives a 74% yield of a crystalline peroxide having the composition $C_7H_{12}O_4$. Examination of the infrared and nuclear magnetic resonance spectra of this peroxide showed it to be 2,5-dihydro-2-hydroperoxy-5-methoxy-2,5-dimethylfuran (CXXXVI). This was converted into the known bis-2,4-dinitrophenylhydrazone of hex-*cis*-3-ene-2,5-dione (CXXXVII). Foote assumes that the photooxidation of (CXXXII) involves the initial formation of a diene adduct of ozonide structure (CXXXIII), which then reacts with the methanol to form the hydroperoxide (CXXXVI).

By the photosensitised oxidation of 2-methylfuran Schenck [140] obtained a peroxide of ozonide structure (CXXXVIII*a*), catalytic hydrogenation of which gave γ-oxovaleraldehyde (CXLI*a*) and γ-oxovaleric acid (CXL*a*). The latter was formed by rearrangement of the peroxide (CXXXVIII*a*) to 4-oxopent-*cis*-2-enoic acid (CXXXIX*a*) followed by hydrogenation. The rearrangement of the adduct (CXXXVIII*a*) to (CXXXIX*a*) readily occurs in alcoholic solution in the presence of vanadium pentoxide. Under these conditions 2-methylfuran gave a 76% yield of the ethyl ether (CXLII*a*) of the lactol form of the acid (CXXXIX*a*), catalytic reduction of which formed the ethyl ether (CXLIII*a*)†.

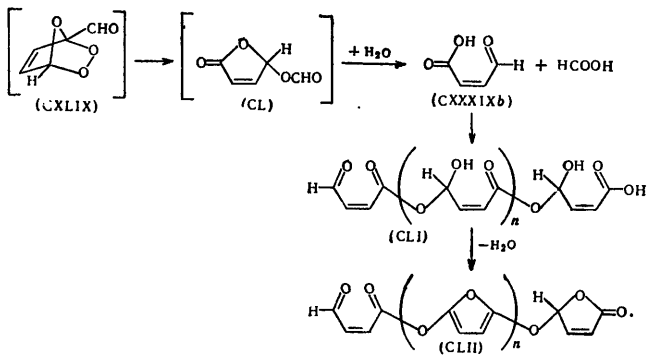
(*a*) R = $CH_3$; (*b*) R = H; (*c*) R = COOH.



Schenck [140] obtained by the photosensitised oxidation of furan an adduct of ozonide structure (CXXXVIII*b*), which rearranged rapidly to 4-oxobut-*cis*-2-enoic acid (CXXXIX*b*), catalytic reduction of which formed γ-oxobutyric acid (CXL*b*). When rearrangement of the adduct (CXXXVIII*b*) was carried out in ethanol medium, the ethyl ether (CXLII*b*) of the lactol form of (CXXXIX*b*) was obtained, and was reduced to the ethyl ether (CXLIII*b*) of the lactol form of (CXL*b*).

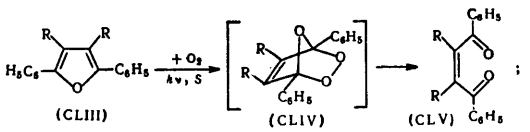
By the photosensitised oxidation of 2-furoic acid and furfural in ethanolic medium Schenck [140] obtained high yields of the ethyl ether (CXLII*b*) of the lactol form of 4-oxobut-*cis*-2-enoic acid. In the former case the intermediate diene adduct (CXXXVIII*c*) is immediately decarboxylated with formation of the adduct (CXXXVIII*b*), which is then converted into the pseudo-ester (CXLII*b*). In the second case the reaction probable involves the initial formation of a diene adduct (CXLIX), which then rearranges to the mixed anhydride (CL) of the lactol form of 4-oxobut-*cis*-2-enoic acid and formic acid, and this undergoes

¶ For the autoxidation of furan and its derivatives in the absence of photosensitisers, see Refs. 140 and 143–146.



† Holeček and Horák [148] found that 4-oxopent-2-enoic acid (CXXXIX*a*) was formed by the photooxidation of 2-methylfuran in acetone medium in the presence of protoporphyrin IX.

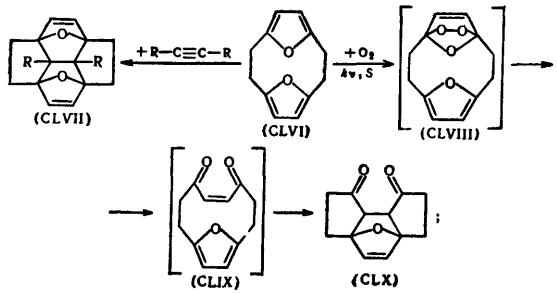
alcoholysis to the pseudo-ester (CXLII*b*) and ethyl formate‡:



(CXLIX) (CL) (CXLII *b*)

Dunlop[153,154] studied the autoxidation of furfuraldehyde, which on standing in the air darkens and acquires an acid reaction. The investigation showed that the autoxidation involves the formation of formic acid, 4-oxobut-2-enoic acid and its polymer, and small amounts of 2-furoic acid. Dunlop assumed the first stage of the reaction to be formation of a 2,5-adduct of ozonide structure (CXLIX), which hydrolysed with the production of formic acid and the unstable 4-oxobut-2-enoic acid (CXXXIX*b*), the latter being converted into the polymeric acids (CLI), and (CLII), responsible for the brown colour of oxidised furfuraldehyde:

(CXLIX) (CL) (CXXXIX*b*) (CLI) (CLII)

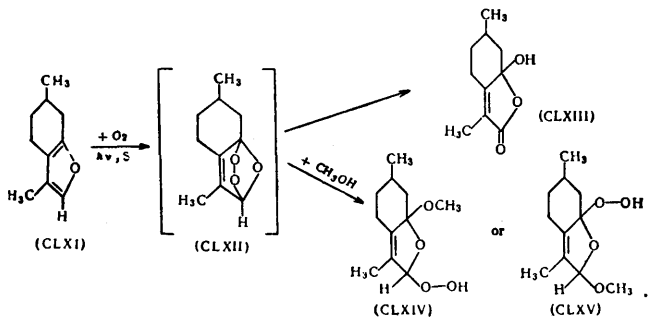


Martel[155] reported that the photochemical oxidation of 2,5-diphenylfuran (CLIII*a*) involves the formation of an unstable adduct of ozonide structure (CLIV*a*), which could not be isolated but whose structure was established by reduction with potassium iodide and acetic acid to 1,4-diphenylbut-*cis*-2-ene-1,4-dione (CLV*a*).

(CLIII) (CLIV) (CLV)

(*a*) R = H; (*b*) R = $C_6H_5$.

Martel[155], Wasserman[156], and Lutz[157] found that the photooxidation of 2,3,4,5-tetraphenylfuran (CLIII*b*) was accompanied by the formation of an unstable peroxide (CLIV*b*), which was reduced with potassium iodide and acetic acid to 1,2,3,4-tetraphenylbut-*cis*-2-ene-1,4-dione (CLV*b*).



(CLVII) (CLVI) (CLVIII) (CLIX) (CLX)

R = $-COOCH_3$.

Cram[158] has shown that 1,4 : 7,10-diepoxydodeca-1,3,7,9-tetraene (CLVI) reacts with dimethyl acetylenedicarboxylate by a mechanism of diene synthesis to form an adduct (CLVII), whose configuration was not established.

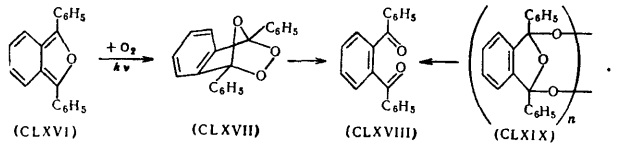
Wasserman[159] established that the photosensitised oxidation of the heterocyclophane (CLVI) in alcoholic solution yields a 1,4-diketone (CLX), the reaction probably occurring in three stages: (i) oxidation of (CLVI) to the monoepidioxide (CLVIII); (ii) reduction of (CLVIII) to an unsaturated 1,4-diketone (CLIX); (iii) intramolecular diene condensation of (CLIX) to (CLX).

In 1958 Schenck and Foote[160] found that the photosensitised oxidation of menthofuran (CLXI) gives a 40% yield of the pseudo-acid (CLXIII). The unstable diene adduct of ozonide structure (CLXII) formed as an intermediate in this reaction could not be isolated even when the experiment was carried out at -20°§.

(CLXI) (CLXII) (CLXIII) (CLXIV) (CLXV)

The photooxidation of menthofuran in methanol medium gave an addition product of a methanol molecule to the epidioxide (CLXII), whose structure was not established. In 1964 Foote[147] reported that the product of the methanolysis of the epidioxide (CLXII) was a hydroperoxide (CLXIV) or (CLXV).

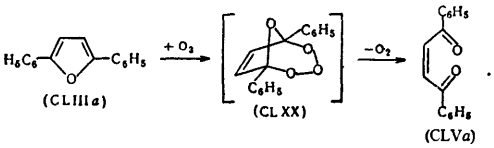
In 1946 Dufraisse[162] showed that, when dilute solutions of 1,3-diphenylisobenzofuran (CLXVI)¶ undergo photooxidation at -40°, an extremely unstable diene adduct of ozonide structure (CLXVII), which explodes at ~18°, is



‡ Schenck[149,150], Ogura[151], and Alder[152] have worked out a method for preparing the pseudo-ester (CXLII*b*) from furfuraldehyde.

§ In 1950 Woodward[161] had investigated the autoxidation of menthofuran, and isolated a 15% yield of the pseudo-acid (CLXIII) from the oxidation products.

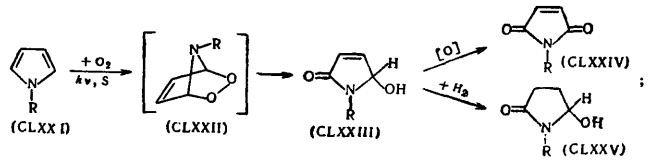
¶ 1,3-Diphenylisobenzofuran, which contains a reactive aromatic 1,3-diene system (*o*-quinoid grouping), readily undergoes diene condensation with maleic anhydride, acrylaldehyde, *p*-benzoquinone, and other dienophiles[163].



formed. In solution this adduct is rapidly converted at room temperature into *o*-dibenzoylbenzene (CLXVIII).

In 1963 Le Berre[164] shook a benzene solution of 1,3-diphenylisobenzofuran (CLXVI) in an atmosphere of oxygen in the dark, and obtained a polymeric peroxide (CLXIX), which decomposed explosively when heated above 100°; quinol inhibits the autoxidation of 1,3-diphenylisobenzofuran. When the polyperoxide (CLXIX) was reduced with potassium iodide and and acetic acid, *o*-dibenzoylbenzene (CLXVIII) was obtained†.

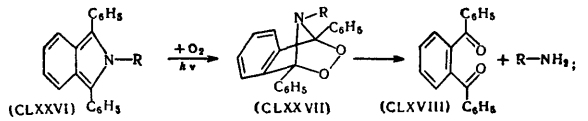
(CLXVI) (CLXVII) (CLXVIII) (CLXIX)



It was established in 1957 that[166] the ozonisation of 2,5-diphenylfuran (CLIII*a*) in acetone or methanol at -40° involves the formation of 1,4-diphenylbut-*cis*-2-ene-1,4-dione (CLV*a*). It is probable that in this case, too, the first stage in the process is 2,5 addition of an ozone molecule to 2,5-diphenylfuran to form the monoozonide (CLXX), the second stage being conversion of the $O_3$-adduct (CLXX) into *cis*-1,2-dibenzoylethylene (CLV*a*):

(CLIII*a*) (CLXX) (CLV*a*)

In 1939 Bernheim and Morgan[167] showed that illumination of an aqueous, alcoholic, or acetone solution of pyrrole in the presence of a photosensitiser (Methylene Blue, Eosin) and oxygen results in the formation of a crystalline substance melting at 102°. The structure of this substance was not determined.

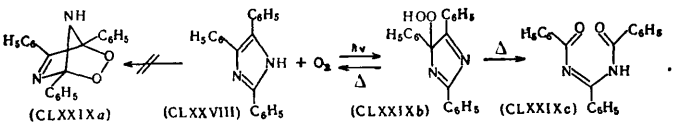


These experiments were repeated by de Mayo and Reid[168] in 1962, who found that, if a 0.1% aqueous solution of pyrrole (CLXXI*a*) was shaken with Eosin in an atmosphere of oxygen while exposed to a 100 W lamp, one molecular equivalent of oxygen was rapidly absorbed. A photooxidation product of composition $C_4H_5NO_2$ and m. p. 102° was isolated in 32% yield from the reaction mixture. Under the same conditions 1-methylpyrrole (CLXXI*b*) gave a 48% yield of a crystalline substance $C_5H_7NO_2$ melting at 85°. These workers assume that the photosensitised oxidation involves the initial formation of unstable diene adducts (CLXXII*a*) and (CLXXII*b*), which then rearrange to the compounds melting at 102° and 85°, for which the formulae (CLXXIII*a*) and (CLXXIII*b*) are proposed. These suggested structural formulae were confirmed by examination of the infrared spectrum of the substance melting at 102° and of the nuclear magnetic resonance spectrum of that melting at 85°. Oxidation of the photooxidation products (CLXXIII*a*) and (CLXXIII*b*) with active manganse dioxide gave respectively maleimide (CLXXIV*a*) and *N*-methylmaleimide (CLXXIV*b*), and catalytic hydrogenation of the photooxidation product of pyrrole (CLXXIII*a*) gave the dihydro-derivative (CLXXV*a*).

(CLXXI) (CLXXII) (CLXXIII) (CLXXIV) (CLXXV)

(*a*) R = H; (*b*) R = $CH_3$.

During 1955–1957 Theilacker and Schmidt[169] studied the oxidation of several derivatives of isoindole, and found that 2-methyl-1,3-diphenylisoindole (CLXXVI*a*) readily forms a diene adduct with maleic anhydride‡. Passage of a stream of air through a boiling solution of 2-methyl-1,3-diphenylisoindole (CLXXVI*a*) in aqueous butanol produced *o*-dibenzoylbenzene (CLXVIII). These workers assume the intermediate formation of an epidioxide (CLXXVII*a*), which is then hydrolysed with the formation of *o*-dibenzoylbenzene, methylamine, and hydrogen peroxide.

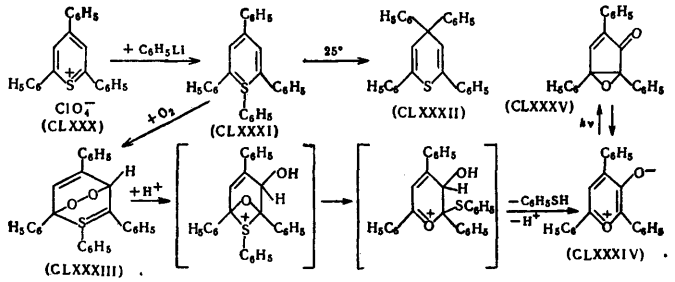


(CLXXVI) (CLXXVII) (CLXVIII)

(*a*) R = $CH_3$; (*b*) R = $C_6H_5$.

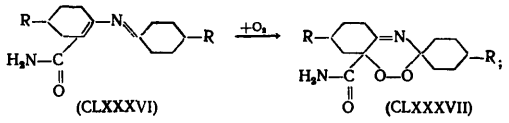
The photooxidation of dilute carbon-disulphide solutions of 1,2,3-triphenylisoindole (CLXXVI*b*), which is the nitrogen analogue of 1,3-diphenylisobenzofuran (CLXVI), gives a good yield of a diene adduct (CLXXVII*b*), which decomposes at 80–90°. Reduction of the adduct (CLXXVII*b*) with zinc and acetic acid produced a high yield of 1,2,3-triphenylisoindole (CLXXVI*b*), whereas reduction of (CLXXVII*b*) with sodium sulphite gave *o*-dibenzoylbenzene and aniline.

In 1957 Dufraisse[170–172] reported that the photooxidation of dilute solutions of lophine, 2,4,5-triphenylimidazole (CLXXVIII), in carbon disulphide at 18° involves the formation of a crystalline peroxide, which when heated to 170° decomposes into lophine (CLXXVIII), oxygen, and *NN'*-dibenzoylbenzamidine (CLXXIX*c*). He assumed the lophine peroxide which he had obtained to be a diene adduct (CLXXIX*a*), but an examination of its ultraviolet, infrared, and nuclear magnetic resonance spectra undertaken in 1964 has shown that it is a hydroperoxide (CLXXIX*b*)[173,174].



(CLXXIX*a*) (CLXXVIII) (CLXXIX*b*) (CLXXIX*c*)

In 1962 Suld and Price[175] reported that phenyllithium reacts in ether with 2,4,6-triphenylthiapyrylium perchlorate (CLXXX) to form the unstable 1,2,4,6-tetraphenylthiabenzene (CLXXXI), which was isolated as an ether complex, a purple amorphous mass. At room temperature (CLXXXI) isomerises to the colourless crystalline 2,4,4,6-tetraphenylthiapyran (CLXXXII). If oxygen is admitted to the reddish violet ethereal solution of tetraphenylthiabenzene (CLXXXI), the solution is rapidly decolorised with formation of an extremely unstable "transannular epidioxide" of 1,2,4,6-tetraphenylthiabenzene



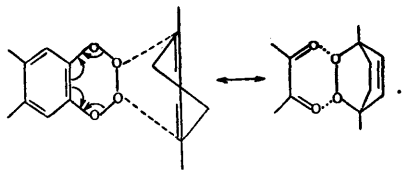
† As early as 1906 Guiot and Catel[165] had observed the formation of *o*-dibenzoylbenzene when benzene or alcoholic solutions of 1,3-diphenylisobenzofuran were in contact with air. They also noted that the oxidation of 1,3-diphenylisobenzofuran is more rapid in the light than in the dark.

‡ For diene syntheses with isoindoles, see Ref. 163, p. 554.

(CLXXXIII), which could not be isolated. In ethereal solution the "epidioxide" (CLXXXIII) reacts rapidly with hydrogen chloride to form benzenethiol and 2,4,6-triphenylpyrylium 3-oxide (CLXXXIV), consisting of dark red crystals. In 1963 Ullman[176] showed that, when an acetonitrile solution of (CLXXXIV) is illuminated, the latter undergoes reversible photochemical conversion into a valency tautomer, 4,5-epoxy-2,4,5-triphenylcyclopent-2-en-1-one (CLXXXV)§.

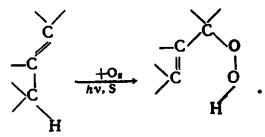
During 1961–1964 McKay[178–180] investigated the condensation of alicyclic ketones with urea. It was found that, when the latter was heated with cyclohexanone, 4-methylcyclohexanone, and 4-t-butylcyclohexanone, the corresponding condensation products (CLXXXVI*a–c*) were formed. In the purfication of these products it was noted that they absorbed oxygen very readily. One molecular equivalent of oxygen was absorbed when chloroform solutions of (CLXXXVI*a–c*) were stirred at room temperature and normal pressure in an atmosphere of pure oxygen for 1 h, and in the presence of 0.1% of cobalt naphthenate this occurred within 5 min. The oxidation products were crystalline peroxides, which were shown to have the structures (CLXXXVII*a–c*). Hence they had been formed by 1,4 addition of oxygen to the conjugated "diene" system of the condensation products (CLXXXVI*a–c*).

(*a*) R = H; (*b*) R = $CH_3$; (*c*) R = $(CH_3)_3C$.



## V. MECHANISM OF PHOTOSENSITISED OXIDATION; OXIDATION WITH SINGLET OXYGEN

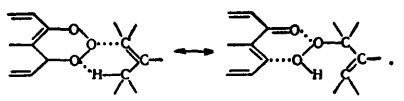
On absorbing radiation, molecules pass into an excited electronic state, from which they return to the normal state with the emission of radiation (fluorescence). This excitation energy can be used for chemical reactions. The excited molecule can either react with a molecule which collides with it, or else transmit its energy to another molecule, which will then become a centre for photochemical reaction. In the latter case the molecule which absorbs the radiation acts solely as a sensitiser, and undergoes no change during the reaction (sensitised photochemical reaction)[181]. The problem of the nature of the intermediate products in the photosensitised oxidation of olefins and conjugated dienes has been discussed by several investigators.



According to the ideas developed by Schönberg[182,183], Schenck[38,40,184–188], and Bowen[189,190], a sensitiser (S), on absorbing light energy, passes into a diradical (.S.), which adds on a molecule of oxygen to form a peroxy-radical (.S–O–O.). The labile oxygen in the peroxy-radical is then transferred to an acceptor A with formation of the peroxide $AO_2$ and the original sensitiser. Schönberg[183] assumes that the transfer of oxygen to the acceptor takes place either in a reaction aggregate or by breakdown of the peroxy-radical into the original sensitiser and active (nascent) oxygen.

$$S \xrightarrow{h\nu} \cdot S \cdot,$$
$$\cdot S \cdot + O_2 \rightarrow \cdot S{-}O{-}O \cdot$$
$$\cdot S{-}O{-}O \cdot + A \rightarrow AO_2 + S.$$

On the basis of Schenck's concepts, Schuller et al.[107] suggested that in the case of the photosensitised oxidation of laevopimaric acid (CII) and palustric acid (CVI) (see Section II, 7) the transition state can be represented (with *o*-benzoquinone as sensitiser) as follows



Schenck[35,38,184,191–200] and other workers[201–203] have established that the photosensitised oxidation of olefins involves migration of an allyl hydrogen atom to the oxygen with displacement of the double bond to a neighbouring position, i.e. by a mechanism of monoene addition. The reaction products are allyl hydroperoxides (CLXXXVIII)¶:

(CLXXXVIII)

Thus the first stage in the photosensitised oxidation of *p*-mentha-1,4(8)-diene (XXVIII) and neoabietic acid (CVIII) is their conversion into the allyl hydroperoxide (XXIX) and (CIX) (see Sections II, 4 and II, 7). Schuller and Lawrence[105,106] assume that in this case the transition state can be represented (with a 1,4-naphthaquinone derivative as sensitiser)

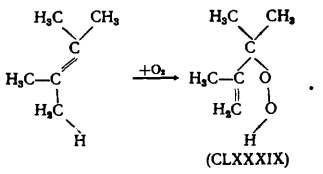
A different reaction mechanism was suggested for photosensitised oxidation by Kautsky[204–206], who regarded the oxidation as caused by photoactive oxygen. According to him the sensitised oxidation comprises two stages — light and dark: the light energy absorbed by a sensitiser

§ In 1964 Dunston and Yates[177] established that 4, 5-epoxy-2,3,4,5-tetraphenylcyclopent-2-en-1-one and 2,4,5,6-tetraphenylpyrylium 3-oxide are also photochemical valency tautomers.

¶ In the case of fused cyclic systems, the reaction occurs stereospecifically; it is the quasi-axial allyl hydrogen atom located in the *cis* position with respect to the newly formed C–O bond which migrates.

molecule is first transferred to an oxygen molecule; and in the second stage, for which illumination is not required, the excited oxygen molecule reacts, in one of two theoretically possible metastable singlet states $^1\Delta_g$ or $^1\Sigma_g$, with the acceptor A to form a peroxide product $AO_2$:

$$S \xrightarrow{h\nu} S^*,$$
$$S^* + O_2 \rightarrow O_2^* + S,$$
$$O^*_2 + A \rightarrow AO_2.$$



As an experimental demonstration of the correctness of his suggested reaction mechanism for photosensitised oxidation, Kautsky prepared separately peroxides of the sensitiser (Trypaflavine) and of the acceptor (the leuco base of Malachite Green), and illuminated mixtures of the two adsorbates (the experiments were carried out at low oxygen pressures). Under these conditions the leuco base was oxidised to the dye. This result provided a convincing proof of the correctness of Kautsky's suggested reaction mechanism.

A similar phenomenon has been observed by Rosenberg[207] in a study of the interaction of oxygen with photoexcited Acriflavine deposited on silica gel.

In 1964 Foote[147] and Corey[208] simultaneously published brief communications describing new methods for the oxidation of cyclic 1,3-dienes to transannular epidioxides with molecular oxygen in an excited singlet state.

Foote[147] obtained singlet oxygen *in situ* by the action of sodium hypochlorite on hydrogen peroxide. The technique of oxidation is very simple: to a solution in methanol of the substance to be oxidised are added 30% hydrogen peroxide, and then 1 M sodium hypochlorite solution with stirring and cooling. Foote's method is suitable for the preparation of epidioxides from cyclic 1,3-dienes and of allyl hydroperoxides from olefins. By the oxidation of cyclohexa-1,3-diene (XXI*c*) was obtained an epidioxide (XXII*c*, yield 20%) previously synthesised by Schenck (see Section II, 4). The oxidation of tetracyclone (LXIV*c*) gave 1,4-diphenylbut-*cis*-2-ene-1,4-dione (LXVI*c*, yield 50%), which had previously been obtained by the photooxidation of tetracyclone (see Section II, 5). The oxidation of 2,5-dimethylfuran (CXXXII*c*) in methanol gave a hydroperoxide (CXXXVI, yield 84%) identical with that obtained by Foote by the photosensitised oxidation of 2,5-dimethylfuran in methanol (see Section IV).

Foote reported that, according to preliminary results, rubrene and other acenes are also oxidised by singlet oxygen to transannular epidioxides. Oxidation of olefins containing allyl hydrogen atoms by means of singlet oxygen yields, with displacement of the double bond, allyl hydroperoxides. Thus the oxidation of 2,3-dimethylbut-2-ene led to 3-hydroperoxy-2,3-dimethylbut-1-ene (CLXXXIX, yield 63%), previously obtained by Schenck[196] by the photosensitised oxidation of 2,3-dimethylbut-2-ene.

(CLXXXIX)

Foote[209] regards his results as indicating that singlet oxygen may be the reactive intermediate in the photosensitised oxidation, too.

Corey[208] has employed the method of transforming molecular oxygen to the singlet state by means of an electric discharge, first described in 1956 by Foner and Hudson[210]. By this method ~10% of the molecular oxygen is converted to the $^1\Delta_g$ metastable state, and only ~0.01% passes into the $^1\Sigma_g$ metastable state. Corey carried out the oxidation of 1,3-dienes at 0° in bromobenzene, chlorobenzene, nitrobenzene, and other solvents. The oxidation of *p*-mentha-1,3-diene resulted in ascaridole (I), previously synthesised by Schenck (see Section II, 3). By the oxidation of 1,3-diphenylisobenzofuran (CLXVI) a high yield of *o*-dibenzoylbenzene (CLXVIII) was obtained. 9,10-Diphenylanthracene (CXIV*a*), anthracene (CXVII*a*), and 9,10-dimethylanthracene (CXVII*d*) were converted into the corresponding epidioxides (CXV*a*), (CXVIII*a*), and (CXVIII*d*), identical with specimens obtained by the photooxidation of these hydrocarbons (see Section III).

Attempts to oxidise 2,3-dimethylbut-2-ene, cyclohex-1-enylbenzene, pin-2-ene, and cholest-4-en-3β-ol to allyl hydroperoxides did not give positive results.

Corey's method cannot yet be employed to prepare transannular epidioxides from cyclic 1,3-dienes. The generator of metastable oxygen which he used enabled only a few millimoles of substances to be oxidised: for example, the oxidation of 100 mg of 9,10-dimethylanthracene to the 9,10-epidioxide lasted 19 h.

## NOTE ADDED IN PROOF

Foote[212] has recently made a comparative stereochemical study of the reaction of *p*-mentha-1,8-diene with singlet oxygen and of the photosensitised oxidation of this compound. The results show that identical intermediates are formed in the two cases. Thus Foote's earlier suggestion[209], that singlet oxygen is formed as intermediate in the photooxidation of alkenes and dienoid compounds, has been confirmed experimentally.

# THE EXTRACTION OF HETEROPOLY--COMPOUNDS AND ITS APPLICATION IN INORGANIC ANALYSIS

I. P. Alimarin, F. P. Sudakov, and V. I. Klitina

CONTENTS

I. Introduction 574
II. Brief historical review 575
III. General characteristics of the extraction of heteropoly-compounds 575
IV. Mechanism of the extraction of heteropoly-compounds 576
V. Chief factors influencing the extraction of heteropoly--compounds 577
VI. Analytical application of the extraction of heteropoly--compounds 580

## I. INTRODUCTION

In recent years, in the analytical determination of silicon, phosphorus, and arsenic, small quantities of which are most reliably determined by photometric measurements on their heteropoly-acids, increasing use has been made of the extraction of these heteropoly-acids by organic solvents.

The increasing introduction of the extraction method in the field of heteropoly-compounds cannot be attributed entirely to the general and nowadays widely known advantages of this method. Certain particular advantages of the extraction method are shown to a greater extent by heteropoly-compounds than by any other types of compounds. In this connection it is sufficient to mention two features.

A serious disadvantage of all analytical methods based on photometric measurements on molybdenum heteropoly--compounds (particularly their reduced blue forms) is the superposition of the light absorption of the reagent itself — molybdate; the use of extraction makes possible the ready and reliable elimination of the influence of molybdate, since isopolymolybdate, unlike heteropolymolybdates, is generally not extracted by organic solvents.

Another frequent obstacle to the analytical application of heteropoly-compounds is the instability of the light absorption of the solutions taken for the photometric measurements. This is due to the existence of complex equilibria in aqueous solutions of the heteropoly-compounds, which are extremely sensitive to very small changes in the conditions. The solutions obtained as a result of extraction of the heteropoly-compound by organic solvents are much more stable than the aqueous solutions.

The study of the extraction behaviour of heteropoly--compounds, apart from its analytical value[1-4], is also of undoubted interest from other viewpoints.

The most important method for the preparation of the heteropoly-acids of most elements is the ether method, based on separation of the heteropoly-acids from acidified solutions of their salts by means of diethyl ether[4].

Extraction may provide a valuable method for studying the physicochemical properties of heteropoly-compounds, for which reliable experimental methods are still urgently required[5].

The combination of the most varied properties in a single chemical individual, so characteristic of heteropoly--compounds, is a favourable factor in obtaining useful and concentrated information on the theory of extraction when these compounds are chosen as objects for study (models).

## II. BRIEF HISTORICAL REVIEW

The first information on the behaviour of heteropoly-compounds towards organic solvents appeared in papers by Marignac[6], Parmentier[7], and Sobolev[8], who studied various physicochemical properties of tungstosilicic, molybdophosphoric, and tungstophosphoric acids, including their solubility in diethyl ether.

Drechsel[9] was the first to make use of the solubility of heteropoly-acids in diethyl ether for their isolation in the free state. The ethereal extraction method for the preparation of heteropoly-acids became a classical method, and was later studied in detail by Scroggie[10], who showed the possibility of replacing diethyl ether by other oxygen-containing organic solvents.

The first views on the mechanism of the extraction of heteropoly-acids by diethyl ether were put forward by Rosenheim[11], and the composition of the compound extracted (for the case of molybdophosphoric acid) was first studied by Copaux[12]. A detailed study of the quaternary system molybdophosphoric acid–sulphuric acid–water–diethyl ether was made by Souchay[13]. Extensive studies of equilibria in the systems formed by saturated heteropoly-acids with organic solvents were made by Nikitina and her coworkers; the results of these studies are described in a recently published monograph[4].

The analytical application of the extraction of heteropoly-acids by organic solvents was begun in work by Denigès[14], who pointed out the possibility of making use of the extraction of the reduced forms of molybdophosphoric and molybdoarsenic acids by diethyl ether or pentanol for the qualitative detection of phosphorus and arsenic†. The extraction of heteropoly-acids was first used for quantitative analysis by Copaux[12], who determined the concentration of phosphorus in native phosphates by measuring the volume of an ethereal extract of molybdophosphoric acid. The first extraction–colorimetric method of analysis using heteropoly-compounds was developed by Shneerson[16] for the determination of phosphorus in steels: the method involves the extraction of reduced molybdophosphoric acid by diethyl ether, followed by colorimetric measurements on the extract using a standard series. The use of extraction for the quantitative separation of elements as the heteropoly-acids was first carried out by Alekseev[17] in the analysis of phosphate–arsenate–silicate mixtures. Of considerable importance for the development of extraction methods for the separation and determination of elements as their heteropoly-compounds were the ideas of Keggin[18], and also the work of Berenblum and Chain[19], Allen[20], Proctor and Hood[21], and Wadelin and Mellon[22].

Bibliographies on the extraction of heteropoly-compounds and its use in chemical analysis are to be found in monographs[4,23] and reviews[3,24-29] on the chemistry of heteropoly-compounds, in a monograph[2] and reviews[1,30-42] on the extraction of inorganic compounds, in textbooks on the photometric determination of elements[43-46], in reviews of the analytical chemistry of phosphorus[47-51] and silicon[52-54], and also in a number of original papers[22,55-62].

As far as we are aware, the present review is the first attempt to systematise the available published material.

† Earlier, Jacobs[15] had made use of the extraction of molybdophosphoric acid by pentanol to remove this acid from the mother-liquor after the precipitation of tungstophosphates, but this work was preparative rather than analytical.

## III. GENERAL CHARACTERISTICS OF THE EXTRACTION OF HETEROPOLY-COMPOUNDS

Heteropoly-acids and their salts are extracted from acidified aqueous solutions by oxygen-containing organic solvents (alcohols, ethers, esters, ketones, and aldehydes)[2-4,10,17,18,22-29,49,53,62-73]. They are not extracted by solvents containing no oxygen (hydrocarbons, halogenohydrocarbons, carbon disulphide, petroleum ether), but solutions of nitrogen-containing compounds (amines) in non-polar solvents (benzene or chloroform) are excellent extracting agents for heteropoly-compounds[57,74,75]. Thus the effective extraction of heteropoly-compounds requires the presence of a basic oxygen or nitrogen atom in the molecule of the organic extractant.

Of the binary heteropoly-acids of molybdenum, the most readily extracted is molybdophosphoric acid; the ease of extraction of the heteropoly-acids studied decreases in general in the order: molybdophosphoric > molybdoarsenic > molybdosilicic > molybdogermanic. It is difficult as yet to say anything definite about the extraction behaviour of other known heteropoly-acids of molybdenum, since they have been little studied in this connection (there are only a few data on the extraction of molybdoceric[76,77], molybdotitanic[78], and molybdozirconic[78] acids).

The behaviour of binary heteropoly-acids of tungsten towards organic solvents is in general similar to that of their molybdenum analogues. This is indicated by the scant but fairly convincing experimental data on the extraction of tungstophosphoric (diethyl ether[8,15,79,80] and pentanol[15,79]), tungstosilicic (diethyl ether[6,9,10], ethyl acetate, etc.[10]), and tungstogermanic (diethyl ether[81], butanol[82], ethyl acetate[82]) acids.

The appearance of a third element in the structure of the heteropoly-complex (in addition to the two necessary elements other than oxygen and hydrogen) also produces no fundamental change in the behaviour of the heteropoly-complex towards organic solvents. The available published data on the extraction of molybdovanadophosphoric[83-93], tungstovanadophosphoric[71,94,95], tungstoarsenophosphoric[96], molybdovanadogermanic[81,82,97], tungstovanadogermanic[81,82], molybdotitanophosphoric[73,98,99], and molybdoniobophosphoric[100,101] acids indicate that ternary heteropoly-compounds are in general readily extracted by oxygen-containing solvents, but are not extracted by solvents containing no oxygen. The ternary heteropoly-acids, for example molybdoniobophosphoric[100], molybdotitanophosphoric[73], and telluromolybdophosphoric[102] acids, however, are not extracted by certain oxygen-containing solvents, in particular butyl acetate. The extraction behaviour of ternary heteropoly-acids possibly depends on whether the third component is the central atom in the structure of the complex or is present in the ligand part of the complex.

The extraction behaviour of reduced heteropoly-compounds, judging from the few data relating to this field[57,69,70,72,75], does not differ in principle from that of the unreduced heteropoly-compounds. This is a further indication that the structures of the reduced (blue) and unreduced (yellow) forms of the heteropoly-compounds are identical[103].

The extraction of heteropoly-compounds, like any process, depends to a marked extent on the conditions, and is influenced by various factors, of which the most important — the nature of the compound being extracted, the nature of the solvent, the acidity of the aqueous phase, the con-

centration of the compound being extracted in the aqueous phase, the presence of neutral salts, and the temperature — are of considerable significance for the utilisation of the extraction of heteropoly-compounds in chemical analysis, and will be examined in more detail below.

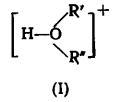
The physicochemical properties of extracts of heteropoly-compounds have been little studied: only a few data relating to their optical characteristics are available. The extracts of both reduced and unreduced heteropoly-compounds retain the colour characteristic of their aqueous solutions (blue and yellow respectively). The general appearance of the absorption spectra of the extracts remains unchanged in both cases[21,22,58,59,67,72,82,104-116], but the light-absorption maxima for the heteropoly-compounds in organic solvents are generally displaced slightly towards shorter wavelengths compared with the maxima of the same heteropoly-compounds in aqueous solutions. For example, unreduced molybdophosphoric acid in aqueous solution shows a light-absorption maximum at 345 mμm[49], and the reduced form shows maxima at 630 and 735 mμm[49]; the corresponding maxima for the same acid in organic solvents lie at 310 mμm[22,59,109,110], or 625 and 725 mμm[21,104,109,111]. Unreduced molybdosilicic acid in aqueous solution has an absorption maximum at 350–355 mμm[53], and the reduced form a maximum at 800–820 mμm[53]; the corresponding maxima for the same acid in organic solvents lie at 330 mμm[22,58], or 630 and 720 mμm[112].

The composition of the forms in which the heteropoly--acids are extracted (the extractable forms) has not been specially studied. Fairly convincing experimental data indicate, however, that at a comparatively low acidity ($< 2\ N$), when the possibility of the extraction of isopolymolybdate is excluded, the stoichiometric composition of molybdophosphate in ethyl acetate[117], butyl acetate[59], and butanol–chloroform[118] extracts corresponds to a constant P : Mo ratio of 1 : 12; this ratio remains unchanged even for the extraction of molybdophosphoric acid with insufficient molybdate[117]. These data indicate that the molybdophosphate complex enters the organic phase in the form of the dodecamolybdophosphoric acid or its salt. An interesting feature is that sodium is extracted into ethyl acetate together with phosphorus and molybdenum in the proportions Na : P : Mo = 2.1 : 1 : 11.9 and 0.7 : 1 : 11.19, depending on the acidity[177]; it is possible that in this case an acid sodium salt of molybdophosphoric acid is extracted.

The increase in the distribution coefficient, for molybdophosphoric and molybdosilicic acids between aqueous solution and butanol, with dilution of the aqueous heteropoly-acid solutions indicates indirectly that the monomeric form of the heteropoly-acids enters the organic solvent during extraction[119,120], since dilution of aqueous solutions of the heteropoly-acids leads to depolymerisation of these acids to forms of low molecular weight. The increase in the extractability of molybdophosphoric and molybdosilicic acids with increase in the hydrogen-ion concentration in the aqueous phase may indicate the preferential extraction of these acids in the undissociated (molecular) form in accordance with the equilibrium[119]

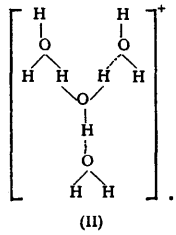
$$\begin{array}{l}(H_nA)_m \rightleftarrows mH_nA \rightleftarrows nH^+ + A^{n-}\ \text{(in water)},\\ \quad\downarrow\uparrow\\ \quad H_nA\qquad\ \text{(in butanol)}.\end{array} \qquad (1)$$

The results of experiments on light-scattering by solutions of tungstophosphoric acid in various organic solvents[121] are of interest in this connection. The molecular weight of tungstophosphoric acid in ethanol and allyl alcohol, determined by the light-scattering method, was found to have the values 2600 and 2900 respectively, showing good agreement with the formula weight for $H_3PW_{12}O_{40}$ (2880) and indicating that tungstophosphoric acid is monomeric in these solvents.



It is quite probable that the formation of a true (molecular) solution as a result of the extraction of heteropoly--compounds by organic solvents is one of the reasons for the greater stability of the organic extracts of heteropoly--compounds (particularly the reduced forms) compared with their aqueous solutions, which, according to some authors[115,122,123], are colloidal solutions and thus have a tendency to undergo gradual decomposition on standing (particularly at high concentrations).

## IV. MECHANISM OF THE EXTRACTION OF HETEROPOLY-COMPOUNDS



Various suggestions have been made regarding the mechanism of the extraction of heteropoly-compounds by organic solvents, but none has been confirmed by special experimental studies.

The earliest suggestion was that oxygen-containing organic solvents (in particular diethyl ether) extract heteropoly-compounds from acidic solutions with the formation of alkyl-substituted oxonium salts (etherates)[11]. If the acidity is not too high, or the solvent present in large excess, only part of the oxygen-containing solvent enters the oxonium salt and the latter dissolves in the excess of solvent, to which it is structurally similar. This mechanism, known as the oxonium mechanism, accounts well for the most important necessary conditions for the extraction of heteropoly-compounds — the presence of an acid medium and of an oxygen-containing solvent.

The oxonium-mechanism theory, previously used to explain many other examples of extraction[30], has recently been subjected to serious criticism. The main assumption in this theory, that the proton of the acid is attached directly to the oxygen atom of the organic solvent with the formation of an oxonium (solvonium) cation (I) is unjustified in a number of cases. Experimental data which have accumulated in recent years on the extraction of strong acids suggest that the main reaction in this case is attachment of the proton of the acid to the oxygen atom of water, with the formation of a hydroxonium cation, which in turn is hydrated by several water molecules (II); the organic solvent is attached to the water molecules polarised in the field of the hydroxonium ion. This extraction mechanism, which has been called the hydrate–solvate mechanism[124,125], has unfortunately not yet been verified for heteropoly-compounds.

(I)

(II)

According to another suggestion, the extraction of heteropoly-compounds with oxygen-containing solvents is

accompanied by formation of a coordination compound between a molecule of the organic solvent (as electron donor) and the anion of the heteropoly-acid (as electron acceptor)[65]; the compound formed in this way is covalent, and dissolves more readily in the organic solvent than in water. In the formation of coordination compounds of this type, a direct part is apparently played by the electronegative oxygen atom of the organic solvent and a molybdenum atom of the heteropoly-anion, which in this case shows a coordination number of 8. This mechanism readily explains cases of the extraction of heteropoly-compounds by non-polar solvents (chloroform or benzene) using amines and other compounds with marked basic (electron-donating) properties[74].

Both of these suggestions regarding the mechanism of the extraction of heteropoly-compounds are based on the assumption that a donor–acceptor interaction takes place between the heteropoly-compound and the extracting agent; the difference lies in which part (cationic or anionic) of the heteropoly-compound reacts with the extracting agent.

Another suggestion is based on the assumption that the extraction of heteropoly-compounds involves physical distribution, in which the heteropoly-compounds are distributed between the aqueous phase (in ionised form) and the organic phase (in molecular form) as a result of the difference in their solubilities in water and the organic solvent, without the formation of saltlike compounds with the latter[30]. This mechanism explains fairly simply certain regular features observed in the extraction of heteropoly--compounds, for example the salting-out action of salts.

Finally, it is also possible that the extraction of heteropoly-compounds involves a so-called colloid-chemical mechanism, in which the compound being extracted is transferred from the aqueous phase to the organic phase in the form of highly dispersed colloidal particles[126].

The data at present available on the mechanism of the extraction of heteropoly-compounds do not make it possible to give preference to any of the above mechanisms. Most of the experimental facts relating to the extraction of heteropoly-compounds are explained equally satisfactorily on the basis of any of these mechanisms; at the same time there are a number of facts which are explained by none of them. For example, the extractability of heteropoly-compounds by amines of high molecular weight dissolved in inert solvents can be interpreted in terms of any of the above mechanisms, but it can also be understood without recourse to them, simply on the basis of the generally accepted anion-exchange mechanism of extraction with amines[127].

## V. CHIEF FACTORS INFLUENCING THE EXTRACTION OF HETEROPOLY-COMPOUNDS

### 1. Nature of the Compound Being Extracted

The extractability of binary heteropoly-compounds (of molybdenum and tungsten) depends to a considerable extent on the nature of the central atom (phosphorus, arsenic, silicon, germanium, etc.). The difference in the extraction behaviour of heteropoly-compounds is revealed as a difference in the percentage extraction for the same solvent and differences in the number of solvents suitable for the extraction.

Heteropoly-acids having quinquevalent elements (phosphorus and arsenic) as central atoms are extracted much more readily than those with quadrivalent elements (silicon, germanium, cerium, etc.). For example, the degree of extraction of molybdophosphoric acid by organic solvents from aqueous solutions of pH 1, is 100% for pentyl acetate, 70% for dibutyl ether, 54% for hexyl butyrate, 50% for diethyl ether, 8% for isopentyl acetate, and 5% for ethyl acetate, n-propyl acetate, isopropyl acetate, n-butyl acetate, and isobutyl acetate; molybdosilicic acid undergoes almost no extraction by any of these solvents under the same conditions[68].

Comparison of the extractability of molybdophosphoric and molybdoarsenic acids (Table 1) shows clearly that the former acid is more readily extracted.

Comparison of the molybdenum heteropoly-acids of quadrivalent elements, for example with respect to their behaviour towards diethyl ether, reveals a clearly defined order: silicon > germanium > titanium > zirconium > > cerium > thorium[78]. The heteropoly-acids of the first three elements are prepared by the ether method: i.e. they are extracted by diethyl ether. But the heteropoly-compounds of the last three elements cannot be prepared by the ether method, since they are not extracted by diethyl ether. The poor extractability of molybdoceric acid (compared with molybdosilicic and molybdogermanic acids) has also been demonstrated for other solvents[76,77].

It is difficult on the basis of data at present available to follow the difference in extraction behaviour between binary heteropoly-acids of tungsten and molybdenum. In the case of the ternary heteropoly-acids, however, it can be definitely stated that the introduction of a third component into the molecule of the heteropoly-acid generally leads to a decrease in the ability of the acid to undergo extraction by organic solvents. Even with molybdovanadophosphoric and tungstovanadophosphoric acids, the range of solvents is slightly restricted (compared with that for the binary acids of phosphorus), and acids such as molybdoniobophosphoric[100], molybdotitanophosphoric[73], and telluromolybdophosphoric[102] acids are not extracted at all, for example, by butyl acetate or isobutyl acetate. Here, of course, a significant feature is the part played by the newly introduced third component, i.e. whether it is the central atom or part of a ligand.

The regular features of the influence of the nature of the central atom have also been observed for reduced heteropoly-acids[69]. The reduced heteropoly-compounds are apparently extracted slightly more readily than their unreduced analogues[69,70,72]. In this case an important part is undoubtedly played by the nature of the reducing

TABLE 1. Extraction of molybdophosphoric and molybdoarsenic acids by various solvents[62].

| Solvent | Percentage extraction | |
|---|---|---|
| | P–Mo | As–Mo |
| Ethyl acetoacetate | 100.00 | 96.67 |
| Butanol + chloroform (1 : 4) | 94.97 | 4.74 |
| Ethyl acetate | 79.92 | 29.46 |
| Butyl acetate | 73.58 | 8.49 |
| Isobutanol + benzene (1 : 1) | 72.63 | 36.76 |
| Isobutanol | 67.21 | 86.05 |
| Butanol | 60.63 | 87.91 |
| Octanol | 29.86 | 14.39 |
| Chloroform | 00.00 | 00.00 |
| Benzene | 00.00 | 00.00 |

agent; recent data[128] suggest that organic solvents are extremely sensitive to the slightest changes in the process of heteropoly-compound reduction and to the reduction products.

The extractability of heteropoly-acids (reduced and unreduced) increases sharply when basic substances (for example amines) are introduced into the system[87,74,75], i.e. when conditions are created for the formation and extraction of the salts of the heteropoly-acids with organic bases (sometimes called "addition products"). As noted above, in this case inert solvents of the benzene and chloroform type may act as extractants for heteropoly--compounds.

## 2. Nature of the Solvent–Extractant

According to Alekseev[17], organic solvents can be divided into two groups — light (sp. gr. $< 1$) oxygen-containing solvents (alcohols and ethers), and heavy (sp. gr. $> 1$) solvents containing no oxygen (chloroform and carbon tetrachloride) — according to their behaviour towards heteropoly-compounds. Such compounds dissolve much more readily in solvents of the first group than in water, and are therefore readily extracted by these solvents from aqueous solutions; heteropoly-acids are almost insoluble in solvents of the second group. The extracting power of solvents of the first group decreases when solvents of the second group are added; the decrease is proportional to the quantity of inert solvent added, and is different for different heteropoly-acids.

The results of a large number of studies[17,22,55,60–73,114] show that, for heteropoly-compounds, alcohols are the most effective extractants and ethers the most selective. Of the aliphatic alcohols, the best extracting properties are shown by those containing 4–8 carbon atoms: lower alcohols do not extract heteropoly-compounds quantitatively from aqueous solutions, and higher alcohols from stable emulsions, which are difficult to remove, at the phase boundary.

The addition of a second solvent (usually inert) to the main solvent (usually containing oxygen), in addition to changing the solvent power of the main solvent, sometimes ensures a distinct boundary of separation between the phases, decreases the mutual solubility of the solvents in the extraction system, improves certain operating parameters of the extracting agent, etc. These advantages of mixed solvents are of course not specific for heteropoly--compounds, but are nevertheless of considerable interest for the application of the extraction of heteropoly-compounds in chemical analysis, and they will be examined in more detail below.

## 3. Acidity of the Aqueous Phase

The extraction of heteropoly-compounds is sensitive to change in the acidity of the aqueous phase (Table 2). At low acidities, heteropoly-compounds are extracted only to a slight extent or not at all; their solubility in organic solvents generally increases with increase in the acidity of the aqueous phase. The upper limit of acidity is determined by the stability of the given heteropoly-complex at high acidities, although the optimum range of acidity for extraction does not always overlap the optimum range of acidity for stability of the heteropoly-complex, and is usually wider.

TABLE 2. Influence of acidity on the extraction of molybdoarsenic acid by butanol[129].

| 10 M HCl added, ml | Optical density of extract (400 μg As) at 370 mμm | | |
|---|---|---|---|
| | for test soln. ($D_1$) | for blank soln. ($D_0$) | true ($D_1 - D_0$) |
| 0.25 | 0.735 | 0.401 | 0.334 |
| 0.50 | 0.556 | 0.146 | 0.410 |
| 0.75 | 0.536 | 0.031 | 0.505 |
| 1.00 | 0.559 | 0.027 | 0.532 |
| 1.33 | 0.569 | 0.029 | 0.540 |
| 1.50 | 0.573 | 0.029 | 0.544 |
| 1.67 | 0.574 | 0.032 | 0.542 |
| 2.00 | 0.570 | 0.025 | 0.545 |
| 2.50 | 0.139 | 0.015 | 0.124 |
| 5.00 | 0.031 | 0.011 | 0.020 |

The optimum acidity for the extraction of heteropoly--acids by different solvents varies considerably for the different cases studied: the range corresponds to 0.01–2.0 $N$ with respect to a strong acid in the aqueous phase for molybdophosphoric acid[16,19,58,59,66,67,106,109,117,118,130–133], pH 1.0–1.3 for molybdoarsenic acid[130,134], 0.25–6.0 $N$ for molybdosilicic acid[58,67,74,108,112,114,135], 0.8–3.0 $N$ for molybdogermanic acid[107], 0.4–1.6 $N$ for molybdovanadophosphoric acid[89,90], 0.3–0.8 $N$ for tungstovanadophosphoric acid[95], 0.5–1.0 $N$ for tungstovanadosilicic acid[136], and 3.6–5.4 $N$ for molybdovanadogermanic acid[97].

If it is assumed that the organic solvent extracts the monomeric form of the heteropoly-acid, and that the heteropoly-acid dissociates to form ions only in aqueous solution, it is possible to examine theoretically the dependence of the distribution coefficient for the heteropoly-acid on the hydrogen-ion concentration in the aqueous phase[60].

If we denote the heteropoly-acid by $H_nA$, its dissociation constant by $K_i$, and the distribution constant by $P$, we obtain

$$K_i = \frac{[H^+][H_{n-i}A^{i-}]}{[H_{n-i+1}A^{-i+1}]} \qquad (1)$$

and

$$P = \frac{[H_nA]_{org}}{[H_nA]_{aq}}. \qquad (2)$$

The distribution coefficient is

$$D = \frac{[H_nA]_{org}}{\sum_{i=0}^{n} [H_{n-i}A^{i-}]_{aq}}. \qquad (3)$$

Putting $i = p$ in Eqn. (1) and making use of (2), we find that

$$[H_{n-p}A^{-p}]_{aq} = \frac{1}{P} \times \frac{\prod_{i=1}^{p} K_i}{[H^+]^p_{org}} \times [H_nA]_{org}. \qquad (4)$$

Substitution of (4) in (3) gives finally

$$D = \frac{P}{1 + \sum_{p=1}^{n} \frac{\prod_{i=1}^{p} K_i}{[H^+]^p}}. \qquad (5)$$

When the values of $K_i$ and $P$ are fixed (for a given heteropoly-acid), $D$ is thus a function of $[H^+]$: i.e.

$$\log D = f(pH). \qquad (6)$$

Despite the fact that in the derivation of formula (5) no allowance was made for the influence of ionic strength, the mutual solubility of the solvents, temperatures, polymerisation, and other factors, the observed extraction

behaviour of molybdophosphoric and molybdosilicic acids conforms to the relationships predicted on the basis of this formula[60].

The nature of the acid used has no significant influence on the extraction of molybdophosphoric[117] and molybdoarsenic[137] acids, but in the case of molybdosilicic acid[135] the optimum range of acidity for extraction is different with hydrochloric, nitric, and sulphuric acids. The dependence of the extraction on the nature of the acid is even more marked with ternary heteropoly-acids; for example, tungstovanadophosphoric acid is extracted quantitatively by ethyl methyl ketone from hydrochloric and sulphuric acids, but is incompletely extracted from nitric acid, and is not extracted at all from perchloric acid medium[95].

## 4. Concentration of Compound Being Extracted

In the extraction of heteropoly-acids by organic solvents from relatively dilute aqueous solutions, the distribution coefficient at first increases, and then decreases, with increase in the concentration of the heteropoly-acid in the aqueous phase[119,120]. These observations can be explained on the assumption that the organic solvents extract the undissociated monomeric forms of the heteropoly-acids. The initial increase in the distribution coefficient is apparently due to the gradual suppression of the dissociation of the heteropoly-acid with increase in its concentration in the aqueous phase, and the subsequent decrease in the distribution coefficient is due to the increase in the polymerisation of the acid.

At a comparatively high concentration of heteropoly--acid, e.g. molybdophosphoric acid, in the aqueous phase, the extraction (for instance by diethyl ether) gives a heavy oily liquid (a saturated solution of the heteropoly-acid in ether), which is usually present in a three-layer system in equilibrium with the pure organic solvent (ether) and water (or aqueous mineral acid solution)[6,7,14,15]. The addition of crystalline heteropoly-acid to this three-layer system leads to the gradual disappearance of the liquid ethereal phase; further addition of the solid heteropoly--acid leads to mixing of the aqueous and etherate phases, with the formation of a single liquid phase in equilibrium with the solid heteropoly-acid, which separates in the form of a hydrate with 14 molecules of water[13].

## 5. Presence of Neutral Salts (Electrolytes)

Neutral salts (NaCl, $NaNO_3$, $Na_2SO_4$, etc.) in low concentrations (1–3%) have no significant influence on the extraction of heteropoly-compounds[138]. The distribution coefficients of molybdosilicic and molybdophosphoric acids decrease at moderate concentrations ($< 1$ M) of NaCl[60] or $NaNO_3$.[120]

At high concentrations, neutral salts increase the distribution ratios of heteropoly-acids, apparently as a result of a salting-out effect[119,120]. The salt effect depends on the pH of the aqueous phase[60,139], but is apparently independent of the nature of the heteropoly-acid. This last feature often leads to a levelling of the extraction of different heteropoly-acids in the presence of large quantities of salts; for example, the ratio of the distribution coefficients for molybdophosphoric and molybdosilicic acids (the separation factor) is quite favourable for their separation by butanol in the absence of salts ($10^2 : 10^{-2}$ at pH 2.5), but decreases considerably when neutral salts are added[139].

In a number of cases, the mechanism of the influence of neutral salts on the extraction of heteropoly-compounds is not quite clear. In this connection it may be noted again that, in the extraction of molybdophosphoric acid by ethyl acetate in the presence of NaCl, partial extraction of sodium together with the heteropoly-acid takes place[117]. Since sodium undergoes almost no extraction with molybdate in the absence of phosphate (or with phosphate in the absence of molybdate)[117], this can be regarded as an example of coextraction[140].

Of particular importance in the examination of the extraction of molybdenum heteropoly-compounds is the question of the influence of an excess of molybdate (sodium or ammonium) on the extraction. The results of special studies[60,120] indicate that the extraction of molybdosilicic or molybdophosphoric acid by butanol begins to decrease even at a low concentration ($> 0.1$ M) of molybdate in the aqueous solution. This cannot be attributed entirely to the influence of the presence of molybdate on the acidity of the aqueous phase and hence on the extraction; the influence of molybdate (sodium or ammonium) as a neutral salt evidently plays some part.

## 6. Temperature

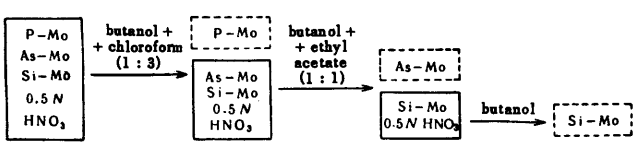
Slight changes in temperature have no appreciable influence on the extraction of heteropoly-compounds[21,60,70,89,141]. In the examination of the influence of temperature, however, allowance must be made for the fact that the equilibria in aqueous solutions of heteropoly-compounds may show a marked dependence on temperature (and on pH). With molybdophosphoric acid, for example, certain authors[142–145] assume that in aqueous solution an equilibrium is established between the colourless and yellow forms of the acid. This equilibrium depends to a marked extent on temperature: at low temperature the colourless form predominates, and at high temperature the yellow form[144,145]. Recent studies have shown that organic solvents (isopentyl acetate) extract only the yellow form of molybdophosphoric acid[146]; thus at low temperatures ($< 9°$) — in the range of stability of colourless molybdophosphoric acid — extraction takes place extremely slowly, whereas at high temperatures ($> 50°$) the extraction is almost instantaneous, as a result of rapid formation of the yellow form.

Analogous equilibria exist in aqueous solutions of other heteropoly-acids. The very interesting equilibrium between the $\alpha$ and $\beta$ forms of molybdosilicic acid, which also depends on temperature[147,148], has unfortunately not been studied from the extraction viewpoint; there are merely reports of the possibility of stabilisation of the $\beta$ form of molybdosilicic acid by extraction with a solution of tridecylamine in toluene[74].

Equilibria are known to be established in the reduction of heteropoly-acids. It may be noted, for the case of molybdosilicic acid, that the different products of the reduction of a given heteropoly-acid are extremely sensitive and specific in their behaviour towards organic solvents[128], Since the equilibrium involving these reduction products is usually markedly temperature-dependent, even slight changes in temperature in this case may lead to marked changes in extraction.

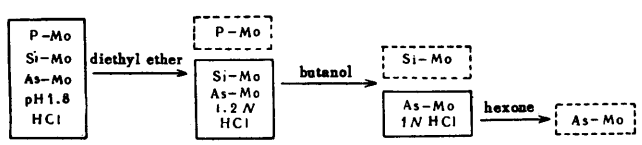
## VI. ANALYTICAL APPLICATION OF THE EXTRACTION OF HETEROPOLY-COMPOUNDS

### 1. Separation of Elements by Extraction



The extraction of heteropoly-compounds by organic solvents provides a valuable method for the separation of mixtures containing phosphorus, arsenic, silicon, and germanium. Such separations are possible in principle for all elements forming heteropoly-compounds.

The separation of elements by extraction as their heteropoly-compounds is based on the creation of conditions for selective behaviour of these compounds towards the organic solvents. This is achieved by changing the acidity of the aqueous phase, by selecting the solvents and combinations of solvents, by using complex-forming reagents, etc. All these cases are well illustrated by three typical examples of the separation of mixtures: scheme *1* for P + As + Si,[17] scheme *2* for P + Si + As,[138] and scheme *3* for P + As + Si + Ge [106] (in these separation schemes the full lines denote aqueous phases, and the broken lines organic phases).



The extraction of molybdophosphoric acid has been used by various workers for the separation of phosphorus from silicon (isobutanol[67,108], diethyl ether[69,138], ethyl acetate[68,130,149,150], butyl acetate[151], isopentyl acetate[68,105], butanol + chloroform[17,58,120], butanol + benzene[60,139], and isobutanol + chloroform[106]), phosphorus from arsenic (pentanol[66,152], diethyl ether[138], ethyl acetate[150], isopentyl acetate[105], butanol + chloroform[17,62,129,137,153,154], isobutanol + chloroform[106], and ethyl acetate + butyl acetate[155]), phosphorus from vanadium (ethyl acetate[117] and ethyl acetate + butyl acetate[155]), phosphorus from calcium and magnesium (butanol + chloroform[156]), molybdophosphate from molybdate (isobutanol + diethyl ether[132]), and molybdophosphate from molybdotitanophosphate (butyl acetate[73,98,99]). Thanks to the ease of extraction of molybdophosphoric acid, it is not difficult to choose an effective and at the same time selective solvent for this compound; from the practical viewpoint, however, it is more convenient in this case to use a mixture of butanol with chloroform or benzene.

The extraction of molybdoarsenic acid has proved suitable for the separation of quinquevalent arsenic from tervalent arsenic (isobutanol[134]), arsenic from silicon (isopentyl acetate + ethanol[105], butanol + ethyl acetate[17], and butanol + ethyl acetate + chloroform[106]), and arsenic from germanium (butanol + ethyl acetate + chloroform[106]); the extraction of molybdosilicic acid for the separation of silicon from arsenic (butanol[138], butanol + chloroform[153], and butanol + ethyl acetate[153]), silicon from phosphorus (isobutanol[67,108]), and molybdosilicate from molybdate (pentanol + diethyl ether[136]); the extraction of molybdogermanic acid for the separation of germanium from arsenic (isopentanol[82,107] and butanol + ethyl acetate[82,107]); the extraction of molybdoniobophosphoric acid for the separation of niobium from titanium and tantalum (butanol[101]); and the extraction of molybdotitanophosphoric acid for the separation of titanium from chromium, copper, nickel, cobalt, manganese, iron, aluminium, lead, tantalum, and hafnium (pentanol + cyclohexanol[73]).

SCHEME *2*

SCHEME *3*

### 2. Extraction–Photometric Determination of Elements

The extraction–photometric method has been used to determine phosphorus, silicon, arsenic, vanadium, and germanium as the reduced or unreduced heteropoly-compounds; it is also possible to determine molybdenum, titanium, cerium, thorium, zirconium, niobium, etc. The chief advantages of the extraction method over other methods are in this case high sensitivity and selectivity and the ease of prevention of interference.

High sensitivity in the extraction–photometric determination of elements as heteropoly-compounds is achieved not only as a result of the usual factors associated with extraction, but also by certain characteristic methods. One such method is the use for the photometric measurements of the decomposition products of the heteropoly--compounds, since these exhibit intense light absorption in the ultraviolet range of the spectrum; the preliminary separation of the heteropoly-compounds from the excess of analytical reagent, identical with the decomposition products, is achieved by extraction. The sensitivity of the determination in this way of, for example, phosphorus[132] and silicon[136] is characterised by molar absorption coefficients of 57 400 and 59 000 respectively.

Direct photometric measurements on the actual heteropoly-compound are avoided also in another original method: after separation of the heteropoly-complex from the excess of reagent by extraction, photometric measurements are made on one of its components, for which sensitive analytical reactions are available. For example, the sensitivity of the determination of phosphorus by photometric determination of the molybdenum from molybdophosphoric acid based on the thiocyanate reaction is characterised by a molar absorption coefficient of 185 000 (calculated as phosphate)[118].

An exceptionally high sensitivity is achieved in the determination of elements by photometric measurements on salts of the corresponding heteropoly-acids with organic bases, which are extractable even by inert solvents of the benzene and chloroform type. Silicon, for example, is

determined with a sensitivity reaching 1 μg litre$^{-1}$ (calculated as $SiO_2$) in the form of the blue polyoxyethyldodecylammonium molybdosilicate, extracted by chloroform[57,75]; the sensitivity of the extraction–photometric determination of phosphorus as the molybdophosphate of safranine[157] is characterised by a molar absorption coefficient of 190 000.

An extremely important feature in the extraction–photometric determination of elements as heteropoly-compounds is the ease of eliminating the interfering influence of an excess of the reagent, e.g. of molybdate when molybdenum heteropoly-acids are used. The non-extractability of unreduced isopolymolybdate under the conditions of the analytical application of heteropoly-compounds is well known and has been convincingly demonstrated in many experiments. Data on the extractability of reduced isopolymolybdate are contradictory, but there is no doubt that by altering the conditions it is possible to achieve complete suppression of the extraction of this form of molybdate also. For well-known reasons, separation from the excess of molybdate helps considerably the attainment of reliable and reproducible results in the determination, since it decreases the size of the blank specimen and opens up new possibilities for increasing the sensitivity of the analysis.

The process of extraction in the photometric determination of elements as heteropoly-compounds has interesting possibilities in connection with the stabilisation of the necessary analytical forms. For example, the main difficulties and errors in the determination of silicon as β-molybdosilicic acid are associated with the instability of this form of molybdosilicic acid in aqueous solution and its gradual conversion into the more stable α form; the extraction of β-molybdosilicic acid by organic solvents contributes appreciably to the solution of this problem, since the β form is stabilised in the organic solvent[74].

In the extraction–photometric determination of phosphorus, n-butanol or isobutanol is most frequently used as solvent. The use of butanol for the extraction of phosphorus as molybdophosphoric acid, with subsequent reduction and photometric determination of the latter in the organic phase, has been used successfully to determine phosphorus in biological materials[19,56,132,158-161], natural waters[21,61,162-167], plant materials[104,141], steels[109,168], aluminium alloys[169,170], vanadium[171], technical products[108], iron ores[168], petrol[172], and artificial mixtures[67]; photometric measurements on a butanol extract of molybdophosphoric acid without preliminary reduction can be used for the determination of phosphorus in biological materials[173].

The use of other alcohols instead of butanol gives no fundamental advantages, although some authors note increased sensitivity in the determination of phosphorus on extraction with isopentanol[174,175] or n-hexanol[176], better separation of the layers when pentanol is used[66], a lower degree of extraction of isopolymolybdate with n-octanol[64] and isopentanol[115], and also the greater availability of isopentyl alcohol[177] compared with butanol.

Extraction properties much better than those of butanol are shown by mixtures of n-butanol with chloroform[17,22,58,110,118,120,154,178-180], isobutanol with chloroform[106,181], and, more particularly, isobutanol with benzene[60,63,133,139,182-186]. This last mixture always has a component ratio of 1 : 1; the composition of the mixtures of butanol with chloroform, used in different cases, varies considerably (from 1 : 1 to 1 : 10), but most authors consider that the optimum butanol : chloroform ratio is ~1 : 3.

Other solvents suitable for the extraction of molybdophosphoric acid in the photometric determination of phosphorus include diethyl ether[55,138,187-197], ethyl acetate[117,130,149], butyl acetate[59,198], isopropyl acetate[199], isopentyl acetate[146,200,201], isobutyl methyl ketone[111], and mixtures of butanol with diethyl ether (1 : 1)[202] and of ethyl acetate with butyl acetate (7 : 3)[203,204].

Butanol is also the solvent most frequently used for the extraction of molybdoarsenic and molybdosilicic acids in the photometric determination of arsenic[129,134,137,153] and silicon[17,58,67,106,108,117,138,179]. The best extractants, however (particularly as regards selectivity), are — for molybdoarsenic acid, isobutyl methyl ketone (hexone)[113,138] and mixtures of butanol with ethyl acetate (1 : 1)[17,107,154,171,179], isopentyl acetate with ethanol (5 : 1)[105], and butanol with ethyl acetate and chloroform (1 : 1 : 4)[106]; and for molybdosilicic acid, n-pentanol[205,206], isopentyl alcohol[135,207], and isobutyl methyl ketone[112].

Butanol[106], isopentyl alcohol[82,107], and a mixture of butanol with ethyl acetate (1 : 1)[82,107] are suitable for the extraction–photometric determination of germanium as molybdogermanic acid.

Extraction of the reduced forms of heteropoly-acids is little used in photometric analysis. The only determinations described are those of phosphorus by extraction as the reduced molybdophosphoric acid (n-butanol[56,208], isobutanol[20,209], isopentanol[115], diethyl ether[16,69,210], isobutyl methyl ketone[211], acetophenone[70], and a mixture of isopentanol with diethyl ether[175]), the determination of arsenic by extraction as reduced molybdoarsenic acid (isopentanol[212-214] and a mixture of isopentanol with diethyl ether[215]), and the determination of silicon by extraction as reduced molybdosilicic acid (isopentanol[207,216]).

The extraction of ternary heteropoly-acids has recently been used successfully for the photometric determination of various elements, Thus for example, the extraction of molybdovanadophosphoric, tungstovanadophosphoric, molybdotitanophosphoric, molybdoniobophosphoric, and molybdovanadogermanic acids has been used for the determination respectively of phosphorus[84,86-93], vanadium[71,94,95], titanium[73,98,99], niobium[101], and germanium[97].

## 3. Other Examples of the Use of the Extraction of Heteropoly-Compounds

The extraction of heteropoly-compounds can be used not only in photometric methods but also in combination with other methods — gravimetric[150], titrimetric[155], spectroscopic[217], and radiometric[62,218,219].

For the determination of comparatively large quantities of phosphorus[12,65,220,221] and arsenic[222], some workers have used a method based on measurement of the volume of the oily layer obtained on extraction of the heteropoly-acid with diethyl ether. The extraction of heteropoly-acids also forms the basis of highly sensitive and selective methods for the detection of phosphate[14,223], arsenate[14,223,224], germanate[224], vanadium[225], and molybdenum[225].

In conclusion, brief mention may be made of other applications of the extraction of heteropoly-acids (other than analytical). The preparative importance of the extraction of heteropoly-compounds is well known: the use of extraction for the preparation of heteropoly-acids has been described in a monograph on heteropoly-compounds[4].

The extraction method is being used successfully to investigate the formation and reduction of heteropoly-complexes [110,128,142,146], and to study their composition [72,96], redox properties [226], etc. [177,189,212,227].

The further study of the extraction behaviour of heteropoly-compounds will undoubtedly facilitate investigation of the structure and nature of the bonding in the molecules of heteropoly-complexes, and will also extend the range of their practical application.

## I. INTRODUCTION

In recent years a large number of papers have been published dealing with the use of amines of high molecular weight as extractants. The extraction of acids with amines and amine salts has attracted the greatest attention[1-40]; the extraction of metal salts by amine salts from hydrochloric-acid[1,17,23,41-84], sulphuric-acid[85-96], and nitric-acid[8,22,97-132] solutions and other media[133-144] has also attracted attention.

High-molecular-weight amines extract acids because, being bases, they are neutralised on contact with aqueous solutions of acids, and the amine salts formed pass into the organic phase.

In the presence of a sufficient excess of acid, the amines are almost completely present as the corresponding salts. Therefore, in the extraction of acids and salts from acid solution, the part of extractant is played in the majority of cases not by the amines themselves, but by their salts.

The relation between the structure of amines and the extractive power of their salts has attracted great attention. The possibility of predicting the extractive properties of amine salts is of great practical importance in the selection of extractants for different purposes. A considerable number of experimental results on the extractive power of amine salts have now been published. The object of the present review is to systematise these results and to interpret them from the point of view of information in the literature on the structure of amine salts. Extraction by amine salts may take place by different mechanism. Therefore, possible mechanisms for the extraction of acids and metal salts by amine salts are first briefly considered.

## II. BRIEF INFORMATION ON THE MECHANISM OF EXTRACTION OF ACIDS AND METAL SALTS BY AMINE SALTS

The extraction of acids by amine salts may proceed with the formation of addition products or by anion-exchange mechanism. The extraction of nitric acid with tri-n-octyl-[3], di-n-octyl-,[4] tri-n-nonyl-,[8] tri-n-decyl-[8], or tri-n-dodecyl-ammonium[129] nitrates is an example of extraction by an addition mechanism; the reaction is of the type†

$$\mathrm{AmineHNO_3}_{org} + \mathrm{H^+}_{aq} + \mathrm{NO_3^-}_{aq} \rightleftharpoons [\mathrm{AmineHNO_3}]\mathrm{HNO_3}_{org}. \quad (1)$$

Examples of the anion-exchange mechanism are provided by the extraction of oxalic acid by tri-n-octylammonium nitrate[6,7]

$$\mathrm{AmineHNO_3}_{org} + \mathrm{HC_2O_4^-}_{aq} \rightleftharpoons \mathrm{AmineH_2C_2O_4}_{org} + \mathrm{NO_3^-}_{aq}, \quad (2)$$

the extraction of nitric acid by an amine perchlorate[106]

$$\mathrm{AmineHClO_4}_{org} + \mathrm{NO_3^-}_{aq} \rightleftharpoons \mathrm{AmineHNO_3}_{org} + \mathrm{ClO_4^-}_{aq}, \quad (3)$$

and the extraction of technetium(VII)[34] by the reaction

$$\mathrm{AmineHNO_3}_{org} + \mathrm{TcO_4^-}_{aq} \rightleftharpoons \mathrm{AmineHTcO_4}_{org} + \mathrm{NO_3^-}_{aq}. \quad (4)$$

Metal salts $MA_m$ are extracted by amine salts AmineHA because compounds are formed that pass into the organic phase; their composition may be expressed by the formula $(\mathrm{AmineHA})_n.MA_m$.[100]‡ The structure of these compounds is more closely represented by the formula $(\mathrm{AmineH})_n[MA_{n+m}]$, since interaction of the molecules of amine with the metal atom is not effected directly but through the system AmineH–A–M, and the absorption spectra indicate the presence of the complex anions $MA_{n+m}^{n-}$ in the molecules of the extracted compounds[97,99,106]. The sum $n+m$ is usually equal to the coordination number of the central atom M.

The formation of the extractable compounds of metal salts may be represented by the addition reaction

$$MA_{m\,aq} + n(\mathrm{AmineHA})_{org} \rightleftharpoons (\mathrm{AmineH})_n[MA_{n+m}]_{org}, \quad (5)$$

by the anion-exchange reaction

$$MA_{n+m\,aq}^{n-} + n(\mathrm{AmineHA})_{org} \rightleftharpoons (\mathrm{AmineH})_n[MA_{n+m}]_{org} + nA_{aq}^-, \quad (6)$$

or by a number of simultaneous addition and anion-exchange reactions

$$MA_{i\,aq}^{(m-i)+} + n(\mathrm{AmineHA})_{org} \rightleftharpoons (\mathrm{AmineH})_n[MA_{n+m}]_{org} + (i-m)A_{aq}^-, \quad (7)$$

where the minimum value of $i$ is 0 and the maximum corresponds to the coordination number of the ion $M^{m+}$.[60,99,100]

Since for reactions (5)–(7), corresponding to different values of $i$, the reaction product is identical but the metal compounds in the aqueous phase are in dynamic equilibrium with one another, the position of the extraction equilibrium for any given composition of the phases does not depend on the reaction by which the compound is formed. For this reason, in spite of the extensive experimental information available on extraction equilibria, there were until recently no convincing arguments in the literature on how to find out by which of the above reactions the extraction of metal salts by amine salts occurs in any individual case.

Investigation of the mechanism of the extraction of uranyl sulphate by an $^{35}S$-labelled amine sulphate showed that, under conditions such that anionic uranyl complexes predominate in the aqueous solution, extraction occurs mainly by an anion-exchange mechanism; but when anionic complexes are not present in solution, extraction by addition reactions predominates[145]. This rule appears to be valid also for the extraction of salts of other metals by amine salts with like anions.

The ability of amine salts to extract acids and metal salts by an addition mechanism depends on the stability of the extractable addition compounds formed by their interaction. The ability of amine salts to extract anions by an anion-exchange mechanism, however, depends on the relation between the stability of the initial amine salt and of the compound formed after anion exchange. If the amine salt is to have the properties of a strong extractant, it is also necessary that this salt and the extracted compound should, as far as possible, be slightly soluble in the aqueous phase, and on extraction should go practically completely into the organic phase. It is usual to employ amine salts with a quite high molecular weight. Compounds of these amines pass practically completely into the organic phase during extraction, and therefore extractive power is largely determined by the stability of the compound extracted.

In this review the main factors connected with the structure of amines that determine the extractive power of their

† The initial amine salt and the addition product may be present in the solutions as polymers[5,19,36-38].

‡ The compound extracted may be solvated by solvent molecules including AmineHA molecules[117].

salts are considered. Since the extractive power of amine salts insoluble in water is determined by the stability of the extractable compounds that they form, the relation between the stability of these compounds and the structure of the amine salts used as extractants will first be considered.

## III. THE EFFECT OF THE STRUCTURE OF AMINE SALTS ON THE STABILITY OF THE COMPOUND EXTRACTED BY DIFFERENT EXTRACTION MECHANISMS

### 1. Extraction of Acids by an Addition Mechanism

A large number of addition products of acids and salts have been described in the literature[146-162]. In 1908 a product of the addition of HCl to tetramethylammonium chloride $(CH_3)_4NCl.HCl$ was isolated[147,148]. There are other reports of the preparation of compounds of this type[149-154]. After these reports, many papers appeared on the formation of acid–salt addition products in solution. It was established that molecules of the acids combine with anions of the salts; on dissociation of the latter this leads to the formation of complex anions of the type $FHF^-$,[155,156] $ClHCl^-$,[157-159] $PiHPi^-$ [160] (Pi = picrate ion), and $HSO_4^-.H_2SO_4$.[161,162] Van Looy and Hammett found that the sulphates of some amines, dissolved in nitromethane, can add on molecules of sulphuric acid with the formation of compounds $(AmineH_2SO_4).2H_2SO_4$, in which these molecules are linked by hydrogen bonds to oxygen atoms of the anions[146]. Frolov and Sergievskii have reported the probable formation of an addition product of sulphuric acid with an amine hydrogen sulphate, $(TOA.H_2SO_4)H_2SO_4$ [163] [TOA = = tri-n-octylamine (Ed. of Translation)]. Recently the addition of hydrohalic acids to anions of halide salts has been studied in detail by McDaniel and Vallee[164], Harmon and Gebauer[165], and Lipovskii and Nikitina[166], who show that the addition of acid molecules to salt anions is due to the formation between them of hydrogen bonds involving the protons of the acid.

It is to be expected that the stability of the hydrogen bond between a given acid and a salt anion will increase with increasing electron-donor properties (basicity) of the atoms forming the anion[167]. Obviously, the electron-donor properties of each anion increase with the displacement of the negative charge of the salt towards this anion, i.e. with the polarity of the salt of which the anion forms part. McDaniel and Vallee[164] determined the free energies and heats of formation of the addition products of HCl, HBr, and HI with corresponding halide salts of the type $R_4NHal$(R = alkyl) of different polarity. The results show, as would be expected, that more polar salts form more stable addition products with acids. For example, the value of $-\Delta H$ for the compound of HCl with the least polar of the salts $(CH_3)_4NCl$ was 11.3 kcal mole$^{-1}$, for the more polar $(C_2H_5)_4NCl$ the value was 13.7, and for the still more polar $(C_4H_9)_4NCl$ it was 14.2 kcal mole$^{-1}$.

From the data presented it would be expected that, in the extraction of acids by amine salts by the addition mechanism, the stability of the extracted compounds (AmineHA)HA will also increase when amines whose salts are more polar are used; and, therefore, in a series of salts of different amines with the same anions, greater extractive power will be shown by salts of more polar structure.

### 2. Extraction of Metal Salts by an Addition Mechanism

The extraction of metal salts by an addition mechanism is due to the formation of complex compounds of the type $(AmineH)_n[MA_{n+m}]$ when an amine salt AmineHA interacts according to Eqn. (7) with various molecules or ions $MA_i^{(m-i)+}$ $(i \leq m)$ present in aqueous solution. In reactions of this type, of which reaction (5) is a particular case, a necessary condition for the formation of the compound to be extracted is the addition to the central atom M of the $M^{(m-i)+}$ group of supplementary anions $A^-$ of the amine salt in quantity sufficient to form the complex anion $MA_{n+m}^{n-}$. The addition of anions of the amine salt to the given central atom M with the formation of a coordinate bond will occur more readily the higher the electron-donor power (basicity) of these anions. As has been noted, the basicity of the anion increases with increasing polarity of the amine salt containing the anion. It could therefore be expected that, as in the extraction of acids, the stability of the extracted compounds of metal salts with amine salts should increase, in a series of salts having the same anion, in the sequence of salts of increasingly polar structure.

After formation of the complex being extracted, the substituted ammonium cation that has entered into the composition of the amine salt occurs in the external coordination sphere. Outer-sphere cations may have considerable influence on the stability of the complex anions linked with them and of the compound as a whole[168-173]. Recently, Sinitsyn and Zvyagintsev made a detailed study of the effect of the properties of outer-sphere cations on the stability of the complex anions linked to them[174]; as an example they used compounds of the type $K_2[RuCl_5NO]$, where K is a singly charged cation. They showed that the stability of the bond to Cl ions in the complex anion increases in the order $Na^+ < K^+ < NH_4^+ < Rb^+ < Cs^+$. For the compounds $(AmineH)_2[RuCl_5NO]$ the effect of the outer-sphere cations increases in the order: primary amine < secondary amine < tertiary amine. Sinitsyn and Zvyagintsev note that an increase in the stability of the Ru–Cl bonds occurs because of a redistribution of electron density in the compounds and particularly because of a displacement of electron density along the line $K \ldots Cl \rightarrow Ru$ in the direction of the Ru atom. Obviously, the more polar the K–Cl bond, the greater will be the displacement towards the Ru atom. This kind of bond may also be expected for compounds of those amines, the salts of which $AmineH^+Cl^-$ are also more polar.

It follows from the foregoing that in a series of amine salts with the same anions, salts of a more polar structure should have a greater extractive power for metal salts by an addition mechanism, as in the extraction of acids.

### 3. Extraction by an Anion-Exchange Mechanism

In extraction by an anion-exchange mechanism, represented by Eqns. (2)–(4) and (6), "ready made" and mostly stable anions take part in the reactions, and the effect of outer-sphere substituted ammonium cations on the stability of the complex anions that form the compounds extracted usually has no material effect on the stability of these compounds. In this case, the stability of the extracted compound is mainly determined by the stability of the bond between the cation and the anion. Factors affecting the stability of such bonds have been widely described[175-185]; they include ionisation potentials, electron affinity and

charge of cation and anion, the sizes of cation and anion, their polarisability, and the energy of interaction with the surrounding medium. The extraction equilibrium depends on the relation between the stability of the initial amine salt and that of the salt formed by exchange of anions.

A special feature of extraction by the anion-exchange mechanism is that the stability of the initial amine salt and that of the amine salt formed after extraction are connected with the properties not only of the cation but also of the anion. In this case, when the two exchanging anions have similar properties, a change in the structure of the amine can affect to the same degree the stability of the salts formed by both anions, and therefore will not materially affect the extraction equilibrium.

A considerable influence of the structure of the amine on the anion-exchange equilibrium may be observed when the stability of the salts of different anions undergoing exchange changes in a different way when the structure of the amine changes. Such different behaviour of anions may be observed in the presence of specific factors affecting the structure and stability of the salts, including steric factors, differences in the power of anions to form hydrogen bonds with different cations, etc. These factors are described in greater detail in the following Section, on the dependence of the structure of amine salts on the nature of the amines. Also, since the polarity of amine salts has a great effect on extraction by an addition mechanism, we shall first consider structural factors of amines that determine the polarity of their salts.

## IV. PRINCIPAL STRUCTURAL FACTORS OF AMINES DETERMINING THE STRUCTURE OF THEIR SALTS

The interaction of amine salts with acids leading to the formation of salts is connected with the presence on the nitrogen atom of an unshared pair of electrons capable of forming a coordinate bond with electron-acceptor atoms and ions[189-191]. A coordinate bond of the nitrogen atom with positive hydrogen ions, which are strong acceptors of a pair of electrons, is particularly easily formed. This explains the basic properties of amines and their ability to form compounds with acids.

The structure of compounds formed by amines with acids depends on the properties of the acid, the base, and the medium in which interaction occurs[192-199]. The structure of amine salts has been studied by many workers in the field of acid–base theory and also by those studying the electrical conductivity of non-aqueous solutions. When sufficiently strong acids and bases (amines) interact, there is complete transfer of a proton from the acid to the base and salts with a polar structure $AmineH^+ \ldots A^-$ are formed[194,198-204]. When the amine is a weak base, i.e. has only a slight tendency to add on protons, or if the acid is relatively weak, i.e. liberates a hydrogen ion with difficulty, interaction between them to form an addition product may involve merely the formation of a hydrogen bond between the amine nitrogen atom and the acid, without transfer of the proton from the acid to the nitrogen atom. The structure of such a product may be schematically represented by the formula Amine ... HA. It has been shown by infrared spectroscopy, by conductivity and dielectric constant measurements, and also by measurements of refraction and dipole moments that e.g. the following compounds have such a structure — tribenzylamine with picric acid[205,206], pyridine with acetic acid[207], aniline with phenol[208], aniline and *p*-nitroaniline with acetic and formic acids[209], hexamethylenetetramine with phenol[199], and ethylamine with *m*-nitrophenol, *p*-nitrophenol, pentachlorophenol, and 2-bromo-5-nitrophenol[210].

When the strength of the base or the acid is increased, a more stable bond is formed between the proton of the acid and the amine nitrogen atom, the link with the anion of the acid is weakened[194,209,211], and the polarity of the salts formed increases. For example, the dipole moments of compounds of pyridine with acetic, chloroacetic, and trichloroacetic acids are respectively 2.98, 4.67, and 7.78 D: i.e. the polarity of these compounds increases appreciably with the strength of the acid[198]. In contrast to the weak acetic acid, hydrochloric acid forms a polar salt with *p*-nitroaniline involving complete transfer of the proton of the acid to the nitrogen atom of the amine[209]. In contrast to the very weak acid *m*-nitrophenol, the stronger acids 2,4-, 2,5-, and 2,6-dinitrophenols form ion-pairs with triethylamine; these contain the $O^- \ldots HN^+$ bond. The weaker base pyridine forms compounds with these phenols without the transfer of a proton to the nitrogen atom[210]. The polarity of the compound of a relatively strong base, tri-n-butylamine, with a strong acid, $HClO_4$, is much higher than the polarity of the compound of a weak base, aniline, with the relatively weak picric acid[192,208]. Detailed information on the effect of the strength of acids and bases on the polarity of the salts formed is given in Shatenshtein's book[194].

In many cases in which the acid proton is transferred to the amine nitrogen atom, the bond between the cation and the anion does not remain purely ionic, and in addition to electrostatic interaction between them, non-coulombic forces may also play a part. For example, in many alkyl- and aryl-ammonium halides the substituted ammonium ions are linked to the anions not only by ionic bonds but also by hydrogen bonds[212-219]. Sato, who studied the infrared spectra of tri-n-octylammonium nitrate $R_3NH^+ \ldots NO_3^-$ in different solvents, found that the frequency of the $N^+-H$ stretching vibrations was strongly displaced towards the long-wave side[32]; he explains this by the presence of a strong hydrogen bond between the cation and the anion of the amine salt.

Hydrogen bonds of substituted ammonium cations are most easily formed with anions of weak acids; they are formed with far greater difficulty with the anions of strong acids[216,217]. The possibility of the formation of a hydrogen bond by a substituted ammonium cation and an anion in compounds of amines with complex salts is greatly reduced, since the negative charges are displaced from the peripheral atoms of the complex anions towards the central atom of the latter[216-219]. Nevertheless, the existence of intramolecular hydrogen bonds has been noted in salts of some complex acids, for example $(R_3NH)[UO_2(NO_3)_3]$ and $(R_3(NH)_2[PuO_2Cl_4]$, and in compounds containing other complex anions of the actinide elements[220-227].

The relation between the dipole moments of salts and the structure of the amines forming them has not been systematically investigated. A considerably greater amount of systematic information has accumulated on the study of the relation between the basicity of amines and their structure[188]. Since it has been established that the polarity of amine salts increases with their basicity, data on the basicity of amines may be used within certain limits to predict how the polarity of amine salts will depend on their structure. However, the basicity of an amine determined in some solvent is not a universal quantitative characteristic of the ability of the amine to form polar

salts with acids under any conditions; for the basicity depends on the nature of the solvent, and the order of basicity of amines of different structure may change with change of solvent[193-196]. It is therefore more rational to consider (using quantitative data obtained in the determination of the basicity of amines of different structure) factors connected with the structure of amines that directly influence the structure (polarity) of their salts. The most important of these factors are the electron-donor power of amines, the formation of intramolecular hydrogen bonds in the amine salt molecules, the solvation of amine salt cations and anions by molecules of solvent, steric factors, and the effect of "inert" non-solvating solvents.

## 1. Electron-Donor Power of Amines

From the point of view of electronic theory, the power of amine molecules to coordinate protons and form polar compounds with acids depends on the mobility of the unshared electron pair on the nitrogen atom[176,177,186-189].

The greater the displacement of electron density in the amine molecule towards the nitrogen atom, the greater will be the mobility of the electron pair of the nitrogen atom capable of forming a donor–acceptor bond. The shift in electron density towards the nitrogen atom depends on the inductive effects of the radicals attached to this atom. Aliphatic radicals have a positive inductive effect, or a greater power of repelling electrons compared with the hydrogen atom. For this reason, the mobility of electrons of the nitrogen atom is greater in alkylamines than in ammonia.

When the number of identical substituents on the nitrogen atom increases, their total inductive effect increases. For the aliphatic amines this leads to an increase in the electron-donor properties of nitrogen in the order — primary < secondary < tertiary amines — which corresponds to a decrease in the ionisation potentials of the amines in this order. Values of the ionisation potentials, which indicate the mobility of the unshared pair of electrons on the nitrogen atom, determined[228,229] for some alkylamines, show (Table 1) that, when the number of alkyl substituents or their length is increased, the ionisation potentials are reduced.

Because of the negative inductive effect of the aryl radicals in aromatic amines, the electron density is displaced from the nitrogen atom in the direction of these radicals, and the unshared pair of electrons on the nitrogen atom is less mobile than in ammonia[215]. The general inductive effect of the substituents in aromatic amines also increases in the order — primary < secondary < tertiary — which reduces the electron-donor power of the nitrogen atom (and the ability of the amines to form polar salts) in the same order.

As mentioned above, the power of amines to form polar salts parallels their power of adding protons (their basicity). Much has been published on the determination of basicity, which confirms how substituents on the nitrogen atom affect the electron-donor power of the amines and their ability to form polar compounds with acids[188]. For aqueous solutions the basicity is expressed quantitatively by the basicity constant

$$K_b = \frac{[\text{AmineH}^+][\text{OH}^-]}{[\text{Amine}]}. \quad (8)$$

For organic systems in aprotic solvents the basicity constant directly characterises the power of the amine to form a polar salt on reaction with an acid. For such solutions this value is given by the formula

$$K_b = \frac{[\text{AmineH}^+ \ldots \text{A}^-]}{[\text{Amine}][\text{HA}]}. \quad (9)$$

The quantities necessary for the calculation of $K_b$ in aqueous solution are mainly determined by means of indicators or by potentiometric and other methods connected with the measurement of hydrogen-ion concentration[232]. The degree of conversion of HA to $A^-$, necessary for the determination of $K_b$ in aprotic solvents, is usually determined spectrophotometrically[210].

The basicity constants of some alkylamines determined in water are given in Table 2. In aqueous solutions, because of the effect of other factors besides electron-donor power of amines (mainly solvation of cations), the expected dependence of $K_b$ on the number of substituents is not observed throughout the series of alkylamines with different substituents. However, Table 2 shows that the basicity of all alkylamines is greater than that of ammonia. The basicity of primary and secondary amines changes little as the length of the alkyl chain is increased; in the tertiary amine series there is a tendency for the basicity to increase as the alkyl chain in lengthened. The basicity constants of the dialkylanilines increase with the length of the alkyl chain. For example, the value for dimethylaniline is $4.5 \times 10^{-10}$, and that for diethylaniline $165 \times 10^{-10}$.[234] The basicity of aromatic amines is lower than that of ammonia, and decreases as the number of aromatic substituents increases. The basicity constant of aniline in water is $3.8 \times 10^{-10}$; that of diphenylamine is $7.6 \times 10^{-14}$.[234]

In aprotic organic solvents, in contrast to aqueous solution because of the relatively weak solvation effect the basicity of amines is in many cases determined by the electron-donor power of the nitrogen atom alone, and the order of basicity expected from the inductive effects of

the substituents is fully observed. It has been shown that in chlorobenzene the strength of amines varies in the order tributylamine > dibutylamine > monobutylamine[210,235,236]. The same order has been established for the ethylamines[237,238], methylamines[238,239], octylamines[46], decylamines[46], and some other amines. Pearson and Vogelsong, who have studied the relation between basicity and structure in the greatest detail, showed that in chlorobenzene and dichloroethane the basicities of tributyl-, triethyl-, and trimethyl-amines are higher than those of the corresponding secondary amines[240]. It has also been shown that the introduction into aromatic amines of substituents with a positive inductive effect, for example alkyl groups, also leads to an increase in basicity[219,241]. Because inductive effects of substituents in amines often have a definite influence on the polarity of salts of these amines, Hall was able to establish a quantitative relationship between the basicity constants $K_b$ and Taft's constants, which characterise the inductive effects[242,243]. Taft proposed the use of a number of parameters (induction constants) $\sigma^*$ which characterise the inductive effects of various substituents attached to a reactant atom or group, and showed that for a number of reactions the following relationship holds§

$$\log k/k_0 = \rho^*\sigma^*, \qquad (11)$$

where $k$ is the equilibrium constant for the substituted compound, $k_0$ is the constant for the reference compound, and $\rho^*$ represents coefficients constant for each type of reaction[244-250].

Hall[242,243] and also Hansson[251] have shown that this equation is applicable to the calculation of the basicity constants of amines. Logarithms of the basicity constants of 46 primary, secondary, and tertiary amines investigated by Hall (except for amines with considerable steric hindrance round the nitrogen atom) depend linearly on $\Sigma\sigma^*$, i.e. the sum of Taft's induction constants for all the substituents attached to the nitrogen atom. A number of other primary, secondary, and tertiary amines show an analogous linear dependence[242,252,253].

Therefore, the order of the basicity of amines of different structure has been confirmed in a great number of cases by consideration of the influence of the inductive effects of substituents on the mobility of the unshared electron pair of the amine nitrogen atom¶. Therefore values of $\sigma^*$, which characterise these inductive effects, may be used to estimate the probable polarity of salts formed by amines of different structure. Values of $\sigma^*$ for some substituents are given in Table 3.

The use of Taft's induction constants to calculate the effect of bulky substituents, e.g. long alkyl chains, is limited by steric effects; apparently they are most successfully applied to evaluate the polarity of primary alkylamine salts.

TABLE 3. Values of Taft's induction constants $\sigma^*$ for some substituents[250,251,255].

| Substituent | $\sigma^*$ | Substituent | $\sigma^*$ |
|---|---|---|---|
| $NO_2$ | +5.3 | $O_2N(CH_2)_2$ | +0.50 |
| $Cl_3C$ | +2.65 | H | +0.430 |

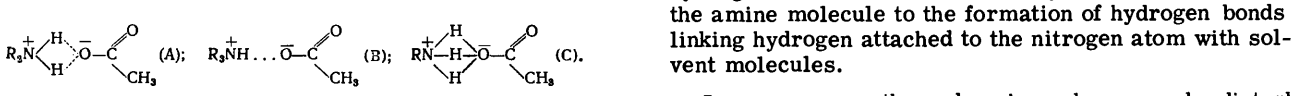
The effect of nuclear substituents in aromatic amines is determined by Eqn. (11) with the aid of Hammett's $\sigma$ constants[254-257], which are less sensitive to steric hindrance if the substituent is in the *para*- or *meta*- position. Values of $\sigma$ for some substituents are given in Table 4. Values of $\rho^*$ for calculating the basicity constants from Eqn. (11) are negative. It may therefore be concluded from the data in Table 3 that all amines in which there are substituents on the nitrogen atom with positive values of $\sigma^*$, exceeding the value of $\sigma^*$ for H, must have a lower electron-donor power (basicity) than ammonia. These amines are less likely to form polar salts with acids. It cannot therefore be expected that salts of amines containing these substituents ($Cl_3C$, $CH_3COO$, $CH_3CO$, $CNCH_2$, $C_6H_5$, etc.) would form stable extraction compounds with acids and metal salts where extraction is by an addition mechanism. Replacement of hydrogen atoms in ammonia by substituents with a value of $\sigma^*$ less than 0.430 should lead to increased electron-donor power and to increased basicity. Values of $\sigma^*$ for substituents having negative inductive effects decrease considerably when a $CH_2$ group comes between them and the nitrogen atom. It follows from the data in Table 3 that the polarity of salts should increase in the order $C_6H_5NH_2 < C_6H_5CH_2NH_2 < C_6H_5[CH_2]_3NH_2$; the polarity of salts of this last amine and the stability of the compounds extracted should be comparable with the stability and polarity of alkylamine salts. It also follows from the data in Table 3

§ A similar relationship

$$\log k/k_0 = \rho\sigma \qquad (10)$$

was previously proposed by Hammett for calculating the effect of substituents in aromatic rings on the reaction constants of different functional groups attached to these rings[254].

¶ In a later paper Mead also established quantitative relationships between the heats of neutralisation of some amines with trichloroacetic acid in benzene and Taft's parameters[258]. Recently Kuča, with the aid of induction constants $\sigma^*$, has established a quantitative relationship between the extractive power of a large number of organophosphorus compounds and their structure[259].



that the polarity of salts and the stability of the extracted compounds of alkylamines should increase with increase in length, number, and degree of branching of alkyl chains linked to the nitrogen atom.

The data in Table 4 show that introduction into the benzene and other aromatic groups of aromatic amines, of such substituents as Cl, $NO_2$, NO, and COOH should lead to a decrease in the electron-donor power (basicity) of the amines and to a reduction in the polarity of their salts. When such substituents as OH, alkoxy-groups, or alkyl groups are introduced into the *para*-position, the basicity of the aromatic amines should increase. Therefore, the polarity of their salts and the stability of compounds extracted by an addition mechanism should also increase.

The data in Tables 3 and 4 may be used for a preliminary evaluation of the probable changes in polarity and extractive power of amine salts when some substituents are replaced by others. However, the electron-donor power of amines is not the only factor that determines the structure of their salts. A number of other factors, considered below, must also be taken into account.

## 2. Intramolecular Hydrogen Bonding

The formation of intramolecular hydrogen bonds in amine salts may have a material effect on the structure of these salts. As has been mentioned above, the anions of weak acids show a tendency to form hydrogen bonds with the hydrogen atoms of substituted ammonium cations. The number of possible intramolecular hydrogen bonds increases with the number of hydrogen atoms attached to the nitrogen atom, the number being greater in primary amines than in secondary, and greater in secondary than in tertiary amines. Barrow and Yerger showed that in chloroform the stability constants of compounds of acetic acid with dibutylamine and diethylamine are higher than with the corresponding tertiary amines[260,261]. They explained this by an increase in the number of intramolecular hydrogen bonds in the compound of the secondary amine (A) in comparison with the compound of the tertiary amine (B). According to these authors, three intramolecular hydrogen bonds are formed in compounds of the primary amine (C):[261]

The presence of hydrogen bonds in these compounds has been confirmed by infrared spectroscopy[261]. Davis[262,263] noted that in solvents that do not solvate cations the absorption spectra of acid indicators change differently in reactions with primary, secondary, and tertiary amines. He explained these differences also by the formation of different numbers of intramolecular hydrogen bonds. Ryan, having compared the absorption spectra of the compounds $Cs_2[UO_2Cl_4]$, $[(C_4H_9)_4N]_2[UO_2Cl_4]$, and $[(C_4H_9)_3NH_2][UO_2Cl_4]$, established that the spectrum of the last compound differs from the spectra of the first two[220,221]; this can also be explained by the presence of an hydrogen bond between the cation $R_3NH^+$ and the anion $[UO_2Cl_4]^{2-}$. Similar spectral differences were observed in compounds of secondary amines $[(C_2H_5)_2NH_2]_2[UO_2Cl_4]$, the differences being more marked in these. According to Ryan's results, the melting points of salts of secondary amines with $[UO_2Cl_4]^{2-}$ are much lower than those of salts of the corresponding tertiary amines; in the author's opinion this also indicates the greater part played by non-coulombic forces in the bond between the anion and the secondary alkylammonium cations. A hydrogen bond is also assumed to be present in compounds of primary amines $[RNH_3]_2[UO_2Cl_4]$.[220] Similar effects, indicating the formation of internal hydrogen bonds, have also been noted in analogous chloride compounds of uranium(IV).[221] Vdovenko, Lipovskii, and coworkers have demonstrated the presence of intramolecular hydrogen bonds in a number of salts of long-chain alkylamines[166,225-227].

The formation of intramolecular hydrogen bonds promotes the approach of the anion and the cation, and therefore the polarity of the amine salt is reduced; this leads to a reduction in the dissociation constants of the amine salts in polar organic solvents and to a decrease in the electrical conductivity of solutions of these salts. According to Kraus[192] the conductivity constants of tetra-, tri-, di-, and mono-butylammonium picrates in nitrobenzene are $>2 \times 10^{-1}$, $1.9 \times 10^{-4}$, and $1.6 \times 10^{-4}$ respectively; the distances between the centres of gravity of the positive and negative charges in these salts of picric acid are: tetrabutylammonium salt (intramolecular hydrogen bond) about 6.29 Å, tributylammonium salt (one hydrogen bond) 1.02 Å, dibutylammonium salt (two hydrogen bonds) 0.977 Å, and monobutylammonium salt (three hydrogen bonds) 0.992 Å. Differences in the polarity of salts of secondary and tertiary amines, due to the greater power of secondary amines of forming intramolecular hydrogen bonds with anions, have also been noted by other workers[211,212].

It follows from the foregoing that the formation of intramolecular hydrogen bonds, just like changes in the electron-donor power, leads (in the absence of other forces affecting the structure of amine salts, considered below) to the polarity of the alkylamine salts varying in the order: tertiary > secondary > primary.

The most favourable conditions for the formation of hydrogen bonds between cation and anion occur when the molecules of solvent do not form hydrogen bonds with hydrogen atoms of substituted ammonium cations. Intramolecular hydrogen bonds are therefore usually observed in such solvents as carbon tetrachloride, chloroform, benzene, xylene, etc. The formation of intramolecular hydrogen bonds is also favoured by steric hindrance in the amine molecule to the formation of hydrogen bonds linking hydrogen attached to the nitrogen atom with solvent molecules.

In some cases, the order given above may be disturbed by solvation of the cation and the effect of steric factors.

## 3. Solvation of Cations of Amine Salts by Solvent Molecules

An example of the effect of solvation of a substituted ammonium cation on the basicity of amines and the polarity of their salts is provided by the disturbance in aqueous solutions of the order of their basicity to be expected from the electron-donor power of the amines. Data in Table 2 show that in aqueous solutions secondary amines have a higher basicity than the corresponding tertiary amines, although tertiary amines have the higher electron-donor power. This deviation is explained in the following way. According to Izmailov's theory[197] ionisation of molecules of acids or bases takes place because of interaction with molecules of bases or acids

respectively, or because of interaction with solvent molecules. Ionisation of an amine in water may be represented by the equations

$$\text{Amine} + \text{aq.} \rightleftharpoons \text{Amine.aq.}, \quad (12)$$

$$\text{Amine.aq.} \rightleftharpoons \text{AmineH}^+\text{.aq.} + \text{OH}^- \quad (13)$$

$$\text{Amine} + \text{aq.} \rightleftharpoons \text{AmineH}^+\text{.aq.} + \text{OH}^- \quad (14)$$

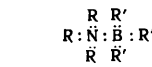
From these equations it follows that the total energetic effect of the ionisation reaction and the equilibrium constant $K_b$ that characterises it are determined, not only by the mobility of the free electron pair of the amine nitrogen atom, but also by the differences in the solvation (hydration) energies of the amine molecules and the corresponding substituted ammonium ions. The higher basicity of secondary and primary alkylamines in comparison with tertiary amines in aqueous solution is explained by the fact that the hydration energy of mono- and di-alkylammonium ions is considerably higher than that of the corresponding trialkylammonium ions[238]. At the same time, the heats of hydration of the unionised amines are considerably lower than those of the ions, and have no material effect on the energy balance of the ionisation reaction. The heats of hydration of ammonium ions are as high as 85 kcal mole$^{-1}$, but the heats of hydration of unionised amines do not exceed 10–11 kcal mole$^{-1}$.[238,264,265]

The increased solvation of incompletely substituted ammonium ions was established by a number of workers as early as the 1920s;[266-268] it is due to the presence in these ions of a greater number of hydrogen atoms linked directly to the nitrogen atom than in completely substituted alkylammonium ions, these hydrogen atoms being capable of forming hydrogen bonds with water molecules. It is assumed that the hydrated ions of primary, secondary, and tertiary amines in water have respectively the structures $RN(H_3O)_3^+$, $R_2N(H_3O)_2^+$, and $R_3N(H_3O)^+$.[238]

The higher solvation of mono- and di-substituted ammonium ions compared with the corresponding trialkylammonium ions makes the ionisation of hydrates of primary and secondary amines energetically more favoured than the ionisation of tertiary hydrates[268]. This rule is followed in aqueous solutions not only by amines having hydrocarbon substituents but also by other aliphatic amines, for example the derivatives of hydroxylamine $NH_2OH$, $NH(CH_3)OH$, and $N(CH_3)_2OH$, and also by the compounds $NH_2OCH_3$, $NH(CH_3)OCH_3$, and $N(CH_3)_2OCH_3$.[269]

In both organic and aqueous solvents, aliphatic amines show a number of deviations from the order to be expected on the basis of electronic interpretations, for the basicity of amines of different structure[244,270]. According to a number of authors, primary and secondary amines are the strongest in several organic solvents as well as in water. Izmailov and Mozharova showed that disturbances of the normal order of amine basicity occur in organic solvents that strongly solvate substituted ammonium cations, for example in alcohols; this can be explained, as for aqueous solutions, by solvation effects[270]. It has also been shown[240] that the addition of alcohols and other diluents capable of forming bonds with hydrogen atoms attached to amine nitrogen atoms has a great effect on basicity constants of amines in aprotic solvents, whereas the addition of alcohols has practically no effect on the basicity or the polarity of salts of tertiary amines, with no free hydrogen directly linked to nitrogen; the strongest effect is obtained with primary amines, which have two such atoms in the molecule. For example, the basicity constant of the tertiary amine $(C_2H_5)_3N$, which is 2680 in chloroform, does not change on the addition of 4–5 mole % of ethanol[240]; the basicity constant of the corresponding secondary amine increases from 1230 to 12 700 (approximately tenfold) when the same amount of alcohol is added to the solution, and the corresponding change in basicity of the primary amine is from 35 to 5830 (~150 times).

Bayles and Taylor have given detailed data (including values of $\Delta G^\circ$, $\Delta H^\circ$, and $\Delta S^\circ$) for the acid–base interaction of amines of different structure in different diluents[271]. As a rule, in pure alcohols the strongest bases are the primary amines, followed by the secondary and tertiary amines.



A change in the expected basicity sequence of amines occurs also because solvation of the cation prevents formation of intramolecular hydrogen bonds. In such solvents as ethyl acetate or alcohol, the oxygen atoms may form hydrogen bonds with the alkylammonium cations. The participation of hydrogen atoms linked to nitrogen in the formation of hydrogen bonds prevents the formation of hydrogen bonds between the cation and the anion. As mentioned above, the absorption spectra of some anions of substituted ammonium salts in benzene changed according to whether tertiary or primary amines were used; this was explained by the different power of the primary amines to form intramolecular hydrogen bonds. In water, however, the absorption spectra of these anions show little difference[262,263]: the hydrogen atoms which would have formed bonds with the anions now form bonds with solvent molecules. Thus, solvation of the substituted ammonium cation leads to an increase in the polarity of amine salts also by eliminating intramolecular hydrogen bonds.

Because of stronger solvation of the cations, the salts of primary amines may be more polar than the salts of secondary and tertiary amines. It is therefore to be expected that, in solvents capable of solvating ammonium cations, the compounds of primary and secondary amines extracted by an addition mechanism will be more stable than the corresponding compounds of tertiary amines. The greatest power of forming bonds with amine hydrogen atoms, and therefore of solvating cations of amine salts, is possessed by molecules of compounds that are electron donors — oxygen-containing organic solvents (alcohols, ethers, esters, ketones, phosphine oxides, alkylphosphonates, etc.)[272-275] and also organic bases (amines, nitriles of organic acids[276-280], dioxan, nitrobenzene[281], etc.).

The solvation of anions in amine salts may take place in solvents the molecules of which have electron-acceptor properties, such as alcohols and carboxylic acids, or in compounds of the chloroform type. Solvation of the anion, like that of the cation, may well lead to some increase in the polarity of the salt. But, since the molecules of extracted compounds attach themselves to the anion, solvation of the anion hinders the formation of compounds to be extracted by an addition mechanism. Solvation of the anions by alcohol molecules[282-284] appears to be the cause of the reduction in the extractive power of amine salts observed when alcohols are added to solutions of these extractants[54,129]. Similar solvation is probably also the main cause of the reduction of partition coefficients when chloroform is added to solutions of amine salts[123,285].

4. Steric Factors

Steric factors also affect the basicity of amines and the polarity of their salts. The effect of these factors on the formation of addition products with amines by acidlike compounds (in Shatenshtein's terminology[193,194]) has been studied in greatest detail. The interaction of amines of different structure with acidlike compounds of the type $BR'_3$ – $B(CH_3)_3$, $B(C_2H_5)_3$, etc. – which are strong electron acceptors, has been studied in detail by Brown and his coworkers[286-294]. The structure of the compounds of $BR'_3$ with $NR_3$ may be represented by the formula

To form a coordinate bond in this compound, the molecules of the two compounds must approach each other sufficiently closely; because of the relatively large volume of the $BR'_3$ molecules, steric factors begin to play an important part. The ability of methylamines to combine with $B(CH_3)_3$ varies in the order $NH_3 < CH_3NH_2 < (CH_3)_2NH \gg \gg (CH_3)_3N$. In this case the tertiary amine is the least basic because of steric hindrance due to the presence of three methyl groups on the nitrogen atom. The order of the strength of the other methylamines is that to be expected from the inductive effects of the substituents. The following order of basicity holds for the interaction of $B(CH_3)_3$ with ethylamines, which have more bulky alkyl groups: $NH_3 < C_2H_5NH_2 > (C_2H_5)_2NH \gg (C_2H_5)_3N$. When the volume of the molecule of acidlike compound increases (as with tributylboron), steric hindrance increases still further, and the stability of compounds of different amines varies in the order: $NH_3 < CH_3NH_2 > (CH_3)_2NH \gg (CH_3)_3N$; $NH_3 > C_2H_5NH_2 \gg (C_2H_5)_2NH > (C_2H_5)_3N$. Thus, when ethylamines react with tributylboron, the order of basicity of the amines is, because of steric hindrance, opposite to that to be expected from the inductive effects of the alkyl groups. The ability of tertiary alkylamines to form addition products with methanol decreases as the alkyl chain is lengthened[20], although the electron-donor power of the amines increases. Other examples of the effect of steric hindrance on basicity include the reducted reactivity with $B(CH_3)_3$ of 2-methylpyridine compared with pyridine itself (Brown and Taylor[286]), the diminished stability of the compound of $SO_3$ with triethylamine compared with the trimethylamine compound[295,296], and of the compounds of $SO_3$ with *o*-substituted compared with *p*-substituted aromatic amines[297], and the decreased stability of iodine complexes with aromatic amines when substituents are introduced in the *ortho*-position[298].

In the reaction of amines with proton acids, steric hindrance due to the alkyl groups is less significant because of the small volume of the proton, than in the reaction of amines with methylboron or with alcohols, and obviously could be important only with amines having sufficiently long hydrocarbon chains.

Hall noted that calculation of the basicity constants of amines on the basis of Taft's induction constants gives accurate results only when there is no steric hindrance to the reaction of the acid with the base[242]. If the alkyl groups attached to the amine nitrogen atom are considerably branched, the basicity constants of the amines are much lower than those calculated by formulae allowing only for the inductive effect of substituents.

Forman and Hume[299] evaluated the effect of steric hindrance on the basicity of amines by comparing values of the basicity calculated with the aid of Taft's induction constants with experimental values from the literature[300,301]. For primary and unbranched secondary amines the calculated values were close to the experimental. For secondary amines with sufficiently long and branched alkyl radicals, and for tertiary amines with long alkyl radicals, the experimental basicity constants were lower than the calculated values. Recently, Chremos and Zimmerman have attempted to allow for steric factors in the calculation of basicity constants by the introduction of a new scale of values for $\sigma^*$, representing both the polar and the steric effects of substituents[252].

When the length of the hydrocarbon chains of amines increases beyond a certain limit it is to be expected that the ability of the amines to add on protons and to form polar compounds with acids will be reduced; the length of the alkyl chain (or volume of other substituent having a positive inductive effect), corresponding to maximum polarity of the salts formed and maximum stability of the compounds extracted, is probably greater for primary than for secondary and tertiary amines.

In considering the effect of steric factors on the polarity of amine salts, it must be noted that these factors affect also the interaction of amines with the solvent, especially the solvation of the cations, and this in turn affects the basicity. It has been noted that, with long-chain primary and secondary amines, solvation of the substituted ammonium cations by alcohol molecules (especially higher alcohols) is made difficult by the formation of hydrogen bonds with hydrogen atoms attached to the amine nitrogen atom[242]. It is to be expected that the role of the solvation of substituted ammonium cations and its effect on the basicity of amines and the polarity of their salts will decrease as the hydrocarbon chains of the amine become longer.

5. Effect of "Inert" Solvents

At present, the field of study of "inert" solvents has considerably contracted, because it has been shown that most solvents investigated are not inert, but are capable of specifically solvating cations or anions of dissolved salts[281,302-304]. As has been shown above, the solvation of cations and anions of amine salts by molecules of solvent has a considerable effect on the structure of these salts, and therefore on their extractive power. Here we shall consider as "inert" non-polar solvents the molecules of which have no fundamental groups capable of forming stable hydrogen bonds with cations or anions of amine salts and also cannot appreciably solvate molecules and ions of amine salts by dipole–dipole interaction, but they may solvate them mainly by dispersion forces[304]. Pearson and Vogelsong established that in non-polar "inert" solvents of the n-heptane type the order of basicity of primary, secondary, and tertiary amines is changed in a similar way to that described above for solvents that solvate the cation[238,240]. Thus, in n-heptane the polar compounds of tri-n-butylamine with the acid indicator 2,4-dinitrophenol are formed with greater difficulty than the corresponding compounds of di-n-butylamine. It is assumed that this order for non-polar solvents which do not form bonds with the cation and anion of the salt may be explained as follows. The energy of interaction of molecules of amine salts with such non-polar solvents is much lower than with the analogous moderately polar solvents, and

apparently far lower than the energy of interaction of the amine molecules themselves with these non-polar solvents[82]. It may therefore be assumed that the difference in the solvation energies of the amines and their salts in such solvents is determined for various amines largely by the differences in the energies of solvation of the amines themselves. In such a case it may be expected that the greater the energy of solvation of the amine molecule, the more energetically unfavourable will be the formation of a polar salt by interaction of the amine with the acid. Because of the greater number of hydrocarbon chains, the energy of interaction of molecules of tertiary aliphatic amines with non-polar hydrocarbon solvents is higher than the energy of solvation of molecules of the corresponding secondary and primary amines[240]. It has been suggested that, on the basis of the variation in solvation energy, the formation of polar salts of tertiary amines in hydrocarbon solvents is less favoured than the formation of such salts of the corresponding secondary and primary amines[240]. The influence of opposing factors — solvation and the inductive effects of the alkyl groups of the amine — is probably the cause of secondary amines having a greater power of forming polar salts than have tertiary amines in non-polar aprotic solvents. When the alkyl chains are lengthened it is probable that the differences in the solvation energies of secondary and tertiary amines in such solvents will decrease, and the main factors determining the structure of the amine salt may be the inductive effect of substituents and steric factors.

Up to now, few papers have been published on the study of amine salts in solvents of this type, because of the very slight solubility of most amines in such solvents, which makes such systems of little practical importance.

## V. THE EFFECT OF THE STRUCTURE OF AMINES ON THE EXTRACTIVE POWER OF THEIR SALTS WITH EXTRACTION BY AN ADDITION MECHANISM

In the extraction of acids and metal salts by the addition mechanism the stability of the compounds being extracted should increase when the structure of the amine is altered in such a way that the polarity of the amine salts is increased. When the structure of an amine changes, there should be a corresponding change in extractive power. When the effect of the various factors mentioned above is taken into account, it is possible to explain published results on the extractive power of amines of different structure.

A number of papers contain data that enable the extractive power of primary, secondary, and tertiary amines to be compared. Shevchenko and his coworkers showed that the nitrate of a tertiary amine (tri-n-octylamine) extracts nitric acid much more strongly than does the nitrate of the secondary amine (di-n-octylamine)[3,4]. These results were confirmed by Skavdahl and Mason[18]. Sinitsyn, Zvyagintsev, and their coworkers showed that the extraction of ruthenium nitroso-complexes by amines from hydrochloric-acid[65,174] and nitric-acid[104] solutions increases when the number of alkyl chains in the amine is increased. Laskorin and Yuzhin established that chlorides of tertiary amines extract gallium(III) better from hydrochloric-acid solutions than do those of secondary amines[49]. Winchester and Maraman showed that the extraction of $Pu^{IV}$, $U^{VI}$, and $Th^{IV}$ from nitric-acid solutions by amine nitrates is greater with secondary and tertiary than with primary alkylamines[98]. Good and his coworkers, having systematically studied the dependence of the extractive power of amines on their structure, found that the extraction of $Fe^{III}$, $Co^{II}$, $Ga^{III}$, and $In^{III}$ by solutions of amine chlorides in benzene is also greater on passing from primary to secondary and then to tertiary alkylamines[61-63,68,305,306]. The same order was established for the extraction of a number of other elements[73,125]. Nemodruk showed that the extraction of uranyl acetate by solutions of amine acetates in a solvent that does not solvate cations is greater with dialkylaniline than with aniline[307]. The order established for the extractive power of primary, secondary, and tertiary amines is in agreement with the order of increasing polarity of salts of these amines and stability of the compounds extracted, which are formed by an addition mechanism.

A deviation from the usual order of the extractive power of primary, secondary, and tertiary amines is observed when solvents capable of solvating cations are used. For example, it was shown[307] that replacement of the non-solvating solvent by isobutyl methyl ketone, which solvates alkylammonium cations, led to a significant increase in the extraction of uranyl from acetic solutions of the primary amine, aniline; as a result, in this solvent aniline became a stronger extractant than the tertiary amine dialkylaniline. This increase in the extractive power of the primary amine may be explained by solvation of the cation of the amine salt by solvent molecules, leading to an increase in the polarity of the amine salt and in the stability of the extracted compound.

Many workers have noted[138] that the introduction into the amines of substituents with negative inductive effects leads to a reduction in extractive power. Thus, amines with aromatic substituents directly attached to the nitrogen atom are relatively weak extractants. This also agrees with the data given above on the reduction of the polarity of salts and the stability of compounds when such substituents are introduced. According to the data in Table 3, the value of $\sigma^*$ is lower for the cyclohexyl and benzyl groups than for the aryl group $C_6H_5$, and even lower than for a hydrogen atom. This explains the relatively high extractive power of benzylamines[44,72,309] and cyclohexylamines[309].

The effect of the length of alkyl chains on the extractive power of symmetrical tertiary n-alkylamines was studied by Wilson, who observed an increase in the extraction of plutonium from nitric-acid solutions when the number of carbon atoms in the alkyl chain was increased to eight[97]. This is in agreement with what would be expected from increased inductive effects in the substituents. With further increase in the chain length the extractive power of the alkylamines begins to decrease. Zvyagintsev and Frolov[26,33,40], Zvyagintsev and Sinitsyn[104,174], Timoshev[275], Baroncelli[310], and their coworkers have described a similar dependence of the extractive power of amines on the length of the alkyl chains. The increase in the extractive power of the trialkylamines when the number of carbon atoms in the chain increases to eight is in agreement with the increase, mentioned above, in the inductive effect of alkyl chains when their length is increased. Timoshev points out that one of the causes of the increase in extractive power with increasing alkyl chain length in amines of low molecular weight is also the reduction in the solubility of the extracted compound in the aqueous phase[275]. The reduction in extractive power with further increase in chain length appears to be due to steric hindrance, which becomes the main factor determining the structure and stability of the extracted compounds[311-313].

Comparison of data on the extraction of nitric acid and uranyl nitrates by tertiary n-alkylamines with more than eight carbon atoms in the chain shows that their extraction is reduced by increasing the length of the amine alkyl chains[8,24,129]. The effect of steric factors also appears in the reduction of the extractive power of amine salts with alkyl chains which branch near the nitrogen atom; this has been observed by many workers[138].

From the foregoing it is clear that the extractive power of amine salts in extraction by an addition mechanism is determined by a number of the same factors as effect their polarity. With substituents of relatively small volume and solvents that do not solvate cations, the extractive power changes with changes in the inductive effect of the substituents. When diluents that solvate cations are used, the effect of cation solvation and rupture of intramolecular hydrogen bonds becomes evident. When very bulky substituents are introduced into the amine molecule, steric factors begin to play a predominating part.

## VI. THE EFFECT OF THE STRUCTURE OF AMINES ON THE EXTRACTIVE POWER OF THEIR SALTS WITH EXTRACTION BY AN ANION-EXCHANGE MECHANISM

Up to now little information has been published on the effect of amine structure on the extraction of simple acids with amine salts by an anion-exchange mechanism. Data on the extraction of metal salts by an anion-exchange mechanism[94,96,308,314] show that the rules governing the effect of the structure of amines on the extractive power of their salts cannot materially differ from the rules governing extraction by an addition mechanism.

The extraction of thorium by tri-n-octylammonium sulphate from aqueous sulphate solutions, in which thorium is present as anionic complexes, is an example of the extraction of a metal salt by an anion-exchange mechanism[90,91]. As previously noted, when an extractable compound is formed in such cases, factors affecting the stability of the complex anion in this compound play a secondary part, and factors that determine the strength of interaction of the cation and the anion are of greater significance. It has been found that thorium is extracted from sulphuric-acid solutions better by primary than by secondary amines, and better by secondary than by tertiary amines. The same behaviour is observed in the extraction of Zr, $U^{IV}$, and $Fe^{III}$, which also readily form anionic complexes in sulphate solutions[68]. This behaviour may be explained in terms of steric concepts. Steric hindrance to the approach of relatively bulky anionic sulphate complexes to monoalkylammonium cations is obviously less than to their approach to di- and tri-alkylammonium cations. To form an extractable compound the complex anion must displace the $SO_4^{2-}$ anion from the amine sulphate molecule. Since the $SO_4^{2-}$ anion is smaller than the complex sulphate anions of Th, $U^{IV}$, and Zr, the differences between primary, secondary, and tertiary amines in relation to steric hindrance to this anion are less important than for complex anions. From this it follows that the sulphate ion will be replaced by a complex sulphate ion more easily in salts of primary amines than in salts of tertiary amines. This probably explains the greater extractive power of primary amines (in comparison with secondary and tertiary amines) in the extraction of Th, Zr, and $U^{IV}$ from sulphate solutions.

The same order of extractive power of amines would obviously also be expected for the extraction of other elements from media in which they form stable anionic complexes greatly exceeding in size the anion of the amine salt which acts as extractant. When the complex anions, although predominating in the aqueous phase, are formed with greater difficulty than in the case considered (Th, Zr, $U^{IV}$), other factors — governing stabilisation of the anion and interaction of cation and anion — may be important at the same time. In view of the opposing effects of these factors, when less stable anionic complexes are formed in the aqueous phase, the differences in extractive power between primary, secondary, and tertiary amine salts may decrease in extraction by an anion-exchange mechanism, and in some cases the extractive power of amines with different numbers of alkyl groups may be practically the same[143]. In these cases it appears that the increase in steric hindrance on passing from primary to tertiary amines is probably compensated for by the increase in the stabilising action of the cation on the complex anion. When the length or volume of the alkyl chains increases, steric factors begin to play a predominating part. Thus, Sato[309,313] has shown that with cyclohexyl- and benzyl-alkylamines ($C_{12}$ alkyl) the extraction of $U^{VI}$ from sulphuric-acid solution decreases when additional alkyl chains are introduced into the amine, i.e. in the order primary > secondary > tertiary. Clearly, all the considerations mentioned above still hold good if the extraction of Th, Zr, U, and Fe sulphates proceeds by an addition mechanism, since the great volume of the complex sulphate anions formed in the extraction can probably give rise to steric hindrance in this case also.

Laskorin and his coworkers have shown[308,314] that triisooctylamine is a much weaker extractant of $V^{V}$ and $Mo^{VI}$ ions than is tri-n-octylamine. This may be explained by the greater steric hindrance to the approach of anion and cation in the case of triisooctylamine.

A more thorough investigation into the structure of amine salts could make possible a more complete elucidation of the principles of extraction by amine salts and the prediction of the relative extractive power of amines of different structure.

## I. INTRODUCTION

Chemiluminescence — the emission of light accompanying chemical reactions — is closely connected with the kinetics and the mechanism of the reaction.

The appearance of excited states in a reaction zone is due to the occurrence of exothermic elementary acts. The measured intensity of emission is proportional to the rate of the elementary process in which energy is evolved, and hence is related to the kinetic parameters of the reaction. Investigation of the kinetics, the temperature dependence, and the spectra of the emission may give much valuable information for an understanding both of the reaction mechanism and of the actual phenomenon of chemiluminescence — of the ways in which chemical energy is transformed into radiation.

It must be emphasised that a study of chemiluminescence divorced from the mechanism of the corresponding reaction can hardly provide a fruitful approach. For example, the weakening of emission accompanying the introduction of a new component into the reaction mixture can be equally well explained by its retarding effect on the reaction velocity or by its quenching action on excited states which appear at the same rate as before. In the absence of information on the rate of the chemical reaction and of the influence of the additive on it, no choice can be made between these fundamentally different effects.

The present review surveys the relationship between the chemiluminescence and the kinetics of reactions. From the considerable number of papers on chemiluminescence, those have been selected which report either the investigation of chemiluminescence in reactions whose mechanism has been reliably established or the parallel study of a reaction by chemiluminescence and chemical kinetic methods.

Special attention has been paid to the prospects for using chemiluminescence as a method for the quantitative investigation of reaction kinetics.

The main information has been divided into three parts — (1) gas-phase reactions (hot and cold flames, reactions of atoms obtained in high concentrations from electric discharges), (2) liquid-phase reactions (oxidation of cyclic hydrazides and of acridine compounds) accompanied by bright chemiluminescence, and (3) reactions accompanied by very weak chemiluminescence, which do not differ fundamentally from the previous reactions, but comprise a wide range of both scientific and practical interest, and therefore are discussed as a separate group.

## II. CHEMILUMINESCENCE OF FLAMES

The intensity of the emission from many flames exceeds the equilibrium value corresponding to the temperature of the flame. In particular, the glow from cold and dilute flames is purely chemiluminescent. The radiation from low-temperature flames is to a greater or lesser extent chemiluminescent[1,2]. The non-equilibrium character of the radiation can be shown by comparing its absolute intensity with the intensity of the radiation from a black body having the same temperature as the flame. Thus according to Kondrat'ev[1] the intensity of the radiation from an oxygen–hydrogen flame at 10 mmHg and 1000°K exceeds the equilibrium value by a factor of $10^{12}$, while the corresponding factor for the $2CO + O_2$ flame at 100 mmHg and 1400°K is $10^{10}$.

The character of the radiation can be assessed also from measurements of the intensity distribution in the emission spectrum. The non-equilibrium character of radiation is indicated by a difference between the true temperature of the flame and the rotational temperature of individual species: in the oxygen–acetylene flame at 1 atm, for example, the true temperature is 3400°K, while the rotational temperature of hydroxyl is 5400°K, and that of $C_2$ is 4700°K.[3] Finally, departures from equilibrium can

be assessed from the characteristic quenching of luminescence with increase in the pressure of the reactants or on the introduction of inert gases. Quenching phenomena have been observed, for example, in the hydrogen and carbon monoxide flames[1].

Flame emission spectra usually comprise one or more band systems observed on a background of a continuous spectrum. The source of the energy responsible for the chemiluminescence is usually the recombination (or disproportionation) of atoms and free radicals, in which a large amount of energy, equivalent to quanta in the visible and ultraviolet regions of the spectrum, is evolved at once, in a single act. Therefore measurements of chemiluminescence in flames give information on the reactivities of atoms and free radicals, their concentrations, and their concentration distributions in the flame and in the combustion products.

The use of chemiluminescence data in the study of reaction kinetics in flames and combustion products is based on the existence of proportionality between the emission intensity $I$ and the rate $w$ of the chemical process resulting in chemiluminescence:

$$I = \eta_{ch}\omega, \quad (1)$$

where $\eta_{ch}$ is a proportionality coefficient representing the quantum yield of the radiation. In general $\eta_{ch}$ may depend on the temperature and on the composition of the mixture in which reaction is occurring. The principal cause of variation in the light yield is change in the composition of the mixture. The coefficient $\eta_{ch}$ may vary both as a result of strengthening or weakening of quenching processes and as a result of energy transfer processes, which may affect the nature of the luminescent species. The temperature variation in the light yield is usually small, and is due mainly to the temperature dependence of the probability of radiationless transitions. The kinetics can be measured by various methods based on chemiluminescence:

(a) Measurement of intensity of emission in a chemiluminescent reaction occurring in the system.

(b) Measurement of intensity of emission from an added luminescent substance. In this case chemiluminescent reactions may be altogether absent in the actual system investigated. The chemiluminescence of the added substance (activator) arises from energy transfer.

(c) Measurement of intensity of emission occurring on addition of a substance which enters into a chemiluminescent reaction with one of the components of the system. In this case, too, chemiluminescent reactions may be absent from the actual system investigated.

All these chemiluminescent methods are used in kinetic investigations of flame reactions. The latter two methods are employed especially frequently.

## 1. Chemiluminescent Reactions with Additives

The flame and the products of the combustion of hydrogen form the subject of most quantitative investigations of chemiluminescence. The reaction involves O and H atoms and the OH radical. The application of chemiluminescent methods makes it possible to measure relative and absolute concentrations of these species and their distribution in the combustion products, and to obtain rate constants for their recombination.

Concentration distributions of H atoms in the hydrogen flame and in the reaction products have been measured, for example, from the emission arising on the introduction of copper into the flame. A bright emission band due to CuH is recorded, its intensity $I_{CuH}$ at $\lambda = 4280$ Å being proportional to the concentration of H atoms[4,5]. Reid and Sugden have shown[6] that the constant $k'$ in the expression $I_{CuH} = k'[H]$ is independent of temperature. Therefore $[H]/[H]^\circ = I_{CuH}/I^\circ_{CuH}$ ($I^\circ_{CuH}$ being the intensity of emission at the concentration of H atoms chosen as standard), and relative concentrations of H atoms can be measured by $I_{CuH}$. These measurements can be converted to absolute concentrations provided that [H] is measured at one point by some absolute method. According to Sugden's data[7] the equilibrium

$$OH + H_2 \rightleftarrows H_2O + H \quad (2)$$

is rapidly established in the products of the combustion of hydrogen. This makes it possible to determine the concentration of OH radicals and their distribution in the products of the hydrogen flame from known values of [H] and the equilibrium constant of process (2). In this way the following recombination rate constants have been obtained[5]

$$H + OH + H_2O \rightarrow H_2O + H_2O \quad k_{1650} = 1.5 \times 10^{-30}\ cm^6\ s^{-1},$$
$$H + H + H_2O \rightarrow H_2 + H_2O \quad k_{1650} = 6 \times 10^{-32}\ cm^6\ s^{-1}.$$

The addition of halogens to hydrogen flames having a high fuel content results in continuous emission in the visible region, due to the reaction $H + X \rightarrow HX + h\nu$, where X is a halogen atom[8]. This emission resembles the continuum of the hydrogen flame arising in the reaction $H + OH \rightarrow H_2O + h\nu$.[9] The weak continuum emitted in the visible region when an alkali metal M is added to a hydrogen flame has an intensity proportional to [OH][M]. The continuum probably arises[10] in the reaction $M + OH \rightarrow MOH + h\nu$. In all these cases the emission intensity can be used to determine the relative concentration of H atoms and OH radicals in different parts of the flame and combustion products. These data can be used also to calculate the distribution of oxygen atoms, since the equilibrium

$$H_2 + O \rightleftarrows H + OH$$

is rapidly established in the flame.

A method suggested by Gaydon[11] has often been used recently to determine the concentration of atomic oxygen. It is based on measurement of the intensity of the yellow-green glow in the reaction.

$$NO + O \rightarrow NO_2 + h\nu. \quad (3)$$

In Gaydon's work this method was employed only qualitatively, the emission serving as an indicator of atomic oxygen. The work of Karmilova and Kondrat'ev[12], who made absolute measurements of the intensity of the yellow-green emission of $NO_2$, showed that the intensity is a quantitative measure of the concentration of atomic oxygen in the CO flame. The concentration of O atoms was close to the equilibrium values in flames having a temperature above 2600°K; at lower temperatures it exceeds the equilibrium value. The possibility of the quantitative use of reaction (3) to measure relative and absolute concentrations of atomic oxygen in flames has been confirmed by later work. Thus James and Sugden[13] have shown that the intensity of the emission from the combustion products of hydrogen to which nitric oxide has been added is proportional to [NO] and to the concentration of O atoms, the latter being calculated from the equilibrium constants.

Measurements of the absolute light yield in reaction (3) taking place in the combustion products of the hydrogen flame have been used[14] to evaluate the rate constant of reaction (3)†. The value of $2\times10^{-18}$ cm$^3$ s$^{-1}$ for the rate constant agrees well with the value obtained by Kaufman[15] using a different method.

### 2. Emission from Luminescent Additives

Emission lines due to various metal impurities can be observed in the spectra of many flames. Gaydon and Wolfhard[3] put forward the hypothesis that the excitation of metal atoms in flames is effected by the energy released by the recombination of atoms and free radicals. The number of excited impurity atoms may correspond to the temperature of the flame, but can also considerably exceed the equilibrium value. This is especially characteristic of low-temperature and highly dilute flames, in which the concentration of atoms and free radicals far exceeds the equilibrium value. Measurements of the emission intensity from a metal impurity can be used as a quantitative method for studying the kinetics of reactions involving atoms and free radicals. Thus the decay of the chemiluminescence of metallic sodium has been used[16] to measure the kinetics of the recombination of atomic hydrogen at 1072°K in the products of combustion from a mixture of $H_2 + O_2 + N_2$. The absolute concentration of H atoms was measured from the rate of their reaction with $D_2O$ or $D_2$.

In the products of combustion, hydrogen is removed by the reactions

$$H+H+M \rightarrow H_2+M, \quad (4)$$

$$H+OH+M \rightarrow H_2O+M. \quad (5)$$

If M = Na, both reactions result in the formation of excited sodium atoms emitting a resonance line. The probability of the excitation of sodium in these reactions is of the order of unity[17].

Since the concentrations of H atoms and OH radicals are balanced by the occurrence of process (2), the decrease in emission intensity can be used to measure the relative concentration of H atoms, although they immediately disappear by the two reactions (4) and (5). The time variation in the emission intensity is almost independent of the relative proportions of $N_2$, $H_2$, and $H_2O$, which are evidently equally effective as third bodies.

Analogous measurements can be made with other metals, e.g. thallium and lead, the resonance emission of which is excited in the processes[18]

$$H+H+Tl \rightarrow H_2+Tl^* \quad (\lambda=535\ m\mu m),$$
$$H+OH+Pb \rightarrow H_2O+Pb^* \quad (\lambda=405.8\ m\mu m).$$

New excitation reactions occur when halogens $X_2$ and metal vapours are introduced simultaneously into a hydrogen flame[19]

$$H+X+M \rightarrow M^*+HX \quad (X=Cl, Br).$$

In these processes the heat of reaction can be almost completely transformed into the energy of excitation of the metal atom. Thus the heat of reaction of H + Cl (102 kcal × × mole$^{-1}$)‡ is almost completely utilised for the excitation of a lead atom (excitation potential 100 kcal). Measurements of the emission of metal atoms in reactions between hydrogen and halogen atoms can also be used in kinetic investigations.

## III. REACTIONS OF NITROGEN, OXYGEN, AND HYDROGEN ATOMS

Methods analogous to those described above are used also to investigate non-flame reactions of nitrogen, oxygen, and hydrogen atoms. In this case the atoms are usually obtained in electric discharges, and their reactions are investigated in a flow apparatus from the distribution of emission intensity along the reaction tube.

### 1. Reactions of Atomic Nitrogen

It was observed in 1900 that nitrogen which has passed through an electric discharge exhibits a yellow afterglow[20], associated with the reactions[21]

$$N(^4S)+N(^4S)+M \rightarrow N_2(^5\Sigma_g^+)+M \text{—rate-determining stage},$$
$$N_2(^5\Sigma_g^+)+M \rightarrow N_2(B^3\Pi_g)+M,$$
$$N_2(B^3\Pi_g) \rightarrow N_2(A^3\Sigma_u^+)+h\nu \text{ — chemiluminescence}.$$

Simultaneous recording of the emission intensity and mass-spectrometric measurement of the concentration of atomic nitrogen[21] have shown that $I = \alpha[N]^2$, the coefficient $\alpha$ being proportional to the pressure of $N_2$. This shows that the luminescence arises from a termolecular recombination. Measurement of the absolute intensity of the glow has yielded an estimated rate constant for the recombination of N of $2\times10^{-33}$ cm$^6$ s$^{-1}$.[21] A more accurate value for the constant — $1.72\times10^{-32}$ cm$^6$ s$^{-1}$ — has been obtained by measuring the distribution of emission intensity along the tube through which the mixture of atomic and molecular nitrogen from the electric discharge is passed[22].

The absolute concentration of nitrogen atoms was determined by a method of "chemiluminescent titration"[23] with NO. The nitric oxide enters from a small volume through a calibrated orifice into the tube along which the jet from the discharge is passing. The very rapid reaction N + NO → $N_2$ + O takes place, and a new chemiluminescent reaction O + NO → $NO_2 + h\nu$ appears. The yellow glow of the nitrogen does not immediately vanish, but a yellow-green luminescence, associated with the reaction of atomic oxygen, appears. Since the vessel containing the nitric oxide has a small volume, the rate of escape of NO drops rapidly, and when its amount becomes insufficient and N atoms remain, a new blue-violet luminescence appears, associated with the reaction[22,24]

$$N+O+M \rightarrow NO(A^2\Sigma^+, B^2\Pi)+M,$$
$$NO(A^2\Sigma^+, B^2\Pi) \rightarrow NO+h\nu \ (\beta \text{ and } \gamma \text{ bands}).$$

At the instant of appearance of the blue-violet glow, the quantity of NO molecules which have entered is equal to the number of N atoms. The presence of NO in the vessel is measured at this point, the flow of NO is determined from a calibration curve, and in this way the concentration of nitrogen atoms is obtained. The "titration" takes a few minutes.

### 2. Reactions of Atomic Oxygen

The recombination of atomic oxygen

$$O(^3P)+O(^3P)+M \rightarrow O_2+M \quad (6)$$

† The hydroxyl concentration was determined by the method of ultraviolet absorption[1]. The concentration of O atoms was calculated from values of the equilibrium constant of the reaction $2OH \rightleftharpoons H_2O + O$.

‡ Henceforward we shall write kcal instead of "kcal mole$^{-1}$".

is not chemiluminescent. Nevertheless, the reaction velocity and the rate constant can be measured by chemiluminescent methods. If small amounts of NO are introduced into a jet containing oxygen atoms, a quite bright emission is produced, whose intensity is proportional to the concentration of atomic oxygen[25-28]. At the same time, the reaction NO + O → $NO_2$ is slow at low NO concentrations, in comparison with other reactions of O atoms, and it has hardly any effect on the concentration of the latter[23]. The nitrogen dioxide which is formed reacts very rapidly with O atoms to regenerate NO:

$$O+NO_2 \rightarrow O_2+NO. \quad (7)$$

Reaction (7) is used for the chemiluminescent "titration" of O atoms. A gradually increasing flow of $NO_2$ is admitted to the jet. As a result of the rapid reaction (7), [O] decreases, while [NO] increases. The emission intensity, which is proportional to the product [O][NO], passes through a maximum. With further increase in the flow of $NO_2$, the intensity falls rapidly. The end-point corresponds to complete disappearance of luminescence from the tube. At this point the supply of $NO_2$ is equal to the concentration of O.[29] In a variant of this method[30], which probably yields more accurate results, measurements of the intensity distribution along the tube and the application of chemiluminescent titration enable the rate constant of reaction (6) to be determined[29,30]. The technique shows promise for the quantitative investigation of other reactions of atomic oxygen. Thus the kinetics of the consumption of oxygen atoms has been examined[29] in the presence of $H_2$, $O_2$, $N_2$, Ar, $CO_2$, CO, $N_2O$, $C_6H_6$, $SO_2$, $Fe(CO)_5$, $H_2O$, $O_3$, $C_2H_4$, $Cl_2$, and $Br_2$. Results obtained by the chemiluminescent method have been discussed in detail in a recent review by Kaufman[31].

### 3. Reactions of Atomic Hydrogen

The recombination of atomic hydrogen catalysed by nitric oxide is accompanied by luminescence in the red and near infrared regions of the spectrum, due to emission by excited HNO molecules[32-34]:

$$H+NO+M \rightarrow HNO^* + M \text{ — rate-determining stage}, \quad (8)$$

$$H+HNO \rightarrow H_2+NO. \quad (9)$$

Radiation from HNO* is observed also in the rapid reaction[33]

$$H+NO_2 \rightarrow OH+NO.$$

The kinetics of the catalysed recombination has been studied[33,34] from the intensity of the red luminescence in a low-pressure (1–2 mmHg) jet. The rate constant of reaction (8) and the intensity depend substantially on the nature of the third species M, where $I \propto [H][NO]$. From the intensity distribution along the jet and calorimetric measurements of the concentration of hydrogen atoms, the rate constant of reaction (8) was found to be $1.3 \times 10^{-32}$ $cm^6$ $s^{-1}$ (with M = $H_2$).

This reaction may perhaps be used in the future as an indicator of atomic hydrogen, and employed to study reactions of the latter with various molecules, as has been done for the reactions of atomic oxygen.

## IV. INFRARED CHEMILUMINESCENCE IN THERMAL REACTIONS

The distribution of energy among the products of exothermic reactions is not the equilibrium distribution. Reference may be made, for example, to a series of results obtained by M. Polanyi and his coworkers, who investigated the reactions of alkali-metal vapours with halogens, as well as with organic and inorganic halogen compounds. The kinetics and the characteristics of the chemiluminescence in these reactions have been discussed in detail in several review articles and monographs[2,35,36]. Here we shall consider only those facts which indicate the formation in these reactions of excited species, present in vibrationally excited or metastable states. The simplest reaction — that between the vapours of sodium and a halogen $X_2$ — occurs according to the scheme

$$Na+X_2 \rightarrow NaX+X, \quad (10)$$

$$X+Na_2 \rightarrow NaX'+Na, \quad (11)$$

$$NaX'+Na \rightarrow NaX+Na^*, \quad (12)$$

$$Na^* \rightarrow Na+h\nu, \quad (13)$$

where NaX′ is an excited molecule. The main evidence for the formation of NaX′ molecules and the excitation of sodium in reaction (12) is based on an investigation of the quenching of chemiluminescence by foreign gases, which showed that the chemiluminescence was extinguished considerably more strongly than was the fluorescence of sodium. If the reaction is carried out in a flow apparatus, the zone of maximum emission intensity is displaced in the flow direction. It is interesting that in individual cases the heat of reaction is almost completely converted into excitation energy; for example, emission of the 0.589 μm (48.5 kcal) sodium resonance line is observed in the reaction $Na_2 + I \rightarrow NaI + Na$, the heat of which reaction is 49.5 kcal.

The formation of vibrationally excited molecules in a chemical process was first detected spectroscopically by McKinley et al.[37] for the reaction of hydrogen atoms with ozone $H + O_3 \rightarrow OH' + O_2$. The reaction was carried out at 0.2 mmHg in a reaction vessel comprising two coaxial tubes. A stream of ozone from the inner tube entered an atmosphere of partly dissociated hydrogen which had passed through a discharge tube. A red glow appeared at the outlet from the inner tube, produced by vibrationally excited OH radicals, whose spectrum was recorded on a photographic plate. The spectrum contained bands corresponding to transitions from vibrational levels right up to the level of quantum number 9. The energy of this highest level (75 kcal) is close to the heat of reaction (78 kcal). Vibrationally excited molecules were detected also in a large number of photochemical and thermal reactions. By the method of flash photolysis, vibrationally excited species have been obtained, for example, in the reactions[38-40] (the numerals in parentheses indicate the highest observed vibrational level)

$$O+NO_2 \rightarrow O_2\,(8)+NO, \quad Br+O_3 \rightarrow BrO\,(4)+O_2,$$
$$O+Cl_2O \rightarrow O_2\,(8)+ClO, \quad O+NH_3 \rightarrow OH\,(2)+NH_2,$$
$$O+O_3 \rightarrow O_2\,(17)+O_2, \quad O+CH_4 \rightarrow OH\,(2)+CH_3,$$
$$Cl+O_3 \rightarrow ClO\,(5?)+O_2, \quad O+HCl \rightarrow OH\,(2)+Cl.$$

The concentrations of excited species are large here, and they are identified from their absorption spectra.

A series of investigations of infrared chemiluminescence has been made by J. C. Polanyi and his coworkers[41-45], who observed from the emission spectra the formation of vibrationally excited molecules, e.g. in the reactions

$$H+NO \rightarrow HNO' \quad H+Br_2 \rightarrow HBr'+Br,$$
$$H+Cl_2 \rightarrow HCl'+Cl \quad H+NOCl \rightarrow HCl'+NO.$$

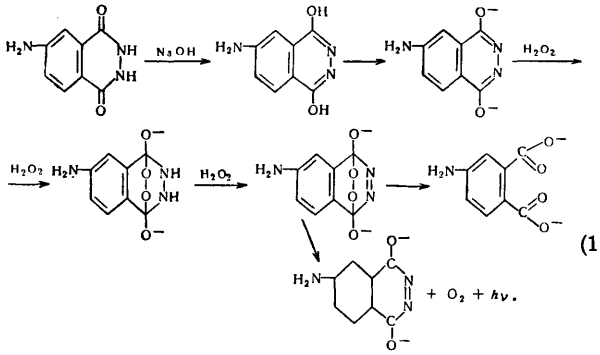
It is seen from the above equations that, in reactions of atoms with triatomic molecules, the heat of reaction is not uniformly distributed among the products. Most of the

energy — and in isolated cases the whole of it — is concentrated on the bond which is formed. Only in the reaction H + NOCl were both species NO and HCl vibrationally excited. Even in this case, however, the distribution of energy was non-uniform: the emission of the NO constituted only a few per cent of that from the HCl.[45]

All the reactions quoted in the present Section were formerly regarded as elementary. However, the formation of excited products in different vibrational states shows that this view is an oversimplification. In fact, the measured rate constant represents the sum of the rate constants of reactions leading to products which are present in various vibrational states. Therefore investigation of the energy spectrum of the resulting products is of exceptional interest for the construction of a quantitative theory of the elementary acts in chemical processes. The first work on these lines has been undertaken recently. In the H + $O_3$ reaction it has been concluded, from measurements on the distribution of OH among vibrational levels with an initial pressure of 2–5 mmHg, that the rate constants for the formation of different excited states of OH are approximately the same[46]. However, this conclusion cannot be regarded as final, and requires further verification. Thus it has been shown[44,45,47,48] for the reactions H + NOCl and H + $Cl_2$ that the distribution of HCl among vibrational levels depends significantly on the initial pressure and the partial pressure of HCl. At higher pressures (0.1–0.2 mmHg for H + $Cl_2$ and 1–2 mmHg for H + NOCl) the HCl exhibits an approximately Boltzmann distribution among vibrational levels, and the relative rate constants for the formation of HCl molecules at a given vibrational level are closely similar for the two reactions, in spite of the differences in the nature of the reactant molecules (the $Cl_2$ molecule being non-polar, while NOCl is polar) and in the heats of reaction. These results can be explained by the fact that, at higher pressures, the original distribution of energy among vibrational levels is strongly distorted by secondary processes involving the redistribution of energy.

At pressures of around 0.01 mmHg in the H + $Cl_2$ system, emission disappears from levels located above $v = 5$ (at higher pressures the level $v = 6$ was observed). In the H + NOCl system no emission is observed from the levels $v = 8$ and $v = 9$, which had been observed at higher pressures. The distribution among vibrational levels becomes markedly different from the Boltzmann distribution, and differs greatly for the two systems. Under these conditions reaction is most rapid to form HCl molecules in their lowest vibrational states; in the H + $Cl_2$ reaction, for example, the rate of formation of HCl($v = 3$) exceeds that of HCl($v = 5$) by a factor of approximately 35. The highest vibrational levels are excited at higher pressures probably as a result of the redistribution of energy.

## V. LIQUID-PHASE OXIDATIONS ACCOMPANIED BY BRIGHT CHEMILUMINESCENCE



### 1. Oxidation of Cyclic Hydrazides

The chemiluminescence accompanying the oxidation of 5-amino-1,2,3,4-tetrahydro-1,4-dioxophthalazine (Luminol) with hydrogen peroxide in alkaline medium was first studied by Albrecht in 1928.[49] The luminescence was long-lived, and so intense that it could be observed with the naked eye. It has also been discovered that bright chemiluminescence accompanies oxidation of the hydrazides of benzenesulphonic[50], pyridinecarboxylic[51], aromatic, and aliphatic[52,53] acids. Several regularities have been observed in the dependence of the intensity of chemiluminescence on the structure of the hydrazides. However, many authors have based their conclusions on the results of visual observations or measurements with instruments of low sensitivity, and therefore their conclusions concerning the absence of chemiluminescence in the oxidation of a particular compound cannot be regarded as final.

Experiment has shown that several hydrazides of phthalic acids, and especially of aminophthalic acids, possess most long-lived and intense luminescence. According to Sveshnikov[54] the brightness of the emission at Luminol concentrations of $10^{-5}$–$10^{-3}$ g $cm^{-3}$ is $3 \times 10^{-7}$ to $2 \times 10^{-6}$ stilb with a layer 1 cm thick. Ordinary photometers can be used to study such reactions. Therefore the oxidation of Luminol in alkaline medium, with and without a catalyst present, has become a kind of model reaction for the study of chemiluminescence in the liquid phase. The oxidants used have been hydrogen peroxide, peroxosulphates[1], permanganate[55], $[CoCl_2(NH_3)_4]Cl$,[56] and other compounds[57]. Catalysts of various types considerably intensify the chemiluminescence[57]. Many workers have attempted to elucidate the mechanism of these reactions, by studying the effect of the nature and position of substituents in the benzene and hydrazide rings on the intensity and spectral region of the emission[58–68]. Several reaction schemes have been suggested for the oxidation of [hydrazides of] phthalic acids with hydrogen peroxide in alkaline medium, which result in the emission of radiation.

Thus Albrecht[49], Tamamushi[70], and Weber[71] assumed that the oxidation of Luminol involves the intermediate formation of a diimide and an excited dilactam form of the hydrazide. A similar hypothesis was put forward by Caen[72] for the oxidation of Rimifon (the hydrazide of isonicotinic acid). However, existence of the diimide was not confirmed experimentally.

Parker and Harris[73], and later Drew and Garwood[63,64,74], suggested that the Luminol molecule adds on a molecule of $H_2O_2$ to form a peroxide. The oxygen bridge is eliminated, and the epidioxide molecule converted into an excited Luminol molecule, which is responsible for the chemiluminescence:

(14)

Several pieces of evidence in support of this hypothesis were given[59,63]. Ojima[75] suggested a similar mechanism for the luminescence of Luminol in the presence of copper salts.

Babko and Lukovskaya[76] showed by the method of isomolar series that copper forms a 1 : 1 complex with

Luminol, and the $H_2O_2$ molecule adds on in turn in this complex, forming a new complex responsible for the emission.

Many workers have shown[63,68,73,77-80] that with variation in the $H_2O_2$ concentration the initial intensity passes through a maximum. However, different authors give different relative concentrations of Luminol and hydrogen peroxide corresponding to this maximum, covering the range 1–50 molecules of $H_2O_2$ per molecule of Luminol.

Especially detailed kinetic investigations were made by Sveshnikov[54,77-79], who used a Fabry–Gelhof photometer to study the time variation of emission intensity in the oxidation of Luminol in alkaline medium at 52°C and the effect of the $H_2O_2$ and alkali concentrations on the intensity. The time curves show that, within the limits of experimental error, the emission intensity $I$ is proportional to the Luminol concentration, while the kinetics of the variation in intensity remains unchanged when the Luminol concentration is diminished by a factor of 100. The rate of change of $I$ increases as the concentration of the hydrazide decreases. According to Sveshnikov, the chemiluminescence corresponds to some secondary reaction which is of the first order with respect to the Luminol concentration. His experimental results support the hypothesis of Drew and Garwood, and are at variance with the Albrecht–Tamamushi scheme, which requires a quadratic dependence of $I$ on the Luminol concentration.

Bernanose[81] showed that, when Luminol is oxidised with sodium hypochlorite and hydrogen peroxide, the luminescence diminishes with time according to an exponential law. Several workers, who have investigated the kinetics of the chemiluminescence of Luminol in the presence of catalysts[71,82-87], have observed the same law for the time variation of the emission. It may be surmised that the same elementary act, perhaps the unimolecular breakdown of Luminol peroxide, is responsible for the chemiluminescence in all cases.

The brightness of the chemiluminescence of Luminol depends significantly on the pH of the medium, reaching a maximum at pH 10–11. Several explanations have been suggested for this phenomenon. Some workers[66,81] consider that the pH influences an equilibrium between two forms — luminescent and non-luminescent — of Luminol. Babko and Lukovskaya[88] assume that the effect of pH is linked with the dissociation of Luminol. Erdey[89], who studied the decomposition of hydrogen peroxide in alkaline medium, showed that the ion $HOO^-$ was formed as active intermediate, the rate of decomposition of $H_2O_2$ being a maximum at pH 12. He postulated that this ion adds on to a molecule of the luminous substance to form a peroxide, whose decomposition causes the chemiluminescence (Drew and Garwood's mechanism). From this point of view the presence of an extremum in the pH dependence of the rate of decomposition of $H_2O_2$ may be one reason for the appearance of a maximum on the chemiluminescence intensity curve.

Thus, although the mechanism of the chemiluminescence of Luminol has not been finally established, Drew and Garwood's scheme (14) seems the most probable.

Besides the above mechanisms of "ionic" type, several investigators suggest "radical" mechanisms for the oxidation of Luminol with hydrogen peroxide[87,90]. These hypotheses are based on theories of the chain decomposition of hydrogen peroxide in acid medium, and also the observed[54,64,83,87,90] quenching action of inhibitors of radical reactions — quinol, Metol, cysteine, etc. — on the chemiluminescence of Luminol, which was restored as the inhibitor was consumed. These schemes do not agree with Sveshnikov's kinetic results, since they presuppose that the intensity of chemiluminescence depends on higher powers of the concentration of the luminescent substance, nor with Erdey's conclusions concerning the formation of $HOO^-$ ion in alkaline medium. Thus further kinetic and spectroscopic study of the chemiluminescent reaction of Luminol is required in order to establish the mechanism of the luminescence accompanying this process.

Although the mechanism of chemiluminescent oxidation has not yet been established, the pH dependence of the bright luminescence of Luminol is widely used in analytical chemistry. Luminol is employed to detect $H_2O_2$,[91] $CuCl_2$, $Br_2$, $KMnO_4$, $NH_3$,[92] and poison gases[53], for the quantitative determination of $H_2O_2$,[94] copper[76,88,94], and several organic compounds[94], and also as an acid–base indicator[95].

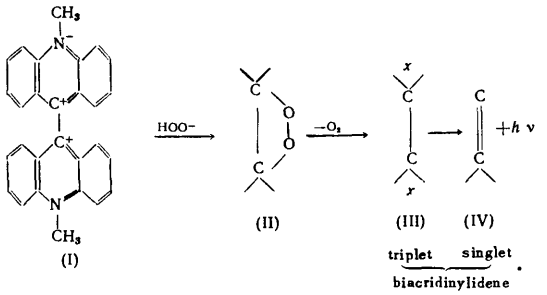
## 2. Oxidation of Lucigenin

The bright green luminescence accompanying the oxidation of alkaline *NN'*-dimethylbiacridinylium solutions with hydrogen peroxide was first investigated in detail by Gleu and Petsch[96,97] in 1935. They gave the name "lucigenin" (generating light) to the compound.

As in the case of Luminol, several hypotheses have been put forward to explain the mechanism of the luminescence of lucigenin. Only hydrogen peroxide and oxygen produce chemiluminescence in alkaline solutions of this compound, and the resulting spectrum is identical with its fluorescence spectrum.

Tamamushi and Akiyama[98,99] consider that the oxidation of lucigenin with oxygen involves formation of a diradical, 10,10'-dimethyl-9,9'-biacridinyl, which on addition of $O_2$ forms lucigenin peroxide. Under the influence of the previously formed $H_2O_2$, this peroxide is converted into a dicarbinol base, which is in an excited state and is responsible for the luminescence.

Gleu and Petsch[96] postulate a reaction scheme in which lucigenin oxide (10,10'-dimethyl-9,9'-biacridinylidene oxide) is directly responsible for the emission, while the intensity of chemiluminescence is proportional to the first power of the lucigenin concentration.



Totter et al.[100] assume that the oxidation of lucigenin involves the intermediate formation not of an oxide or a peroxide but of 10,10'-dimethyl-9,9'-biacridinylidene, followed by a monocarbinol base, which is responsible for the luminescence.

Erdey[101] considers that in alkaline medium the lucigenin molecule reacts with the $HOO^-$ ion formed on decomposition of $H_2O_2$, to yield lucigenin peroxide (similarly to the scheme of Gleu and Petsch).

Grigorovskii and Simeonov[102], having synthesised several derivatives of lucigenin, showed that lucigenin oxide and 10,10'-dimethyl-9,9'-biacridinylidene are able to emit a bright yellow-green chemiluminescence in alkaline medium under the influence of hydrogen peroxide, whereas the monocarbinol base does not emit light under these conditions.

Very interesting spectroscopic investigations were made by Karyakin[103], who studied the chemiluminescence, phosphorescence, and fluorescence spectra of lucigenin brom-

ide (I), *NN'*-dimethylbiacridinylidene oxide (II), and *NN'*-dimethylbiacridinylidene (III) (see Table). Since the chemiluminescence spectra of aqueous solutions of lucigenin and of lucigenin oxide are not identical, Karyakin considers that the oxide is not an intermediate product in the oxidation of lucigenin, and that the emission from the oxide represents an independence process. The chemiluminescence spectra are similar to the phosphorescence spectra. This implies that an excited triplet level is responsible for the chemiluminescence. Karyakin[103] and Erdey[104] suggest an emission mechanism for lucigenin comprising the stages — (1) $H_2O_2$, or most probably the $HOO^-$ ion, reacts with the starting material to form a transannular epidioxide; (2) the latter decomposes thermally with the evolution of $O_2$ and formation of the corresponding diradical (triplet) state; and (3) the diradical passes into the ground state, emitting a quantum of light:

On addition of a catalyst, lucigenin peroxide (II) decomposes to form an excited methyloxoacridine, which emits a blue glow.

In a study of the kinetics of the chemiluminescence of lucigenin and the dependence of the intensity of chemiluminescence on the concentrations of lucigenin, $H_2O_2$, and alkali[54,79], Sveshnikov showed that, whereas with Luminol the curve for the time variation in the intensity represents a complicated process, in the case of lucigenin the curves follow exactly an exponential law. The kinetic curves show that the rate of variation in chemiluminescence increases with decrease in the concentration of the substance, as in the case of Luminol. This confirms the hypothesis that both lucigenin and Luminol inhibit the decomposition of $H_2O_2$. Furthermore, Sveshnikov showed that, with lucigenin too, the dependence of the initial intensity of chemiluminescence on the concentration of the substance in the presence of large excesses of $H_2O_2$ and NaOH is not quadratic. Moreover, the strengthening of chemiluminescence with increase in lucigenin concentration is even less than was to be expected for a linear relationship[54]. Sveshnikov's results, and also those of Kroh[105] indicating that the oxidation of lucigenin is of the first order, make the Gleu and Petsch and Karyakin–Erdey scheme the most probable. Tamamushi and Akiyama's hypothesis, according to which a quadratic dependence of reaction velocity on lucigenin concentration should be observed, obviously does not correspond to reality.

Lucigenin, like Luminol, is employed in analytical chemistry for the detection of copper(II), lead, and mercury(II)[104,106,107], as a chemiluminescent indicator[108,109], etc.

TABLE. Positions of chemiluminescence and photoluminescence maxima for lucigenin bromide (I), *NN'*-dimethylbiacridinylidene oxide (II), and *NN'*-dimethylbiacridinylidene (III).

| Compound | Position of maximum | | |
|---|---|---|---|
| | chemiluminescence | fluorescence | phosphorescence |
| I | 480,515 | 480,515 | 480,515 |
| II | 550 | 505 | 548 |
| III | 525 | 515 | 523 |

## VI. SYSTEMS SHOWING WEAK CHEMILUMINESCENCE

We have discussed above reactions which are accompanied by bright chemiluminescence. The high emission intensity in these reactions is due either to a high rate of occurrence of exothermic processes or to a high yield, i.e. the efficient conversion of chemical into light energy. These conditions are not satisfied in reactions occurring at moderate temperatures (low rates) and with the formation of products which are unable to luminesce efficiently (low yields). Such reactions will therefore be accompanied not by bright but by weak chemiluminescence, even if they include stages in which the energy evolved is equivalent to quanta of visible light. Nevertheless, it is clear that there is no fundamental, qualitative difference between systems having bright and those having weak chemiluminescence, and emission may be observed in many slow "ordinary" reactions provided that a sufficiently sensitive detector is available.

The first investigations of weak chemiluminescence were made before the Second World War by Audubert and his coworkers[110,111]. With the aid of Geiger–Müller counters they detected extremely weak ultraviolet emission in many reactions, such as the neutralisation of strong acids by strong alkalis, the hydration and dehydration of quinine sulphate, several oxidation–reduction reactions — the autoxidation of bisulphite, the oxidation of organic substances by permanganate, chromic acid, bromine, and iodine, the anodic oxidation of aluminium, magnesium, silicon, etc. The number of photons emitted from 1 $cm^2$ of surface in 1 s did not exceed $10^4$ (in isolated cases $10^5$). Hence the yield, i.e. the ratio of the number of photons emitted to the number of molecules which have reacted, was of the order of $10^{-14}$–$10^{-15}$, which is extremely low. Only in the decomposition of azides was the emission sufficiently intense for its temperature coefficient and its spectrum to be determined.

A striking feature of Audubert's experiments was the huge size of the quanta emitted, the range 200–240 mμm corresponding to amounts of energy of 140–120 kcal. Nevertheless, the sum of the heat of reaction and the activation energy of the reactions investigated did not exceed 50–80 kcal. Audubert assumed that twin collisions could occur between energy-rich molecules of the products, but this hypothesis remained unproven.

At the end of the 1930s Audubert ceased to investigate chemiluminescence, and did not return to it again. One of his last papers on chemiluminescence finished with the words: "In the present state of the exceptionally unfavourable and technically difficult method it is not surprising that the number of results as yet obtained is small. But it is to be hoped that advances in the technique of photoelectric counters will make possible the widespread use of a method which has already yielded such interesting conclusions"[111]. In fact the application of highly sensitive light transducers — photomultipliers, photoresistors,

etc. — has enabled a weak emission to be detected in many chemical reactions, and its regularities to be investigated[112,113]. Luminescence in the visible region of the spectrum has been studied in — the thermal decomposition of peroxides, hydroperoxides, and azo-compounds in solution[112-115]; the thermal decomposition and oxidation in the gas phase of peroxides, hydroperoxides, alkyl iodides, alkyl nitrites, nitric acid, nitromethane[113,114], acetaldehyde[116], propionaldehyde and butyraldehyde[117], ethyl hyponitrite[118], n-hexane, and diethyl ether[117]; the electrolysis of ethanol, acetic acid, potassium acetate[113,114], sodium acetate, sodium propionate, sodium citrate, sodium tartrate, Grignard reagents, amino-acids, and several other organic substances[119]; the oxidation with oxygen of hydrocarbons and other organic compounds in solution[114,120-123]; the condensation of acid chlorides with amines and ketones, and polycondensation (production of nylon)[124,125]; the oxidative degradation of polypropylene and other polymers[126]; the oxidation of urea with hypohalites[127]; the oxidation of sodium sulphite in aqueous solution catalysed by metal salts[128]; and the oxidation of oxalyl chloride with hydrogen peroxide[129]

Thus chemiluminescence has been detected in a large number of reactions of the most varied classes and types. In view of these results, chemiluminescence must evidently be regarded as a general phenomenon, accompanying the occurrence of any reaction in which exothermic stages are involved.

## 1. Chemiluminescence in Induced Oxidations

Until recently no quantitative investigation had been made of chemiluminescence accompanying oxidation by molecular oxygen. In order to find a reaction in which excited species are formed, and compare the regularities in chemiluminescence with the kinetic regularities, a series of investigations[113,114,130,131] were based on induced oxidation as model reaction, the kinetics of which is well known[132-134]. The reaction scheme of an induced oxidation is

$$\begin{array}{l} \text{1) chain initiation (appearance of radicals R) at rate } w_i \\ \left.\begin{array}{l} \text{2) } R + O_2 \xrightarrow{k_2} RO_2 \\ \text{3) } RO_2 + RH \xrightarrow{k_3} ROOH + R \end{array}\right\} \text{chain propagation,} \\ \left.\begin{array}{l} \text{4) } R + R \rightarrow R{-}R \\ \text{5) } R + RO_2 \rightarrow ROOR \\ \text{6) } RO_2 + RO_2 \rightarrow \text{inactive products} + O_2 \end{array}\right\} \text{chain termination.} \end{array} \qquad (15)$$

where RH is the substance undergoing oxidation, ROOH the hydroperoxide, R the hydrocarbon radical, and $RO_2$ the peroxy-radical.

Examination of the energetics of reactions (1)–(6) in scheme (15) shows that only reactions (4)–(6) are sufficiently exothermic to excite luminescence in the visible region of the spectrum (the range 350–620 mμm corresponds to 80–45 kcal or 3.3–2.0 eV). At sufficiently high oxygen concentrations the radicals R are converted by reaction (2) into peroxy-radicals, and only $RO_2$ radicals recombine. Under these conditions the emission intensity $I$ is proportional to the rate of recombination $w_{rec}$:

$$I = \eta_{ch} w_{rec} = \eta_{ch} k_6 (RO_2)^2, \qquad (16)$$

where $\eta_{ch}$ is the number of photons emitted in a single act of recombination.

Under steady-state conditions the rate of destruction of radicals is equal to their rate of formation $w_i$, which is proportional to the rate of decomposition of the initiator:

$$w_i = 2 f_{cell} k_0 c, \qquad (17)$$

where $c$ is the initiator concentration, $k_0$ its decomposition rate constant, and $f_{cell}$ the probability of escape of primary radicals from the "cell", the factor 2 indicating that the decomposition of one molecule yields two radicals.

It follows from Eqns. (16) and (17) that

$$I = 2\eta_{ch} f_{cell} k_0 c.$$

If decomposition is slow, the intensity will not vary with time, and at a given temperature will be determined by the formula

$$I = 2\eta_{ch} f_{cell} c a_0 e^{-E/RT} = \text{const}\, e^{-E/RT}, \qquad (18)$$

where $a_0$ is the preexponential factor and $E$ the activation energy of decomposition.

Eqn. (18) indicates an Arrhenius temperature dependence for the intensity. This relationship is in fact well satisfied (Fig. 1), the activation energy determined experimentally from the chemiluminescence $E_{ch}$ proving to be identical with $E$, the activation energy of decomposition of the corresponding substance measured by chemical methods[112-114,135].

If the rate of decomposition of the substance at the experimental temperature is considerable, the concentration will decrease according to the exponential law $c = c_0 e^{-k_0 t}$. The emission intensity should decay according to the same law:

$$I = I_0 e^{-k_0 t} \text{ or } \log I = \log I_0 - 0.43\, k_0 t.$$

This relationship has been observed, for example, in the decomposition of the intermediate product in the ozonisation of 2,7-dimethyloctane[136] and of ethylbenzene hydroperoxide[121], as well as of peroxides formed by the exposure of solutions of deoxyribonucleic acid to X-rays[137]. The decomposition rate constants determined from chemiluminescence data coincided with those obtained by chemical methods.

The kinetics of chemiluminescence may be different in complex reactions, since the rate of the exciting process may vary in a complicated fashion in the course of the chemical change. In the decomposition of the hydroperoxide of 1,1-diphenylethane in glacial acetic acid, for example, the emission intensity increases as a sigmoid curve, passes through a maximum, and then falls[115] (Fig. 2). An investigation comprising experiments with the addition of reactant and products while the reaction is

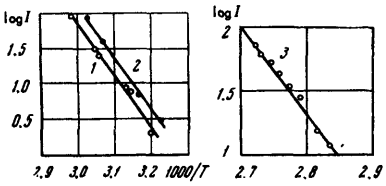


Fig. 1. Temperature dependence of the intensity of chemiluminescence in the oxidation of a series of hydrocarbons initiated by:
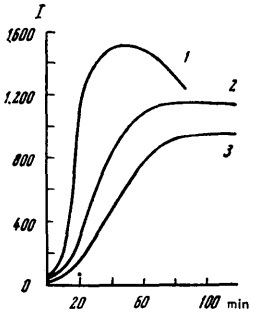
1) 2,7-dimethyloctane hydroperoxide; 2) tetralin hydroperoxide; 3) azoisobutyronitrile.



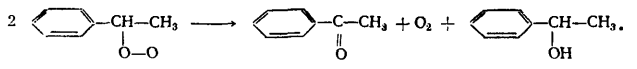


Fig. 2. Kinetic curves of chemiluminescence in the decomposition of 1,1-diphenylethane hydroperoxide in acetic acid at different temperatures and hydroperoxide concentrations: 1) 98.5° and 0.048 M; 2) 87° and 0.050 M; 3) 75.4° and 0.078 M.

progressing, dilution of the reaction mixture during the reaction, and studies of the effects of temperature and of the initial concentration of hydroperoxide has shown that the observed kinetics of chemiluminescence is governed by the formation of intermediate products. Breakdown of one of these products results in the formation of radicals, whose recombination excites the chemiluminescence[115]. Examples of the application of chemiluminescent methods to detect intermediate products in complicated reactions have been given also in papers[117,138] which are considered in other Sections of the present review.

It has been reported many times (see e.g. Ref. 139) that oxygen intensifies chemiluminescence, although it is an effective quencher of luminescence. This apparent contradiction has been eliminated by work[130] showing that oxygen exerts both stimulating and quenching effects. The stimulating action is observed at low oxygen concentrations, and is chemical in nature.

It follows from the reaction scheme (15) that, as the oxygen concentration increases, the concentration of $RO_2$ radicals also increases, as does the contribution of process (6). Hence the intensity changes, too, since the emission yield will depend on the structure of the reactant radicals and the products formed. The products of the recombination of $RO_2$ radicals are oxygen-containing compounds which luminesce in the visible or near ultraviolet region. Recombination of R radicals involves the formation of molecules which do not luminesce in the visible range. Therefore the conversion of chemical into excitation energy and the subsequent emission of light should occur far more efficiently in the former than in the latter case. This results in an intensification of the luminescence with increase in the concentration of oxygen. The stimulating effect of oxygen ceases when all the radicals have been converted into peroxy-radicals[120,130,138,140,141,159].

The disproportionation of, for example, peroxy-radicals of ethylbenzene involves the formation of 1-phenylethanol, acetophenone, and molecular oxygen[142]:

In order to identify the excited state, determinations were made of the quantum yield of the emission, the life of the excited state, and the luminescence spectra[140,143-145]. Examination of the results showed that the excited species responsible for the emission in the oxidation of ethylbenzene was acetophenone in its triplet state (one molecule of triplet acetophenone was formed in the reaction per $10^5$–$10^6$ acts of recombination). Thus the chemiluminescence represents the radiative transition of acetophenone to the ground (singlet) state; the yield of this process is 1 photon per $10^3$–$10^4$ excited molecules[140,145].

The views on the chemical mechanism of the intensification of luminescence by oxygen and on the excitation of chemiluminescence in the recombination of peroxy-radicals, formulated in Ref. 130, have subsequently been checked many times, and have been quantitatively confirmed by various methods.

## 2. Measurement of Rate of Oxidation

The marked difference in the emission yield of the recombination of $R^\cdot$ and of $RO_2^\cdot$ radicals has been used to measure the rate of induced oxidation[140,146]. In an experiment the solution was saturated with air or oxygen, and the reaction vessel closed. At this instant a gradual decrease in the concentration of dissolved oxygen in the system began. After a certain time $t_f$ a fall in emission intensity was observed, caused by the complete exhaustion of $O_2$ and replacement of $RO_2^\cdot$ by $R^\cdot$ ("oxygen fall"). With many hydrocarbons the rate of oxidation is independent of the $O_2$ concentration right down to very low values of the latter ($10^{-6}$–$10^{-5}$ M), which, incidentally, is responsible for the sharpness of the drop in emission. It may therefore be assumed that

$$w_{O_2} = \frac{d[O_2]}{dt} = \frac{[O_2]_0}{t_f}. \qquad (19)$$

and the rate of oxidation may be determined from $t_f$ and $[O_2]_0$. The reliability of this method of measuring rate of oxidation has been tested and confirmed on the oxidation of several organic substances (ethylbenzene, cumene, toluene, decalin, cyclohexane, methyl oleate, n-decane, n-heptane, and ethyl methyl ketone) initiated by the thermal decomposition of azoisobutyronitrile and dicyclohexyl peroxodicarbonate[140]. According to scheme (15), the rate of oxidation is

$$w_{O_2} = \frac{k_3}{\sqrt{k_6}}[RH]\sqrt{w_i} + \frac{1}{2}w_i. \qquad (20)$$

The higher the concentration of hydrocarbon, the higher the rate of oxidation and the shorter the time $t_f$. This is clearly evident from Fig. 3. Eqns. (19) and (20) can be used to determine the concentration of dissolved oxygen $[O_2]$ and the ratio of the elementary rate constants $k_3/\sqrt{k_6}$, provided that the rate of initiation $w_i$ is known. From the change in rate due to decomposition of the initiator and the known value of $w_i$ we can determine the decomposition rate constant of the initiator $k_0$ and its efficiency $f_{cell}$[147] with the same accuracy as by the use of other methods for measuring the rate of oxidation.

Measurement of rate of oxidation at low hydrocarbon concentrations enables us to estimate the relative efficiencies of active initiator radicals in abstracting a hydrogen atom from the hydrocarbon[147]. It is also possible to obtain some qualitative information on the reaction. In a pure inert solvent, for example, $w_i = w_{O_2} = [O_2]_0/t_f$[146,147], whence it follows that molecular oxygen is not evolved in

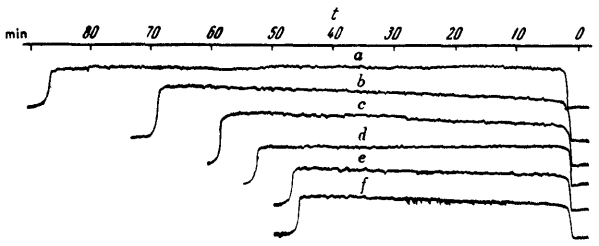

Fig. 3. "Oxygen falls" in chemiluminescence accompanying the oxidation of ethylbenzene in chlorobenzene as solvent, initiated by azoisobutyronitrile ($w_i = 1.9 \times 10^{-7}$ M $s^{-1}$), with different concentrations (M) of ethylbenzene:
*a*) 0.078; *b*) 0.234; *c*) 0.391; *d*) 0.548; *e*) 0.704; *f*) 0.781.[140,146]

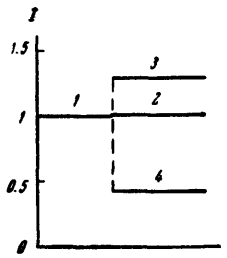

Fig. 5. Change in intensity of chemiluminescence accompanying decomposition of 1,1′-diphenylazoethane in chlorobenzene on addition of 2 vol.% of various hydrocarbons:
1) pure chlorobenzene; 2) addition of ethylbenzene; 3) diphenylmethane; 4) cyclohexene.

the recombination of active radicals of the initiator azoisobutyronitrile, whereas oxygen is always liberated in the recombination of hydrocarbon peroxy-radicals.

The kinetics of the consumption of oxygen and of the variation in emission intensity have been calculated on an M-20 electronic computer[140,148]. As can be seen from Fig. 4, the theoretical curve shows a considerable lack of symmetry: i.e. it has the same shape as the experimental curves. Comparison of theoretical and experimental curves enables the ratio $k_3/\sqrt{k_6}$ to be assessed as of the order of $10^3$ litre$^{\frac{1}{2}}$ mole$^{-\frac{1}{2}}$ $s^{-\frac{1}{2}}$ for most of the hydrocarbons investigated.

The yield and intensity of chemiluminescence differ for the recombination of peroxy-radicals of different hydrocarbons[114,145,149,150]. The effect of radical composition on emission intensity is shown in Fig. 5, which illustrates the changes in intensity accompanying the decomposition of 1,1′-diphenylazoethane $C_6H_5.CH(CH_3).N:N.CH(CH_3).C_6H_5$ in chlorobenzene on addition of various hydrocarbons[150]. Decomposition of this azo-compound in the presence of molecular oxygen yields peroxy-radicals of ethylbenzene, the luminescence arising as a result of their recombination.

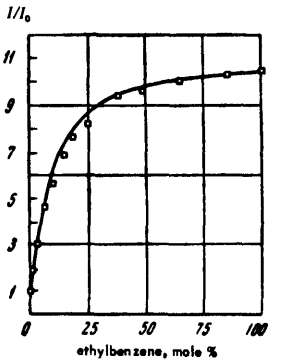

Fig. 6. Dependence of intensity of chemiluminescence on composition of mixture in the simultaneous oxidation of cumene and ethylbenzene initiated by the decomposition of azoisobutyronitrile at 60° and $w_i = 10^{-7}$ M $s^{-1}$. The points represent experimental values; the curve has been calculated.

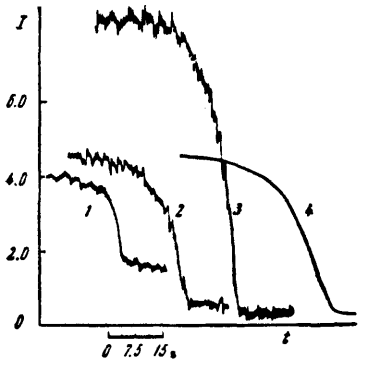

Fig. 4. Kinetic curves for the weakening of chemiluminescence, caused by replacement of peroxy-radicals by hydrocarbon radicals[140], in the oxidation, initiated by the thermal decomposition of azoisobutyronitrile (0.061 M) in benzene at 63°, of the hydrocarbons:
1) toluene; 2) ethylbenzene; 3) decalin; 4) theoretical curve.

Addition of 2% of ethylbenzene does not affect the emission intensity, since the concentration and composition of the radicals remain unchanged. Additions of other substances capable of reacting with peroxy-radicals of ethylbenzene change the intensity owing both to the appearance of a new species of radicals and new recombination reactions and to the decrease in the rate of recombination of the peroxy-radicals of ethylbenzene.

For the same reasons the intensity of luminescence in the simultaneous oxidation of two substances will depend on the composition of the mixture and the emission yields as well as on the kinetic parameters, the ratios of the rate constants for the elementary acts. Fig. 6 shows the dependence of emission intensity on the composition of a mixture of cumene and ethylbenzene undergoing oxidation. The full line represents the dependence calculated from the rate constants[151] and the measured quantum yields of chemiluminescence. The good agreement between calculated and experimental curves indicates that measurements of chemiluminescence can be used to determine the kinetic parameters of this complicated reaction[150].

### 3. Chemiluminescence in Inhibited Oxidations and the Activity of Inhibitors

The intensity of chemiluminescence in various oxidations with hydrogen peroxide and molecular oxygen has been observed to diminish on the addition of inhibitors of free-radical reactions[113,119,126,152-155]. In several cases the dependence of emission intensity on inhibitor concentration has been used to determine the concentration of the latter[122,156]. Until recently no quantitative study had been made of the relation between the activity of an inhibitor InH and its ability to diminish the intensity of luminescence. It became possible to solve this problem as a result of work establishing the mechanism of the excitation of chemiluminescence in oxidations with molecular oxygen[113,114,130]. In order to describe the process of inhibited oxidation, scheme (15) must be supplemented by the reactions[157,158]

$$\left.\begin{array}{ll} 7)\ \mathrm{InH}+\mathrm{RO}_2^{\bullet} \xrightarrow{k_7} & \mathrm{In}^{\bullet}+\text{products},\\ 8)\ \mathrm{RO}_2^{\bullet}+\mathrm{In}^{\bullet} \xrightarrow{k_8} & \\ 9)\ \mathrm{In}^{\bullet}+\mathrm{In}^{\bullet} \xrightarrow{k_9} & \end{array}\right\}\ \text{stable products.}$$

The inhibitor radical In$^{\bullet}$ which is formed is usually inactive and incapable of participating in chain propagation. Additions of an inhibitor lower the concentration of peroxy-radicals and thus retard the oxidation. Since luminescence is associated with the recombination of $RO_2^{\bullet}$ radicals, the diminution in their concentration produced by the addition of inhibitors results in a weakening of chemiluminescence. After such addition new chemiluminescent reactions do not arise, since the In$^{\bullet}$ radicals formed are relatively inactive, and the heat evolved in reactions (8) and (9) is insufficient to excite luminescence in the visible region of the spectrum. This kinetic scheme, in which the power of inhibitors to weaken emission is linked with their activity towards $RO_2^{\bullet}$ radicals, has been put forward by one of the present authors[159].

As can be seen from the scheme (15), the rate of a chain oxidation is

$$w = k_3(\mathrm{RO}_2^{\bullet})(\mathrm{RH}). \qquad (21)$$

Therefore $w/w_0 = [RO_2^{\bullet}]/[RO_2^{\bullet}]_0$, where the subscript 0 denotes the absence of inhibitor. On the other hand,

$$\frac{I}{I_0}=\frac{[\mathrm{RO}_2^{\bullet}]^2}{[\mathrm{RO}_2]_0^2},\ \text{or}\ \sqrt{\frac{I}{I_0}}=\frac{[\mathrm{RO}_2]}{[\mathrm{RO}_2]_0^2}. \qquad (22)$$

Comparison of Eqn. (21) with (22) shows that

$$\frac{w}{w_0}=\sqrt{\frac{I}{I_0}}. \qquad (23)$$

The relationship (23) has been tested and confirmed experimentally[123,160]. Its applicability shows that the weakening of chemiluminescence is caused by the diminution in the concentration of peroxy-radicals§, and that the intensity of chemiluminescence is a measure of their relative concentration. Hence it at once follows that the relative activities of inhibitors can be characterised by their concentrations at which the emission intensity decreases, e.g. is halved[161] (which corresponds to a 30% decrease in the concentration of peroxy-radicals). The reciprocal of the inhibitor concentration is then taken as a measure of the activity. In this way a series of inhibitor activities — for phenols and amines[161] — has been obtained, characterising their reactivity towards peroxy-radicals.

New chemiluminescent methods have been proposed, based on the above kinetic scheme, for determining the activity of inhibitors. The dependence of emission intensity $I$ on inhibitor concentration $[\mathrm{InH}]_0$

$$\sqrt{\frac{I}{I_0}}=1+1.1\frac{k_7}{\sqrt{k_6}}\frac{[\mathrm{InH}]_0}{\sqrt{w_i}} \qquad (24)$$

has been obtained[162] from this scheme. The kinetic parameter $k_7/\sqrt{k_6 w_i}$ is then determined from the slope of the linear plot of $\sqrt{I/I_0}$ against $[\mathrm{InH}]_0$.

The kinetic chemiluminescence curve, representing the increase in concentration of peroxy-radicals resulting from the gradual consumption of inhibitor, is S-shaped (Fig. 7), with a point of inflection at $I/I_0 = 0.55$.[162]

It has been shown[148] that in general the slope at the point of inflection on the kinetic curve of chemiluminescence $[d(I/I_0)/dt]_{max}$ should be proportional to the ratio $k_7\sqrt{w_i}/\sqrt{k_6}$ if the emission intensity varies as a result of the consumption of some substance by reaction with the radicals responsible for the luminescence. Proportionality is then maintained independently of what other elementary acts enter the reaction scheme. An actual calculation of the above scheme has enabled the proportionality coefficient to be evaluated[162]:

$$\left[\frac{d(I/I_0)}{dt}\right]_{\max}=0.22\frac{k_7}{\sqrt{k_6}}\sqrt{w_i}, \qquad (25)$$

and measurements of the maximum slope to be used to determine the parameter $k_7/\sqrt{w_i/k_6}$. By combining the relations (24) and (25) we can use chemiluminescence measurements to obtain values of the parameter $k_7/\sqrt{k_6}$, which characterises the relative activity of an inhibitor, and the rate of initiation $(w_i)_{calc}$.

Experiments on fifteen inhibitors (phenols and amines) have shown[163] satisfactory agreement with Eqn. (24). Application of Eqn. (25) revealed that the slope of the kinetic curves decreases with increase in the initial concentration of inhibitor $[\mathrm{InH}]_0$. This was explained by a decrease in activity of the inhibitor as its concentration

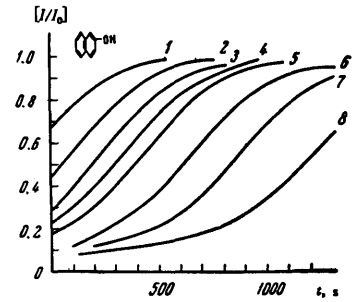

Fig. 7. Kinetic curves representing the variation in intensity of chemiluminescence accompanying the oxidation of ethylbenzene, initiated by the decomposition of azoisobutyronitrile at 60° and $w_i = 4.14 \times 10^{-7}$ M s$^{-1}$, in the presence of different initial concentrations (in $10^{-5}$ M) of 2-naphthol:
1) 0.69; 2) 1.38; 3) 2.07; 4) 2.76; 5) 3.45; 6) 5.17; 7) 6.9; 8) 9.5.

§ Many phenols are known as deactivators of excited states. Therefore the weakening of the luminescence might have been attributed *a priori* to physical quenching. The applicability of Eqn. (23) indicates that, under the experimental conditions, physical deactivation is negligible, if present at all, the chemical reaction of $RO_2^{\bullet}$ with InH being decisive.

increases. The same conclusion, on the concentration dependence of activity, was reached independently[164] from measurements of the activity of inhibitors from the rate of oxidation of styrene. The dependence of $k_7$ on $[InH]_0$ can be eliminated if data for a series of experiments with different values of $[InH]_0$ are used to extrapolate the maximum slope to $[InH]_0 \to 0$. Then simultaneous application of Eqns. (24) and (25) yields values of $k_7/\sqrt{k_6}$ and also of $(w_i)_{calc}$, the latter being practically identical with values of $w_i$ specified in the experiment[163]. This identity of the values of $w_i$ is a criterion of the correctness of the new chemiluminescent methods[163].

Experiments with a single inhibitor but in different oxidisable substances revealed a significant dependence of the ratio $k_7/\sqrt{k_6}$ on the nature of the oxidisable substance. The activity of $RO_2^\cdot$ varies comparatively little with the natue of the radical R,[151] so that values of $k_7$ should be similar for different $RO_2^\cdot$ radicals. At the same time, values of $k_6$ may differ by several orders of magnitude. If, therefore, values of $k_7/\sqrt{k_6}$ in two non-polar substances undergoing oxidation differ by a factor of more than 3–4, this is usually to be attributed to a difference in the values of $k_6$. On this reasoning it was concluded[163] that $k_6$ is considerably lower for 2,7-dimethyloctane than for ethylbenzene. This conclusion has been confirmed by direct experiments[165], in which concentrations of peroxy-radicals have been measured, by the electron spin resonance method, during the progress of liquid-phase oxidations.

Curves of the initial emission intensity and of the time of reaching the point of inflection, plotted as functions of the initial concentration of inhibitor from a series of kinetic chemiluminescence curves (Fig. 7), can be employed as calibration curves to determine inhibitor contents[122]. The sensitivity of the method depends on the value of $w_i$, and also on the activity of the inhibitor, reaching around $10^{-7}$ M. Since chemiluminescence is observed in the oxidation of various classes of substances — aldehydes, ketones, acids, alcohols, hydrocarbons, etc. — the proposed method can be used to determine inhibitor contents in practically any oxidisable substance[122].

The use of calibration curves enables us to determine with which radicals ($R^\cdot$ or $RO_2^\cdot$) a given inhibitor reacts. Experiments are carried out in which the inhibitor is subjected to the action of initiator radicals $R^\cdot$ in the absence of $O_2$ for a definite time. After this the kinetics of chemiluminescence, now in the presence of $O_2$, is recorded, and the change in concentration of inhibitor during reaction with $R^\cdot$ radicals is determined from the calibration curve. The experiments have shown, for example, that ionol does not react with $R^\cdot$ radicals[148].

### 4. Chemiluminescence in the Oxidation and Decomposition of Hydroperoxides Catalysed by Salts of Metals of Variable Valency

Chemiluminescence has been observed[115,121,166] in the oxidation of toluene, cumene, ethylbenzene, and diphenylmethane catalysed by the acetates or stearates of cobalt, manganese, and copper. The quantitative relationship between the kinetics of chemiluminescence and the kinetics of the reaction has been investigated in the oxidation of ethylbenzene in glacial acetic acid with cobalt acetate as catalyst[121,166]. Recently the kinetics of this reaction has been studied quantitatively by the usual methods[167,168]. Chemiluminescence was measured with the same specimen of catalyst under the same conditions. As a result, the kinetics of chemiluminescence could be directly compared with the reaction kinetics. The experiments showed that, in the course of the process, the emission intensity increases to a constant value independent of the catalyst concentration. Increasing the latter merely shortens the time needed to reach the steady state. Initial additions of a hydroperoxide eliminate the stage of increasing emission. The initial intensity of luminescence is proportional to the concentration of the additive. Soon after the start of the experiment the intensity reaches the same level as in the absence of an initial addition. Hence it follows that the observed kinetics of chemiluminescence is associated with the accumulation of hydroperoxide, and that the steady emission intensity corresponds to a steady state of oxidation, in which the rate of consumption of hydroperoxide is constant. The intensity of luminescence in the steady state is proportional to the rate of oxidation. As a result, intensity measurements can be used to obtain the fundamental kinetic parameters of the reaction — the dependence of rate of oxidation on the concentrations of hydrocarbon and of catalyst, and the activation energy of the reaction.

The observed regularities in chemiluminescence are explained quantitatively by the scheme representing the kinetics of the catalysed oxidation of ethylbenzene[167]. This scheme differs from that of oxidation initiated by thermal decomposition solely in the initiation reaction. In the present case formation of $R^\cdot$ or $RO_2^\cdot$ radicals at a rate $w_i$ occurs on reaction of the hydroperoxide with the catalyst:

$$ROOH + nCo(AcO)_2 \xrightarrow{k_i} \text{free radicals}.$$

When the rates of formation and consumption of hydroperoxide become equal, the maximum reaction velocity $w_{st}$ is reached, equal to the rate of initiation

$$w_{st} = k_i^2[RH]^2/k_6 = w_i.$$

The emission intensity is given by the equation

$$I_{st} = \eta_{ch}k_6[RO_2^\cdot]^2 = \eta_{ch}w_i = \eta_{ch}k_i^2[RH]^2/k_6,$$

i.e. $I_{st} \propto w_{st}$, in conformity with experiment[121].

In order to describe quantitatively the kinetics of chemiluminescence in the initial, non-stationary stage of the oxidation process, an investigation was made of the catalytic decomposition of ethylbenzene hydroperoxide by a chemiluminescent method and by analysis of the consumption of hydroperoxide[169]. Experiments were made with initial additions of hydroperoxide to a solution of the hydrocarbon in acetic acid. Fig. 8 shows that the emission intensity and the hydroperoxide concentration diminish exponentially during the course of the decomposition reactions. The straight lines have practically the same slope. This permits measurements of the kinetics of chemiluminescence to be used to determine $k_{eff}$, the effective decomposition rate constants for the hydroperoxide. Since the emission intensity is proportional to the hydroperoxide concentration, comparison of the initial intensity accompanying a definite initial addition of hydroperoxide with the steady-state intensity will yield the steady-state hydroperoxide concentration $[ROOH]_{st}$¶. It follows from the kinetic scheme that the rate of oxidation is

$$w_{O_2} = -\frac{d[O_2]}{dt} = k_{eff}[ROOH]_{st}.$$

¶ This method of determining the hydroperoxide concentration is of intrinsic interest, and can be employed to estimate traces of peroxy-compounds. Its limiting sensitivity of $5-10 \times 10^{-7}$ M considerably exceeds that of chemical methods of analysis[169].

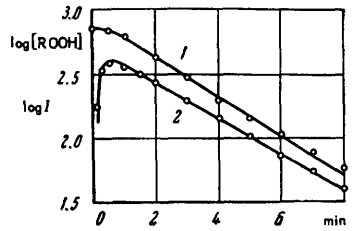

Fig. 8. Semilogarithmic anamorphoses of kinetic curves at 47° for 20% ethylbenzene (RH) in acetic acid containing 0.037 M ROOH and 0.032 M $Co(OAc)_2$: 1) decomposition of ethylbenzene hydroperoxide; 2) chemiluminescence.

To check the accuracy of chemiluminescent methods of determining $k_{eff}$ and $[ROOH]_{st}$, a comparison was made between values of $w_{O_2}$ and $k_{eff}[ROOH]_{st}$, which showed that the difference did not exceed 10–15%.[169]

Chemiluminescent methods have also enabled the mechanism of the catalysed decomposition of the hydroperoxide to be investigated[138]. The initial stage of the decomposition was observed to be accompanied by an increase in the emission intensity (Fig. 8), which was shown to be associated with the formation of an intermediate product, a cobalt(III) salt. This salt reacts with the hydroperoxide according to Eqn. (27):

$$\begin{aligned} &ROOH + Co(OAc)_2 \rightarrow RO_2^{\bullet} + Co(OH)(OAc)_2, \\ &Co(OH)(OAc)_2 + AcOH \rightarrow Co(OAc)_3 + H_2O, \end{aligned} \qquad (26)$$

$$ROOH + Co(OAc)_3 \rightarrow RO_2^{\bullet} + Co(OAc)_2 + AcOH, \qquad (27)$$

which results in an increase in the rate of decomposition and a corresponding intensification of the luminescence. From kinetic measurements on the growth and subsequent fall in the emission, the latter due to consumption of the hydroperoxide, the equilibrium concentration of the intermediate product could be determined kinetically. Calculations gave values of the order of 1% based on the concentration of the bivalent salt. Similar values for the concentration of the tervalent form of the catalyst were obtained in independent spectrophotometric experiments[170].

Chemiluminescent methods show that two different radicals are actually formed in the catalytic decomposition of the hydroperoxide[138]. When decomposition is carried out in the presence of oxygen, RO• radicals are converted into peroxy-radicals according to the scheme

$$\begin{aligned} &RO^{\bullet} + RH \rightarrow ROH + R^{\bullet}, \\ &R^{\bullet} + O_2 \rightarrow RO_2^{\bullet}. \end{aligned}$$

Half the peroxy-radicals are then formed from RO•, since in the steady state the reactions (26) and (27) occur at the same rate. If, when the steady state has been established, oxygen is removed from the system (by bubbling a pure inert gas through), the emission intensity drops sharply to a definite level lower than half the previous value. This result can be explained by the fact that, in the absence of oxygen, conversion of RO• into $RO_2^{\bullet}$ radicals is impossible, and that some of the $RO_2^{\bullet}$ radicals are used up by reaction with the hydrocarbon and hydrocarbon radicals. From the rate of decomposition of the hydroperoxide and the emission intensity before and after removal of oxygen, the rate of recombination of $RO_2^{\bullet}$ in the absence of oxygen can be determined. These results were used, with reactions (4) and (5) of scheme (15) taken into account, to calculate values of the parameter $k_3/\sqrt{k_6}$, which were close to those obtained by the usual kinetic methods[138].

## 5. Chemiluminescence in Low-Temperature Gas-Phase Oxidations

Little study has yet been made of chemiluminescence in the gas-phase oxidation of organic substances. Until recently, in effect, only visual observations had been made, in which the temperature range of the luminescence was determined. The emission intensity was found to increase with rise in temperature, and the range of chemiluminescence was displaced to lower temperatures with increase in concentration of the oxidisable substance[171,172]. Just as with liquid-phase reactions, the application of highly sensitive photometric instruments has made it possible to detect chemiluminescence in various reactions. In the case of reactions in which it had been known earlier, the limits to its observation could be greatly shifted towards lower temperatures.

A more detailed investigation has been made of the chemiluminescence accompanying the oxidation of acetaldehyde[116,117,173], the kinetics of which has been studied thoroughly[174,175]. Investigations were made at 100–200° and initial pressures of the reaction mixture varying from a few tenths to several hundred millimetres of mercury. Fig. 9 shows kinetic curves for the luminescence and the variation in pressure obtained in one of the experiments, as well as kinetic curves for the consumption of the reactants and the accumulation of the products of the reaction. The emission curve passes through two maxima, the first of which is sharp and the second very flat. The former

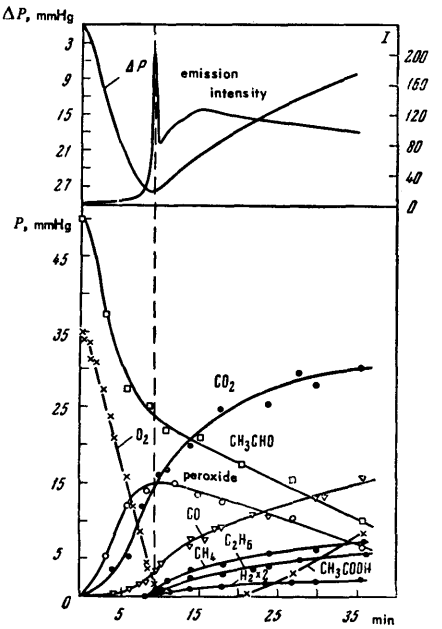

Fig. 9. Kinetic curves for intensity of chemiluminescence, pressure, consumption of reactants, and accumulation of products in the oxidation of acetaldehyde at 182°.

corresponds to a minimum on the pressure curve. This relationship is maintained however the experimental conditions are varied (by changing the temperature, pressure, and composition of the mixture, or adding a homogeneous catalyst). Oxygen quenches chemiluminescence, and the emission becomes stronger when its concentration is diminished[116]. At the instant at which the first maximum is reached, the process of oxidation with molecular oxygen terminates. This is evident both from the oxygen consumption curve and from the appearance of products ($CH_4$, $C_2H_6$, $H_2$) which could not be formed in the presence of oxygen. Thus the first luminescence maximum represents a change in the nature of the process, a transition from oxidation by molecular oxygen to oxidation by peroxy--compounds[174]. A similar sharp luminescence maximum was first observed in work on the oxidation of pentane[176], the author concluding from indirect arguments that this maximum was associated with the complete exhaustion of oxygen in the system.

Since the rate of consumption of oxygen is constant (Fig. 8), the time required to reach the first luminescence maximum can be conveniently used to determine the reaction velocity and its dependence on various parameters. It is obvious that

$$w_{O_2} = \frac{[O_2]_0}{t_{max}}.$$

With the rate of oxidation known, it is possible to obtain the principal kinetic characteristics — the activation energy, and the order with respect to the aldehyde, oxygen, and the total pressure — of the first stage of the reaction[117]. Kinetic parameters determined by the chemiluminescent method and from the fall in pressure are practically identical and agree with those determined by other methods[174,175].

It is possible to create artificially conditions under which the rate is constant, or the reaction will follow a known kinetic law. This can be achieved, for example, by carrying out a low-temperature initiated oxidation. In this case $t_{max}$ can be used as a kinetic characteristic of different reactions, since an oxygen maximum is observed in the oxidation of many substances[117]. Determinations of the dependence of $t_{max}$ on $[O_2]_0$ have enabled kinetic parameters to be evaluated[117] in the radical reaction of the oxidative decomposition of di-t-butyl peroxide and the chain oxidation of acetaldehyde:

for the reactions

$$CH_3^{\cdot} + O_2 \rightarrow CH_3OO^{\cdot} \ (k_2)$$

and

$$CH_3^{\cdot} + CH_3^{\cdot} \rightarrow C_2H_6 \ (k_4),$$

$k_2/\sqrt{k_4}$ = 123 litre$^{\frac{1}{2}}$ mole$^{-\frac{1}{2}}$ s$^{-\frac{1}{2}}$ at 105°;

for the reactions

$$CH_3CO^{\cdot} + O_2 \rightarrow CH_3CO_3^{\cdot} \ (k_2')$$

and

$$CH_3CO^{\cdot} + CH_3CO^{\cdot} \rightarrow (CH_3CO)_2 \ (k_4'),$$

$k_2'/\sqrt{k_4'}$ = 510 litre$^{\frac{1}{2}}$ mole$^{-\frac{1}{2}}$ s$^{-\frac{1}{2}}$ at 87°.

Determination of the chemiluminescence spectra has shown[173] that the luminescent species in the oxidation of acetaldehyde is the excited formaldehyde molecule. The presence of formaldehyde among the reaction products has been detected also by chemical analysis. From the dependence of the intensity of chemiluminescence on the concentration of oxygen, which obeys the Stern–Volmer equation, the lower limit to the life of excited formaldehyde has been found to be $\tau \geqslant 1.3$ μs.[177]

The problem of routes to the formation of excited formaldehyde has been discussed in the literature[178-182], mainly in connection with investigations on cold flames. The general view has now apparently become established that excitation occurs in reactions involving alkoxy-radicals[179-182]: e.g. in the case of methoxy-radicals

$$CH_3O^{\cdot} + CH_3O^{\cdot} \rightarrow CH_3OH + CH_2O + 76 \text{ kcal (Ref. 178)}, \quad (28)$$

$$CH_3O^{\cdot} + OH^{\cdot} \rightarrow H_2O + CH_2O + 98 \text{ kcal (Ref. 182)}, \quad (29)$$

$$CH_3O^{\cdot} + CH_3^{\cdot} \rightarrow CH_4 + CH_2O + 82 \text{ kcal}. \quad (30)$$

These heats of reaction are sufficient to excite formaldehyde (77 kcal)[183].

The formation of excited formaldehyde molecules is not a distinguishing feature of cold-flame oxidation, as has generally been assumed, for it occurs at considerably lower temperatures in slow oxidation processes. It has therefore proved possible to study the mechanism of the formation of excited formaldehyde molecules in model systems containing radicals of known composition[184]. The following sources of free radicals were used — (*a*) $CH_3^{\cdot}$ radicals from di-t-butyl peroxide $(CH_3)_3C.O.O.C(CH_3)_3$; (*b*) $CH_3O^{\cdot}$ radicals from[185] methyl nitrate $CH_3ONO_2$, methyl nitrite $CH_3ONO$, and dimethyl peroxide $CH_3OOCH_3$; and (*c*) $CH_3O^{\cdot}$ and $HO^{\cdot}$ from[185] methyl hydroperoxide $CH_3OOH$.

Luminescence was absent from the decomposition of methyl nitrate, methyl nitrite, dimethyl peroxide, and also a mixture of dimethyl and di-t-butyl peroxides, which enabled reactions (28) and (30) to be eliminated. The luminescence of formaldehyde was observed on decomposition of the hydroperoxide. The emission was sharply increased by additions of dimethyl peroxide, which itself decomposes without luminescence. The observed intensification of the emission is readily explained by an increase in the concentration of $CH_3O^{\cdot}$ radicals. Hence it follows that the excited formaldehyde is formed in reaction (29). An advantage of this process compared with (28) and (30) is its large heat of reaction.

Since there is no difficulty in introducing $CH_3O^{\cdot}$ radicals into a chemical system (by adding dimethyl peroxide, hyponitrites, etc.), the luminescence of formaldehyde may provide a convenient indicator for the detection of hydroxy--radicals. It is obvious that, conversely, hydroxyl may be an indicator of methoxyl (perhaps of alkoxyl) radicals[184].

---o0o---

The results discussed in the present paper demonstrate the great possibilities and prospects for the application of chemiluminescent methods in the quantitative investigation of the kinetics and mechanism of various chemical processes. Recently the range of application of chemiluminescent methods of investigation has been greatly extended by the discovery of new chemiluminescent reactions. Chemiluminescent methods have been suggested for controlling technological chemical processes[186]. This in considerable measure stimulates interest both in the phenomenon itself and in the use of chemiluminescence to study the kinetics and the mechanism of chemical reactions.

## NOTE ADDED IN PROOF

New results have recently been published on the luminescence of Luminol and lucigenin[187-189].

## I. INTRODUCTION

Lipids of natural origin are usually mixtures of aliphatic compounds of different *classes*, characterised by a definite number of polar functional groups, COOH, OH, $NH_2$, etc. The structural differences between lipids within a given class are determined entirely by two parameters — the number of methylene groups and the number and position of double bonds. A set of lipids in which one of the parameters is constant while the other changes monotonically forms a *homologous series*. Each class may contain several such series. Their detailed analysis is of considerable theoretical and practical importance.

A mixture of lipids is separated into individual classes by adsorption chromatography; separation of the classes into homologous series and separation within the series generally does not take place in this case, since the differences in polarity among lipids within a class are small compared with the changes in polarity due to the functional groups. Even these relatively slight differences, however, are quite sufficient for the separation of lipids within classes and homologous series by the method of *partition chromatography*†.

Partition chromatography, discovered in 1941 by Martin and Synge [1], was applied in the field of lipids only in 1948, in work by Ramsey and Patterson [2] and Boldingh [3]. In the last 17 years, several hundred scientific papers and a large number of reviews [4-19] have been devoted to the partition chromatography of lipids.

The subject of the present review is the use of various types of partition chromatography in the analysis of natural

† This term, which is now firmly established, cannot be regarded as appropriate, since the mass is partitioned between solid, liquid, or gaseous phases in *any* chromatographic separation. Here and subsequently we shall have in mind *a system of two immiscible liquid phases*, one mobile and one stationary.

lipids. The theoretical principles of the method and the characteristic features of the apparatus used are not examined in detail: this information can be found in textbooks [9,17]. Little reference is made to studies on the chromatography of aliphatic compounds with short chains (up to $C_8$), steroids, and other isoprene derivatives, or to the extremely large number of papers in which established chromatographic methods have been applied without any fundamental modification. The present review covers the most important work on the partition chromatography of lipids published before 1st March 1964.

## II. CHROMATOGRAPHY WITH A POLAR STATIONARY PHASE

Following the historical order, we shall examine first of all systems in which the stationary phase is more polar than the solvent passing through, although at the present time these forms of chromatography are used in the field of lipids much less frequently than are reversed-phase systems (see Section III).

### 1. Column Chromatography

Column chromatography has been used for the purification, separation, and identification of aliphatic acids and other lipids.

Columns of cellulose powder have been used to purify phospholipids from peptides and amino-acids. The lipids were eluted with a mixture of chloroform, butanol, and water [20], chloroform, ethanol, and water (80 : 20 : 2.5) [21], or chloroform and methanol [22]. In the chloroform–methanol system, the phospholipids left the column in the sequence — phosphatidic acids, Φ-choline (Φ = phosphatidyl), sphyngomyelin, Φ-aminoethanol, Φ-serine, and Φ-inositol [23]. Phospholipids have also been separated by means of acetone at -18°. [24] A mixture of methanol, hexane, water, and acetic acid (30 : 50 : 5 : 1) has been used for the fractionation of the hydroxamate derivatives of the "even" $C_{14-22}$ saturated and $C_{18}$ unsaturated acids. The hydroxamates were detected by their reaction with $Fe^{3+}$ and identified from their melting points. The retention time increased with increase in polarity; derivatives with the same polarity were not separated. An advantage of the hydroxamates over the original acids is their greater solubility in the stationary phase [25].

In 1948, Ramsey and Patterson [2] proposed the use of silica gel as carrier for the partition chromatography of aliphatic acids. This method was standardised with $^{14}C$ acids [26,27] and has been used repeatedly for the separation of lipids [28–33]. For partition chromatography the silica gel was suspended in the lower phase of the system [2,29,30,33], and the column was filled under pressure [29–31,33]. The specimen (3.3–3.8 mg of lipids per g of carrier) [30,33,34] was dissolved in the upper phase and introduced into the column. The solvent (upper phase) was passed at a rate of 0.6–1.2 ml $min^{-1}$. [29,30] The acids were separated in the systems: furfuryl alcohol–2-aminopyridine (1 : 1)/hexane [2], 0.25 *N* $NH_4OH$ in methanol/isooctane [29], 0.2 *N* $NH_4OH$ in a mixture of 2-methoxyethanol and water (9 : 1)/hexane [30], and 0.3 *N* NaOH in methanol/cyclohexane [34]; thus the aliphatic acids moved along the column as the salts of organic or inorganic cations. Hydroxy-acids have been separated by means of the systems: 0.1 *N* $NH_4OH$ in 95% methanol/petroleum ether [35] or methanol–hexane–acetone (2 : 10 : 1); [36] and dicarboxylic acids formed by the oxidative splitting of lipids have been separated using the systems: 0.2 *N* $NH_4OH$ in a mixture of 2-methoxyethanol and water (9 : 1)/mixture of hexane and dibutyl ether (1 : 1), [30] 1 M Na citrate (pH 5.4)/chloroform–butanol [37] or methanol–water–hexane–acetone (7.7 : 1.9 : 77 : 34). [33] The products obtained by the oxidation of triglycerides with a permanganate–periodate mixture were separated in the 90% ethanol/petroleum ether system [38]. Neutral derivatives of the acids have been fractionated in the systems: nitromethane/petroleum ether [31,39] or 2-phenoxyethanol/heptane [32]. The time required for the analysis on columns of silicic acid was 20 h. [30] For the quantitative determination, the individual fractions of the eluate were titrated with 0.05 *N* NaOH using phenolphthalein [2,33] or Phenol Red [30] as indicator. The silica gel can be impregnated with indicator before the separation; in this case the acids migrate in the form of coloured bands [29,30]. Derivatives of aliphatic acids form coloured zones on the column in the absence of indicators [31,32,39]. The eluate contained 95–105% of the original lipids [2,29,30,33].

The lipids leave the column in order of increasing polarity. The even saturated $C_{10-22}$ mono- and di-basic acids are readily separated [2,29,30,34,37]; a difference of one $CH_2$ group is sufficient for separation of the $C_{6-10}$ dicarboxylic acids [33]. Ricinoleic and dihydroxy stearic acids are separated from one another and from other acids [35,36]. The products of the oxidation of glycerides have been separated into fractions SSS + SSA and SAA + AAA, where S and A are the acyl groups of saturated acids and azelaic acid [38]. In the series of *p*-phenylazophenacyl esters of $C_{2-18}$ saturated acids [32] and the 2,4-dinitrophenylhydrazones of these esters [31], homologues differing by one $CH_2$ group were separated completely. The homologous series formed by the 2,4-dinitrophenylhydrazones of the $C_{2-18}$ aliphatic aldehydes was fractionated by Ramsey's method using columns [39]. In agreement with Martin's fundamental equation [1] for partition chromatography, the logarithm of the retention volume $V_R$ for these compounds in the column was found to depend linearly on chain length. This relationship was used for the identification of lipids [28,29,40].

The new method of *crystallisation chromatography* in a column has been used for the separation of the triglycerides of saturated acids. A brass column was filled with steel wool and sand. The temperature in the lower part of the column was 20 deg lower than that in the upper part; the central portion was kept at a constant temperature. The mixture of glycerides was introduced into the upper part, and the column was filled with acetone; hexane or carbon tetrachloride was then supplied at the rate of 1–2.8 ml $min^{-1}$. The high-melting components were retained in the column in the form of crystals of the stable $\beta'$ form. The MyrMyrMyr glyceride left the column first, followed by the PalPalPal and StStSt glycerides‡. The eutectic mixture of PalStPal and StPalPal glycerides was not separated [41].

### 2. Paper Chromatography

In early work, *aliphatic acids* of decreasing polarity were eluted from the point of application with aqueous methanol or acetone; by selection of a suitable solvent, the mixture of acids was partly separated into two or even three

‡ Myr, Pal, and St represent the myristoyl, palmitoyl, and stearoyl radicals.

components[42-50]. The triglycerides[44] and polymerised lipids[44,45,47] remained at the starting point. The salts of aliphatic acids were separated from the other lipids by means of water[42]. Petroleum ether, ether, and dichloro--ethylene were used for the separation of mixtures of di-, tetra-, and hexa-bromostearic acids respectively[51]. Di-, tetra-, and hexa-hydroxystearic acids, obtained by the permanganate oxidation of unsaturated $C_{18}$ acids, were separated in the butanol–ethanol–water–conc. $NH_4OH$ (75 : 15 : 8 : 2) system[52]. Aliphatic acids containing conjugated bonds were treated with maleic anhydride vapour before separation; the products of the diene synthesis remained at the start, and the unsubstituted acids moved in the solvent front with 75–99% methanol[45,46]. Mono- and di-basic $C_{2-12}$ acids (products of the oxidation of lipids) can be separated in 1 *N* $NH_4OH$ in 78% ethanol[53]. This separation is more frequently carried out by chromatography of the hydroxamates in water-saturated butanol or phenol; the hydroxamates are detected with $Fe^{3+}$.[54-58].

The lipids from skin, blood serum, and spinal fluid, and also triglycerides from vegetable oils, have been separated into several fractions in 99% methanol[59,60], a mixture of methanol with acetone[61], or a mixture of diisobutyl ketone, acetic acid, and water (8 : 5 : 1).[62] Phospholipids[7,11,17] were separated by means of a mixture of chloroform, methanol, and water (32 : 8 : 1),[63] a mixture of acetone with methanol followed by water-saturated phenol[64], aqueous ethanol[65], a mixture of lutidine with methanol (3 : 2),[66] and (with the use of aminoethylcellulose anion-exchange paper) a mixture of diisobutyl ketone, acetic acid, and water (8 : 5 : 1).[67] The efficiency of separation on untreated paper is usually low. A mixture of Φ-choline and sphyngomyelin has been separated from a mixture of Φ-aminoethanol and Φ-serine[63]. The compounds Φ-choline, Φ-serine, and Φ-aminoethanol have been separated by successive treatment with two solvent systems[64]. Saturated and unsaturated Φ-choline and lyso-Φ-choline have been separated in a one-dimensional system[65]. Acetylation of the $NH_2$ groups of Φ-aminoethanol leads to its complete separation from Φ-choline and sphyngomyelin[66]. A more effective separation was observed on anion-exchange paper; the $R_f$ values at 4° were — Φ-inositol 0.29, sulpholipid 0.30, Φ-glycerol 0.42, digalactolipid 0.49, Φ-aminoethanol 0.58, Φ-choline 0.61, galactolipid 0.68, and triglycerides 0.98.[67]

Aliphatic acids and other lipids are sometimes separated with a non-aqueous polar phase. The monobasic $C_{4-14}$ unsaturated acids (10–100 mg) have been separated on paper impregnated with potash alum, a mixture of carbon tetrachloride, methanol, and conc. $NH_4OH$ (81 : 18 : 1) being used[68]. The same acids, in the form of their 2,4-dinitrobenzyl esters, were separated with dimethylformamide in a mixture of cyclohexane and hydrocarbons of b.p. 190–220°.[69] Glycerol and the mono- and di-glycerides of stearic acid have been separated in the system n-butanol–acetic acid–water (4 : 1 : 5)/formaldehyde[70]. The $R_f$ value was always proportional to the chain length.

Phospholipids have been separated on paper with formaldehyde, the solvent being a mixture of butanol, acetic acid, and water (4 : 1 : 5), or by a two-dimensional system with the same mixture and a neutral solvent, tetrahydrofuran–diisobutyl ketone–water (45 : 5 : 6).[71-73] In the acid solvent the lipids were arranged in the order (from the front) triglycerides, Φ-aminoethanol + Φ-choline, lyso-Φ-choline, Φ-serine, Φ-inositol, lyso-Φ-inositol, and glycolipid[71]; in the neutral system, sphyngomyelin, Φ-choline, Φ-aminoethanol, polyglycero phosphatide and cerebroside, and also lyso-Φ-choline and lyso-Φ-aminoethanol, were separated[72,73].

Lipids are detected by the usual reactions (see Section III4E); thus phospholipids give colour reactions with molybdophosphoric acid, stannous chloride, ninhydrin, Schiff's reagent, permanganate, iodine, or Nile Blue[64,71]. For neutron-activation analysis, the dry chromatograms were irradiated in an aluminium container with slow neutrons ($5 \times 10^{11}$ neutrons $cm^{-2}$ $s^{-1}$) for 15 h. The strip was kept for 1 week until the short-lived isotopes had decayed completely, after which the strip was exposed with X-ray film, or the radioactivity of the zones was measured with a Geiger counter. The minimum detectable quantity of lipids ($z$) amounted to 0.05 μg P $cm^{-2}$.[74,75]

## III. REVERSED-PHASE CHROMATOGRAPHY

### 1. General Features of Reversed-Phase Chromatography

We have so far examined the chromatography of lipids in ordinary partition systems where the stationary phase is the more polar. For effective separation by partition chromatography, however, the stationary phase should be a substance in which the components to be analysed have a higher solubility; during the chromatographic process these compounds are slowly eluted by a larger volume of the mobile phase, in which they are less soluble. Since lipids containing > 10 C atoms are sparingly soluble in water but have a high solubility in non-polar substances, it is better to carry out the separation of lipids with systems in which the stationary phase is less polar than the mobile phase, so that the lipids are distributed on the chromatogram in the opposite order to that given above (see Section II), so-called reversed-phase systems. This term reflects the historical development of chromatography, since systems with the "normal" relationship of polarities for the individual phases were developed before reversed--phase chromatography (see Section I), which was first used by Boldingh in 1948 to separate the methyl esters of aliphatic acids[3], and was later developed by Howard and Martin[76], Kaufmann[7], Inoue[56], Schlenk[14], Gunstone[77], Buchanan[78], and others.

The solubility of lipids in non-polar phases is determined by the interaction between the aliphatic chains of the lipids and the solvent resulting from van der Waals forces, which increase with increasing chain length and decrease under the influence of double bonds. The chain is shortened to the minimum extent by *trans* double bonds, whose influence on the van der Waals forces is not so marked as that of *cis* bonds, which reduce considerably the effective length of the molecule; this makes it possible to separate geometric isomers (see Section III4D). The appearance of a double bond in the chain leads to an appreciable increase in the solubility of lipids in the polar phase, as a result of the occurrence of dipole interactions.

The main rule in reversed-phase chromatography is that within a given class the appearance of a double bond in the aliphatic chain of a lipid (at a sufficient distance from the ends of the chain) and shortening of the chain by two $CH_2$ groups usually increase the chromatographic mobility to equal extents. This relationship makes it possible to predict the relative mobility of lipids from their composition, on the basis of the polarity constant $K = 100 - m + 2e$, where $m$ is the number of carbon atoms and $e$ the number of double bonds: lipids with equal values of $K$ are not

separated from one another in reversed-phase systems. Deviations from this rule are rarely observed (see Sections III3 and III4F).

It may be assumed that lipids of equal polarity have equal values for the distribution coefficient $\alpha$. For the experimental determination of $\alpha$ for aliphatic acids in the aqueous acetone/paraffin oil system, 2 mg of the acid was dissolved in 0.5 ml of the non-polar phase, the solution mixed with 0.5 g of carrier (kieselguhr), and 5 ml of aqueous acetone added. The system was brought to equilibrium at 35° and centrifuged, and 2 ml specimens of the upper phase were titrated with $A$ ml of 0.001 $N$ potassium hydroxide in methanol. The residue was treated with 5 ml of 95% acetone, which eluted completely the acid from the non-polar phase, and 2 ml specimens were titrated with $P$ ml of alkali. The value of $\alpha$ (the ratio of the concentrations of acid in mobile and stationary phases) was calculated from the formula $\alpha = AV/(6P - A)$, where $V$ is the volume of the non-polar phase. The percentage accuracy $T$ of the determination, found from the equation $T = 100NE(2A + 3P)/W$, where $N$ is the normality of the alkali, $W$ the weight of acid, and $E$ the equivalent of the acid, usually amounted to 100 ± 5%. The values of $\log_{10} 100\alpha$ for different aliphatic acids, plotted against the concentration of acetone in the solvent, gave a family of parallel straight lines; these straight lines coincided for acids of equal polarity. The optimum conditions for separation were achieved at a solvent concentration at which $\alpha$ for the given acid was 0.16 and its value for the next higher homologue was 0.08. [79]

The following symbols were introduced for the mathematical description of the reversed-phase system for the separation of palmitic and stearic acids: $\alpha'$ is the distribution coefficient of the acids under the conditions of the chromatographic separation; $p$ the number of theoretical plates in the column; $a$ the number of the eluate fraction, where each fraction has a volume equal to the volume of the mobile phase in a theoretical plate; $E_a$ the fraction of dissolved substance present in the eluate $a$; $V_m$ the volume of mobile phase in the column; $v$ the volume of each eluate in the experiment; $f$ the number of the experimental eluate fraction containing the greatest quantity of dissolved substance, counted from the moment when the solvent front leaves the column; $E'_{max}$ the fraction of dissolved substance in eluate $f$; $c = V_m/v$ is the volume of mobile phase in the column, expressed as the number of eluate fractions in the experiment; and $A_\epsilon\{x\}$ is the area of the normal error curve for the argument $\{x\}$.

A column containing $p$ plates was considered. On the assumption that each plate behaves like a separating funnel in countercurrent distribution, the quantity of dissolved substance $T_{n,r}$ with distribution coefficient $\alpha$ in the $r$th plate after $n$ transfers was determined from the formula for countercurrent distribution:

$$T_{n,r} = \frac{n!}{r!\,(n-r)!} \times \left(\frac{1}{\alpha+1}\right)^n \times \alpha^r. \qquad (1)$$

After $p$ transfers the solvent front reaches the last $p$th plate, after which a known quantity of dissolved substance $E_{a+1}$ leaves the column with the eluate:

$$E_{a+1} = \frac{(p+a)!}{p!\,a!} \times \frac{(\alpha')^{p+1}}{(\alpha'+1)^{p+a+1}} = \frac{p+a}{a(\alpha'+1)} \times E_a. \qquad (2)$$

The fraction of dissolved substance in the eluate reaches a maximum when $\alpha' = p/a$. The ratio $a/p$ is equivalent to the total volume of eluate necessary for the attainment of the maximum, expressed in volumes of the mobile phase of the column:

$$1/\alpha' = a/p = fv/V_m. \qquad (3)$$

Eqn. (3) and data on the position and height of each peak on the experimental elution curve obtained with 67% acetone as solvent were used to calculate the actual distribution coefficient $\alpha'$ for palmitic (0.50) and stearic (0.22) acids. Division of $\alpha'$ by the ratio of the liquid phases in the column (2.5) gave the true distribution coefficients $\alpha$ as 0.20 and 0.09 respectively in good agreement with the experimental values of 0.16 and 0.08.

From Eqns. (2) and (3) we can obtain the equation

$$p = 2\pi(1+\alpha') \times \left(\frac{E'_{max} \cdot V_m}{\alpha' \cdot v}\right)^2 = 2\pi f\,(f+c)\,(E'_{max})^2, \qquad (4)$$

which makes it possible to calculate the number of plates $p$ for each acid from the position and height of the eluate maximum on the elution curve. For palmitic and stearic acids, the values of $p$ were 70 and 114 respectively. The calculated values of $\alpha'$ and $p$ were substituted in Eqn. (2), and used to construct the theoretical elution curve; this showed satisfactory agreement with the curve obtained experimentally.

The percentage contamination of each peak by the substance corresponding to the neighbouring peak $\eta$ was determined from the equation to the normal error curve

$$\eta = 100\left(0.5 - A_\epsilon\left\{\frac{\sqrt{p}(\sqrt{B}-\sqrt{A})}{\sqrt{AB}}\right\}\right),$$

where $A = 1 + 1/\alpha'_A$ and $B = 1 + 1/\alpha'_B$. Thus to obtain fractions of the required purity ($\eta \geqslant 0.2\%$) in the separation of an acid having $\alpha' = 0.50$ from another acid, in a reversed-phase system with an efficiency $p = 100$, the value of $\alpha'$ for the latter acid should not exceed 0.23. It can be seen that the system used by the authors cited [79] ensures almost complete separation of palmitic ($\alpha' = 0.50$) and stearic ($\alpha' = 0.22$) acids.

Mathematical treatment of a reversed-phase chromatographic system makes it possible to select the optimum conditions of solvent composition and column efficiency for the separation of a lipid mixture.

## 2. Column Chromatography

A. Preparation of columns. In 1950, Howard and Martin [76] proposed the use of hydrophobic Celite treated with dimethyldichlorosilane vapour as stationary-phase carrier. The Celite was mixed with neutralised (with alumina) paraffin oil [77] (1:0.8 by weight [14,80], 1:1, [76,81], or 1:1.4 [77]), suspended in the mobile phase, and transferred to the column. The paraffin oil can be replaced by silicone oil (b.p. 195–230° at 0.25 mmHg) [14,81] or acetylated castor oil [77], isooctane [82], heptane [83,84], or cyclohexane [85].

Rubber powder swollen in benzene [86], petroleum ether [35,87,88], or acetone [89] has been used simultaneously as carrier and non-polar phase. Soya-bean oil polymerised with $S_2Cl_2$ ("factice") has properties similar to those of rubber [90]; separation using factice is no less effective than that using Celite and paraffin oil [84]. Polyethylene powder swollen in acetone [91,92] or polyethylene on Celite [93] can be used for a separation not merely 3–8 times in succession, as in the case of the phases given above, but for an unlimited period. Use has also been made of cellulose impregnated with paraffin oil [94] and of nylon fibres, on

which 2–6 μg of acids were separated by means of a mixture of acetone, ethanol, and water and detected with Bromocresol Green[95].

B. Production of chromatogram. A specimen containing 1–10 mg of each component for columns of diameter 1–2 cm [76,77,84,93,96] or 150–250 mg of the mixture for broader columns [14,97] is introduced in the form of a solution in the mobile [76,93] or stationary [14,84,96] phase, depending on the solubility of the lipids. The volume of the solution should correspond to one theoretical plate [84]. The rate of flow of the mobile phase may vary over the range (ml $h^{-1}$) 4–20, [85,91,93] 35–60, [76,84,90,98] 120–180, [14,99] and up to 300, [83] the efficiency of the column being slightly higher at lower rate of flow. The temperature of the separation should be kept constant. Unsaturated acids are usually separated at 10°, [96,98] mixtures of acids on rubber and polyethylene columns at 20–25°, [86,92] and columns containing paraffin oil are kept at 35°. [14,76,80,99] The eluate is collected in an automatic collector [87], and the concentration of lipids in the fractions is determined gravimetrically [35,85] or by titration with 0.01 *N* potassium hydroxide in methanol using Bromothymol Blue as indicator [76,77,80,82,92,96,99]. In other cases two volumes of water are added to the eluate, and nephelometer readings $S$ and $S_1$ for the specimen and a standard are determined. In the range 2–20 μg, the relationship between $\log_{10}(S/S_1)$ and the mass of the lipids was linear [14,81,100]. The concentration of glycerides was determined colorimetrically with hydroxylamine and $Fe^{3+}$. [84] A differential refractometer has been used for the continuous recording of lipids at the column outlet; the area of the peaks on the chromatogram was not proportional to the mass [90]. Between 97% and 103% of the original lipids was detected in the eluate [35,77,80,82,89–91]. The purity of the specimens isolated reached 99–100%. [14,83]

Aqueous solutions of acetone, saturated with the non-polar phase, are commonly used as solvents for the separation of lipids. The following acetone concentrations (%) have been used for the elution of saturated acids — $C_6$ 30, $C_8$ 40, $C_{10}$ 50, $C_{12}$ 53, $C_{14}$ 58–60, $C_{16}$ 65–67, $C_{18}$ 70–73, $C_{20}$ 75–78, $C_{22}$ 80–83, and $C_{24}$ 85–90. [14,76,77,80,89,91,96] A mixture of acetone, heptane, and water (5 : 1 : 0.629) has been used as solvent for the separation of triglycerides from coconut oil [84], and 95% acetone for that of glycerides from linseed oil [90]. Increase in the concentration of water increases $V_R$ and the efficiency of the column [76,84]. Acids and their derivatives have also been separated by means of a mixture of methanol with acetone (3 : 1), [86] 65–100% methanol [82,98], 40–70% ethanol [93], a mixture of acetonitrile with methanol (17 : 3), [83] and a mixture of acetic and formic acids with water (2 : 2 : 1). [94] Acids and their methyl esters have been separated in the acetonitrile–water (3 : 1) system [14,81]. The use of aqueous ethanol for the fractionation of 2-mono- and 1,2-di-glycerides led to their conversion to the stable 1-mono- and 1,3-di-isomers; in aqueous acetone no migration of the acyl groups was observed [85].

C. Separation of the lipids. Saturated normal aliphatic acids differing by one $CH_2$ group are readily separated and leave the column in order of decreasing values of the constant $K$. [14,76,77,80–82,86,87,91] The value of $V_R$ for lactobacillic acid (11,12-methyleneoctadecanoic acid) coincides with that for stearic acid [87]. Unsaturated acids are separated from one another, but not from saturated acids having the same value of $K$. [8,77,83,87,99]

For the quantitative analysis of a mixture, a specimen of acids is hydrogenated in the presence of 5–20% Pd on carbon for 24 h; [77,97,101] the hydrogenation products (saturated acids) are readily separated on a column [8,102–104]. Another specimen of the acids is cleaved at the double bonds by means of 5% permanganate [99,104], hydroxylated with peroxyformic acid [87,105], or subjected to ozonolysis in methyl acetate at -40° for 5 min. [77] The results of the simultaneous determination of the original acids and the products of their hydrogenation and oxidation make it possible to establish fairly precisely the composition of a given mixture [77]. Thus oleic and petroselinic acids are not separated in a reversed-phase system, but the pelargonic and lauric acids produced by their oxidation are readily separated in this system [99].

Hydroxy-, epoxy-, and keto-acids, because of their high polarity, leave well away from ordinary acids, and are separated both in unchanged form [76,86–88,99] and as their acetates on columns containing acetylated castor oil [35,77]. The value of $V_R$ for hydroxystearic acid coincided with that for lauric acid [35,77]. The chlorophenacyl esters [93] and fluorides of aliphatic acids [94] were separated in the same way as the unsubstituted acids. Columns containing paraffin oil were used to separate mono-, di-, and tri-glycerides [85] and also triglycerides differing by four $CH_2$ groups or by two double bonds; glycerides differing by two $CH_2$ groups or by one double bond were not separated completely [84]. Methyl esters, cholesterol esters, and triglycerides were separated on a factice column into fractions having identical values of $K$; the values of $\log V_R$ were found to vary linearly with the number of carbon atoms in these compounds [90].

### 3. Chromatography on Glass Plates

Chromatography on a thin layer of adsorbent attached to a glass plate has now been widely adopted as a method for the separation of lipids by adsorption. At the same time plates carrying silicic acid are being used in the chromatography of lipids on an ever increasing scale as carriers of a non-polar phase.

For the *reversed-phase* separation, activated plates were treated with 10–15% undecane in petroleum ether [106–108], 10% dodecane in hexane [109], or 5% tetradecane [107,108,110–115], 0.5% [116,117] or 10% [118–120] paraffin oil, or 5% silicone oil [110,121] in ether. Heavy oils cannot be removed from the plate by heating [110]. The separation of lipids and the detection of the individual zones are carried out by the methods generally used in thin-layer chromatography [122].

The results of partition chromatography on plates in general do not differ from those obtained in other forms of reversed-phase chromatography; the possibility of working on the ultramicro-scale, however, makes it possible in a number of cases to achieve higher rates and efficiencies of separation. Plates are often used for two-dimensional chromatography: the lipids are separated in one direction into classes without the application of a non-polar phase, after which part of the plate is impregnated with hydrocarbons and the lipids of each class are separated into fractions of different polarity [106,109].

The $C_{10-18}$ aliphatic acids (0.5–20 μg) have been separated with a mixture of acetic acid and acetonitrile (1 : 1) [107,108] or 85% acetic acid [119] in 1 h. For the separation of acids having equal values of $K$, 0.5% bromine was added to the polar phase: the transformation of the unsaturated acids led to a marked increase in their mobility [108,112]. Lipids having the same polarity can also be separated by *hydrogenation*:

the acids on the plate are sprayed with a 1–2% palladium suspension, hydrogenated with $H_2$ in a desiccator, washed with 5% HCl, and separated by means of undecane [108,112,119]. The saturated $C_{18-34}$ acids have been separated in the propan-2-ol–ethanol–acetic acid–water (8:3:4:1.3)/tetradecane system at 42°, and determined quantitatively with Cu acetate (see Section III4E*a*)[114]. The $C_{13-25}$ 2-methyl--4-keto-acids and $C_{12-22}$ hydroxy-acids have been separated by the use of 80% acetic acid [111]. The solvents used for the $C_{12-34}$ aliphatic alcohols have been 85% acetic acid and 90% acetone [114,115].

Methyl esters have been separated in acetic acid–acetonitrile–water (2:14:5) [121] and acetone–acetonitrile (7:10) [109] mixtures. Saturated and unsaturated esters of equal polarity were separated at 4–6° (see Section III4D) or in the presence of peracetic acid (Section III4F). [121] Methyl and ethyl esters with different numbers of double bonds have been separated on a non-impregnated plate carrying silicic acid, by fourfold treatment with a mixture of petroleum ether and benzene (4:1); the plate was then impregnated with paraffin oil, and fractions differing in the number of carbon atoms were separated. The methyl esters were separated from the ethyl esters of the same acids [119]. An analogous method was used to separate cholesterol esters; ethyl methyl ketone–acetonitrile (7:3) [118,119] and acetic acid–chloroform (80:15) [116,117] were used as solvents.

Triglycerides have been separated by means of an acetone–acetonitrile (4:1) mixture [107,119] and acetic acid [117]; in 35–100 min, linseed oil was separated into nine fractions and soya-bean oil into six fractions. In most cases no separation of triglycerides of equal polarity took place. The mobilities of glycerides with the same values for $K$ are not always identical, however [110]. Repeated treatment of plates with a single solvent, with drying after each treatment, leads to the separation of 1–2 μg of components of equal polarity. Thus the following glycerides are separated — LenLenLen from LauLauLau, LolLolLol from MyrMyrMyr, OlOlLol from MyrOlOl, OlOlLol from PalPalLol, OlOlOl from PalOlOl, OlOlOl from PalPalPal, PalPalOl from PalPalPal, etc. §. Threefold treatment made it possible to separate a mixture of OlOlOl, PalOlOl, PalPalOl, and PalPalPal glycerides, and also to separate the glycerides of oleic acid from the corresponding glycerides of elaidic acid. In this case linseed oil is separated into not 9 but 15 fractions, soya-bean oil into 13 fractions, ground-nut oil into 12 fractions, etc. [113]. Thus the double bond of the triglycerides is compensated for not by exactly two $CH_2$ groups, as in the previous case, but by approximately 2.4 groups; the $Rf$ value for the more unsaturated component increases with increase in the difference in the number of double bonds in lipids of equal polarity. Decrease in the molecular weight of the stationary phase, an unfavourable ratio between the components of the specimen, and increase in the weight of the specimen lead to a decrease in the efficiency of separation of the glycerides [123]. A solution of 0.5% of bromine in a mixture of propionic acid and acetonitrile (3:2) is suitable for the separation of triglycerides of equal polarity; the hydrogenation method described above is also used [108,112].

§ Lau, Ol, Lol, and Len represent the acyl radicals of lauric, oleic, linoleic, and linolenic acids.

## 4. Paper Chromatography

A. Preparation of paper and application of stationary phase. Suitable grades of chromatographic paper for the separation are those exhibiting sufficient strength during washing in water [17]. These requirements are satisfied by the following papers: Whatman No. 1 [15,124–128], No. 3 [17,129], and No. 4 [124,130]; Schleicher and Schüll No. 595 [3,15], No. 598 [131], No. 2040*b* [132,133], No. 2043*b* [7,17,123,134,135], and No. 2043*b* Mgl [136,137]; Toyo No. 2 [138,139]; and Macherey Nagel No. 214 [134]. "B" or "M" paper from Leningrad Factory No. 2 [140–145] or No. 69 "Goznak" [146,147] have also been used; these grades are less satisfactory than those listed above [144]. The paper was purified by washing with 0.5–10% hydrochloric acid [144,148], 3% nitric acid [142], 20% formic acid [147], 95% acetic acid [127], aqueous acetone [149], ethanol [148], ether [127,146,148], or benzene [150], washed with water, dried at 90–120°, [125,128,130,135,144] and kept over ignited calcium chloride [136,150].

In early work, attempts were made to convert cellulose into its ethers in order to give the paper hydrophobic properties. To obtain the octadecyloxymethyl ether the paper was treated with 0.5% octadecyloxymethylpyridinium chloride in toluene at 90° for 3 h. [151] The hydroxamates of acids have been separated on paper acetylated with acetic anhydride in benzene at 70° [152,153] or palmitoylated in the same way [105]. Cellulose esters have not been widely used in chromatography, since hydrophobic paper is more readily prepared by impregnating ordinary paper with high-boiling lipophilic substances.

For the separation of the $C_{10-20}$ aliphatic acids, the paper is usually impregnated with undecane saturated with the mobile phase [134,139,154–163], pressed out with filter paper under a load of 4 kg for 10–30 min, and kept in air for 10 min. [137,140,144,150,156] The optimum undecane content is 100–250 mg $g^{-1}$. [133,136,150,164] After the separation, the concentration of undecane in the front is double its original value, and the concentration at the point of application falls almost to zero. The flow of undecane can be decreased by decreasing its original concentration, by using hydrophobic paper as carrier, and by keeping the chromatograms horizontal during the separation. The rate of movement of the mobile phase increases appreciably if the initial section of the strip is not impregnated [159]. Undecane can be removed from the paper at 80–95°.

With decrease in polarity of the lipids to be separated, it is generally necessary to use stationary phases of higher molecular weight and lower polarity. As a result of the lower solubility of these substances in the mobile phase, the efficiency of separation and the limiting weight of the specimen increase; removal of the phase before application of the colour tests for lipids becomes impossible, however. Saturated and unsaturated acids and methyl esters have been separated using 10% tetradecane in petroleum ether [135], 5–10% liquid paraffin in benzene, ether, or carbon tetrachloride [141,142,145–147,165,166], or a 10% mixture of liquid paraffin and paraffin oil in benzene [141,145]. Saturated acids from $C_{20}$ upwards, and also triglycerides, have been separated on paper impregnated with 5–15% paraffin oil ($d$ = 0.885–0.890) in benzene, ether, and petroleum ether [127–131,148,149,167–174]. The paper is usually impregnated by drawing the strip through the solution or by ascending and horizontal suction [147,170,171,175]. The non-polar phase corresponds to 10–15% on the weight of the paper [165].

Paper impregnated with 10–30% rubber latex, after swelling in acetone, can be used to separate acids and methyl esters

in methanol–acetone (1 : 1) and 80% methanol–isooctane systems[3,168]. A mixture of 0.5% rubber and 30% naphthalene in benzene (4 : 1) has also been used[176]. Tetralin and decalin have been used to separate the 2,4-dinitrophenylhydrazones of *p*-bromophenacyl esters ("bromazones"), the 2,4-dinitrophenylhydrazones, acetol-, and acetoxymercurimethoxy-derivatives of unsaturated methyl esters, glycerides, and phospholipids[138,163,177-184], and also aliphatic acids[185].

Vegetable oils have been used for impregnation only in early work[124,186,187]; the efficiency of hydrocarbon phases is exceeded only by that of castor oil in the separation of hydroxystearic acids[126].

Among organosilicon compounds, use is made of silicone oil (1–5% Rodorsil 240, Dow Corning 200, Tip-2 in cyclohexane or ether), which is sparingly soluble in mobile phases[49,125,139,143].

The concentration of stationary phase in the system determines the duration of the experiment: at an undecane concentration of 150 mg $g^{-1}$, analysis of the acids takes 1–2 h, and at 600–700 mg $g^{-1}$ movement of the polar phase ceases[188]. If the concentration of this phase is 0.1%, the saturated acids up to $C_{26}$ can be separated without heating the chamber[189]. The differences in the $R_f$ values ($\Delta R_f$) increase with decrease in the concentration of the phase, so that the reversed-phase system is a true partition system, in which there is no adsorption[16,188]. To obtain reproducible $R_f$ values, the concentration of the phase should be uniform along the length of the strip[5].

B. Production of chromatogram. If the concentration of individual lipids in the mixture is low, they must be isolated by preparative methods before separation. Higher $C_{20-36}$ acids have been concentrated from wax by crystallisation with urea[141]. Polyunsaturated acids from fish oils have been fractionated as the Li salts[190]. Aliphatic acids from wood have been separated from resin acids by chromatography[191]. On paper impregnated with potassium hydroxide, alcohols moved with the toluene front and acids remained at the point of application[192].

A sample containing 10–100 μg of each component[7,78,141,170,174,176] or 100–500 μg of a mixture of lipids[15,126-128,134,147,161,167,193] in solution in chloroform[15,78,126], alcohol[127,167,170], ether[128], acetone[146,147], or benzene[16,179,193] is applied to a starting line at a distance of 2–6 cm from the edge[78,126,147] in the form of bands[147,193] or spots[126]. To prevent crystallisation, saturated $C_{20-30}$ acids should be kept at 80–90° before the separation[15]. Unsaturated acids with conjugated bonds should be applied immediately after isolation, to avoid polymerisation[194]. The common unsaturated acids are also decomposed on paper in the absence of solvent[125].

The strip is treated in the vapour of the mobile phase[126,137,155,195] and developed by descending[78,126,128,140,164,179], ascending[141,144,146,167,176,184,196], horizontal[7,188,197], or circular[160,161,163,173,198] methods; the last method can be used for the preparative separation of lipids (more than 10 mg)[172]. The mobile phase usually moves a distance of 20–35 cm from the point of application. The efficiency of the separation increases if the upper part of the strip is wedge-shaped, as described by Matthias[17,132,199]. Ascending chromatography in test-tubes is used for the rapid analysis of acids[137].

C. Mobile phases. The mobile phase should have high polarity and low volatility, it should readily dissolve the lipids of the specimen, and its miscibility with the non-polar phase should be low. With increase in the polarity of the phase, $\Delta R_f$ increases and the solubility of the lipids decreases. If, however, the quantity of water is decreased, the duration and efficiency of separation are reduced. The mobile phases unavoidably contain the stationary phase of the system (80–90% saturation).

Acetic acid is almost always present in the mobile phase. The 90% acetic acid/undecane system separates the $C_{16-18}$ saturated and unsaturated acids[15,16,137,140,144,156-158,161,163,193], cyclopentenyl aliphatic acids[200], and aliphatic alcohols[192]. Sometimes 90% acetic acid is used with paraffin oil[126,173] and liquid paraffin[146]. The 95–100% acetic acid is used for the $C_{20-34}$ saturated acids[15,126,127,129,160,174,201,202] and polyunsaturated glycerides[132,172,198], and 50–75% acetic acid is used for the $C_{10-14}$ unsaturated acids and $C_{10-18}$ hydroxy-, epoxy-, and keto-acids[15,126,127,140,157,168,202], the thiocyanato-derivatives of the acids[203], monoglycerides[143], and oximes of $C_{8-18}$ aldehydes[204]. If the specimen contains $C_{10-24}$ aliphatic acids, separation with an acetic acid concentration gradient from 50% to 90% is used; the concentration $Ct$ at time $t$ is calculated from the formula $C_t = C_0 e^{-vt/V}$, where $C_0$ is the original concentration of acid, $V$ the volume of the mixing chamber, and $v$ the rate of supply of acid to the chamber[15,170]. The use of formic acid for the separation of aliphatic acids — 98% acetic acid–85% formic acid–water (30 : 10 : 1)[141,142,145,147,166] or 85% acetic acid–88% formic acid (1 : 1)[205] — increases the efficiency of separation and makes the zones more compact. Systems containing acetonitrile or acetone dissolve lipids readily, increase the rate of separation and $\Delta R_f$, and withstand temperatures up to 45°.[7,15,188] Acetic acid–acetonitrile (5 : 7)[190], acetone–acetic acid–water (8 : 2 : 1)[7,16,133,188], acetone–acetic acid (3 : 1)[165], or 85% acetone–90% acetic acid (3 : 2)[164] mixtures are used for acids; acetone–acetonitrile (4 : 1)[131,150,172] and acetone–methanol (9 : 1[128,172] or 3 : 1[130]) mixtures are used for triglycerides; and acetic acid–acetonitrile (3 : 1)[196,204,206] is used for the acetoxymercurimethoxy-derivatives of the allyl esters of saturated acids and the allylurethanes of higher alcohols, and also for the oximes of diesters of dihydroxyacetone. Aqueous 80–98% solutions of acetone have been used to separate mono- and tri-glycerides[134] and aliphatic acids[126,207].

Systems containing methanol — methanol–acetic acid (30 : 1), 90% methanol–acetic acid (30 : 1)[179], methanol–acetic acid (5 : 1)[139,163,178,182], 90% methanol–acetic acid (5 : 1)[178,181,183], and 70% methanol–acetic acid (3 : 2)[184] — have been used for the separation of "bromazones" and the acetoxymercurimethoxy-derivatives of unsaturated lipids and phospholipids. Saturated $C_{20-36}$ acids have been separated in the systems methyl acetate–acetic acid–water (5 : 20 : 2)[139,162], 99.5% propan-2-ol–96% ethanol–acetic acid–water (8 : 2.5 : 4 : 1.25)[135], and methanol–acetic acid–water (5 : 4 : 1)[16]. Aqueous 75–95% methanol[167,176,177] and ethanol[124,186], 55–65% propan-2-ol[156], and propan-2-ol–methanol–water (11 : 5 : 4)[208] are hardly ever used at the present time for the separation of acids, because of the low values of $\Delta R_f$ and the "mutual dissolution" taking place when zones with low lipid concentration are absorbed by larger neighbouring zones[193]. Mixtures of methanol with chloroform (1 : 3)[205] or with tetrahydrofuran and carbon tetrachloride[125] and an acetic acid–chloroform mixture (16 : 3)[209] have been used for the separation of triglycerides.

The 2,4-dinitrophenylhydrazones of $C_{8-18}$ aldehydes have been separated in the dimethylformamide–formamide (5 : 2)/hydrocarbons of b.p. 150–180° system, and their acetoxymercurimethoxy-derivatives have been separated in the same system with tetralin[7,210,211].

D. Temperature of separation. Mutual saturation of the phases and chromatographic separation are usually carried out at 20 ± 2°. Increase in temperature increases $R_f$ and the rate of separation, but leads to flow of the non-polar phase [16]. Cooling to 17° stops the separation of saturated acids, whose solubilities (in g per 100 g of acetic acid) have the following values at 20° and 30° respectively — $C_{10}$ 567 and 8230, $C_{12}$ 81.8 and 297, $C_{14}$ 10.2 and 51.1, $C_{16}$ 2.14 and 8.11, and $C_{18}$ 0.12 and 1.68. [159,188]

The decrease in solubility with temperature is used for the separation of saturated and unsaturated acids of equal polarity. The saturated acids can be precipitated before separation from petroleum ether at -20°. [163,212] In the acetone–undecane system, the following saturated acids remain at the point of application — $C_{18}$ and above at -20°, $C_{16}$ and above at -30°, $C_{14}$ and above at -38°, and $C_{12}$ and above at -50° — the acids which move at a given temperature being separated from one another [188]. After application of the acids, the strip was kept at -30° and then developed for 20 h in the systems (1) acetone–propionic acid–water (4 : 3 : 0.5)/undecane at -30°, or (2) 85% acetic acid–85% formic acid–water (10 : 10 : 1)/silicone oil at -10°. The saturated acids from $C_{14}$ did not move [15,125,188]. In two-dimensional chromatography, system (2) was used in the first direction, and 93% acetic acid at 20° in the second direction [213]. In the separation of *cis*- and *trans*-isomers, system (1) eluted oleic acid, while elaidic acid remained at the point of application [18,214].

To increase the solubility of the saturated acids, the temperature in the chamber has to be raised to 30° for the $C_{20-26}$ acids [7,15,125,127,188,205], to 45–55° for the $C_{24-28}$ acids [139,145,149,173], and to 55–85° for the $C_{26-34}$ acids [129,135,141,174].

E. Detection and quantitative determination of lipids. Coloured lipids, for example the "bromazones" of aliphatic acids, can be determined quantitatively at once by photometric methods [181]. Most lipids of the aliphatic series are colourless, however. These are detected and determined quantitatively by means of the colour reactions given by the carboxyl, hydroxyl, and other groups, double bonds, or the aliphatic chain itself.

(*a*) *Reactions of the carboxy-group.* Aliphatic acids and other acidic lipids are most readily detected by a non-specific test with an indicator [7]: 0.2–0.4% Bromothymol Blue in alcohol, pH 8–8.3, [151,168,176] Bromophenol Blue [134,215,216] or Bromocresol Green [177], 0.05% Cresol Red and cresolphthalein in 0.8% NaOH, [198,217] Malachite Green [185], Nile Blue [158,217], thymolphthalein, and Phenol Red [217,218]. With Pyrogallol Red, $z$ = 15 μg. [219] The colour produced by the acids disappears rapidly. The results obtained by titrating the acids with 0.005 *N* NaOH using Bromothymol Blue as indicator after their extraction from the paper agreed with the results of the thiocyanatometric determination [134,215].

Hydroxamic acids have been detected with acidic 1.5–2% $FeCl_3$ in a mixture of ethanol and butanol (1 : 4) in the form of purple zones [152,153]. The sensitivity of this reaction is lower than that of the reaction with indicators [178]. The methyl esters of aliphatic acids, obtained with $^{14}C$-diazomethane, were determined quantitatively by scanning a radio autograph of the chromatogram on an MF-4 microphotometer [165,220].

Aliphatic acids are usually determined as the heavy-metal salts [7]. To obtain the Co salts, the strip was held in $NH_3$ vapour, immersed for 1 h in 0.03–2.5% $^{59}Co$ acetate at pH 5.8–6.0, containing 2–3 μc $^{60}Co$ $ml^{-1}$, treated with ammonium sulphide to develop the colour, and measured on a Geiger counter with an accuracy of 2.5%. [221,222] The $^{59}Co$ salts alone are not suitable [43].

Basic copper(II) acetate is used more frequently than other salts [7]. The strip is immersed in a mixture of saturated copper acetate and water (1 : 49) for 20 min, and washed with water acidified with acetic acid to reveal the pale green zones due to the acids [186]. Potassium cyanoferrate(II) (1–1.5%) is used to obtain the dark brown colour of copper cyanoferrate(II) ($z$ = 5 μg). [155,156,158,167] If this solution is acidified, the salts are converted into the free aliphatic acids. Thus the reaction with copper acetate and potassium cyanoferrate(II) can be carried out repeatedly, to increase the sensitivity [188]. Under the influence of 5% ferric chloride, copper cyanoferrate(II) gives blue zones of $FeCu[Fe(CN)_6]$. [146]

In the reaction of copper salts, treated with ammonia vapour [133], with a basic 0.03% alcoholic dithiooxamide (rubeanic acid) solution, $z$ = 0.1 μg Cu. [126,223,224] By repeated development of the colour, the $C_{30-36}$ acids from wax, which can be separated only in very small quantities, have been detected [224]. The same reaction is given by aldoximes and ketoximes [204].

Copper salts can be detected from the liberation of oxygen and foaming with hydrogen peroxide and $NH_4OH$ ($z$ = 5–10 μg). [225] When Cu acetate solution moves along the paper, the aliphatic-acid zone brings about distortion of the front [59]. The colour of the copper salts of aliphatic acids is intensified by 0.5% Rhodamine B [43,49] and aniline–ethanol (1 : 1). [137]

The stoichiometric reaction leading to formation of the copper salts of acids from $C_{12}$ upwards is often used for quantitative determinations. For an approximate estimate, measurements are made of the area of the spot $T'$, and the quantity of acid $C'$ is calculated from the formula $T' = k \log C' + b$, where for oleic acid $k$ = 182 and $b$ = 166, and for linoleic acid $k$ = 134 and $b$ = 189. [193] The ratio of the zones is usually determined quantitatively with a photoelectric densitometer. The coloured chromatograms or their photographs are drawn past the 1 mm slit of the photoelement, and the light absorption is recorded. The area of the peaks on the curve is proportional to the molar concentration of the acids [144,146,155,223]. To obtain a uniformly low light-absorption background, it is necessary to purify the paper (see Section III4A) and to remove as far as possible the stationary phase, acetic acid (without heating), and the copper salt solution, whose pH should not exceed 5. [53,126,204,226] If the non-polar phase cannot be removed from the paper, acids with low values for $K$ are not converted completely into the copper salts, and a correction must be introduced into the calculation [126]. When the light absorption between the peaks does not return to zero, the area for each component is found by means of supplementary lines [126,227]. Beer's law is obeyed over the range 1–60 μg of the acids [126,228]. The accuracy of the determination of acids whose concentration exceeded 2% [7] reached ±3%. [228]

Polarographic and colorimetric methods have proved that the reaction is stoichiometric. Copper ions were eluted with 0.06–1 *N* $H_2SO_4$. A linear relationship between the height of the step on the polarogram and the quantity of copper was observed for 1–7 μg copper $ml^{-1}$. [227,229,230] In the colorimetric estimation with 0.1 M tetraethylthiuram

disulphide [231] or 0.001% dithizone [232], Beer's law was obeyed over the range 10–30 μg ml$^{-1}$. The accuracy of both methods was ±5%. [230,231]

Silver salts were obtained in 1% ammoniacal silver nitrate within 5–30 min; excess of the salt was washed out, and the Ag was fixed with dilute HCl. [186] For the $C_{20-34}$ acids, the solution was heated to 55–85°. [129,174,186] The silver salts were coloured by heating to 140–150° for 10 min [129,194] or by treating with ammonium sulphide [167,186], sodium sulphide [147], hydrogen sulphide [156], phenylhydrazine [43], and 0.03–0.5% *p*-diethylaminobenzylidenerhodanine [43,174,233]. The accuracy of the densitometric determination of the $C_{16-18}$ acids on an MF-4 apparatus with a supplementary projecting lens was adequate [147]; photographs of chromatograms of the $C_{24-34}$ acids were scanned on an MF-2 apparatus with unsatisfactory results [174]. After the paper had been ashed, the accuracy of the determination of 0.2–2 μmole of silver with dithizone was ±5%. [233] Aliphatic acids can also be determined radiometrically with $^{110}$Ag. [234]

The mercury salts (0.1% $Hg^{2+}$ acetate in 0.5% acetic acid for 15 min) were more stable to hydrolysis by water than were the copper salts, and the paper background was lighter. The salts were coloured with 0.2% 1,5-diphenylcarbazone [78,173], the colour was eluted with methanol and toluene (1 : 1), and measurements were made at 530 mμm. [15,173] The radiometric determination was carried out with $^{203}$Hg. [234]

The lead salts (1–3% lead acetate, pH 5.3–5.7, 20–40°) were coloured with hydrogen sulphide, 1.5% ammonium sulphide, or a solution of 2 g of sodium sulphide, 100 g of ammonium nitrate, and 30 ml of hydrogen peroxide per litre ($z$ = 0.05 μg of acid). 2-Hydroxy-acids are not detected by means of lead [139,164,168]. After extraction from the paper with 10% nitric acid, the lead was determined with dithizone at 520 mμm. Satisfactory accuracy in the measurements was achieved by thorough purification of the paper, reagents, and the quartz vessel from traces of heavy metals [142]. The reaction of the acids with bismuth nitrate (at 70–80°) and ammonium sulphide gave values of $z$ equal to those for reactions with the lead salts [127,141,148].

(*b*) *Reactions of the hydroxy-group.* The vicinal OH groups of monoglycerides and polyhydroxystearic acids have been detected by Schiff's reaction with 1% periodate, sulphur dioxide, and pararosaniline ($z$ = = 10–20 μg) [70], or with a solution containing 35% borax, 0.8% potassium iodide, 0.9% boric acid, and 3% starch (the lipids gave white spots on a blue background) [52]. For radiometric determination, mono- and di-glycerides were acetylated with $(^{14}CH_3CO)_2O$. [220]

(*c*) *Reactions of the double bond.* Unsaturated lipids are detected by oxidation or replacement of the double bonds. On oxidation in 0.1–1% alkaline permanganate, unsaturated lipids after 1.5–5 min give brown spots of manganese dioxide [48,132,139,141,166]; acid permanganate gives white spots on a pink background [7]. Densitometric measurement of the colour produced by the action of alkaline permanganate has been carried out in reflected light; the concentration of aliphatic acids, glycerides, and sterol esters was determined from the height [209] or the area of the peaks with an accuracy of 3–5%. [166] Unsaturated acids were oxidised with sodium periodate and 1% potassium permanganate, and scanned on a microphotometer [235].

In the ozonisation, the band was treated with sodium hydrogen sulphite, then with oxone for 20–60 min, and finally with Schiff reagent [208,236].

Unsaturated lipids on a moist strip without hydrocarbons or with silicone oil give brown or yellow spots in iodine vapour at different pH values [125,132,150,220]. The colour was scanned with a blue filter [205]. The iodine reacting with the double bonds was detected with 0.5–1% starch in the form of blue spots on a light background ($z$ = 3–4 μg) [127,128] or with 0.2 *N* silver nitrate and the photographic developer Eukobrom [237]. Bromine and thiocyanogen may be partly liberated from the double bonds in ammonia vapour: $Br^-$ was detected with Phenol Red and chloramine ($z$ = 0.1 μg) [238], and $CNS^-$ with $Fe^{3+}$ salts [203]. The vapour and solutions of $^{131}$IBr have been used for the radiometric microdetermination of the mass and iodine number of lipids [222,234,239,240].

Mercury(II) acetate in methanol is also used for the replacement of double bonds in *salts and esters* of aliphatic acids [7,15,229]:

$$-CH{=}CH- \xrightarrow{Hg(OCOCH_3)_2,\ CH_3OH} -CH(OCH_3)-CH(HgOCOCH_3)- .$$

The acetoxymercurimethoxy-derivatives of the esters are synthesised before separation [178,184,196]; the derivatives of the salts are prepared on the paper in 2% mercury(II) acetate containing 1% acetic acid only after the separation [241]. The combined mercury is detected with 0.1–0.2% alcoholic 1,5-diphenylcarbazone and ammonia vapour [78,196]; hydrogen sulphide colours mercury after its displacement from the derivatives by hydrogen chloride vapour ($z$ = 1 μg of linolenate) [184,188]. Colorimetric determination with 1,5-diphenylcarbazone [178] or dithizone [196], polarography [229], and densitometry [184,196] are used for the quantitative determination. Kaufmann used the acetoxymercurimethoxy-derivatives to determine saturated and unsaturated acids having equal values of $K$, for example palmitic and oleic acids. Parallel chromatograms were coloured with copper or mercury acetate. Since the carboxy-group is equivalent to one-half of a copper or mercury atom, and the double bond to one mercury atom, the value of $y$ (the percentage concentration of the saturated acid) was calculated from the formulae

$$y = [(2e + 1 - x)/2e] \times 100;\ x = F_{Hg}^{corr}/F_{Cu};\ F_{Hg}^{corr} = F_{Hg}(F_{Cu}^{stand}/F_{Hg}^{stand}),$$

where $e$ is the number of double bonds in the unsaturated acid which is not separated from a given saturated acid, $F_{Cu}$ and $F_{Hg}$ are the areas of the peaks for a non-separating mixture of the saturated and unsaturated acids, obtained by scanning chromatograms coloured with copper and mercury salts respectively, and $F_{Cu}^{stand}$ and $F_{Hg}^{stand}$ are the areas for the standard (stearic acid) [241].

Osmium tetroxide vapour detects 5 μg of oleic and 2.5 μg of linoleic acids as grey spots on a light background [7,161].

(*d*) *Reactions of the aliphatic chain.* A number of methods for the detection of lipids are based on the selective adsorption of lipophilic dyes and other substances from aqueous–alcoholic solutions or on the formation of inclusion compounds [11]. Of the fluorescent dyes, use is generally made of 0.05% Rhodamine B, [7] which detects mono-, di-, and tri-glycerides and aliphatic alcohols as white spots, which exhibit blue fluorescence, on a pink background ($z$ = 2 μg) [7,134,192]. Under the influence of permanganate, the colour of the spots changes to yellow [130]. The colour of Rhodamine is intensified by Nile Blue, quinine, Acridine Orange, etc. [43,61,242]. Rhodamine B has been used for the approximate determination of monoglycerides from the area of the spot [134,215]. Protoporphyrin detects phospholipids, acids, and glycerides as fluorescent red spots on a light background ($z$ = 1 μg) [243].

The complexes of lipids with fat-soluble dyes, readily detectable in visible light, are formed only after the

removal of hydrocarbons from the paper [158,167]. Sudan IV, [3] Oil Red O, [62] and other dyes have been tested; the best was found to be Sudan Black B, [150] which detects the esters of polyhydric alcohols and stearins, but which, unlike Rhodamine, does not colour the esters of monohydric alcohols [244]. Unsaturated lipids combine with Sudan more readily than do saturated lipids; in direct light the colour changes to pinkish brown [245]. Solutions of fat dyes in 50% diacetin have been used for the densitometric determination of glycerides; the accuracy of the measurements was improved by impregnating the strip with paraffin oil, 1-bromonaphthalene, and an emulsifying agent [246]. Because of their surface-active properties, lipids can be detected from the change in the hydrophilic nature of separate sections of the strip after the separation. On paper carrying paraffin oil, the esters of aliphatic acids and sucrose and triglycerides gave transparent spots in water and potassium hydroxide solution respectively [132,247]. Triglycerides can be hydrolysed on paper with 10–20% potassium hydroxide at 95°, and then detected by means of copper salts. On complete hydrolysis, no colour is produced by Sudan [131,150,248,249].

$\alpha$-Cyclodextrin, combined with lipids by inclusion reactions, is not coloured by iodine vapour and gives white spots on a blue ground. Di- and tri-glycerides, which do not form inclusion compounds, must be hydrolysed beforehand on the paper by means of pancreatin [125,220]. The inclusion reaction has been used for the densitometric determination of triglycerides and methyl esters [205].

F. Separation of lipids. Homologues differing by a $CH_2$ group and, in series of equal chain length, homologues differing by a free or substituted double or triple bond, hydroxy- or keto-group, etc., are separated in a reversed-phase system. *Homologous series* which have now been separated include the normal saturated $C_{10-36}$ aliphatic acids, even and odd [78,127,141,201], mono-, di-, tri-, and poly-unsaturated $C_{11-28}$ acids [126,141,157,190], mono-, and di-acetylenic acids [126], cyclopentenyl unsaturated acids [200], $C_{14-24}$ normal saturated 2-hydroxy-acids [127], $C_{30}$ mycolic acids [169], saturated and unsaturated hydroxy-, dihydroxy-, and keto-acids [126,158,177,202], $C_{14-26}$ saturated 2-methyl-4-oxo-acids [222], di-, tetra-, and hexa-bromo-derivatives of stearic acid [158], adducts of maleic anhydride with acids containing conjugated double bonds [216], the 2,4-dinitrophenylhydrazones of $C_{2-22}$ normal saturated acids, even and odd [178], the "bromazones" of $C_{2-26}$ normal saturated and unsaturated acids, aldehydes, and ketones, and their acetoxymercurimethoxy-derivatives [139,178,182], the acetoxymercurimethoxy-derivatives of unsaturated acids [179] and the allyl esters of $C_{20-30}$ saturated acids [196], $C_{10-18}$ saturated and unsaturated alcohols [192] and their allylurethanes [206], the acetoxymercurimethoxy-derivatives of the allylurethanes of $C_{10-30}$ saturated and unsaturated alcohols [206], the 2,4-dinitrophenylhydrazones of $C_{8-18}$ saturated and unsaturated aldehydes and their acetoxymercurimethoxy-derivatives [210], the oximes of $C_{8-18}$ esters of dihydroxyacetone and higher aldoximes [204], the esters of saturated and unsaturated acids with mono- and poly-hydric aliphatic and aromatic alcohols [244], mono-, di-, and tri-glycerides of the same or different acids [125,134,162,205,208], the triglycerides, of synthetic [125,132,144,162,183,205] and natural origin, containing residues of $C_{8-24}$ saturated and unsaturated acids [128,130-132,134,150,162,183], and also the acetoxymercurimethoxy-derivatives of the glycerides [183].

Tuberculostearic and nonadecanoic acids have equal $R_f$ values, so that chain branching does not influence mobility [126,200]. If the double bond is sufficiently far from the ends of the chain, the polarity rule applies (see Section III1). A double bond next to a carboxy-group, however, does not alter $R_f$ values: thus octadec-2-enoic and stearic acids are not separated [126]. Mobilities are the same for cycloalkene and alkene double bonds [200], isolated and conjugated double bonds [126], and double bonds in the *cis*- and *trans*-positions [126,157]. Replacement of a double bond in a chain by a triple bond increases the $R_f$ value [126,157]. The polarity of the OH group is greater than that of the CO group, so that 12-hydroxy- and 12-oxo-stearic acids are separated from one another [126]. In a series of hydroxy- and keto-acids, the chromatographic mobility decreases as the functional group approaches the carboxy-group [158,202].

The acetoxymercurimethoxy-derivatives of Φ-cholines have been separated into five fractions of different acid composition, the degree of unsaturation of the acyls increasing with increase in the $R_f$ value [182]. Soya-bean Φ-cholines have been hydrogenated and hydrolysed on paper in a study of the acid composition [250].

If members of different homologues series have the same values for $K$ and the same $R_f$ values, separation of these lipids requires either elimination of the unsaturated components or displacement of the polarity equilibrium in the mixture by saturation of the double bonds with hydrophilic or hydrophobic substituents. Before the chromatographic separation, the aliphatic acids were separated into saturated and unsaturated acids by the early method of Twichell and Bertram [7,155], by crystallisation of the copper salts from ethanol [186], or by crystallisation of the acids from 55% acetonitrile [251]. The unsaturated components were detected and determined by parallel separation of the original lipids and the lipids oxidised by 1% alkaline permanganate [126,141]. For complete decomposition of the unsaturated acids during the separation, use was made at 37° of the mobile phase acetic acid–formic acid–hydrogen peroxide (9 : 1 : 1 or 6 : 1 : 1), containing peroxyformic acid; the saturated acids were not oxidised in this phase [78].

On hydroxylation with permanganate or addition of thiocyanato-groups to the double bonds, the $R_f$ values for the acids increased, and on halogenation with iodine bromide the $R_f$ values decreased [252,253]. The mobility of unsaturated acids increased after bromoacetoxylation and bromomethoxylation with *N*-bromosuccinimide and also after formation of the acetoxymercurimethoxy-derivatives of the "bromazones" of these acids. The diastereoisomers of the bromoacetoxy- and bromomethoxy-derivatives of polyunsaturated acids each form two zones on the chromatograms [136,139,254]. Aliphatic acids with equal $R_f$ values have been separated by *hydrogenation* of the double bonds, with the formation of corresponding saturated acids of lower polarity [15,125]. In some cases the acids were separated before and after hydrogenation in the presence of palladium oxide on barium sulphate in ethanol [197], or of platinum oxide by Adams' method in acetic acid [126]. If the lipids contain palmitoleic acid, the complete mixture of acids is not hydrogenated, but only the fraction containing the palmitoleic, myristic, and linoleic acids; the hydrogenation products are subjected to further separation [191,224,255]. In other cases the hydrogenation was carried out directly on the paper (see Section III3), after which the hydrogenated and non-hydrogenated mixtures were separated [256-259]. For the determination of linolenic and $\alpha$-elaeostearic acids, which have identical $R_f$ values, adducts of elaeostearic acid with maleic anhydride are prepared in the presence of iodine, and the mixture of acids is hydrogenated and subjected to further separation [260,261]. Carbonyl groups in lipids are

reduced with a solution of sodium hydroborate in tetrahydrofuran[262]. For the determination of acids of equal polarity, use has also been made of low-temperature chromatography (see Section III4D) and the reaction of the double bonds with mercury salts (Section III4E*a*).

Thus the polarity rule introduces considerable difficulties in the analysis of lipids. On the other hand, the identification of complex mixtures, e.g. of triglycerides, where a fraction of given polarity may contain six, seven, or more components, is sometimes greatly facilitated, since lipids of known structure are correlated with a given chromatographic zone on the basis of a strict relationship.

Reversed-phase systems are seldom used for the fractionation of lipid mixtures into classes: the differences in polarity are so great that separation in any one system becomes impossible (see Section I). Moreover, lipids from different classes, with different values for $K$, often have the same $Rf$ values. Thus octadec-*cis*-9-en-1-ol is not separated from myristic acid, and diglycerides are superimposed on the stearic acid zone[192,208]. The concept of a "universal" polarity constant $K_{univ}$ has been introduced to compare classes on the basis of their absolute polarity. A standard of reference is provided by the homologous series of esters of monohydric alcohols and even normal aliphatic acids: for these the values of $K$ and $K_{univ}$ coincide. For lipids of another homologous series, $K_{univ}$ is equal to the value of $K$ for the substance of the reference system which has the same $Rf$ value as this lipid. The increment $i$, i.e. the difference between $K_{univ}$ and $K$ for a given lipid, is constant for a given series. The additive value of $i$ depends on the number of $CH_2$, COOH, and OH groups, double or ester bonds, the position of the functional groups, and other factors. The value of $i$ is 14 for triglycerides, 12 for the esters of unsaturated acids, 10 for 2-hydroxy--acids, 2 for the esters of aromatic alcohols, etc. This absolute polarity scale is extremely useful for the identification of lipids according to their classification in a specific homologous series[202,244].

It can be seen that the mobility of lipids during separation depends on their composition. The relationship between the $Rf$ value in different systems and the parameters of the molecule have been described by *empirical equations*: $Rf = 1.42 + (-0.062)m$; $Rf = 1.671 - 0.1326m + 0.0028m^2$; and $Rf = 1.50 - 0.0625m$ for saturated aliphatic acids, or $Rf = 1.42 - (-0.062)(m-2)$ and $Rf = 1.57 - 0.06m$ for unsaturated acids[124,133,195]. The dependence of the $Rf$ values on $m$ for aliphatic acids or their *p*-phenylazophenacyl esters was linear[32,201]. This relationship was not observed for triglycerides[150]. The $Rf$ values for $C_{18}$ unsaturated acids was found to be a linear function of the number of double bonds in the chain[134].

---o0o---

The methods of partition chromatography are now being widely used for the separation of lipids of natural origin. The various methods are not all equivalent, however.

Column chromatography with a polar stationary phase is used for the analysis of an individual homologous series of aliphatic compounds or their polar derivatives; more modern methods are necessary for the separation of mixtures of several series of lipids. The analysis of lipids on paper with a polar stationary phase has now been largely replaced by other forms of chromatography, which give much more effective separations. Of considerable practical interest is the application of this procedure to the analysis of the oxidation products of lipids and the separation of phospholipids; ion-exchange paper or paper impregnated with hydrophilic organic phases such as formaldehyde or formamide must be used.

Of much wider application are reversed-phase systems, which are used in column chromatography for the preparative separation of lipids, in particular of lipids with oxygen--containing functional groups in the chain. This method does not require complicated and expensive equipment, and makes it possible to obtain several grammes of pure specimen in sufficiently high yield under mild conditions. This form of chromatography is less suitable for analytical separations, since it requires several centigrammes of material and the actual operations are fairly tedious[8].

Reversed-phase chromatography on glass plates is now being used on an ever increasing scale for analytical separations. In combination with the highly effective methods of thin-layer chromatography, in particular with separation on silica gel impregnated with silver nitrate, lipids of a given class can be characterised from the values of $m$ and $e$ on a single plate. The possibilities for the preparative separation and quantitative determination of lipids are apparently more restricted in this case, although work of this nature has recently been reported[123].

Reversed-phase chromatography on paper continues to occupy a leading position among partition-chromatographic methods for the study of lipids. By changing the compositions of the stationary and mobile phases, the temperature, the duration of the experiment, and other factors, the optimum separation conditions for a specific mixture of lipids are rapidly found. The time required for the separation (several hours) and the sensitivity of the detection of the lipids (fractions of a microgramme) approach in a number of cases of paper chromatography, those characteristic of thin-layer and gas–liquid chromatography. An extensive range of qualitative reactions which can be carried out directly on the paper is available for the identification of lipids. The analytical separation is readily combined with densitometric quantitative determination and radiographic measurement of the activity of individual zones.

The simplicity and reproducibility of the separation are two of the most important advantages of paper chromatography: the analysis can be carried out without great expenditure of labour or money, in any laboratory equipped with the minimum of apparatus and reagents. The method is not only very convenient for the rapid estimation of the composition of individual fractions of the eluate from a chromatographic column, but can also be used by itself in preparative work for the isolation of lipids in quantities of 1–50 mg.

Thus reversed-phase partition chromatography on paper is entirely suitable for the analysis of classes and homologous series of lipids of simple composition. For the identification of multicomponent natural mixtures of lipids and the identification of individual compounds, this method must be combined with adsorption and gas–liquid chromatography, spectroscopy, and other modern methods for the analysis of lipids.

# THE CHROMATOGRAPHY OF BIOPOLYMERS ON CALCIUM PHOSPHATE GELS

S. A. Kibardin

CONTENTS

I. Introduction 629
II. Methods of preparation and characteristics of calcium phosphate sorbents 629
III. Methods of elution and characteristic features of the chromatography of biopolymers on calcium phosphate columns 630
IV. The use of calcium phosphate gels for the chromatography of enzyme proteins 632
V. The chromatography of serum proteins and other proteins on calcium phosphate 633
VI. The chromatography of nucleic acids and viruses on calcium phosphate gels 634
VII. The further development and future prospects of the chromatography of biopolymers on calcium phosphate 635

## I. INTRODUCTION

An important factor determining the success of a chromatographic separation is the choice of a suitable adsorbents. Progress in this field in recent years has led to the appearance of two main types or groups of adsorbent[1], which are now widely used for the chromatography of the most varied biopolymers.

One of these groups — calcium phosphate sorbents or gels — consists of molecular adsorbents. The other group consists of various ion exchangers, based chiefly on cellulose[2].

Both groups of adsorbent have an extensive, well hydrated surface, but the adsorption of biopolymers on these materials takes place in different ways. The principles of the action of these adsorbents also differ[3] and their chromatographic selectivity with respect to biopolymers is probably not the same[1]. Both groups of adsorbents are now widely used for the chromatography of the most varied biopolymers.

A number of reviews have been published[4-6] on ion exchangers based on cellulose. No reviews have been published on the use of calcium phosphate gels for the chromatography of biopolymers.

The aim in the present review has been to collect and summarise available published data on the chromatography of biopolymers on calcium phosphate sorbents.

## II. METHODS OF PREPARATION AND CHARACTERISTICS OF CALCIUM PHOSPHATE SORBENTS

Until recently, only tricalcium phosphate $Ca_3(PO_4)_2$ and calcium hydrogen phosphate or brushite $CaHPO_4.2H_2O$ were generally employed in chromatographic practice. In recent years, a particular form of calcium phosphate — hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$ — has begun to be used extensively in the chromatography of proteins. Tricalcium phosphate was at one time used fairly extensively as an adsorbent for the chromatography of proteins. Mention may be made, for example, of the isolation and purification of catalase by the use of tricalcium phosphate[8,9].

Tricalcium phosphate is now seldom used for the chromatography of proteins in column experiments. We shall therefore not deal further with this type of calcium phosphate, except to point out that $Ca_3(PO_4)_2$ usually contains a considerable quantity of hydroxyapatite[10]. This is due to the fact that the primary product formed in the preparation of tricalcium phosphate is pseudoapatite[11], which is subsequently converted into one modification of tricalcium phosphate and partly into hydroxyapatite[12].

A second example of a calcium phosphate gel, which is still used in the chromatography of proteins, in calcium hydrogen phosphate or brushite. The structure of brushite obtained by mixing solutions of $CaCl_2$ and $Na_2HPO_4$ depends to a marked extent on the pH. Formation of the precipitate usually takes place at pH 6.3–6.5. At the same time, it is known[10] that at pH 6.2 and above, calcium hydrogen phosphate may undergo slow hydrolysis into another form of calcium phosphate with the structure of hydroxyapatite.

Since the chromatography of proteins and other biopolymers is usually carried out in the approximate pH range 6.8–7.2 (i.e. above pH 6.2), the experimenter is in fact concerned with the unstable changing structure of an adsorbent containing a considerable proportion of hydroxyapatite.

In this respect, an undeniable advantage is shown by another calcium phosphate gel, which is now widely used in the column chromatography of biopolymers, namely hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$. This material has a high stability over a wide pH range.

The modern chromatography of biopolymers on calcium phosphate columns may be taken as dating from 1956, when Tiselius, after a number of preliminary experiments[13-16], published a method for the preparation of hydroxyapatite suitable for the chromatography of proteins[10]. In this

method, 0.5 M solutions of $CaCl_2$ and $Na_2HPO_4$ are run at the same rate into a vessel with constant stirring; after decantation, the resulting precipitate of brushite ($CaHPO_4$) is washed with distilled water and boiled with 40% NaOH solution for 1 h. The precipitate is then washed repeatedly with a series of phosphate buffer solutions of different molarities. In this method the operation of boiling the $CaHPO_4$ precipitate with alkali is extremely important, since at this stage the calcium hydrogen phosphate is hydrolysed to a new form of calcium phosphate — hydroxyapatite.

The acidic precipitate of brushite, which usually forms large crystals, is converted, during this operation in alkaline medium, into fine crystals of hydroxyapatite suitable for the chromatography of proteins. X-Ray diffraction study of the resulting adsorbent[10] showed it to be hydroxyapatite, but the molar Ca/P ratio was found to be 1.53 instead of the usual value of 1.67 for hydroxyapatite[10]. This is apparently due to the ability of sodium or phosphate ions to enter the crystal lattice of the adsorbent in different proportions.

Hydroxyapatite prepared by Tiselius' method is now widely used in the chromatography of proteins. The actual preparation of the adsorbent, however, involves a large number of operations and is very time-consuming. To obtain a satisfactory rate of flow it is usually necessary to apply external pressure. A recent paper[17] reports that, to obtain hydroxyapatite by Tiselius' method with a satisfactory rate of flow from the column, it is necessary to prevent the deposition of highly dispersed material after the adsorbent has been washed with water. The need for extremely thorough stirring of the precipitates when the adsorbent is boiled has also been reported[17].

Somewhat later, in 1959, Main and his coworkers proposed a new method for the preparation of hydroxyapatite[18] with properties similar to those of hydroxyapatite prepared by Tiselius' method. In this case the precipitate obtained after mixing solutions of $CaCl_2$ and a sodium phosphate buffer of pH 6.7 is boiled in concentrated $NH_4OH$ solution. The precipitate is converted into hydroxyapatite during this operation. X-Ray diffraction study of the resulting adsorbent[18] showed it to consist of pure hydroxyapatite with Ca/P = 1.53. The hydroxyapatite obtained by this method, however, sorbs proteins comparatively weakly[17]. Main et al.[18] used this adsorbent chiefly for the chromatography of nucleic acids.

Anacker and Stoy[19] recently proposed another method for the preparation of hydroxyapatite suitable for the chromatography of proteins. In this method, 1.5 M $K_2HPO_4$ and 1.4 M $CaCl_2$ solutions are added with constant stirring to 0.1 M $CaH_4(PO_4)_2$ solution. The precipitate obtained in this way is converted into hydroxyapatite in 0.05 M NaOH at 40° over a period of several days. The resulting precipitate consists of pure hydroxyapatite.

Comparison of the adsorptive properties for proteins exhibited by hydroxyapatites prepared in different ways shows that the adsorbents prepared by the methods of Tiselius[10] and Anacker[19] give similar adsorption curves. Hydroxyapatite prepared by Main's method[18], however, gives a curve which differs sharply from them. The ability of this hydroxyapatite to sorb proteins is much lower.

Thus although hydroxyapatites obtained by different methods have the same chemical composition, their abilities to adsorb proteins are different. There is also a significant difference in the rates of flow of liquid through columns filled with calcium phosphate gels prepared by different methods. For the adsorbent prepared by Tiselius' method[10] the rate of flow through a standard column may reach an average of 20–22 ml $h^{-1}$ with the application of external pressure. For the hydroxyapatite prepared by Main's method[18] the average is given as 25–30 ml $h^{-1}$ without pressure, whereas for columns filled with hydroxyapatite prepared by Anacker's method[19] the rate of flow reaches 200 ml $h^{-1}$ without the application of pressure.

These differences in the adsorptive power of hydroxyapatites prepared by different methods indicate that the magnitude of the adsorption of proteins on calcium phosphate gels depends not only on the chemical nature of the adsorbents (the chemical formula is the same for all three hydroxyapatites) but also on the physical non-uniformity of the adsorbent surface.

In general, the magnitude of the adsorption of a solute is determined both by the adsorption on unit area of the adsorbent–solution interface and also by the specific surface of unit mass of the adsorbent, accessible to the solute molecules[20]. In the comparison of the magnitude of the adsorption on different adsorbents of unknown specific surface, the factor responsible for differences in the adsorption is always unknown. In some cases the difference may be due to a difference in the specific surfaces of the adsorbents[20].

Hydroxyapatites prepared by different methods give precipitates with different degrees of dispersion. These probably have different specific surfaces, and the surface is apparently characterised by different degrees of physical non-uniformity. This is possibly responsible for the difference in the adsorptive power for proteins.

All this points to the need for careful standardisation of methods for the preparation of calcium phosphate sorbents, in order to obtain reproducible results in the chromatography of biopolymers on columns.

## III. METHODS OF ELUTION AND CHARACTERISTIC FEATURES OF THE CHROMATOGRAPHY OF BIOPOLYMERS ON CALCIUM PHOSPHATE COLUMNS

### 1. Methods of Elution

Phosphate buffer solutions of different concentrations are now used almost exclusively as eluants in the chromatography of biopolymers on calcium phosphate. The sorption of proteins on columns is usually carried out at low concentrations of phosphate buffer solution, and elution at higher concentrations of the same buffer, most frequently at the same pH value. Change in pH in chromatography on calcium phosphate sorbents has an extremely small influence on the experimental results compared with change in the buffer concentration[10].

Two main method are now used for the elution of biopolymers from calcium phosphate — gradient elution (gradual increase in the concentration of phosphate buffer added to the solution) and stepwise elution (the increase in the concentration of phosphate in the column is carried out in separate stages).

Under certain conditions, gradient elution usually makes it possible to detect all the components of the mixture being studied. When this method is used, however, the mutual

influence of the proteins[10] often leads to considerable overlap of adjacent fractions on calcium phosphate sorbents, and in a number of cases, even when the solution being studied contains several protein components, only one greatly elongated protein zone is obtained at the column outlet. The homogeneity of a material of this type is determined by a further chromatographic separation.

Usually in such cases it is possible to isolate the individual components of the mixture being studied. One such example is given in a paper by Tiselius[10] on the chromatography of $\gamma$-globulin from human serum on hydroxyapatite.

In stepwise elution there is always a danger that the components leaving the column may be of complex composition: proteins of different character may be present in individual fractions. On the other hand, proteins with a broad elution range may give more than one component for a given protein on leaving the column, particularly if the elution is carried out at buffer concentrations differing little from one another. The appearance of these spurious components and the conditions for their formation in the chromatography of proteins on calcium phosphate columns have been discussed in detail[3].

In most cases the chief method used to assess the results obtained in the chromatography of biopolymers on calcium phosphate is further chromatography of the products. Where the biopolymers have in fact been separated into their components, the latter are always eluted from the column in the subsequent chromatographic experiment by the same buffer solution concentrations as in the original chromatographic experiment. At the present time, the chromatography of a test material on calcium phosphate columns is usually carried out by both methods of elution, which to a certain extent supplement one another. In the examination of the material obtained, it is of course desirable to use other methods for the study of protein components in addition to further chromatographic separations.

What is the mechanism of the elution of protein polymers from calcium phosphate columns? Hardly any special study has been made of this problem. Nevertheless, on the basis of work carried out chiefly by Tiselius and his coworkers[10,16], the mechanism can now be assumed to involve replacement of the proteins by phosphate ions. The ability of calcium phosphate to take part in extensive exchange with calcium and phosphate ions from the surrounding medium has been demonstrated directly[21] using the radioactive isotopes $^{32}P$ and $^{45}Ca$. This tendency is particularly marked with phosphate ions. These ions can effectively replace ions from calcium phosphate not only in the hydrate layer but also in the interior of the crystal lattice of the adsorbent[21].

Burley and Cook[22], using a different experimental technique, showed directly that the presence of phosphate groups in proteins essentially determines the behaviour of the latter during chromatography on calcium phosphate columns. Thus egg-yolk $\alpha$- and $\beta$-lipovitellins, which have different phosphate contents, show different behaviour on elution from hydroxyapatite. $\beta$-Lipovitellin leaves the column at a phosphate buffer concentration of 0.6 M, and $\alpha$-lipovitellin only at a concentration of 2.0 M. After treatment of $\alpha$-lipovitellin with phosphatase (removal of some of the phosphate groups), however, this protein shows behaviour similar to that of $\beta$-lipovitellin and is eluted from the column with 0.6 M phosphate buffer. There is need for further studies in this direction in order to elucidate all the details of the mechanism of the elution of proteins from calcium phosphate columns.

## 2. Characteristic Features of the Chromatography of Biopolymers on Calcium Phosphate Columns

In the chromatography of proteins on calcium phosphate adsorbents, the electrostatic bonds between protein and adsorbent play an important part. Hydrogen bonds and van der Waals forces are also significant[1,7]. Since a large number of bonds are formed between the protein and the adsorbent, their simultaneous dissociation during desorption of the protein is unlikely[1]. Under certain conditions, therefore, there is a danger that reversible partial denaturation of the protein will take place with a possible change in various structures (tertiary and quaternary) in the protein molecule[23].

Moreover, the non-simultaneous dissociation of the large number of bonds of different types between the proteins being chromatographed and the surface of the adsorbent may create a complex picture, whose interpretation is as yet impossible, and may lead to internal interaction between the proteins as they move downwards through the column during the chromatographic process.

The effects of internal interaction and the mutual influence of proteins play an important part in chromatography on calcium phosphate columns[10].

Chromatographic studies are usually carried out with various protein mixtures in order to isolate a definite protein from other proteins present in the mixture. Chromatography is often the final stage in the purification or one of the operations preceding purification. Thus the "ballast" proteins present in the experimental mixture may be present in various proportions relative to the protein to be isolated.

Recent work on the chromatography of proteins on columns has shown that the affinity of a protein for a sorbent often depends on the nature of the other proteins present in the solution[10]. A protein with a high sorptive affinity usually displaces another protein with a lower affinity for the sorbent; mutual replacement of the proteins takes place on the column. The mutual replacement of proteins on calcium phosphate was first utilised by Polis and Shmukler[24] for the purification of milk peroxidase. The following factors play an important part in the mutual replacement of proteins on calcium phosphate columns, the first being the affinity of the proteins for the sorbent. It is important that the difference in the affinities for the sorbent, shown by the displacing protein and the protein being displaced from the column, should be considerable. Satisfactory results can be obtained by the mutual replacement of proteins only if the condition is satisfied. Other important factors are the quantity of replacing protein added to the column, and the concentration of the buffer solution in which the replacing protein is dissolved. All these factors have been examined in detail by Boman[25].

In addition to the replacement of proteins during chromatography on calcium phosphate columns, other effects due to the mutual influence of the proteins may be produced. It has been noted[10] that in many cases a protein (usually strongly sorbed on columns) in the presence of another protein (with a lower sorbability) itself shows a reduced sorbability during chromatography on columns.

The mutual influence of proteins evidently plays an important part in chromatography on calcium phosphate columns and may influence significantly the results of chromatographic experiments. It is thus important to understand and make allowance for all the factors influencing the chromatography of proteins and to extend our knowledge in this field, where, up to the present, a purely empirical approach to the selection of optimum conditions for the chromatography of biopolymers has been adopted.

## IV. THE USE OF CALCIUM PHOSPHATE GELS FOR THE CHROMATOGRAPHY OF ENZYME PROTEINS

In recent years, the methods of adsorption chromatography have been widely used in preparative biochemistry, particularly for the purification and isolation of the most varied enzyme proteins. Almost all work on the fractionation of enzymes now involves the use of chromatography. Chromatography is often the chief method leading to successful results in the isolation of enzyme proteins.

It is not our aim to cover completely all the literature on the use of calcium phosphate sorbents for the chromatography of enzymes, and we shall restrict ourselves chiefly to work carried out in the last ten years. It is during this period that particularly extensive use has been made of adsorption chromatography on columns in work on enzyme proteins. Thus French workers[26,27] have recently described the isolation, purification, and study of hog pancreas lipase. This work was carried out with chromatographic columns containing various adsorbents — tricalcium phosphate, brushite, hydroxyapatite, and ion-exchange cellulose. In chromatography on calcium phosphate sorbents, the chromatogram of the eluted enzyme shows one peak, irrespective of the method of elution; several active enzyme fractions were obtained on ion-exchange cellulose. The appearance of a large number of lipase components during chromatography on ion-exchange cellulose was attributed to artefacts[27]. This work is of methodological interest, since different adsorbents were used for the chromatographic study of the same material, and for pancreas lipase calcium phosphate appears to have a definite advantage over ion-exchange cellulose.

Choline esterase from human blood serum has been obtained by chromatography on hydroxyapatite[28]. In this work, the ion-exchange resin Dowex-2 was also used for the chromatographic study of the enzyme, and hydroxyapatite showed considerable advantages over ion-exchange resins. Among the enzymes which split ester linkages, enzymes hydrolysing esters of phosphoric acid have been studied by chromatography on calcium phosphate gels — phosphomonoesterase from human red blood corpuscles[29], and alkaline phosphatase from hog kidneys[30] — the chromatographic separation giving in the latter case several fractions exhibiting enzymatic activity. The question of their nature remains open. Esterase from hog liver has been separated from "ballast" proteins and obtained in the pure state by means of hydroxyapatite columns[31]. The behaviour of the purified liver esterase on hydroxyapatite columns showed that the enzyme can be separated into two or three fractions having similar specific activities[32]. Analysis of these fractions showed that their appearance is due not to differences in their primary structure but apparently to partial association of the molecules of this enzyme[32,33]. This example in particular shows the importance of making an all-round study of the products of the chromatographic separation. Chromatography on calcium phosphate gels has also been used for the study of other enzymes — amylase from wheat flour[34] and phenolase[35], where several fractions exhibiting cresolase activity were obtained. The presence of several active fractions was shown for nicotinamidase[36] by chromatography on hydroxyapatite. In this case the fractions obtained were examined in an ultracentrifuge and also by further chromatographic experiments. It was concluded that the existence of these fractions was due to an artefact produced as a result of autolysis in the early stages of isolation of the enzyme. Among the group of enzymes bringing about transfer reactions — transferases — various dehydrogenases have been subjected to chromatography on calcium phosphate sorbents[37-45]. Among the oxidases, chromatography on calcium phosphate gels has been used successfully for the isolation of monoaminooxidases from cow's blood[46]. In this case, several active enzyme fractions with similar specific activities were obtained. Another enzyme from this group — the aminooxidase from cow's blood — has recently been studied by chromatography on a column of hydroxyapatite[47]. In this case, a combination of column methods with different adsorbents — calcium phosphate and ion-exchange cellulose — was used. The advantages of hydroxyapatite over cellulose for this enzyme were noted.

Among the transaminases, enzymes which bring about the transfer of an amino-group, tyrosine–oxoglutarate–transaminase[48] and alanine–oxoglutamate–transaminase[49] have been examined by chromatography on calcium phosphate gels. In both cases, several active enzyme fractions showing different chromatographic behaviour were detected, but unfortunately they were not investigated further. Other enzymes which have been examined by chromatography on calcium phosphate gels include bacterial polynucleotide phosphorylase[50], trans-ketolase from hog liver[51], transferase from rabbit liver[52], etc. An interesting attempt has been made to use chromatography on a column of hydroxyapatite for the separation of brain enzymes[53]. Some separation of the enzyme peaks was achieved, although a more complete separation of the latter might apparently be achieved by further chromatographic experiments. This work is of interest since it is the first attempt to use chromatography on calcium phosphate for the isolation and fractionation of enzymes from brain tissue.

The above examples show that the chromatography of enzymes on calcium phosphate columns often gives several fractions exhibiting the same enzymatic activity. The same phenomenon is observed in the chromatography of enzymes on ion-exchange cellulose[7]. The question of the chromatographic heterogeneity of enzyme proteins on their elution from columns undoubtedly deserves attention. The results of chromatographic experiments on columns cannot always be interpreted unambiguously, and the reason for the appearance of enzyme fractions with different chromatographic behaviour, but the same activity, is often obscure.

Recent work on the column chromatography of biopolymers has shown that, in addition to the difficulties introduced into the interpretation of the experimental results by the actual elution technique (see Section III for more details), there are a number of other factors, not related to the method of elution, which make difficult an unambiguous explanation of the experimental data. These may be responsible for the appearance of a number of protein fractions with the same (or different) enzymic activity.

We give below examples of such cases and an assessment of the factors responsible for the appearance of a large number of components in protein polymers during chromatography of the latter on calcium phosphate columns. Thus in the chromatography of phycocyanin and phycoerythrin on hydroxyapatite, chromatographically different fractions of these proteins may appear as a result of association–dissociation effects[10].

In the case of ribonuclease from hog pancreas[54], the appearance of chromatographic heterogeneity in the enzyme was due to the removal of polyanions combined with the protein.

Changes produced by various factors in the secondary, tertiary, or quaternary structure of a protein may also be responsible for the appearance of a number of components when the protein is subjected to chromatographic study[23,55].

In other cases, the appearance of a number of components may be due to differences in the age of the material being studied[56]. The nature of the chromatographic curve may sometimes be influenced by spontaneous hydrolysis of the protein material being studied[57]. A difference in the quantity of phosphate groups in the protein can also apparently lead to the appearance of a number of components on elution from calcium phosphate columns[17]. Finally, the existence of individual active forms of the same protein may correspond to its true state. This has recently been shown in work on the chromatography of various proteins on different adsorbents[48,58-60].

Thus the above details show that a variety of factors may be responsible for the appearance of a number of components in the same protein during chromatography on columns. In all such cases, a special study of the protein fractions by different independent methods is desirable in order to evaluate the results obtained. These supplementary data will make it possible in each individual case to establish the reasons for the appearance of a number of components in the proteins being studied. It must apparently be assumed that there are a number of factors leading to the appearance of heterogeneity in protein polymers during column chromatography.

## V. THE CHROMATOGRAPHY OF SERUM PROTEINS AND OTHER PROTEINS ON CALCIUM PHOSPHATE

In recent years there has been a considerable increase in the number of papers devoted to the chromatography of plasma and serum proteins on calcium phosphate gels.

The chromatography of the proteins of normal human serum on hydroxyapatite columns was studied in detail by Hjerten[3]. The protein components were found to leave the column in a definite order. It is of interest to compare the behaviour of serum proteins on hydroxyapatite columns with the behaviour of the same proteins during chromatography on ion-exchange cellulose. Work by Sober et al.[61] revealed the distribution of the components of human serum during chromatography on diethylaminoethyl cellulose.

Table 1 illustrates the behaviour of serum proteins during chromatography on hydroxyapatite and on diethylaminoethylcellulose columns. The order in which the serum proteins leave the column is different for hydroxyapatite and diethylaminoethylcellulose (Table 1). On elution from hydroxyapatite, $\alpha_1$-globulin and albumin appear first, and $\gamma$- and $\beta$-globulins appear last; whereas on

TABLE 1.

| Adsorbent | Components of serum proteins eluted from column | | | | |
|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5* |
| Hydroxyapatite | $\alpha_1$** | Al*** | $\alpha_2$** | $\gamma$** | $\beta$** |
| Diethylaminoethylcellulose | $\gamma$** | $\beta$** | $\alpha_1$** | Al*** | $\alpha_2$** |

* The figures give the order in which the proteins leave the column.
** Globulin.
*** Albumin.

diethylaminoethylcellulose columns, $\gamma$-globulin and $\beta$-globulin appear first, and albumin and $\alpha_2$-globulin appear last. On elution from columns of ion-exchange cellulose, proteins having higher isoelectric points appear before proteins with lower isoelectric points; whereas on elution from hydroxyapatite, this dependence on the isoelectric points of the proteins is not observed.

From this it follows that the principles of the separation of proteins on calcium phosphate gels and on ion exchangers based on cellulose are different, that the chromatography of proteins is different for these materials, and that these groups of sorbents cannot replace one another[3].

A number of workers have studied the behaviour of individual serum protein components during chromatography on calcium phosphate columns. The albumins of human serum[3,34], ox serum[10,62,63], and horse serum[17] have been studied by chromatographic methods.

Table 2 summarises data on the chromatography, on hydroxyapatite columns, of serum albumins from different sources. Albumins of different origin, on chromatography on hydroxyapatite, give three components which are always eluted from the columns at definite phosphate buffer concentrations (Table 2). The slight difference in the percentage ratio of components eluted can apparently be attributed to a difference in the purity of the original albumin specimens and to differences in the methods used to prepare the hydroxyapatites.

An interesting feature is that the chromatography of human serum albumin on ion-exchange cellulose[61] also

TABLE 2*.

| Albumin from serum | Phosphate buffer used for elution, M | | | Ref. |
|---|---|---|---|---|
| | 0.07 | 0.11 | 0.40 | |
| Ox | 50 | 30 | 20 | 10 |
| Ox | 50 | 37 | 13 | 62 |
| Ox | 67 | 25 | 8 | 63 |
| Horse | 67 | 21 | 12 | 17 |
| Human | 50 | 30 | 20 | 3 |
| Human | 62 | 28 | 10 | 34 |

* The figures give the percentage of protein eluted from the columns.

gives not less than three different components. The reason for the appearance of chromatographic heterogeneity in serum albumin is not completely clear.

Various workers have studied the behaviour of other serum proteins — $\alpha$-globulin[3,65], $\beta$-globulin[3], and $\gamma$-globulin[3,10] — on calcium phosphate columns. In chromatography on hydroxyapatite columns, $\gamma$-globulin usually gave three components, whose real existence was confirmed by further chromatographic study[10]. Columns of hydroxyapatite have been used to separate an electrophoretically rapid component of $\gamma$-globulin from a component of lower mobility[3]. A scheme has been proposed for the isolation of $\gamma$-globulin directly from serum by means of hydroxyapatite columns[3,64].

A number of papers have been devoted to the chromatography of ceruloplasmin on calcium phosphate columns[3,66-68]. This protein has been shown to be chromatographically heterogeneous[68]. The behaviour of fibrinogen from human plasma has been studied on calcium phosphate columns[69,70]. An interesting feature is that the chromatography of fibrinogen was found to be more satisfactory at room temperature than at +4°.[69]

Thus the behaviour of proteins both from whole serum and from its individual components has been studied in some detail on calcium phosphate columns, and a number of components have been shown to be heterogeneous.

Chromatography on calcium phosphate columns has been applied successfully not only to serum proteins but also to other proteins, such as milk albumin[71], egg albumin[10,17], milk proteins[72,73], egg proteins[74], saliva proteins[75], and soya-bean proteins[76,77]. Calcium phosphate gels have also been used for the chromatography of acid mucopolysaccharides (hyaluronic acid and chondroitin sulphuric acid[78]).

It has been found that acidic mucopolysaccharides are sorbed satisfactorily only by calcium phosphate precipitated under definite conditions at pH 9.2, whereas hydroxyapatite prepared by Tiselius' method[10] sorbs these proteins very weakly. This shows again the importance of standardising methods for preparing calcium phosphate sorbents and the possibility of variation in the properties of the latter.

Finally, a number of papers have been devoted to the use of calcium phosphate gels for the chromatography of hormones — insulin[79], lactogenic hormone from sheep hypophysis[80], the luteinising hormone from hypophysis[81], the follicle-stimulating hormone from hog hypophysis[82], and the hormone which stimulates the formation of sheep plasma erythrocytes[83].

These papers show that it is possible to separate and isolate various hormone proteins by means of calcium phosphate columns. In the case of insulin[79] and the luteinising hormone from sheep hypophysis[81], chromatography has shown the existence of several fractions exhibiting hormone activity. Chromatography on calcium phosphate has also been used to isolate and purify certain protein toxins[84,85].

## VI. THE CHROMATOGRAPHY OF NUCLEIC ACIDS AND VIRUSES ON CALCIUM PHOSPHATE GELS

Calcium phosphate gels have been used only fairly recently for the chromatography of nucleic acids. One of the first papers in this field is that by Semenza[86], who used hydroxyapatite for the chromatography of DNA from calf thymus. An interesting feature is that DNA is sorbed on hydroxyapatite much more strongly than are ordinary proteins. The chromatography of DNA from calf thymus on calcium phosphate columns has also been carried out by other workers[87].

The DNA eluted from the column appears a single sharp peak[86], in contrast to the results obtained, for example, on ECTEOLA cellulose[88], where considerable heterogeneity of the DNA was observed.

According to modern ideas, DNA from cells have very high molecular weights, and are apparently not divided into subunits, but form continuous polynucleotide chains[89]. In the chromatography of these structures, there is, of course, a real danger of fragmentation and disaggregation of the DNA molecules. It is not impossible that the appreciable heterogeneity of DNA of a given type, observed in chromatography on ECTEOLA cellulose, is due to breakdown of a single DNA molecule[90]. In this respect, calcium phosphate gels apparently have an advantage, since chromatography on the latter usually gives only one peak (or a maximum of two or three) for DNA.[87] Calcium phosphate gels have been used by other workers[18,91] for the chromatography of DNA.

It has recently been shown that chromatography on calcium phosphate columns can be used for the successful separation of mixtures of DNA and RNA.[92,93] A mixture of DNA from calf thymus and RNA from tobacco mosaic virus can be separated[92] in a single operation on a calcium phosphate column.

A good separation of mixtures of DNA and RNA isolated from *Salmonella typhimurium* bacteria has also been achieved[93]. Two peaks are obtained for RNA and one peak for DNA at the column outlet. This work shows the great importance of chromatographic methods using calcium phosphate columns for the separation of complex biological mixtures such as those formed by the nucleic acids. Fairly good separation of the nucleic acids is achieved.

Interesting work has been done on the chromatography of deoxyribonucleotides isolated from the spleen of normal mice and of mice subjected beforehand to radiation[94]: a considerable difference was observed in the elution profiles for the deoxyribonucleoproteins from the irradiated and normal animals. This work indicates new possibilities for the use of calcium phosphate columns and their ability to reflect structural differences between normal and pathological cell deoxyribonucleoproteins. Chromatography on calcium phosphate columns has been carried out not only with DNA but also with RNA from different sources, high-molecular RNA from the cells of Ehrlich's ascites tumour[95], RNA from rabbit liver[96], and soluble RNA from rat liver[97] and from *Escherichia coli* microbial corpuscles[98].

This last paper[98] reported chromatography on hydroxyapatite columns to separate, in one operation, soluble RNA specific to the amino-acids valine and phenylalanine. Development of work in this direction is of considerable interest for the preparation of different types of soluble RNA specific to individual amino-acids.

Noteworthy papers have recently appeared on the chromatography of virus RNA on calcium phosphate gels — RNA obtained from Krebs' ascites tumour cells infected with encephalomyocarditis virus[99], virus RNA isolated

from foot and mouth disease virus[100], and RNA from tobacco mosaic virus[92,101] – and in some of this work[99,100], the RNA was eluted from the column in several peaks. It should be noted, however, that calcium phosphate gels have as yet been comparatively little used for the isolation and characterisation of nucleic acids; nevertheless these sorbents are extremely effective for the chromatographic study of both RNA and DNA obtained from the most varied sources.

The use of adsorption column methods for the chromatography of viruses has been carried out successfully only in recent years. Chromatographic studies on calcium phosphate columns have been carried out for the viruses of influenza[102,103], herpes[104], encephalomyocarditis[105], and encephalitis[106,107], arbor viruses[108], adenoviruses[109], measles virus[110], and also plant viruses[101,111]. The use of column-chromatographic methods in the study of macromolecules such as virus molecules, which have a very high molecular weight and complex structure, presented considerable difficulties, but suitable techniques and adsorbents have been found, which make it possible to isolate virus nucleoproteins from a complex mixture of substances by column chromatography.

Experiments with individual viruses[100] have shown that the medium in which the virus to be tested is cultivated is of importance in chromatography. For example, the chromatographic behaviour of herpes virus depended on whether the virus had been grown in a cell culture or in a chick embryo cavity. Preliminary treatment of the test material with sodium ethylenediaminetetraacetate was also important[100].

Interesting work with arbor viruses[108] has shown that chromatography on calcium phosphate columns may be a convenient and simple method for preparing stable haemagglutinin and complement-fixing antigens, both for the diagnosis of these viruses and for the detailed study of their physicochemical properties.

With adenoviruses, for example, chromatography on calcium phosphate gels can be used for rapid determination of the virus type, using type-specific sera[109], and for the isolation of three different components of adenoviruses, giving the complement-fixing reaction[109]. This last feature has also been shown in the chromatography of adenoviruses on diethylaminoethylcellulose[112].

Finally, mention may be made of the chromatography of coliphages on calcium phosphate columns[113]. An interesting feature is that the ability of calcium phosphate gels to adsorb virus nucleoproteins is much more marked than that for bacteriophages[113].

## VII. THE FURTHER DEVELOPMENT AND FUTURE PROSPECTS OF THE CHROMATOGRAPHY OF BIOPOLYMERS ON CALCIUM PHOSPHATE

In recent years a number of papers have pointed out new possibilities for using calcium phosphate gels in the chromatography of biopolymers. It has been shown[10,99,114] that chromatography on calcium phosphate columns can probably differentiate biopolymer molecules according to molecular weight. Protein molecules of small dimensions are eluted from a column by a lower phosphate buffer concentration than are molecules of high molecular weight. Thus chromatography on calcium phosphate columns can be used for the approximate estimation of the molecular dimensions and weight of protein materials to be studied by chromatographic methods.

Interesting papers on the use of calcium phosphate sorbents[10,22] point out that chromatography on calcium phosphate columns can be used successfully to detect and observe the phenomenon of the association–dissociation of protein polymers in cases where these processes take place in a pH range the same as (or adjacent to) that in which the chromatographic process is carried out.

Calcium phosphate sorbents have also been applied in a completely different field[115,116]. It has been shown that chromatography on calcium phosphate can be used to follow the changes in the protein components of blood serum in certain illnesses. Thus the presence, in the patient's blood, of different fractions of the protein ceruloplasmin alters the chromatographic curve[115] and indicates different stages of the pathological process. Chromatography on calcium phosphate columns apparently provides a sufficiently sensitive and flexible method of study and can probably be widely used for the detection of various pathological changes in blood proteins in certain illnesses.

Calcium phosphate gels have found a very interesting application in the study of serological reactions[117,118]. It has been shown possible to study the reaction of an antigen with an antibody directly on the columns. Finally, recent work has revealed a new property of calcium phosphate gels, namely their ability to adsorb certain elements[119] and heavy-metal ions[120] from the surrounding medium.

A recent interesting discovery is related to the behaviour of calcium phosphate gels in the transfer of the calcium phosphate residues of nucleosides to the surface of these gels[121]. This transphosphorylation process may take place over wide ranges of temperature and of pH. It is apparently of definite importance in the chromatography of compounds containing free phosphate groups, which may take part in this reaction.

The above review of the chromatography of biopolymers on calcium phosphate gels shows the various fields of study in which columns of calcium phosphate gels may be used. Further study of the properties of these gels, extension of the range of their application, and detailed investigation of the mechanism of the chromatography of biopolymers on calcium phosphate columns are desirable.

# REACTIONS OF ACETALS WITH UNSATURATED ETHERS

L. S. Povarov

CONTENTS

I. Introduction 639

II. Mechanism of the reaction 640

III. Effect of catalysts 642

IV. Effect of acetal structure 643

V. Effect of temperature 643

VI. Migration of alkoxy-radicals 644

VII. Hydrolysis and elimination of alcohol from alkoxy-acetals 644

VIII. Reactions of acetals of various classes 645

1. Reactions of aliphatic saturated acetals 645
2. Reactions of unsaturated aliphatic and alicyclic acetals 646
3. Reactions of aliphatic–aromatic and aromatic acetals 647
4. Reactions of heterocyclic acetals 648
5. Reactions of substituted acetals 648
6. Reactions of cyclic acetals 648
7. Reactions of ketals 649
8. Reactions of ortho-esters 649
9. Reactions of thioacetals 650

IX. Related reactions 650

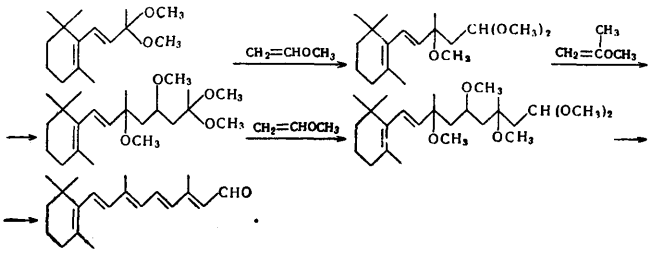
1. Reactions of acetals with alkenes 650
2. Reaction of aldehydes with $\alpha\beta$-unsaturated ethers 651
3. Autocondensation of acetals 651
4. Autocondensation of vinyl ethers 652

X. Syntheses based on the reaction of acetals with $\alpha\beta$-unsaturated ethers 652

1. Synthesis of isoprenoid systems 652
2. Synthesis of unsaturated dicarboxylic acids 653
3. Synthesis of arylated polyene hydrocarbons 653
4. Synthesis of polyenals and 1-alkoxypolyenes 653
5. Synthesis of quinolines 654

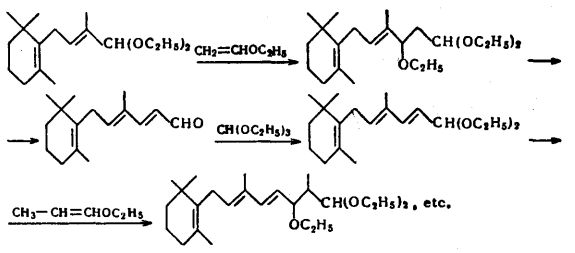
## I. INTRODUCTION

Acetals are a broad and readily available class of organic compounds, but for a long time they found no significant application in organic synthesis. The only synthetic reaction in which the acetal group was used was that between acetals and organomagnesium compounds discovered by Chichibabin[1]. But this reaction, occurring under severe conditions, at temperatures above 100°, did not find wide use. The main use of acetals was connected with the need to protect carbonyl groups, for example, in the synthesis of steroids[2]. Characteristically, acetals formed as intermediates in the industrial syntheses of alcohols from carbon monoxide and hydrogen are considered to be undesirable products and find only limited application[3].



The position changed only after Müller-Cunradi and Pieroh's discovery[4], in 1939, of the reaction of acetals

with alkyl vinyl ethers under the influence of boron trifluoride. Ten years later Hoaglin and Hirsh[5], by defining the mechanism of the reaction, showed that it could be used for obtaining unsaturated aldehydes. After this, the reaction was intensively developed by the chemists of many countries and several patents and research works devoted to this reaction have appeared.



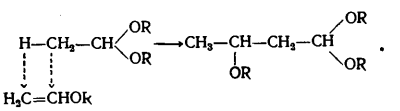
The preparation of unsaturated aldehydes by the reaction of acetals with alkyl vinyl ethers is brought about thus:

$$R{-}CH(OR')_2 + CH_2{=}CHOR' \longrightarrow R{-}(CH{-}CH_2)_n{-}CH(OR')_2 \longrightarrow R{-}(CH{=}CH)_n{-}CHO.$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OR'$$

This method of synthesising polyene compounds was considered extremely promising and even one of the first patents, taken out by Copenhaver[6], contained the idea of using it to obtain Vitamin A. The essence of the proposed method was the successive condensation of $\beta$-ionone dimethyl acetal with methyl vinyl ether and isopropenyl methyl ether:

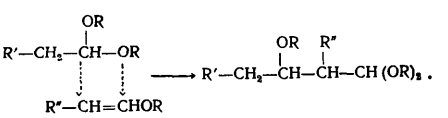
However, it is now clear that this scheme for obtaining vitamin A, which is masterly in its simplicity, is impracticable in that form and is evidently purely theoretical. Although there are others, the most unreal aspect of this scheme was the preparation of the initial acetal of $\beta$-ionone by the method described in the patent. It was only recently (1963) that Mikhailov and Povarov[7] obtained $\beta$-ionone acetal and described its properties and reaction with ethyl vinyl ether. In 1956 Isler[8] used a similar scheme to construct the $\beta$-carotene polyene chain, the starting point being not $\beta$-ionone acetal, but the acetal of the so-called $C_{14}$ aldehyde obtained from $\beta$-ionone; the route was rather complex:

Isler and coworkers[9-13], and also Inhoffen and Erdmann[14] used the same route to synthesise lycopene, zeaxanthin, cryptoxanthin, and several other carotenoids and intermediates. Mikhailov and Povarov used the reaction of acetals with alkyl vinyl ethers to synthesise difficultly accessible arylated polyene hydrocarbons[15-17].



The success in the synthesis of polyene compounds encouraged the rapid increase in investigations in this direction and a further widening of the field of application of the new reaction. It was found that an extremely wide range of acetals and unsaturated ethers could be used in the reaction, and also some other unsaturated compounds with an activated double bond. For example, aliphatic or alicyclic saturated or unsaturated acetals, aromatic or heterocyclic acetals, cyclic acetals, ketals, ortho esters, etc. can be used as the acetal component. Alkyl vinyl ethers, unsaturated ethers which are substituted in the 1- or 2-positions, $\alpha\beta$-unsaturated sulphides, $\alpha\beta$-unsaturated cyclic ethers, alkoxydienes, ketens, ethoxyacetylenes, etc. can be used as the ether component. Zinc chloride, iron(III) chloride, aluminium chloride, etc. can be used instead of boron trifluoride as the catalyst.

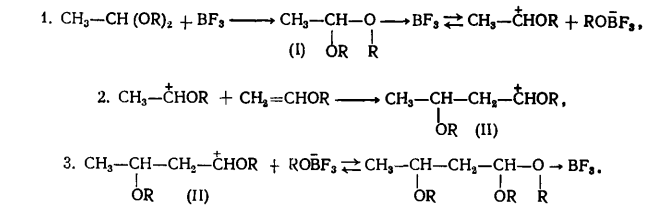
All these facts show that the reaction of acetals with unsaturated compounds has great prospects for future development.



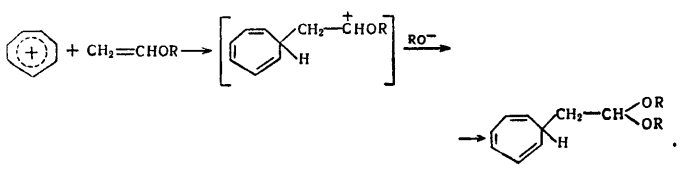
The progress achieved in investigating the reaction has already been partly surveyed in several reviews[18-20]; but there have been many new papers since then, some of which are of great interest. Furthermore it is now necessary to consider in greater detail the special features of the reaction mechanism in the light of the latest results and to generalise the information on the reactivity of acetals and ethers in this reaction. The present article is devoted to these questions.

## II. MECHANISM OF THE REACTION

Müller-Cunradi and Pieroh[4], on discovering the reaction of acetals with alkyl vinyl ethers, considered that the condensation proceeds through the mobile hydrogen of the acetal by the scheme:



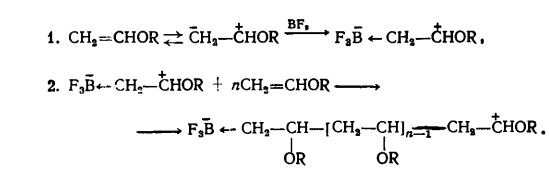
This seemed natural by analogy to some extent with the aldol condensation. However, in later work Hoaglin and Hirsh[5] found the error in this explanation without much difficulty, by performing the reaction with substituted acetals and substituted alkyl vinyl ethers. It transpired that the products are formed in accordance with another reaction scheme:



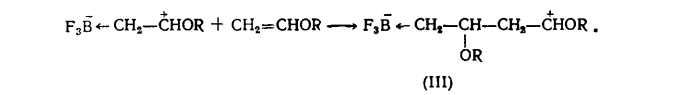
This mechanism was completely new to organic chemistry and there was no known analogy to it. Before long it received confirmation from the results of an investigation of the reactions of benzaldehyde dialkyl acetals with alkyl vinyl ethers[21,22]. In these reactions there were high yields of addition products whose formation under these circumstances was possible only by the second scheme.

Hoaglin and Hirsh[5] proposed the following scheme for the reaction mechanism with participation of the boron

trifluoride catalyst, and this was accepted subsequently by other investigators:



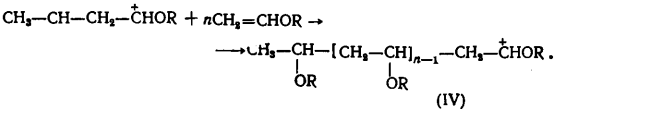
Vol'pin and coworkers[23] specially investigated the problem of the probability of a carbonium ion arising in a side reaction. For this purpose they studied the reaction of the stable tropylium ion with ethyl vinyl ether. It appeared that tropylium salts readily react with various vinyl ethers, and that the tropylium cation always attacks only the $CH_2$ group of the vinyl ether, to form a cycloheptatrienylacetaldehyde acetal:



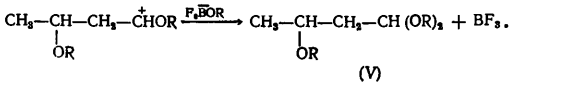
These results confirm the course of the reaction through the formation of a carbonium ion.

In simple vinyl ethers, when there is an alkoxy-group at the double bond not only is there an inherent negative induction effect but there is also a positive mesomeric effect due to the conjugation of the lone pair of electrons of the oxygen atom with the $\pi$ electrons of the double bond. The actions of these effects on the $\pi$ electrons are opposite but the mesomeric effect predominates in this instance, and as a result the electron density at the $\beta$ carbon atom is increased and consequently this atom acquires enhanced nucleophilic properties. Such a picture also holds with the analogues of simple vinyl ethers, such as cyclic unsaturated ethers of the dihydrofuran and dihydropyran type, alkoxydienes, $\alpha\beta$-unsaturated sulphides, and ketens. This can explain the high reactivity of these compounds towards electrophilic reagents, and particularly the carbonium ion produced by the action of boron trifluoride on acetals in accordance with the scheme given above, and the absence of this behaviour with unsaturated compounds having an electron-acceptor substituent at the double bond.

It is noteworthy that Hoaglin and Hirsh's ionic mechanism[5] for the reaction of acetals with vinyl ethers is reminiscent of the mechanism of cationic polymerisation, characteristic for the simple vinyl ethers[24]:



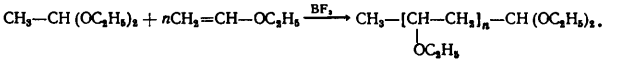
Evidently during the polymerisation a cation (III) analogous to cation (II) is produced:



(III)

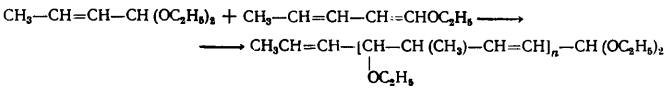
However, unlike cation (III), to which there is further addition of the vinyl ether during the polymerisation, the fate of cation (II) in the reaction of acetals with vinyl ethers can be different: in the presence of an excess of a vinyl ether it can serve as the initial link in a cationic polymerisation (first boundary case):

(IV)

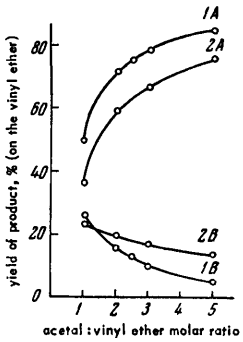


In the presence of a large excess of acetal, cation (II) is stabilised by addition of an alkoxy-group (another boundary case):

(V)



In real intermediate cases, a mixture of reaction products is formed, containing both (V) and (IV) with various values of $n$. For example, Hoaglin and Hirsh[5] obtained a curve (see Figure) for the dependence of the yield of the primary condensation product (a 1,1,3-trialkoxybutane) on the ratio of the initial acetal and vinyl ether.



Makin and Sudakova[25] investigated the distribution of the addition products at different ratios of the initial reagents in the reaction:

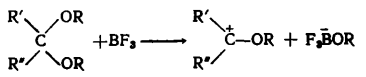
Their results are in Table 1.

There are similar results for the reactions of unsaturated acetals with alkoxydienes, for example, for the reaction of crotonaldehyde diethyl acetal with 1-ethoxypenta-1,3-diene[26] (see Table 2):

Dependence of the yields of condensation products on the acetal : vinyl ether ratio: 1A) 1,1,3-trimethoxybutane; 2A) 1,1,3-triethoxybutane; 1B) 1,1,3,5-tetramethoxyhexane; 2B) 1,1,3,5-tetraethoxyhexane.

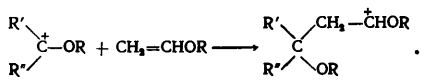
TABLE 1. Distribution of the addition products as a function of the reagent ratio.

$CH_3-[CH(OC_2H_5)-CH_2]_n-CH(OC_2H_5)_2$



| Acetal : ether molar ratio | Yield of addition products, % | | | | | |
|---|---|---|---|---|---|---|
| | $n=1$ | $n=2$ | $n=3$ | $n=4$ | higher | total yield |
| 2 | 63 | 14.9 | 3.6 | 1.6 | — | 83.2 |
| 0.75 | 26.5 | 38.6 | 11.3 | 5.5 | 4.5 | 86.0 |
| 0.5 | 16.5 | 19.0 | 31.0 | 12.8 | 6.5 | 85.8 |
| 0.2 | 3.9 | 8 | 11.1 | 22.0 | 17.8 | 62.7 |

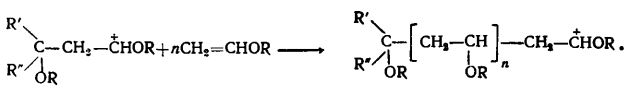
TABLE 2. Distribution of the addition products as a function of the ratio of initial reagents.



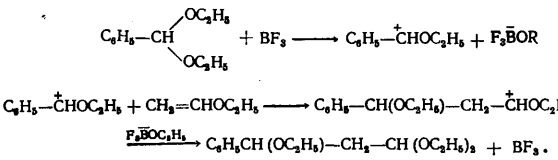
$CH_3CH=CH-[CH(OC_2H_5)-CH(CH_3)-CH=CH]_n-CH(OC_2H_5)_2$

| Ethoxydiene : acetal molar ratio | Yield of addition products, % | | | | |
|---|---|---|---|---|---|
| | $n=1$ | $n=2$ | $n=3$ | $n=4$ | total yield |
| 1:2 | 48 | 30 | 12 | 3 | 93 |
| 2:3 | 28 | 41 | 16.5 | 5 | 90.5 |
| 1:1 | 27 | 12 | 37 | 8.5 | 84.5 |
| 2:1 | 9.5 | 6 | 26.5 | 26.5 | 68 |

Hence the reaction of acetals with unsaturated ethers behaves as a reaction which is regulated by ionic telomerisation[27], in which the proportions of the products depend on the ratio of the initial reagents: the acetal (telogen) and the unsaturated ether (taxogen). However, the analogy with telomerisation reactions is not always observed. In the instances considered above, the addition of a molecule of the unsaturated compound to the type (I) cation led to the formation of a type (II) cation, differing little in reactivity from the initial cation (I). Moreover, it is obvious that the nature of the products formed will depend on the relation between the reactivities of cations (I) and (II) as well as on the ratio of the reagents. When the reactivity of cation (I) is extremely low in comparison with cation (II) then the reaction product will be a polymer. This occurs, for example, with certain acetals of ketones, the reaction being:

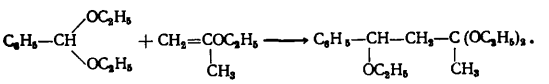


(VI)



(VII)

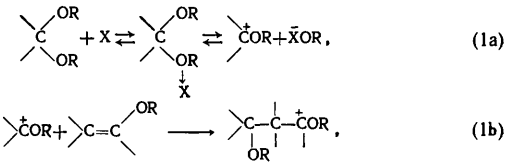
The cation (VII) formed is much more reactive than cation (VI) and hence the further addition of the unsaturated ether is to (VII) (the first boundary case):



Thus, Mikhailov and Povarov[28] observed that in the reaction of the acetal of 4-ethoxy-6-methylhept-5-en-2--one with ethyl vinyl ether the primary reaction product — an acetal of 3,5-diethoxy-3,7-dimethyloct-6-enal (an acetal of diethoxycitronellal) — was formed in only insignificant quantities even when there was a large excess of the original acetal. Obviously the moderate yield of the product obtained on condensing an acetal of 6-methylhept-5--en-2-one with ethyl vinyl ether[29] was for the same reason.

When the reactivity of the initial type (I) cation is much higher than that of the newly formed type (II) cation (the opposite case to the previous one), a primary addition product of type (V) will be formed almost exclusively. An example of this is the condensation of benzaldehyde diethyl acetal with ethyl vinyl ether[22]. Even at a 1 : 1 ratio of the original reagents the primary condensation product (1,1,3-triethoxy-3-phenylpropane) is obtained in $>70\%$ yield, that is, the reaction proceeds mainly according to the scheme:

Another example is the condensation of a benzaldehyde acetal with ethyl isopropenyl ether[17]. Here the yield is still greater (81%) since the primary product formed — 1,3,3-triethoxy-1-phenylbutane — is even less reactive in subsequent condensations.



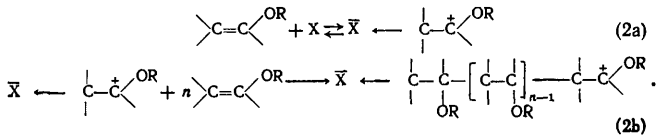
The reaction of acetals with $\beta$-bromovinyl ethers[30] and ketens[31] is also of this type, the products formed being incapable of further condensation. These reactions are considered in detail below.

Hence in these instances there is no analogy with telomerisations. In addition to the above factors the nature of the catalyst employed greatly affects the course of the reaction.

## III. EFFECT OF CATALYSTS

Lewis acids and metal chlorides are used as catalysts of the reaction; they include boron trifluoride[5], zinc chloride[8], iron(III) chloride[32-34], and also aluminium chloride, titanium(IV) chloride, and tin(IV) chloride[35], etc. The ether addition compounds of boron trifluoride and zinc chloride are most frequently employed, the latter in the form of solutions in ether, ethyl acetate, or acetic acid. Of the catalysts mentioned, boron trifluoride is the most effective, but its use is limited by its vigorous reaction with the initial acetals. For example, the acetals of the $\alpha\beta$-unsaturated series (in particular terpenes) undergo resinification in the presence of boron trifluoride. A milder catalyst in this sense is zinc chloride, particularly its solutions in ether and ethyl acetate. But it is not just a matter of the reactive nature of the catalyst with respect to the acetals.

As already mentioned, the reaction of the acetals with unsaturated ethers is connected with the dissociation of the acetals:



(1a)

(1b)

where X is the catalyst.

On the other hand the catalyst can cause direct cationic polymerisation of the unsaturated ether:

(2a)

(2b)

Usually the two reactions occur simultaneously but it is obvious that for the preferential occurrence of condensation by reaction (1b) it is necessary for dissociation by scheme (1a) to proceed more rapidly than the formation of the cation by scheme (2a), leading to polymerisation by Eqn. (2b). It is also evident that the ratio between the rates of reactions (1a) and (2a) will depend on the catalyst X. This can explain the fact that when ethyl isopropenyl ether reacts with an acetal of benzaldehyde in the presence of boron trifluoride the ether is polymerised according to Eqn. (2b) but in the presence of zinc chloride an addition product is formed according to Eqn. (1b) in high yield[17]. Consequently, with boron trifluoride ionisation according to scheme (2a) predominates, but with zinc chloride dissocation proceeds according to scheme (1a).

Other examples can be mentioned where the correct choice of catalyst was the deciding factor for successfully effecting the condensation. For example, 1-alkoxydienes condense with acetals almost exclusively in the presence of zinc chloride[28,36,37]. However, some acetals have not been condensed with unsaturated ethers, despite the use of a variety of catalysts. This demonstrates the low reactivity of acetals, for which their structure is responsible.

## IV. EFFECT OF ACETAL STRUCTURE

The reactivity of acetals has not been determined directly but it can be judged from how they participate in reactions with various types of unsaturated ethers. In polymerisations by scheme (2b) 1-substituted alkyl vinyl ethers are more reactive than the unsubstituted ethers[38,39]. 1-Alkoxydienes are still more reactive[40]. Hence from their tendency to polymerise, unsaturated ethers can be arranged in a series: vinyl ethers unsubstituted in the 1-position < 1-substituted vinyl ethers < 1-alkoxydienes. The tendency to ionisation by scheme (2a) will increase in the same sequence. Saturated acetals readily react with alkyl vinyl ethers unsubstituted in the 1-position according to scheme (1), but in their reaction with ethyl isopropenyl ether (ethyl 1-methylvinyl ether) and 1-alkoxydienes the polymerisation of the unsaturated ethers by scheme (2) predominate. Aromatic acetals react by scheme (1) with alkyl vinyl ethers, whether substituted or unsubstituted in the 1-position, but do not give addition products with 1-alkoxydienes. Finally, $\alpha\beta$-unsaturated acetals readily give addition products with all three types of unsaturated ethers. Consequently, here dissociation by scheme (1a) takes place most readily and predominates over ionisation by scheme (2a) with any of the unsaturated ethers mentioned. On this basis these types of acetals can be arranged in the following sequence of reactivity: saturated acetals < < aromatic acetals < $\alpha\beta$-unsaturated acetals. Moreover, this order agrees with the tendency of these acetals to hydrolyse. Table 3 shows the equilibrium constants determined by Hartung and Adkins[41] for the formation of acetals (the back reaction to hydrolysis). The decrease in $K$ corresponds to an increase in the tendency to hydrolysis. For acetals such as that of bromoacetaldehyde $K$ is high and this corresponds to the complete inability of this acetal to react even with ethyl vinyl ether by scheme (1). As a result of this reaction only a polymer by scheme (2) is formed. On the $\alpha\beta$-unsaturated acetals only acrolein acetal has an equilibrium constant higher than the aromatic benzaldehyde acetal. This suggests that acrolein acetel will be less able to condense with unsubstituted ethers, but there are no experimental results on this.

TABLE 3. Equilibrium constants for the reaction:

$$RCHO + 2\,ROH \rightleftarrows RCH(OR')_2 + H_2O$$

| R | $K$ | $-RT \ln K$ | R | $K$ | $-RT \ln K$ |

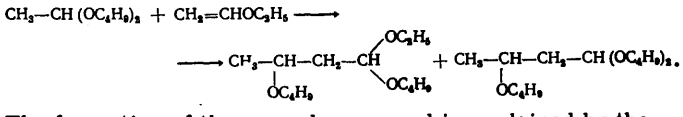
## V. EFFECT OF TEMPERATURE

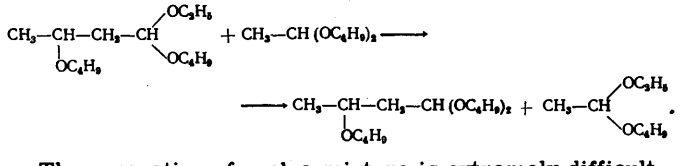
The possibility of influencing the course of the reaction with unsaturated ethers by changing the temperature is very restricted. Usually the reactions are performed within the limits 5–50°. On raising the temperature the reaction rate increases, but there is also a decrease in the stability of acetals sensitive to acids, both the initial acetals and those formed in the reaction. On heating, even in the

presence of insignificant amounts of acidic reagents, acetals readily decompose into unsaturated ethers and alcohols[28]:



This determines the upper temperature limit of the reaction.

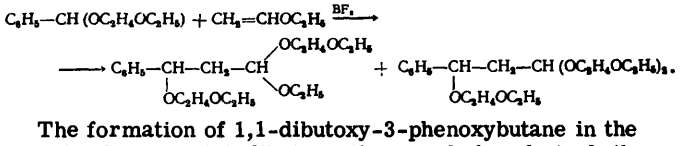
In many instances the reaction proceeds with evolution of heat and the reaction mixture must be cooled to avoid overheating. Occasionally, when the acetals are stable the reactants can be heated to 130–140°.[43] With highly reactive and acid-sensitive unsaturated compounds, such as 1-alkoxydienes and keten, the reaction takes place at reduced temperatures, in the last instance at -80°.[31]



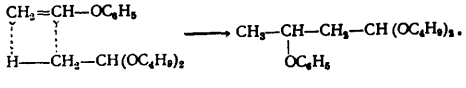
## VI. MIGRATION OF ALKOXY-RADICALS

Alkoxy-radicals in acetals exhibit great mobility and are able to migrate in the presence of acid catalysts[44,45]. This phenomenon also occurs in the reaction of acetals with unsaturated ethers under the influence of Lewis acids.

Hoaglin and Hirsh[5] showed that when an acetal and a vinyl ether have different alkoxy-groups the reaction results in the formation of a mixture containing products of the exchange of alkoxy-groups. For example, 1,3-dibutoxy-1-ethoxybutane and 1,1,3-tributoxybutane were isolated from the products of the reaction of 1,1-dibutoxyethane and ethyl vinyl ether:

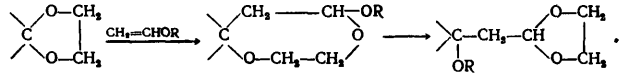


The formation of the second compound is explained by the reaction:

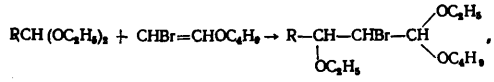


The separation of such a mixture is extremely difficult, therefore to obtain an addition product of known structure it is necessary to start with an acetal and an unsaturated ether with the same alkoxy-groups.

Povarov and Mikhailov[46] observed the migration of alkoxy-groups in studying the reaction of benzaldehyde bis-ethoxyethyl acetal with ethyl vinyl ether. They also obtained a mixture of products:



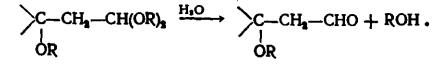
The formation of 1,1-dibutoxy-3-phenoxybutane in the reaction between 1,1-dibutoxyethane and phenyl vinyl ether, studied by Shostakovskii and Bogdanov[43], was evidently due to the migration of the phenoxy-group. The presence of this product in the reaction mixture led to authors to conclude that there was another mechanism for the reaction of acetals with phenyl vinyl ether:



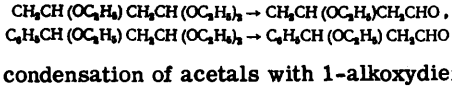
However, the formation of this product is undoubtedly due to the redistribution of the butoxy- and phenoxy-groups, particularly as the reaction is carried out at 120°.

Mikhailov and Povarov[47] showed that in the reaction of cyclic acetals with alkyl vinyl ethers the primary condensation product undergoes rearrangement, which can be explained by the intramolecular migration of alkoxy-groups:

The reaction of acetals with alkyl 2-bromovinyl ethers is another matter[30]. The course of this reaction is quite analogous to that for the alkyl vinyl ethers but there are several peculiarities. The condensation products are 2-bromoacetals in which the alkoxy-groups are only slightly mobile. The result is the absence of migration of alkoxy-groups, which was established by the example of the condensation of benzaldehyde diethyl acetal and 1,1-diethoxyethane with 2-bromovinyl butyl ether. Only the normal addition products were isolated; products of the migration of alkoxy-groups were not observed:

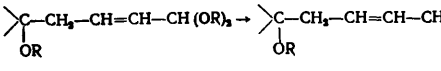


where R = $CH_3$ or $C_6H_5$.

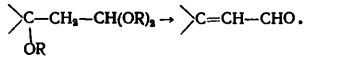


Another peculiarity of the reaction was the absence of products of secondary condensation with the unsaturated ether, also the result of the deactivating action of bromine in the 1-position on the mobility of alkoxy-groups.

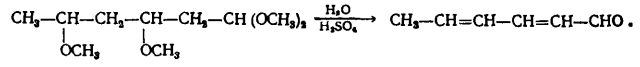
## VII. HYDROLYSIS AND ELIMINATION OF ALCOHOL FROM ALKOXYACETALS



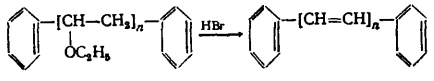
Usually the condensation products of acetals and unsaturated ethers — alkoxyacetals — are not used directly, but are hydrolysed to liberate aldehydes or ketones:



3-Alkoxyacetals are similar to saturated acetals as regards hydrolysis; they are hydrolysed by heating with aqueous acid. For example, 3-ethoxybutanal[5] and 3-ethoxy-3-phenylpropanal[22] were thus obtained:

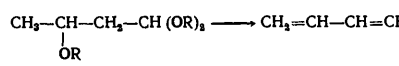


In the condensation of acetals with 1-alkoxydienes, $\alpha\beta$-unsaturated acetals are formed, which are readily hydrolysed in the presence of mineral acids in the cold[37]:



Often the hydrolysis of acetals is accompanied by the elimination of an alcohol with the aim of making unsaturated carbonyl compounds:

This is done in various ways. For example, hexa-2,4-dienal was obtained from 1,1,3,5-tetramethoxyhexane by boiling with 5% sulphuric acid[5]:

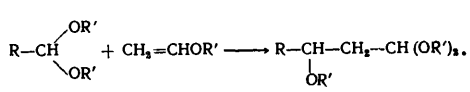


Usually under such conditions the reaction is accompanied by marked resinification, and therefore milder reagents and conditions are used, for example, heating with acetic acid in the presence of sodium acetate[8], heating with a dilute solution of phosphoric acid in dioxan[8], heating with a dilute solution of *p*-toluenesulphonic acid in toluene[37]. As Mikhailov and Povarov found[15-17], the best method of eliminating an alcohol from the diphenylpolyalkoxyalkanes, obtained as the products of the condensation of benzaldehyde acetals with vinyl ethers, consists of boiling with alcoholic hydrogen bromide:

where $n$ = 2, 3, 4, or 5.

Sometimes an alcohol is eliminated from alkoxyacetals in an anhydrous medium without hydrolysis. For example, 1-alkoxydienes are obtained from 1,1,3-trialkoxyalkanes in this way:

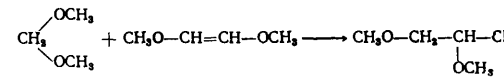
Mikhailov and Povarov[28] developed a liquid-phase method of carrying out this reaction under the action of *p*-toluenesulphonic acid in quinoline. Others have also employed this method[48].



The earlier known method of vapour-phase splitting of 1,1,3-alkoxybutanes[40,49,50] were perfected by Nazarov and his coworkers[51] and used for the synthesis of several 1-alkoxydienes. Makin and Sudakova[52] employed it to make 1-ethoxyhexatriene and 1-ethoxyoctatetraene. The possibility of eliminating an alcohol from alkoxyaldehydes with aluminium oxide has also been demonstrated[53].

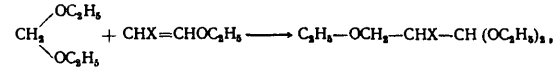
The above general rules for the reaction of acetals with unsaturated ethers do not exhaust the special features inherent in the reactions of various classes, which will be considered in the following Sections.

## VIII. REACTIONS OF ACETALS OF VARIOUS CLASSES



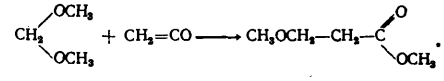
### 1. Reactions of Aliphatic Saturated Acetals

Aliphatic saturated acetals, in reacting with unsaturated ethers, form primary addition products in rather high yields (60–70%) when the reaction is carried out with a large (three- to five-fold) excess of the acetal[5]:

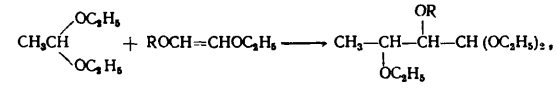


The 3-ethoxyacetals thus formed are also rather highly reactive in comparison with the initial acetals and, as they accumulate, compete with them for the molecules of vinyl ether, giving secondary addition products. When there is an excess of the vinyl ether, high-molecular-weight telomers are formed[33].

The simplest acetal, formaldehyde dimethyl acetal (methylal), was shown by Shostakovskii and coworkers[54] to react with 1,2-dimethoxyethylene, giving 1,1,2,3-tetramethoxypropane in 50% yield:



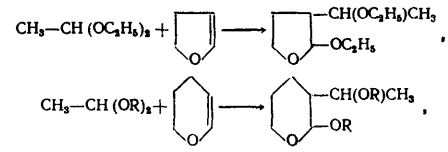
Formaldehyde diethyl acetal (ethylal) condensed with ethyl 2-chloro- and ethyl 2-bromo-vinyl ethers[55], addition products being obtained in high yields in each instance:



where X = Cl or Br.

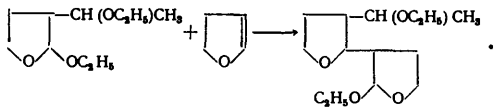
Formaldehyde dimethyl acetal gives an addition product with keten[56], the yield being high:

The reaction is done in the presence of boron trifluoride between -60° and -80°.



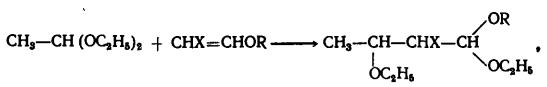
The reactions of acetaldehyde dialkyl acetals have been the most widely investigated. The dimethyl[5,57], diethyl[5,58], and dibutyl[32-34] acetals of acetaldehyde react smoothly with alkyl vinyl ethers. 2-Alkyl-substituted vinyl ethers react with an acetaldehyde acetal similarly to the unsubstituted vinyl ether — the substituent in the 2-position has no significant effect on the condensation[5,58]. However, addition products are not obtained with an alkyl 1-methylvinyl ether; the ether polymerises even in the presence of zinc chloride. Acetaldehyde acetal condenses with 1,2-diethoxyethylene and 2-ethoxy-1-phenoxyethylene at an initial component ratio of 1 : 1, giving a high yield of addition products according to the scheme[59]:

where R = $C_2H_5$ or $C_6H_5$.



Obviously the ethoxy- or phenoxy-group in the 2-position to the acetal group deactivates the latter, preventing the formation of telomers.

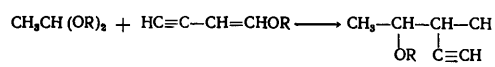
Cyclic $\alpha\beta$-unsaturated ethers, such as dihydrofuran and dihydropyran, react with acetaldehyde dialkyl acetals to form derivatives of tetrahydrofuran and tetrahydropyran, respectively[60]:



where R = $CH_3$, $C_2H_5$, or iso-$C_4H_9$.

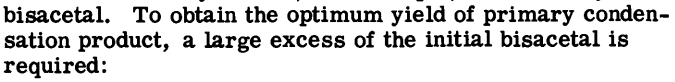
Secondary condensation products are also formed:

However, the reactivity of the primary condensation products is less than for the initial acetaldehyde acetal, so that with a 1 : 1 ratio of the reagents there is a high yield of primary products (60–80%).



2-Chlorovinyl ethyl ether[55,61], 2-bromovinyl ethyl ether[30,55,61], and 2-bromovinyl butyl ether[30] react analogously to alkyl vinyl ethers with acetaldehyde diethyl acetal:

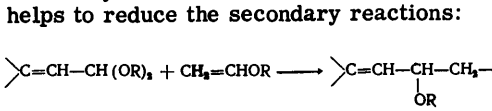
where X = Cl or Br and R = $C_2H_5$, or $C_4H_9$.



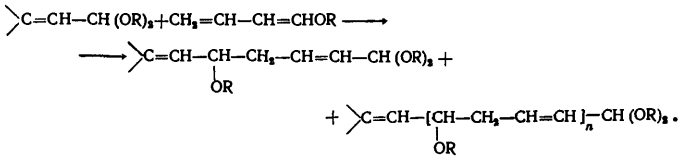
This reaction is interesting because the halogen in the vinyl ether neither reverses the order of addition of the acetal nor inhibits the reaction, although the presence of halogen atoms might be expected to change considerably the nature of the polarisation of the double bond.

Addition products of acetaldehyde acetals with 1-alkoxydienes have not been obtained. Under rigorous conditions (125–140°) alkyl 2-ethylvinyl ethers react according to the scheme[62]:

In the reaction of 1,1-dimethoxyethane with keten, methyl 3-methoxybutyrate is obtained as an addition product[63]. With diketen there is a complex reaction giving a mixture of three products[64].

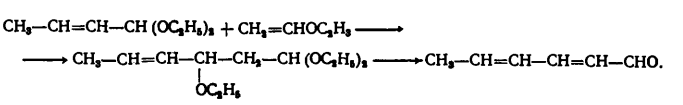


The acetals of propionaldehyde[58,56] and butyraldehyde[58] react with alkyl vinyl ethers analogously to acetaldehyde acetals. Vinyl ethers can also be condensed with saturated acetals of dialdehydes[66,67], for example, malonaldehyde bisacetal. To obtain the optimum yield of primary condensation product, a large excess of the initial bisacetal is required:



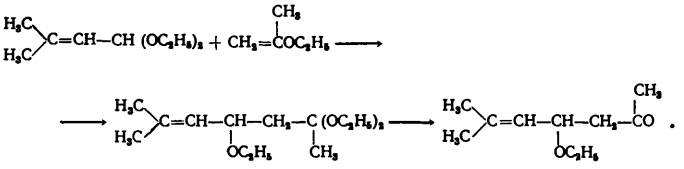
The bisacetal of glyoxal does not react with vinyl ethers under these conditions.

## 2. Reactions of Unsaturated Aliphatic and Alicyclic Acetals

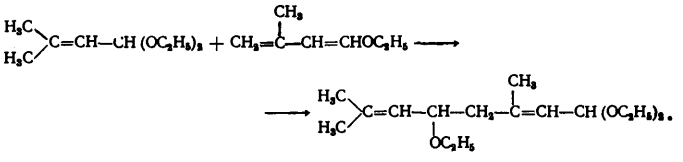


$\alpha\beta$-Unsaturated acetals readily add on to alkyl vinyl ethers[8–12], including also 1-substituted ethers[28,68], and give high yields of the addition products (sometimes over 90%). The reaction products here are 3-alkoxyacetals, whose reactivity is much less than that of the initial acetals, which helps to reduce the secondary reactions:

In addition, $\alpha\beta$-unsaturated acetals are able to add on to 1-alkoxydienes[28,37,69–72]. Addition at the 1,4-positions occurs and as a result of the reaction $\alpha\beta$-unsaturated acetals are regenerated, with reactivities similar to the original acetals. As a result, telomers are formed as well as the primary addition products:

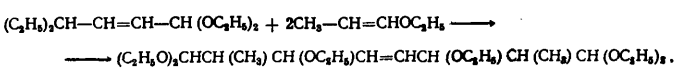


The reaction of $\alpha\beta$-unsaturated aldehydes is very widely used to make polyene compounds. Crotonaldehyde acetal reacts with ethyl vinyl ether in the presence of zinc chloride to form 1,1,3-triethoxyhex-4-ene, which on hydrolysis and elimination of ethanol gives sorbaldehyde[68]:

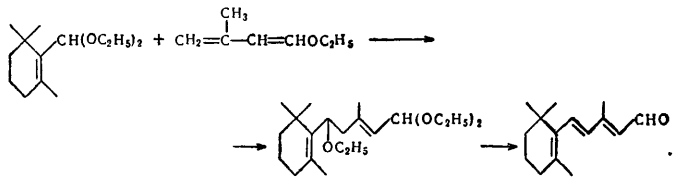


The reaction with ethyl isopropenyl ether also proceeds readily. The reactions of crotonaldehyde acetal with various 1-alkoxydienes, such as 1-ethoxybutadiene[70], 1-ethoxy-2-methylbutadiene and 1-ethoxy-3-methylbutadiene[73], and 1-ethoxypenta-1,3-diene[26], have also been studied.

3-Methylcrotonaldehyde acetal and ethyl isopropenyl ether form 2,2,4-triethoxy-6-methylhept-5-ene, in 60% yield, which on hydrolysis gives 4-ethoxy-6-methylhept-5-en-2-one[28]:

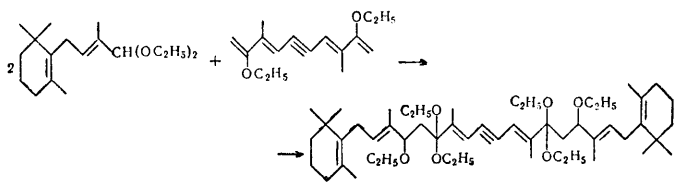


The latter was used in the synthesis of monoarylated polyene hydrocarbons[74]. The reaction of the ethyl acetal of 3-methylcrotonaldehyde with 1-ethoxybutadiene and 1-ethoxy-3-methylbuta-1,3-diene proceeds smoothly. The second combination gives an acetal of ethoxycitral[28,37]:

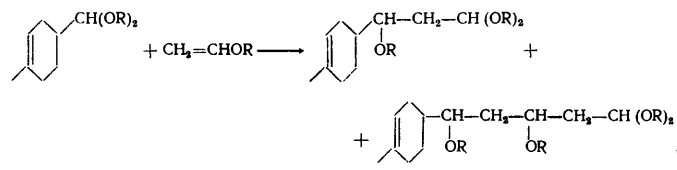


High yields of additions products are given by sorbaldehyde acetal with ethyl vinyl and ethyl isopropenyl ethers[68]. Products of the condensation of citral acetal with one and two molecules of 1-ethoxy-3-methylbuta-1,3-diene have been obtained[28].

The acetals of unsaturated dialdehydes react with unsaturated ethers to form addition products at both acetal groups[75–78], for example:



The $\alpha\beta$-unsaturated acetals of the alicyclic series react with unsaturated ethers quite analogously. For example, condensation products of cyclocitral acetal with 1-ethoxybutadiene and with 1-ethoxy-3-methylbuta-1,3-diene have been obtained[37]. From the latter reaction β-ionylideneformaldehyde [3-methyl-5-(2,5,5-trimethylcyclohex-1-enyl)penta-2,4-dienal (Ed. of Translation)], which is an intermediate in the production of Vitamin A, was isolated after hydrolysis and elimination of alcohol:



This synthesis path for β-ionylideneformaldehyde appears rather simple, but cyclocitral acetal itself is not readily available. Furthermore the reaction is complicated by the formation of telomers.

The reaction of $\alpha\beta$-unsaturated ethers with the acetal of 2-methyl-4-(2,6,6-trimethylcyclohex-1-enyl)but-2-enal — the so-called $C_{14}$ aldehyde — has been used for a series of syntheses of carotenoids. With ethyl vinyl ether the condensation product is formed in yields of up to 92%.[8] The bis-addition product of an acetal of the $C_{14}$ aldehyde with an unsaturated ether of such a complicated structure as 2,9-diethoxy-3,8-dimethyldeca-1,3,7,9-tetraen-5-yne has been obtained[79]:

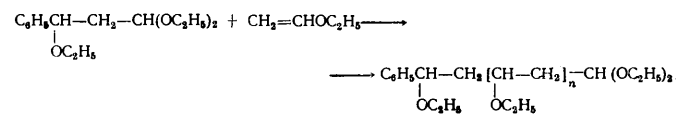
The bis-addition product obtained was used to synthesise β-carotene. Apart from the $C_{14}$ aldehyde acetal, other analogous $\alpha\beta$-unsaturated alicyclic acetals have also been used for the synthesis of carotenoids[80,81]. The reaction of β-ionylideneformaldehyde acetal with 1-ethoxy-3-methylbuta-1,3-diene has been described[53].

Unsaturated cycloaliphatic acetals with the double bond distant from the acetal group react like saturated acetals. Thus, in the reaction of acetals of 4-methylcyclohex-3-enal with alkyl vinyl ethers a mixture of primary and secondary condensation products was obtained[82]:

where R = $C_2H_5$ or $C_4H_9$.

The yield of the primary condensation product is not high (~12%). Hence the double bond in the $\beta\gamma$-position does not activate the acetal group.

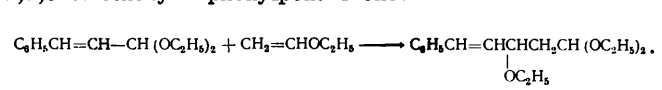
Acetals containing a triple bond in the $\alpha\beta$ position, such as propiolaldehyde acetal, do not react with unsaturated ethers.



## 3. Reactions of Aliphatic-Aromatic and Aromatic Acetals

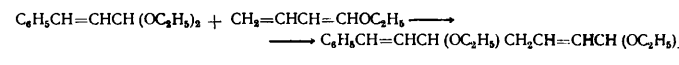
The reactions of acetals of the aliphatic-aromatic series with $\alpha\beta$ unsaturated ethers have been little studied. However, the available literature suggests that a phenyl ring in the 3-position in the acetal group no longer has any significant effect on the reactivity of the acetal and the reaction proceeds as for unsaturated aliphatic acetals.

Only condensation with keten has been described[63] for phenylacetaldehyde acetal. This reaction yields ethyl 3-ethoxy-4-phenylbutyrate:



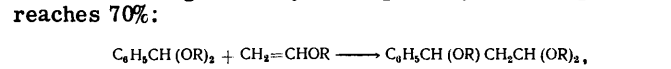
Mikhailov and Povarov[22] studied the reaction of 3-ethoxy-3-phenylpropanal acetal (obtained in the condensation of benzaldehyde acetal with ethyl vinyl ether) with ethyl vinyl ether. As a result they obtained a primary addition product 1,1,3,5-tetraethoxy-5-phenylpentane, in only 10% yield at a 1:1 ratio of the initial reagents and in 50% yield when the acetal was in threefold excess. In addition there was a telomerisation product:

where $n$ = 1, 2, or 3.



Analogously, in the condensation of 3-ethoxy-3-phenylpropanal acetal with ethyl propenyl ether 1,1,3,5-tetraethoxy-2-methyl-3-phenylpentane was obtained in 50% yield[17]. The reaction of 3-ethoxy-3-phenylbutanal acetal with ethyl vinyl ether has also been studied[72].

Aliphatic-aromatic acetals with a double bond in the $\alpha\beta$ position to the acetal group behave analogously to $\alpha\beta$ unsaturated aliphatic acetals in their reaction with unsaturated ethers. An example is the reaction of cinnamaldehyde acetal, which with ethyl vinyl ether and either boron trifluoride[47] or zinc chloride[69] readily forms 1,1,3-triethoxy-5-phenylpent-4-ene:

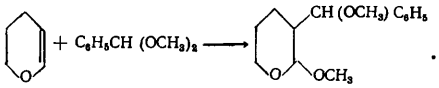


Methylcinnamaldehyde acetal also reacts smoothly with ethyl vinyl ether[72].

Like the aliphatic $\alpha\beta$-unsaturated acetals, cinnamaldehyde acetal reacts with 1-ethoxybutadiene, forming 1,1,5-triethoxy-7-phenylhepta-2,6-diene in good yield[69]:

Higher condensation products are also formed.

Of the aromatic acetals, the benzaldehyde dialkylacetals have been best studied as regards reaction with unsaturated ethers. In the presence of boron trifluoride, the dimethyl acetal[21] and diethyl acetal[22] form with alkyl vinyl ethers 3-alkoxy-3-phenylpropanal acetals, and even at a 1:1 molar ratio of the reagents the yield of primary addition product reaches 70%:



where R = $CH_3$ or $C_2H_5$.

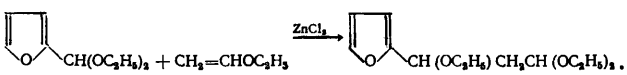
Products of further condensation are also formed in small quantities, but their yield is insignificant, as the reactivity of 3-alkoxy-3-phenylpropanal acetals is much less than that of the original benzaldehyde acetal. Condensation with ethyl isopropenyl ether in the presence of zinc chloride[17] is even better and as a result a 4-ethoxy-4--phenylbutan-2-one acetal is formed in 81% yield. However, benzaldehyde acetals do not give addition products with 1-alkoxydienes under these conditions, which shows that although the aromatic acetals surpass the saturated acetals in reactivity they are less reactive than the $\alpha\beta$-unsaturated acetals. However, benzaldehyde acetal evidently reacts with alkoxydienes such as 3-ethoxy-1-phenylbuta-1,3--diene. This was explained[83] by the formation of 3,3,5-triethoxy-1,5-diphenylpent-1-ene:

$$C_6H_5CH(OC_2H_5)_2 + C_6H_5CH{=}CHC(OC_2H_5){=}CH_2 \longrightarrow C_6H_5CH{=}CHC(OC_2H_5)_2CH_2CH(OC_2H_5)C_6H_5.$$

As this equation shows, the addition to the alkoxydiene here takes place at the 1,2 positions of the conjugated diene system. Benzaldehyde bisethoxyethyl acetal — readily obtainable from benzaldehyde and Ethyl Cellosolve — gives an addition product with ethyl vinyl ether[46].

The reaction of benzaldehyde dimethyl acetal with the cyclic unsaturated ether dihydropyran, leads to the 2-methoxy-3-(methoxyphenylmethyl)tetrahydropyran[60]:

Benzaldehyde acetal reacts with alkyl 2-halogenovinyl ethers in the presence of boron trifluoride to form 3-alkoxy-2-halogeno-3-phenylpropanal acetals in high yields. The reactions are carried out either at 50°[30] or at higher temperatures (100–200°).[84] The halogen atom evidently makes the 3-alkoxy-2-halogeno-3-phenylpropanal acetal stable not only as regards further condensation but also to decomposition at high temperatures.



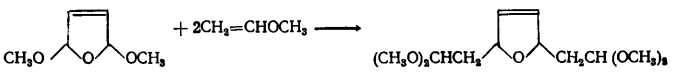
Esters of 3-ethoxy-3-phenylpropionic acid were obtained by reaction of keten with benzaldehyde acetal[63].

A mixed acylal benzaldehyde acetal also reacts with keten, esters of 3-ethoxy-3-phenylpropionic acid again being formed[85].

The reaction of terephthalaldehyde bisacetal with ethyl vinyl ether simultaneously at both acetal groups has also been described[86].

## 4. Reaction of Heterocyclic Acetals

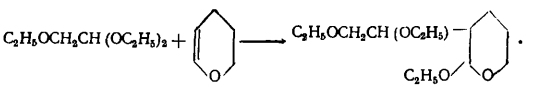
Only a few representatives of the heterocyclic aldehydes have been studied in reactions with unsaturated ethers. Mikhailov and Ter-Sarkisyan[69] showed that furfural acetal reacts with ethyl vinyl ether to give (similar to benzaldehyde acetal) 3-ethoxy-3-furylpropanal acetal in high yield even at a 1:1 ratio of the initial reagents:



5-Nitrofurfural acetal reacts analogously[87].

Unlike benzaldehyde acetal, furfural acetal gives an addition product with 1-ethoxybutadiene, although the yield of the primary addition product is very moderate (23.7% on the converted acetal and ~5% on that taken).[69] Secondary condensation products are also formed. This is evidence of the somewhat higher reactivity of furfural acetal.

3-(Fur-2-yl)acrolein acetal reacts smoothly with ethyl vinyl ether, like an $\alpha\beta$-unsaturated acetal, and with 1-ethoxybutadiene, forming 1,1,3-triethoxy-5-(fur-2-yl)-pentene in 74.6% yield with the former and 1,1,5-triethoxy--7-(fur-2-yl)hepta-2,6-diene in 40.4% yield with the latter[69].



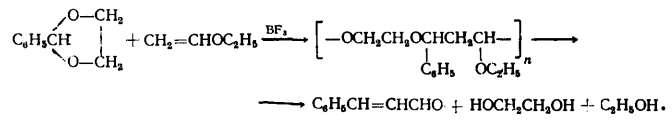
We must also remember the reaction of tetrahydro-4--keto-2,2-dimethylpyran diethyl acetal with ethyl vinyl ether, leading to 4-(2,2-diethoxyethyl)-4-ethoxytetrahydro--2,2-dimethylpyran[88].

The unusual heterocyclic bisacetal 2,5-dihydro-2,5-dimethoxyfuran has been shown to react with methyl vinyl ether, forming addition products at both acetal groups[89]:

## 5. Reactions of Substituted Acetals

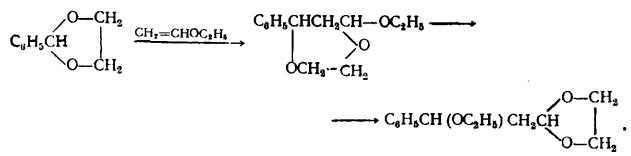
Functional substituents have most effect only when they are situated at the 2-carbon atom with respect to the acetal group. More distant substituents do not affect the reactivity significantly. For example, 2-ethoxyacetaldehyde acetal does not condense with ethyl vinyl ether under ordinary conditions, while the vinyl ether polymerises[60]. 2-Ethoxyacetaldehyde acetal gives an addition product with dihydropyran but the yield (37%) is only half that for acetaldehyde acetal:

2-Bromoacetaldehyde acetal also does not form an addition product with ethyl vinyl ether[90].



Mikhailov and Povarov[30] noted that acetals such as 1,1,3-trialkoxy-2-bromo-3-phenylpropane and 1,1,3-trialkoxy-2-bromobutane do not react with unsaturated ethers.

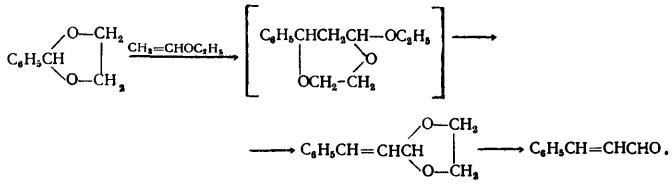
As already mentioned, the presence of an alkoxy-substituent in the 3-position to the acetal does not affect its reactivity. The presence of an ethoxycarbonyl group in the 3-position also does not affect the reactivity of crotonaldehyde acetal, which reacts with ethyl vinyl ether to form the ethyl ester of 1,1-diethoxy-2-methylbut-2-en-4-oic acid[91]. An addition product is formed similarly by 6,6-diethoxyhexanoic ester with ethyl vinyl ether[92]. 3,3-Dichloroacrolein, 5,5-dichloropenta-2,4-dienal, and 7,7-dichlorohepta-2,4,6-trienal acetals react smoothly with vinyl ethers[83,84]. Their behaviour does not differ from that of the corresponding unsubstituted, unsaturated acetals.



## 6. Reactions of Cyclic Acetals

Because of the special structure of the acetal group, cyclic acetals react uniquely with unsaturated ethers. It has been shown[47] that the reaction of benzaldehyde ethylene acetal [2-phenyl-1,3-dioxolan (Ed. of Translation)] in the

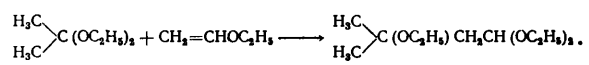
absence of a solvent leads to a polymer which in the presence of mineral acids is readily hydrolysed and splits off an alkoxy-group, giving cinnamaldehyde:



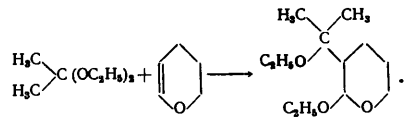
When the reaction is carried out in dilute solution an unstable primary condensation product can be isolated as a mixture with the stable isomer formed by rearrangement:

Aliphatic cyclic acetals and ketals† react analogously [95].

Reactions of cyclic acetals with alkyl vinyl ethers are used for the synthesis of several unsaturated aldehydes and ketones. The ethylene acetals of benzaldehyde, cinnamaldehyde, and 3-ethoxycarbonyl-2-methylacrolein have been condensed with ethyl vinyl and ethyl propenyl ethers, as also has been β-ionone ethylene ketal [96]. Different conditions were used to treat the reaction mixture and ethylene acetals were isolated from the reaction products hydrolysed further to the corresponding unsaturated aldehydes and ketones, for example:



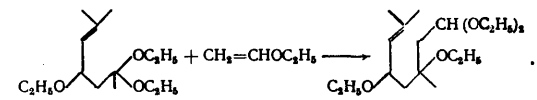
The mechanism of formation of cinnamaldehyde ethylene ketal (2-styryl-1,3-dioxolane) is not completely clear.



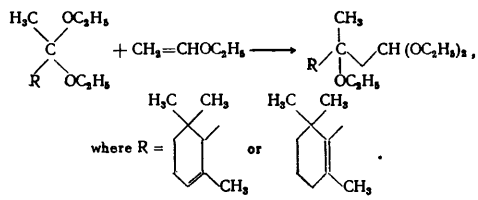
## 7. Reactions of Ketals†

The reactions of ketals with αβ-unsaturated ethers proceed mainly by analogy with the reactions of acetals, but at the same time are distinguished by special features.

2,2-Diethoxypropane with ethyl vinyl ether forms 1,1,3-triethoxy-3-methylbutane:



The reaction was performed in the presence of boron trifluoride both at 50° [89] and under milder conditions (at 5°) [51]. Reaction with methyl vinyl ether [21] and ethyl propenyl ether [88] have also been described. 2,2-Diethoxybutane reacts with ethyl vinyl ether analogously to 2,2-diethoxypropane [88]. 2,2-Diethoxypropane forms an addition product with dihydropyran [60]:



The ketals of cyclic ketones (cyclopentanone, cyclohexanone, pyranone) react with alkyl vinyl ethers by the usual scheme [88].

Ketals have frequently been used to synthesise terpene derivatives. Thus diethoxycitronellal acetal was obtained by condensing 2,2,4-triethoxy-6-methylhept-5-ene with ethyl vinyl ether [28]:

By condensing 2,2,4-triethoxy-6-methyl-hept-5-ene with ethyl vinyl ether, 1,1,3-triethoxy-3,7-dimethyloct-6-ene was obtained similarly, and was converted into citral by hydrolysis and the elimination of ethanol [29].

Mikhailov and Povarov [7] obtained ketals of α- and β-ionones and condensed them with ethyl vinyl ether:

The acetals obtained were converted into α- and β-ionylideneacetaldehydes.

In several instances the reactions of ketals are accompanied by elimination of alcohol, as ketals are more sensitive to the action of acid agents. For example, it has been reported that 1,3,3-triethoxy-1-phenylbutane formed by the reaction of benzaldehyde acetal, is partly converted into 3-ethoxy-1-phenylbutadiene by the elimination of the elements of the alcohol [83]:

This work also showed that 1,3,3-triethoxy-1-phenylbutane does not condense very well with ethyl vinyl ether.

Mikhailov and Ter-Sarkisyan [72] observed the formation of acetaldehyde acetal in the reaction of 1,1-diethoxy-1-phenylethane with ethyl vinyl ether, which was explained by the reaction of ethyl vinyl ether with the alcohol eliminated from the reaction product.

As already noted, cyclic ethylene ketals of acetone and ionone react with ethyl vinyl ether in a similar manner to cyclic acetals [96].

## 8. Reactions of Ortho-Esters

Ortho-esters — of which esters of orthoformic acid and, to a lesser extent, orthoacetic acid have been studied

† This name has been abandoned by IUPAC (Ed. of Translation).

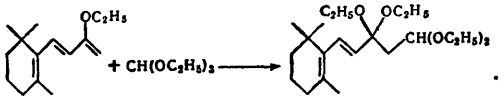
— form addition products (bisacetals) with various $\alpha\beta$-unsaturated ethers, including 1-substituted ethers:

$$CR(OR')_2 + CH_2{=}CHOR' \rightarrow RC(OR')_2CH_2CH(OR')_2,$$

where R = H or $CH_3$.

At the same time they are evidently incapable of forming addition products with alkoxydienes. This is evidence that ortho-esters are more reactive than saturated acetals but less reactive than $\alpha\beta$-unsaturated acetals. That is, just the same as aromatic acetals. As with aromatic acetals, even at a 1 : 1 ratio of the initial reagents (ortho--ester and vinyl ether) the yield of the primary addition product is high (~ 75%) despite the fact that the addition product formed is a bisacetal capable of further addition. However, its reactivity is evidently less than that of the original ortho-ester.

Hultquist[97] brought about the first reactions using an orthoformic ester and ethyl vinyl ether. In later years many patents were taken out for the use of this reaction to synthesise bisacetals[98-113].



Protopova and Skoldinov[66] made a detailed study of the reaction between ethyl orthoformate and methyl vinyl, ethyl vinyl, propyl vinyl, and butyl vinyl ethers. They found that in addition to the primary addition product the products of further condensation are formed, for example, the bisacetal of ethoxyglutaraldehyde [1,1,3,5,5-pentaethoxypentane (Ed. of Translation)]:

$$CH(OC_2H_5)_3 + CH_2{=}CHOC_2H_5 \rightarrow (C_2H_5O)_2CH[CH_2CH]_n CH_2CH(OC_2H_5)_2,$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OC_2H_5$$

where $n$ = 0, 1, 2, or over.

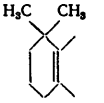
Yanovskaya and coworkers[114] brought about the reaction of triethyl orthoformate with ethyl propenyl, ethyl isopropenyl, ethyl 1,2-dimethylvinyl, cyclohexenyl ethyl, and 2-bromovinyl ethyl ethers. Whereas with vinyl ethers unsubstituted in the 1-position the reaction proceeds with 75% yields, the yield with methyl-substituted ether was appreciably less (35%). In the same work the reaction between orthoacetic ester and ethyl isopropenyl and 1,2-dimethylvinyl ethyl ethers was studied.

Orthoformic ester is capable of adding on to 1-substituted vinyl ethers of complex structure. Thus, it has been shown[115] that ethers of the enolic forms of $\alpha$- and $\beta$-ionones react with orthoformic ester. For example, the reaction for the ether of the $\beta$-ionone enol proceeds thus:

It was also found[116] that orthoformic ester reacts with keten to form an ester of 3,3-diethoxypropionic acid:

$$CH(OC_2H_5)_3 + CH_2{=}CO \rightarrow (C_2H_5O)_2CHCH_2C(=O)OC_2H_5.$$

The reaction of orthoformic ester with diketen is more complex[114].



The addition of an ortho-ester to 1-chloro-1,2-diethoxyethylene has been described[117].

9. Reactions of Thioacetals

Mikhailov and Ter-Sarkisyan[118,119] investigated the reaction of thioacetals with ethyl vinyl ether. It appeared that thioacetals of aldehydes such as benzaldehyde, cinnamaldehyde, cyclocitral in the presence of boron trifluoride or zinc chloride react with ethyl vinyl ether by the same scheme as acetals:

$$RCH(SC_2H_5)_2 + CH_2{=}CHOC_2H_5 \longrightarrow RCH(SC_2H_5)CH_2CH\begin{matrix}OC_2H_5\\SC_2H_5\end{matrix},$$

where R = $C_6H_5$, $C_6H_5CH{=}CH-$, or

The yields of the primary addition products are considerably less than for the corresponding acetals. The formation of secondary condensation products is also noted. The example of 1-ethoxy-1,3-bisethylthio-3-phenylpropane showed that monothioacetals react with ethyl vinyl ether with loss of an alkylthio-group and not of an alkoxy-group:

$$C_6H_5CH(SC_2H_5)CH_2CH\begin{matrix}OC_2H_5\\SC_2H_5\end{matrix} + CH_2{=}CHOC_2H_5 \longrightarrow$$
$$\longrightarrow C_6H_5CH(SC_2H_5)CH_2CH(OC_2H_5)CH_2CH\begin{matrix}OC_2H_5\\SC_2H_5\end{matrix}.$$

Even earlier, the reaction of trithioorthoformic ester with ethyl vinyl ether was investigated, also in the presence of boron trifluoride. This reaction leads to 1-ethoxy--1,3,3-trisethylthiopropane[120]:

$$CH(SC_2H_5)_3 + CH_2{=}CHOC_2H_5 \longrightarrow (C_2H_5S)_2CHCH_2CH\begin{matrix}OC_2H_5\\SC_2H_5\end{matrix}.$$

Later the trithioorthoformic esters were condensed with ethyl vinyl and butyl vinyl esters and also with ethyl vinyl and phenyl vinyl sulphides[121]. The last gave bisthioacetals of malonaldehyde:

$$CH(SC_2H_5)_3 \xrightarrow{CH_2{=}CHSC_2H_5} (C_2H_5S)_2CHCH_2CH(SC_2H_5)_2$$
$$CH(SC_2H_5)_3 \xrightarrow{CH_2{=}CHSC_6H_5} (C_2H_5S)_2CHCH_2CH\begin{matrix}SC_2H_5\\SC_6H_5\end{matrix}.$$

## IX. RELATED REACTIONS

The progress in the investigation and application of the reactions of acetals with unsaturated ethers has entailed the realisation of a whole series of conversions of analogous nature, involving acetals, aldehydes, unsaturated ethers, and alkenes.

1. Reactions of Acetals with Alkenes

Several studies have shown that under the influence of boron trifluoride, acetals are capable of addition to alkenes just as they do to unsaturated ethers. With unsaturated

ethers the reaction proceeds in such a way that the alkoxy--group adds on to the 1-carbon atom of the ether.

The $\alpha$ carbon atom in unsymmetrical alkenes has a lower electron density than the 1-carbon atom of unsaturated ethers, therefore the order of the addition is the reverse. This corresponds to the orientation observable in the reaction of formaldehyde with alkenes[122]. For example, in the reaction of methylal with propene the main reaction product is 1,3-dimethoxybutane[123]:

$$CH_3OCH_2OCH_3 + CH_3CH{=}CH_2 \xrightarrow{BF_3} CH_3CH(OCH_3)CH_2CH_2OCH_3\ (39\ \%).$$

The reaction of methylal with 2-methylprop-2-ene, styrene, and $\alpha$-pinene is similar. With styrene, 1,3-dimethoxy-1--phenylpropane is formed in 72% yield. With ethylal these alkenes react more slowly. The reaction of acetals of acetaldehyde and higher aldehydes with 2-methylprop-1--ene is still more difficult. For example, in the reaction of acetaldehyde acetal the "normal" product of the addition — 2,4-diethoxy-2-methylpentane — was obtained in a yield of only 15.5%. Several other products were also obtained[124]:

$$CH_3CH(OC_2H_5)_2 + (CH_3)_2C{=}CH_2 \xrightarrow{BF_3} CH_2{=}C(CH_3)CH_2CH(OC_2H_5)CH_3 +$$

$$+ CH_3C(CH_3)(OC_2H_5)CH_2CHCH_3 + CH_3CH(OC_2H_5)C(C_2H_5O)=CH_2 + CH_3CH(OC_2H_5)CHCH_3 + (CH_3)_3COC_2H_5.$$

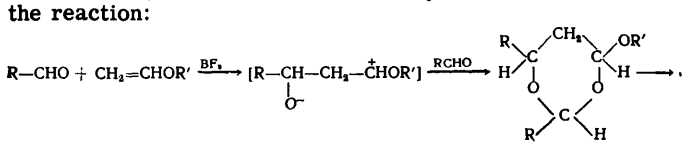
The reaction of ortho-esters with alkenes is of considerable interest. Copenhaver[125] took out a patent on the addition of ortho-esters to 2-methylprop-1-ene, indene, and cyclopentadiene. Another patent[126] described the reaction of trithioorthoformic ester with styrene in the presence of boron trifluoride at 50°.

The condensation of triethyl orthoformate with styrene[114] proceeds thus:

$$C_6H_5CH{=}CH_2 + CH(OC_2H_5)_3 \rightarrow C_6H_5CH(OC_2H_5)CH_2CH(OC_2H_5)_2.$$

but the yield of 1,1,3-triethoxy-3-phenylpropane does not exceed 5%, most of the styrene remaining unchanged.

## 2. Reaction of Aldehydes with $\alpha\beta$-Unsaturated Ethers

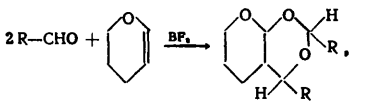


A considerable number of investigations[127-137] concern the reaction of aldehydes with $\alpha\beta$-unsaturated ethers. The mechanism of this reaction is somewhat similar to that of the reaction of cyclic acetals with vinyl ethers. As a result, a polymer is formed, the acid hydrolysis and destruction of which leads to unsaturated aldehydes:

$$R{-}CH{=}O + CH_2{=}CHOR' \xrightarrow{BF_3} R{-}CH(O{\cdot}BF_3){-}CH_2{-}CH(OR'){\rightarrow}$$

$$\rightarrow [-OCH(R){-}CH_2{-}CH(OR'){-}]_n \xrightarrow{H^+} R{-}CH{=}CH{-}CHO.$$

In this way, cinnamaldehyde was obtained in 60% yield from benzaldehyde and ethyl vinyl ether[127].



Saikachi and Ogawa[87] and Hoaglin and Hirsh[128] have shown that 1,3-dioxan derivatives may be intermediates in the reaction:

$$\rightarrow R{-}CH{=}CH{-}CHO + R{-}CHO + ROH.$$

Such an intermediate was isolated in the reaction with *p*-nitrobenzaldehyde[87]. An intermediate could not be isolated when furfural was used.

The reaction was also extended to cyclic unsaturated ethers. As it transpired[133], butyraldehyde and isobutyraldehyde react with dihydropyran to form 2,4-dipropyl- and 2,4-diisopropyl-hexahydropyrano[2,3-*d*]-*m*-dioxin respectively, with ~59% yields, according to the scheme:

where R = n-$C_3H_7$ or iso-$C_3H_7$.

It was also shown[130-132] that, depending on the aldehyde and catalyst, the reaction can go in another direction, with formation of alkoxyaldehydes. For example, in the condensation of crotonaldehyde with ethyl vinyl ether 3-ethoxyhex-4-enal was obtained in 46% yield:

$$CH_3{-}CH{=}CH{-}CHO + CH_2{=}CHOC_2H_5 \longrightarrow CH_3{-}CH{=}CH{-}CH(OC_2H_5){-}CH_2{-}CHO.$$

There are several patents on the use of this reaction[127-129], from which it appears that it can be employed with both aliphatic saturated and unsaturated aldehydes and also aromatic and heterocyclic aldehydes.

Krasnaya and Kucherov[134] showed that aldehydes also react with 1-alkoxydienes:

$$RCH{=}CHCHO + CH_2{=}C(R'){-}CH{=}CHOR'' \xrightarrow{BF_3}$$

$$\rightarrow RCH{=}CHCH(OR'')CH_2C(R'){=}CHCHO + RCH{=}CH[CH(OR'')CH_2C(R'){=}CH_2]CHO.$$

The reactions were carried out with crotonaldehyde, dimethylacrolein, citral, benzaldehyde, and furfural. The yields sometimes exceeded 40%.

Arens and his coworkers[135,136] found that aldehydes, and also ketones, are able, in the presence of boron trifluoride, to react with ethoxyacetylene and form esters of unsaturated acids:

$$R_2C{=}O \ldots BF_3 + HC{\equiv}COC_2H_5 \longrightarrow \left[R_2C(O{\cdot}BF_3){-}CH{=}C{-}OC_2H_5\right] \longrightarrow$$

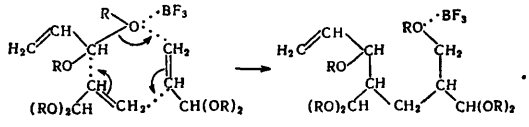
$$\rightarrow R_2C{=}CHCOOC_2H_5.$$

Krasnaya and Kucherov[137] also used in this reaction such unsaturated aldehydes and ketones as crotonaldehyde, heptadienone, cyclocitral, etc., the yields of addition products reaching 67%.

## 3. Autocondensation of Acetals

Under the influence of boron trifluoride or zinc chloride acetals of saturated aldehydes dimerise with loss of a molecule of alcohol[138]:

$$R{-}CH(OC_2H_5)_2 + R{-}CH_2CH(OC_2H_5)_2 \xrightarrow{BF_3 \text{ or } ZnCl_2}$$



$$\rightarrow R{-}CH(OC_2H_5)CH(R)CH(OC_2H_5)_2 + C_2H_5OH.$$

1,1,3-triethoxybutane can be obtained by this reaction with yields of up to 50%.

The dimerisation of the acetals of $\alpha\beta$-unsaturated aldehydes takes place by addition at the double bond:

$$2R{-}CH{=}CH{-}CH(OR')_2 \longrightarrow R{-}CH{=}CHCH(OR')\overset{R{-}CH{-}OR'}{\overset{|}{C}}HCH(OR')_2.$$

For example, crotonaldehyde diethyl acetal gives a dimer of the above structure with a yield of up to 80%. Yufit and Kucherov[139] made a detailed study of the autocondensation of acrolein acetal and found that the dimer is obtained in 5–10% yield, the main product of the reaction being a trimer, whose formation they explained by the following mechanism of cyclic electron transfer in a six-membered ring:

The formation of a trimer here seems to be a self-contained reaction taking place in parallel with the formation of the dimer.

## 4. Autocondensation of Vinyl Ethers

Vinyl ethers are known to polymerise extremely readily in the presence of Friedel-Crafts catalysts[44], but low-molecular-weight polymerisation products have not been obtained. Hoaglin and coworkers[140] found that the use of boron trifluoride in conjunction with mercury(II) acetate enables polymerisation to be avoided and dimers, trimers, and tetramers of alkyl vinyl ethers obtained. Polymers are also formed but in reduced amounts. The products of the dimerisation are unsaturated acetals and ketals. The authors suggested that the mercury(II) acetate participated in the formation of the dimers thus:

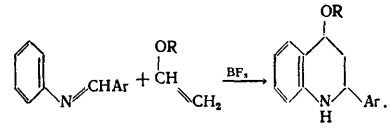
$$CH_2{=}CHOC_2H_5 + Hg(OCOCH_3)_2 \rightleftarrows CH_2{-}\underset{\displaystyle HgOCOCH_3}{\underset{|}{C}}H{-}CH\begin{matrix}OC_2H_5\\OCOCH_3\end{matrix} \xrightarrow{CH_2=CHOC_2H_5}$$
$$\rightarrow CH_2{-}\underset{\displaystyle HgOCOCH_3}{\underset{|}{C}}H(OCOCH_3)CH_2CH(OC_2H_5)_2 \rightarrow$$
$$\rightarrow CH_2{=}CHCH_2CH(OC_2H_5)_2 + Hg(OCOCH_3).$$

The formation of trimers and tetramers evidently takes place as a result of the reaction of the acetals thus obtained with the alkyl vinyl ether by the usual mechanism. The dimer of ethyl vinyl ether — a vinylacetaldehyde acetal — was obtained in 72% yield, ethyl but-1-enyl ether gave a dimer in 30% yield, and ethyl isopropenyl ether gave only 11% yield.

The autocondensation of vinyl ethers has also been described in a Japanese patent[141]. In this work the autocondensation of methyl vinyl and ethyl vinyl ethers with catalysts such as boron trifluoride/mercury(II) acetate and boron trifluoride/mercury(II) oxide was studied.

Makin and Kruptsov[142] studied several complex catalysts, such as boron trifluoride/mercury(II) sulphate, iron(III) chloride/mercury(II) oxide, iron(III) chloride/mercury(II) acetate, and zinc chloride/mercury(II) oxide. The best results were obtained with boron trifluoride/mercury(II) acetate and boron trifluoride/mercury(II) oxide. With the last, the reaction mechanism is thought to be:

$$HgO + CH_2{=}CHOR \rightleftarrows CH_2{-}\underset{\displaystyle Hg{-}O}{\underset{|}{C}}HOR \xrightarrow{CH_2=CHOR}$$
$$\longrightarrow CH_2{-}\underset{\displaystyle Hg{-}O}{\underset{|}{C}}H{-}CH_2{-}CH(OR)_2 \longrightarrow CH_2{=}CHCH_2CH(OR)_2.$$



The authors investigated the autocondensation of ethyl vinyl, butyl vinyl, and pentyl vinyl ethers.

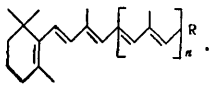
Apart from acetals and their sulphur analogues (thioacetals), nitrogen derivatives of carbonyl compounds, such as imines, have been used in the reaction with $\alpha\beta$-unsaturated ethers. Povarov and Mikhailov[143] showed that imines react with ethyl vinyl ether in an acetic acid medium; the reaction has many similarities to that with acetals and leads to 3-*N*-alkyl- or 3-*N*-aryl-aminoacylals (I). When the latter are split they give, like the 3-alkoxyacetals, an unsaturated aldehyde:

$$C_6H_5CH{=}NR \xrightarrow{H^+} [C_6H_5\overset{+}{C}H{-}NHR] \xrightarrow[-OCOCH_3]{CH_2=CHOC_2H_5}$$
$$\longrightarrow C_6H_5CH(NHR)CH_2CH\begin{matrix}OC_2H_5\\OCOCH_3\end{matrix} \xrightarrow[-RNH_2]{H_2O} C_6H_5CH{=}CHCHO.$$
(I)

where R = $-CH_2CH{=}CH_2$, iso-$C_4H_9$, or $C_6H_5$.

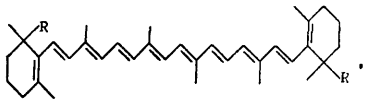
The same authors[144] found that in the presence of boron trifluoride, aromatic imines (Schiff bases) also react with $\alpha\beta$-unsaturated ethers, but here the reaction not only occurs at the carbonyl group, but also by addition of the $\alpha\beta$-unsaturated ethers in the 1,4 position to the diene system formed by the aromatic ring and the iminomethine group:

This reaction will not be discussed in this review.



# X. SYNTHESES BASED ON THE REACTION OF ACETALS WITH $\alpha\beta$-UNSATURATED ETHERS

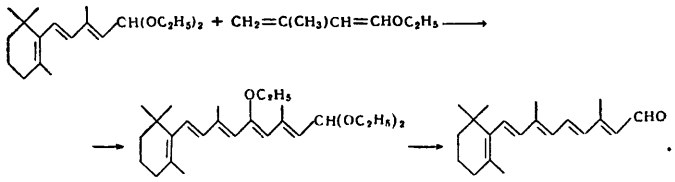
## 1. Synthesis of Isoprenoid Systems



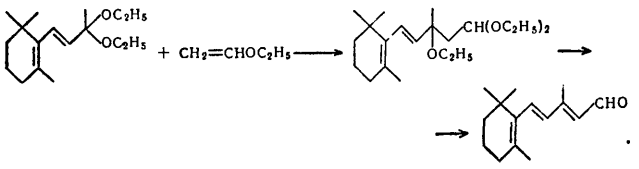
The use of the reaction of acetals with unsaturated ethers in the synthesis of isoprenoid systems seemed especially fruitful. Here above all mention must be made of the many papers and patents of Isler and his coworkers[8-13,145-160] and certain other patents[161-164]. With this reaction the authors obtained a series of yellow and red carotenoid pigments. The isoprenoid chain was built up by successive condensations of the initial acetals with ethyl propenyl and ethyl vinyl ethers:

$$RCH(OR')_2 \xrightarrow{CH_3CH=CHOR'} RCH(OR')CH(CH_3)CH(OR')_2 \xrightarrow[H_2O]{H^+}$$
$$\longrightarrow RCH{=}C(CH_3)CHO \xrightarrow{CH(OR)_3} RCH{=}C(CH_3)CH(OR')_2 \xrightarrow{CH_2=CHOR'}$$
$$\longrightarrow RCH{=}C(CH_3)CH(OR')CH_2CH(OR')_2 \xrightarrow[H_2O]{H^+}$$
$$\longrightarrow R\dot{-}CH{=}\overset{CH_3}{\overset{|}{C}}{-}CH{=}CH\dot{-}CHO, \text{ etc.}$$

By combining the reaction of acetals and unsaturated ethers with the Reformatski and Wittig reactions and with the acetylene synthesis, Isler and his coworkers obtained, in high yields, β-carotene, lycopene, zeaxanthin, cryptoxanthin, and other carotenoids of the type:



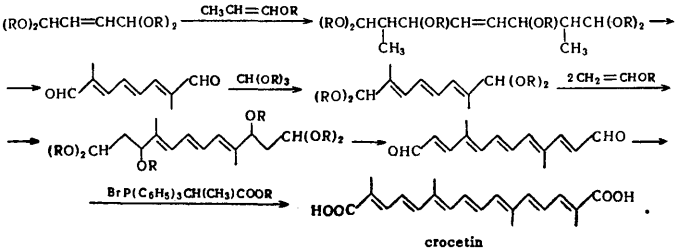
This method was also used to synthesise homologues of carotene[165]:



where R = $C_2H_5$ or iso-$C_4H_9$.

Krasnaya and Kucherov[53] arrived at the aldehyde of Vitamin A, by using the reaction of 1-ethoxy-3-methylbuta-1,3-diene with the acetal of β-ionylideneacetaldehyde:

Vitamin A itself was also obtained by reduction of the aldehyde.

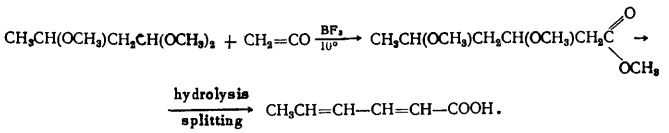


Mikhailov and Povarov[7] obtained an intermediate product in the synthesis of Vitamin A — β-ionylideneacetaldehyde — by condensation of β-ionone ketal with ethyl vinyl ether:

The condensation of acetals and ketals with unsaturated ethers has been used in the synthesis of bicyclodehydrofarnesenic acid[166], pseudoirone[67], citral[29], dihydrocitral[37], etc.

## 2. Synthesis of Unsaturated Dicarboxylic Acids

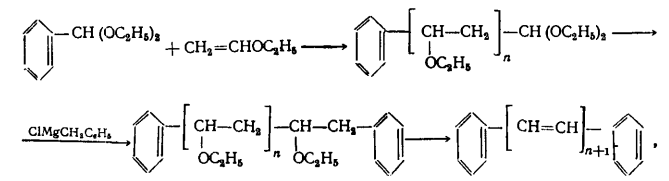
Isler and his coworkers[75,168] developed methods of synthesising polyene dicarboxylic acids, such as crocetin, and bixin. For this they used the reaction of bisacetals with ethyl propenyl and ethyl vinyl ethers in conjunction with subsequent Wittig reactions with a carbethoxyethylenephosphorane:



crocetin

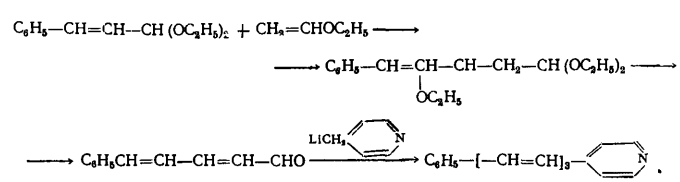
Bixin was obtained by an analogous path.

Kucherov, Yanovskaya, and their coworkers[78,169-171] developed a path for synthesising polyenedicarboxylic acids of the corticrocin type containing either an even or an odd number of bonds in the chain, also providing a combination of the bisacetal condensation and the Wittig reaction.



A convenient method of obtaining monobasic polyene acids is the reaction of 3-alkoxyacetals with keten[172]:

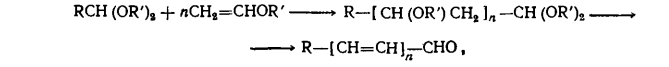
The yield of sorbic acid reaches 85%.



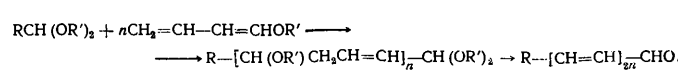
## 3. Synthesis of Arylated Polyene Hydrocarbons

Mikhailov and coworkers[15-17,36,74,173] developed new methods of synthesising arylated polyene hydrocarbons on the basis of the condensation of acetals with alkyl vinyl ethers and alkoxydienes. After Kuhn's well-known work, diphenylpolyenes from 1,4-diphenylbutadiene to 1,10-diphenyldecapentaene were obtained for the first time[15]:

where $n$ = 1, 2, 3, or 4.



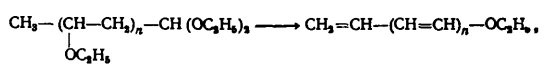
In addition, unsymmetrical diarylpolyenes[16], diphenylpolyenes methylated in various positions[17], and monoarylated polyenes[74] have been obtained. Mikhailov and Ter-Sarkisyan[173] obtained polyenes with heterocyclic substituents, by using phenylpolyenals obtained by the condensation of cinnamaldehyde acetal with ethyl vinyl ether or 1-ethoxybutadiene:



Arylated polyenes are of interest as organic luminophores.

## 4. Synthesis of Polyenals and 1-Alkoxypolyenes

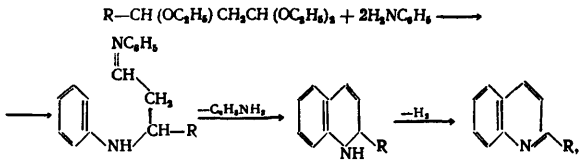
An extremely large number of syntheses of polyene aldehydes and ketones which previously were inaccessible or obtained with difficulty have been effected by the scheme:



or by use of 1-alkoxydienes by the scheme:

Alkoxyacetals are now widely used to make 1-alkoxydienes, which are valuable intermediates in several syntheses:

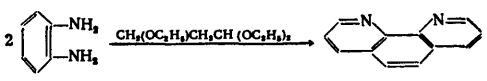
Polyenes and other higher 1-alkoxypolyenes have been obtained by using the corresponding polyalkoxyacetals[25]:



where $n$ = 2, 3, or 4.

5. Synthesis of Quinolines

$\gamma$-Ethoxyacetals of the type:



which can be obtained[65] by condensations with alkyl vinyl ethers, give quinoline derivatives on reacting with aromatic amines. By analogy with the suggested mechanism of the quinaldine synthesis, the reaction mechanism can be represented as follows:

where R = H, $CH_3$, $C_2H_5$, or $C_6H_5$.

With diamines, phenanthrolines are formed similarly:

The examples given do not exhaust all the fields of use of the reactions of acetals with unsaturated ethers.
